

**Mosaic trisomy 2 and trisomy 11 in myelodysplastic syndrome (MDS).** *M. Gustavo<sup>1</sup>, M. DaCosta<sup>1</sup>, V. Mizhiritskaya<sup>2</sup>, M.J. Macera<sup>2</sup>, R.M. Chandra<sup>2</sup>, R.S. Verma<sup>1,2</sup>.* 1) Department of Medicine, SUNY Health Science Center, Brooklyn, NY; 2) Department of Medicine, Wyckoff Heights Medical Center, Brooklyn-New York Hospital/Weill Medical College of Cornell Medical Center, New York, NY.

DH is an 86 year-old African-American woman who came with fatigue which continued to worsen. She has a long history of hypertension and was treated with Ca<sup>++</sup> channel blocker. Her past medical history included colonic polyps with rectal bleeding complicated by cardiac arrest during colonoscopy 5 years ago, a hysterectomy for uterine fibroids 30 years ago and spinal disc surgery 25 years ago. The peripheral blood smear showed about 15% of blasts that morphologically belong to the myeloid series. A CBC was as follows: WBC 1.63 k/ml, HGB 4.5 gm/dl, HCT 13.8%, MCV 111 fl and platelets were 65 k/ml. The bone marrow aspirate showed diffuse infiltration with blast cells with prominent nucleoli. A few normal erythroid and myeloid cells were scattered among the immature blasts. By flow cytometry the blasts in the peripheral blood were positive for CD33 and CD13 and negative for B- and T- cell markers. Cytogenetic findings with G-banding revealed 17 cells with 47,XX,+11 and three cells with 47,XX,+2 i.e. 47,XX,+11[17]/47,XX,+2[3]. The FISH technique using alphoid centromeric probes for chromosome 2 and 11 revealed 69 nuclei with an additional chromosome 11, six cells with trisomy 2 and 48 normal cells. By interphase cytogenetics, we were able to identify a normal clone. Though on initial presentation, the peripheral blood and bone marrow morphology was that of de novo AML, the recovery of the platelet count and the presence of karyotypically normal cells in the bone marrow suggest that this patient may have a myelodysplastic syndrome in transition to AML. Although trisomy 11 is a known cytogenetic abnormality in AML, the presence of an additional clone with trisomy 2 has not been described and its molecular pathogenesis and prognostic significance are unknown.

**New cytogenetic findings in acute myelomonocytic leukemia.** *F.P. Chaudhri<sup>1</sup>, P. Hegde<sup>1</sup>, N.C. Shah<sup>1</sup>, V. Mizhiritskaya<sup>2</sup>, M.J. Macera<sup>2</sup>, R.S. Verma<sup>2</sup>.* 1) Department of Medicine, Flushing Hospital Medical Center, Flushing, NY; 2) Department of Medicine, Wyckoff Heights Medical Center, Brooklyn-NY Hospital/Weill Medical College of Cornell University, New York, N.Y.

The diagnosis of acute myelomonocytic leukemia [AMMoL] based on hematologic features alone has been an arduous task. Although the cytogenetic findings remain inconclusive, the inversion or deletion of chromosome 16 are the most frequent and consistent genetic changes. Other changes with a relatively high incidence are trisomy 8, monosomy 7, 11q-, and t(1;11). A 75 year-old male with cytopenia and chronic leukemia was referred for evaluation. CBC revealed: WBC 13.6, Hb 9.3, Hct 27.7, HCV 105 and plat 95,000. The differentials were 7% segmented neutrophils and bands, 28% lymphocytes, 62% monocytes and pro-monocytes and 3% blasts. Based on the aforementioned findings, a diagnosis of CMMoL was suspected. Bone marrow aspirate revealed 77% blasts (myeloid and monocytic). Immunophenotyping revealed an immature myelomonocytic population with the following immunophenotype: HLA-DR+/CD15+/CD33+/CD4+/CD13+/CD34/CD11c/CD14 (greater than 20%). All those changes are consistent with AMMoL [FAB-M4]. Cytochemistry revealed myeloperoxidase positive, and alpha-naphthyl butyrate esterase and chloroacetate esterase both greater than 20%. Cytogenetic analysis using G-banding revealed an abnormal 45,XY,t(7;17)(p11.1;q11.2). Molecular analysis using WCP painting probe for chromosomes 7 and 17 revealed 47XY,t(7;17)(p11.1;q11.2).ish(wcp17+,wcp7+;wcp17-,wcp7-). The loss of the short arms of both chromosome 7 and 17 during translocation is a significant finding. As such, the complete monosomy of chromosome 7 may not be a factor for the development of this malignancy and these new findings may be of interest to hematologists.

**Chromosomal basis of renal cell carcinoma.** *S.M Bahieg*<sup>1</sup>, *R.S Verma*<sup>1,2</sup>. 1) Div. of Molecular Med. & Gen., Wyckoff Heights Medical Center, Brooklyn, NY; 2) New York Hospital/Weill Medical College of Cornell Medical Center, New York, N.Y.

Renal cell carcinoma [RCC] is the most common cancer in the kidney affecting over 30,000 new cases with an annual mortality of 12,000 individuals. Most commonly it occurs between the ages of 50-70 years and affects male twice as often as females. A genetic basis has become the single most significance factor and chromosomal aberrations are gaining importance in RCC. Specific chromosomal alterations have been associated with different types. The most common translocation in clear RCC are: t(3;6)(p13;q25); t(3;8)(p14;q24); t(3;12)(q13;;q24) t(3;14)(q12;q13). The chromosomes that are involved in deletions include: 3p12; 3p13; 3p14; 3p21; 3p25-26; 6q23-qter; 8p22; 8q11-qter; 9p, 9q; 14q22-qter and 17p13. Chromosome 5 band q22 was found to be duplicated. The chromosomes that are frequently lost include 8, 9, 10, 13 and 14 while chromosomes 3, 12 and 20 are most frequently gained. In papillary RCC, t(X;1)(p11;q21) was involved in translocation, band 17q21 was duplicated the Y-chromosome was lost and chromosomes 7, 12, 16, 17 and 20 were found to be in gain. The frequent loss of chromosomes 1, 2, 6, 10, 13, 17 and 21 were noted in chromophobe tumors. In renal oncocytoma, loss of heterozygosity at on chromosomes 1,2, and 3p has clinical significance. In collecting duct carcinoma, monosomies of chromosomes 1, 6, 14, 15, and 22 and trisomies of chromosomes 7, 12, 16, 17 and 20 have been observed. Loss of 8p and 13q have poor prognosis in collecting duct carcinoma. In addition we present a detailed account of molecular markers and discuss their clinical relevance.

**Advances in molecular biology of BCR-ABL gene.** *P. Chandra, R.S. Verma.* Department of Medicine, Wyckoff Heights Medical Center, Brooklyn-New York/Weill Medical College of Cornell University, New York, N.Y.

The landmark discovery of the Ph-chromosome in chronic myelogenous leukemia [CML] resulting in a balanced translocation between the long arms of chromosomes 9 and 22 has provided an inspiration for the investigation into the molecular basis of other neoplasia. The hallmark of CML is the formation of a BCR-ABL fusion gene that was thought to play a central role in pathogenesis of CML has now shown a remarkable diverse function in numerous groups of hematologic malignancies. It is the position of the translocation breakpoints in the BCR gene that alters the amount of protein produced after fusion. Certain breakpoints within the BCR gene appear to influence the phenotype of associated leukemias. The p190, p210, and p230 fusion proteins are associated with acute lymphoblastic leukemia [ALL], CML and chronic neutrophilic leukemia [CNL] respectively. The numerous variations of this molecular aberration have now been investigated. For example, there are cases with Ph-negative chromosome who have had neither a discernable BCR-ABL [bcr-negative] rearrangement nor BCR-ABL message and result in highly variable presentation. Then there are patients with reverse BCR-ABL translocation whose prognosis is still poorly understood. What is the prognosis of patients in whom the BCR-ABL gene is translocated to other chromosomes during variant translocations? Is it the BCR-ABL gene resulting in chimeric protein that initiates the event or different fusion proteins drive the expansion of different hematopoietic population? How does the chimeric protein regulate the intracellular signaling pathway? How do p190, p210, and p230 fusion proteins regulate the myeloid cells? A brief account of the latest advances in molecular biology of BCR-ABL gene shall be the subject of debate and discussion.

**Identification of New Chromosomal Aberrations as Prognostic Indicators for Pediatric Acute Lymphoblastic Leukemia.** *S.M Chenevert<sup>1</sup>, D. Johnston<sup>1</sup>, D. Mahoney<sup>2</sup>, F. Elder<sup>1</sup>, H. Northrup<sup>1</sup>, L. Cooley<sup>1</sup>.* 1) Pediatrics, University of Texas, Houston, US; 2) Texas Children's Hospital, TX.

Cytogenetic abnormalities, structural and numerical, have been determined to be significant independent prognostic indicators above clinical features present at diagnosis in pediatric acute lymphoblastic leukemia (ALL) cases. Because long-term survivors of ALL are at risk for late effects of therapy, it is important to identify factors that classify the disease as accurately as possible. Based on the premise that some of the most significant prognostic indicators are seen in only 1-2% of ALL cases, we predicted that there are non-random chromosomal aberrations that are yet to be identified. If a chromosomal aberration is shown to correlate with a very favorable or unfavorable outcome, children with this aberration may be moved from the intermediate-risk group to either low-risk or high-risk therapy group for optimal treatment and outcome. POG provided karyotype, clinical and outcome information on 2,263 pediatric patients diagnosed with ALL and followed over a period of 4.5-13 yrs. The data was analyzed for the identification for new non-random, recurrent chromosomal abnormalities and breakpoints. Ninety-one karyotypic abnormalities were selected. A binary database was set up in order to perform two standard statistical analysis techniques, univariate survival analysis and Cox model regression, that identify chromosome abnormalities that can alter the risk of failure as defined by incidence of relapse. Each abnormality was assessed for overall value as a prognostic indicator as well as its value as a prognostic indicator within the context of clinical parameters and ploidy risk groups. The results of this analysis identified several new non-random recurrent cytogenetic abnormalities that were determined to be significant prognostic indicators. Stratification of each abnormality into several risk groups provided information necessary to propose an algorithm to predict risk of relapse. This model could be used to help more accurately determine the appropriate therapy for patients with ALL, thus improving the quality of life for the patients both during and after treatment.

**Cytogenetic abnormalities in leukemic patients from Saudi Arabia: a report of 236 cases.** *R.K. Graham, S. Parker, B. Al Muzaini, S. Tashkandi, I. Al Abdulkarym.* Riyadh Armed Forces Hospital Riyadh, Saudi Arabia.

Cytogenetics forms a crucial part in the diagnosis of hematological malignancies due to the presence of common recurring chromosomal aberrations. This study summarizes the cytogenetic findings in 236 leukemic patients with karyotypic abnormalities diagnosed at the RAF Hospital from 1990 to 2000. Cytogenetic analysis was performed on bone marrow samples after 24h incubation using G-banded chromosomes. The objective was to determine the presence of nonrandom and specific chromosomal abnormalities for the Saudi population and make a comparison with previously published hematological cytogenetic aberrations. The report focuses on ALL (Acute Lymphoblastic leukemia), AML (Acute Myeloblastic Leukemia), CGL (Chronic Granulocytic Leukemia), CML (Chronic Myeloid Leukemia) and MDS (Myelodysplastic Syndrome). Overall, 60% were male and 40% female. Clonal evolution was seen in 16% of cases. In ALL, of which there were 48 cases, 27% were adult males and 22% pediatric males in contrast to 4% adult females and 46% pediatric females. The main findings were +4, +6, +8,+10,+12,+21,+X, -7 and -9. Predominant translocations included t(15;17) and t(9;22). In addition, del(1q) and del(6q) were noticeable. In AML (n=54) the majority were adults and the main findings were +4, +8, -7, -14, -20, -X, -Y, 8q-, der(7) and inv(16). Concerning translocations, t(15;17) and t(8;21) were common. Frequent translocations involving chromosome 1 were also noted. In both ALL and AML marker chromosomes were frequently observed. Regarding CGL (n=42) and CML (n=41) the majority of cases were adult and contained the t(9;22). However in CGL, t(9;22) was seen as the sole anomaly in 70% of the cases whereas in CML a significant number also contained additional abnormalities such as +8,+19,+Y, -13 and inv(9). In MDS (n=14) noticeable changes included +8, der(5), -7, and -13. In conclusion, although common recurring chromosomal aberrations are present some variations to the published literature exist. These findings emphasize the importance of classifying the cytogenetic abnormalities in leukemogenesis for this population, which is essential for appropriate clinical care and management.

**Racial differences and cytogenetic abnormalities in hematologic malignancies: A five year retrospective study.** *L. Cheng, K.H. Ramesh, E.R. Burns, J.C. Park, L.A. Cannizzaro.* Department of Pathology, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY.

We studied the cytogenetic makeup of 1100 patients with clinically proven or suspected hematologic malignancies in an ethnically diverse population of New York City. Varying degrees of chromosome abnormalities were detected in 302 patients (238 adults and 64 children). The influence of genetic factors associated with the occurrence and progression of the disease was also investigated. Our cohort was 14% black, 26% Hispanic, 21% white, and 39% others/unknown ethnic origin. Our study concentrated on the cytogenetic classifications, the incidence and types of chromosomal alterations, and the frequency of unrelated abnormal clones among black, Hispanic, and white groups. Our findings showed: 1) Among adult acute myeloid leukemia (AML) patients with chromosome abnormalities involving either 5, 7, or 8, 100% of blacks had involvement vs. 36% for Hispanics ( $p=0.011$ ) and 40% for white ( $p=0.016$ ); 2) Among pediatric acute lymphoblastic leukemia (ALL) patients, blacks had 44% of ploidy anomalies vs. 80% for Hispanics ( $p=0.045$ ); 3) Overall, 12% of Blacks had unrelated abnormal clones vs. 2.5% for Hispanics ( $p=0.039$ ) and 5% for whites ( $p=0.085$ ); 4) There was no association between karyotypic patterns and patients with myelodysplastic syndromes (MDS), lymphoma or multiple myeloma (MM) in the three ethnic groups studied; 5) Overall, there was no statistical difference in the percentage of complex chromosomal abnormalities among these three groups. Our findings suggest an association between ethnic background and chromosomal abnormalities in certain hematologic malignancies. Further studies are needed to determine the genetic mechanisms that may have an influence on hematologic malignancies.

**A rare retroperitoneal synovial sarcoma not diagnosed until detection of translocation (X;18)(p11.2;q11.2) and SYT/SSX fusion gene.** *Y.C. Dai, H.M. Wu, C.W. Chang, C.C. Tzeng.* Department of Pathology, National Cheng-Kung University Hospital, Tainan, Taiwan, Republic of China.

Malignant spindle cell neoplasms are often a diagnostic challenge in histopathology, regardless of their location. In this report we described a huge primary retroperitoneal malignant spindle cell tumor, measuring 30 x 20 x 15 cm, in a 19-year-old woman. It was not accurately diagnosed until detection of the characteristic chromosomal translocation (X,18)(p11.2;q11.2). Priority of differential diagnoses of retroperitoneal tumors usually depends on patients' age, histopathological and immunological features, their relationship to kidney, and relative incidence at this location. Initially, the tumor of this report was considered to be a Wilms' tumor, with almost purely blastemal component and no immature tubular or glomerular structure. In fact, synovial sarcomas occurred commonly in para-articular regions, with less than 30 tumors arising from retroperitoneum reported in the English literature. Whilst, only two of these retroperitoneal tumors were genetically confirmed so far. This report described the third one well documented by detecting characteristic translocation (X;18)(p11.2;q11.2), as well as demonstrating the presence of SYT/SSX, type II, fusion transcripts with reverse transcriptase polymerase chain reaction (RT-PCR) and sequencing. Furthermore, together with the clinicopathological features of this patient, we supported that the SYT/SSX, type II, fusion genes has a close relationship with monophasic subtype of the synovial sarcoma, as well as a favorable prognosis.

**Karyotypic study of two immature ovarian teratomas after chemotherapy induced maturation.** *S.A. Faruqi, U. Chapa, R.B. Deger, J.S. Noumoff.* OB/GYN, Div Gynecologic Oncol, Crozer-Chester Medical Ctr, Upland, PA.

We report the karyotypic study of two cases of grade three immature ovarian teratomas after their chemotherapeutic maturation. In the first case the tissue was that of the metastatic mature post-chemotherapy tumor, while in the second case both the primary tumor as well as the residual mature post-chemotherapy tumor were available. The treatment included cisplatin, bleomycin and etoposide combination chemotherapy. Histologically, both the primary tumors contained immature glial tissue but the residual tumors following chemotherapy contained only mature elements. In the first case, the metastasis was found to have monosomies in eleven chromosomes and trisomies in four chromosomes. In the second case, trisomies of chromosomes 7 and 9 were the only two abnormalities which were present both before and after chemotherapy. One other chromosomal anomaly of partial trisomy of chromosomal 11 although present in the primary tumor, was not found in the residual material. It is interesting to note that the MDR-1 gene has been mapped on chromosome 7. Overexpression of its gene product, p-glycoprotein, has been implicated in chemotherapy treatment and worse prognosis in myeloid leukemias. The most important finding in this study is the disappearance of the clone with partial trisomy 11, the chromosome which has the protooncogene cyclin-D, while the other clones survived this particular chemotherapy.

**Fine mapping of chromosome 3q amplifications in head and neck squamous cell carcinoma by molecular cytogenetics, and high resolution CGH micro arrays.** *S.P. du Manoir<sup>1</sup>, K. Wanherdrick<sup>1</sup>, D. Muller<sup>2</sup>, J. Abecassis<sup>2</sup>, R. Redon<sup>1</sup>.* 1) Human genetics, IGBMC, INSERM-CNRS-ULP, Strasbourg; 2) Paul Strauss center, Strasbourg.

Gain or amplification of the telomeric part of the chromosome 3 is common in HNSCC carcinoma. We analysed a series of 21 well differentiated, node and metastasis negative HNSCC tumors by comparative genomic hybridization. Recurrent gain of the 3q26-qter region was found in 78 % of the cases. Correlation with overall survival suggests a possible predictive value for the 3q26 region gain. After six years, only 50% of patients are still alive in the population with a gain at 3q26 against 90% for the population normal for this locus : patients with 3q26 gain have a shorter survival, even if this difference is not significant (Mantel-Cox test). We extended our series to 45 cases using FISH on interphasic nuclei with a BAC clone containing the PIK3CA gene. In these larger series, after 6 years, 44% of patients with the gain are alive Vs 67% in the normal population : these results suggest a predictive value for 3q26 gain, but were not statistically significant (Mantel-Cox test). Gains targeting 3q26-qter were mapped by interphasic FISH using BAC and YAC clones localized on the long arm of the chromosome 3. Among the tumors exhibiting a gain, five showed a restricted amplification, among them three are amplified only for a part of this region : two different consensus sites of amplification were found around 3q26 and 3q27-qter. Finally, to systematically assess the extend of gains, we designed a high resolution CGH arrays with 60 BAC clones from the chromosome 3 and used it to delineate aberrations in three HNSCC cell lines and the selected tumors with amplification.

**Distinct Molecular Cytogenetic Profile in Six Pediatric Patients with Rhabdomyosarcoma.** Z. Chen<sup>1</sup>, C.M. Coffin<sup>2</sup>, B. Issa<sup>1</sup>, S. Arndt<sup>1</sup>, R. Shepard<sup>1</sup>, L. Brothman<sup>1</sup>, J. Stratton<sup>1</sup>, A.R. Brothman<sup>1</sup>, H. Zhou<sup>2</sup>. 1) Dept Pediatrics/Cytogenetics, Univ Utah Sch Medicine, Salt Lake City, UT; 2) Dept Pathology, Univ Utah Sch Medicine, Salt Lake City, UT.

Rhabdomyosarcoma (RMS) represents the most common soft-tissue sarcoma in children under the age of 15 years. Histologically, RMS can be subdivided into two major subtypes: embryonal (E-RMS) and alveolar (A-RMS) rhabdomyosarcoma, with E-RMS being the most common. Genetically, A-RMS is characterized by a t(2;13) (PAX3-FKHR fusion product) or a t(1;13)(PAX7-FKHR fusion product), whereas E-RMS by gains of chromosomes 2,8,11,12, and 13. In addition, loss of heterozygosity (LOH) at 11p,16q, 6p and 18p has been frequently observed in both types as well. However, molecular cytogenetic studies on other subtypes of RMS are scarce. In the present study we performed cytogenetics, fluorescence in situ hybridization (FISH), Spectral Karyotyping (SKY), and immunohistochemical antibody analysis on six pediatric patients with RMS, including one A-RMS, three E-RMS, one botryoid RMS, and one anaplastic non-classified RMS (N-RMS). Our findings in A-RMS and E-RMS were generally consistent with previous reports; however, i(15)(q10), del(4)(q21q31), and del(9)(p21) observed here have been rarely reported in the literature. Importantly, our botryoid RMS showed a cytogenetic profile consistent with E-RMA, further confirming it is a variant of E-RMA. An add(11)(q21) observed in this tumor, together with a t(8;11)(q12-13;q21) reported previously, highly indicate that 11q21 rearrangements may be specifically related to botryoid RMS. In addition, our N-RMS expressed a cytogenetic pattern similar to that observed in E-RMS, thus providing strong genetic evidence that some anaplastic N-RMS may be a very anaplastic form of E-RMS. Immunohistochemical stains in this tumor also displayed high reactivity for p53, diffuse reactivity for vimentin and desmin, and focal reactivity for muscle specific actin. Anaplasia in RMS is a poor prognostic feature, as is nuclear p53 expression.

**Analysis of a homozygous *BRCA1* mutant breast cancer cell line using CGH, SKY and LOH: A model for the comprehensive evaluation of publicly available tumor cell lines.** *D. Boles<sup>1</sup>, E. Cedrone<sup>1</sup>, L. Cavalli<sup>2</sup>, J. Rone<sup>2</sup>, C. Long<sup>1</sup>, D. Burkhardt<sup>1</sup>, P.S. Donover<sup>1</sup>, B. Haddad<sup>2</sup>.* 1) American Type Culture Collection, Manassas, VA; 2) Georgetown University Medical Center, Washington, DC.

A large number of tumor cell lines are available in the public domain. Many of these cell lines have been characterized using conventional cytogenetic studies and nearly all of those examined carry chromosomal aberrations. Such studies, while important, need to be complemented using newer approaches. Today, new molecular technologies including comparative genomic hybridization (CGH), spectral karyotyping (SKY) and loss of heterozygosity (LOH) studies allow tumor genomes to be surveyed for chromosomal aberrations in a more thorough and comprehensive way thus allowing the identification of tumor-specific chromosomal anomalies with a high degree of accuracy. The availability of such information on publicly available tumor cell lines will provide researchers with a valuable resource. As a model of such an approach, we have used CGH, SKY and LOH to characterize the cell line HCC1937 (ATCC # CRL-2336) derived from an identical triplet who developed breast cancer at age 24 and has a homozygous germline mutation in *BRCA1* (*BRCA1* 5382insC). Initial analyses using classical cytogenetics revealed a highly transformed karyotype with a modal chromosome number of 100 and at least 43 marker chromosomes involving nearly every chromosome. The complexity of this karyotype prevented clear breakpoint designations or identification of partner chromosomes in all rearrangements. However, the combination of SKY and CGH allowed a comprehensive characterization of these chromosomal findings. LOH data provided further insights on specific genes lost. With such an approach, description of newly identified aberrations is possible, previously unidentified structural rearrangements are resolved and new breakpoints are defined. We conclude that such studies should be undertaken to complement existing conventional cytogenetic information on publicly available tumor cell lines in a more systematic way.

**Transient Leukemia with Trisomy 21 Showing T-Cell Phenotype.** *Q.L. Hu, H.O. Shah, I. Akhtar, S. Korsuri, D. Sabatino, J. Sherman, B. Feldman, J. Lin.* Pathology and Laboratory, Nassau County Medical Center, East Meadow, NY.

Nassau County Medical Center, East Meadow, New York, Health Science Center, State University of New York at Stony Brook, New York. Transient leukemia (TL) has been reported in 10% of infants with Down syndrome and showed predominately megakaryoblastic phenotype. TL usually disappears spontaneously. But in approximately 25 percent of the cases who recover will develop acute megakaryocytic leukemia (M7) in next four years. Its clonal proliferation and tissue infiltration favor TL to be a specific form of leukemia. Here we present a case of TL with T-lymphocyte phenotype by cytochemical approach. The full term infant was born to a 20-year old female spontaneous with delivery. Physical examination showed features of Down syndrome with yellow, crusty skin rash on face and hepatosplenomegaly. Peripheral blood cell counts (PBC) at birth: WBC 47.7K/cubic millimeter, blasts 42 percent, RBC 4.53 million/cubic millimeter, and platelets 122.8K/cubic millimeter. Bone marrow aspirate at the second week of birth showed 27.3 percent of blasts, which were positive for acid phosphatase in paranuclear pattern, negative for alpha-naphthyl acetate esterase, ASD-chloroacetate esterase and CD61. Cytogenetic study of the bone marrow confirmed trisomy 21. The patient was managed with supportive therapy and clinical observation alone. On 92nd days of birth, the WBC count was 9.1K/cubic millimeter with a normal differential and there were no blasts present. The baby has since been doing well up to now at nine months of age. Even though majority of TLs is of megakaryocytic nature, TLs of T-lymphocyte phenotype is very rare. TLs may possess totipotential properties to differentiate into other cellular lineages, such as this, into T-cell phenotype.

**Hepatoblastoma in a child with mosaic trisomy 18.** *B. Kohn<sup>1</sup>, K. Ayelew<sup>1</sup>, M. Mannikal<sup>1</sup>, S.M. Kleyman<sup>2</sup>, M.J. Macera<sup>2</sup>, R.M. Chandra<sup>2</sup>, and R.S. Verma<sup>2</sup>.* 1) Long Island College Hospital, Brooklyn, NY; 2) Wyckoff Heights Medical Center, Brooklyn- New York Hospital/Weill Medical College of Cornell University, New York, NY.

Hepatoblastoma is a rare tumor occurring most frequently in children under three years of age. Adult cases have occasionally been reported. Most of the cytogenetic evaluation has been carried out on tumor-derived cell lines. No consistent hepatoblastoma-specific genetic markers have been established. Most hepatoblastomas are diploid or hyperdiploid, often displaying trisomies for chromosomes 2 and 20, 2q+, 11p-, and 13q-. A 16 month-old female, the product of a 37-week gestation to a 41-year-old mother and 42 year-old father was referred for failure to thrive and severe hypercalcemia. Her birth weight was 3 lbs. The pregnancy was complicated by premature labor. A brief clinical presentation included failure to thrive with poor weight gain and delayed motor and verbal milestones. Clinical examination revealed dysmorphic features including strabismus, prominent occipital and narrow bifrontal diameter, low-set ears, narrow palatal arch, micrognathia, hypoplasia of the nails on fingers and toes, short sternum, small areola and small pelvis. The liver was enlarged to 3 cm below the right costal margin and hypotonia was detected. Neurological development was delayed. Abdominal CT denoted a large heterogeneous mass in the right hepatic lobe. Tumor pathology confirmed a hepatoblastoma. Cytogenetic findings with G-banding revealed a mosaic karyotype for chromosome 18 {i.e. 47,XX,+18[37]/46,XX[13]} in her peripheral blood. Tissue was unsuccessful in culture, however, interphase cytogenetics by FISH revealed the presence of both cell lines, suggesting that both normal cells and tumor cells were present. Since neoplasias arise from a single cell, only one tumor cell line was expected. It has been suggested that trisomy 18 may predispose to both hepatoblastoma and Wilms' tumor. This is a rare tumor and unfortunately, cytogenetic findings are not available, so a definitive conclusion concerning the chromosomal basis of hepatoblastoma could not be drawn.

**Identification of two distinct variant *bcr/abl* translocations in Ph-negative Chronic Myeloid Leukemia cases by FISH.** M. Mohammed, S. Shin, G.J. Schiller, C.L. Sawyers, P.N. Rao. UCLA School of Medicine, Los Angeles, CA.

Approximately 5-10 % of patients with morphologically typical CML, appear to be Ph-negative, presenting with variant translocations in which the *bcr-abl* fusion gene may be cytogenetically masked. The mechanisms of their formation and the clinical significance are still unclear. The location of the fusion gene on chromosomes other than 22q-remains rare. We present here two CML patients with Ph-negative karyotypes and unusual *bcr-abl* presentations. **Case 1** : A 42-year-old female, with morphologic findings consistent with CML. Bone marrow cytogenetics revealed a Ph-negative abnormal karyotype, 46,XX,t(13;20)(q14;q13.1)c. To confirm the CML status, FISH with *bcr-abl* probe (Vysis) was performed. The fused gene was found to be localized to chromosome 9q34, and not on chromosome 22q11. Additional FISH analyses with the DiGeorge/VCFS probe (Vysis), showed both, the TUPLE1 probe which is slightly distal to the *bcr* probe, and the ARSA (control) probe, hybridized to chromosome 22. Given the close proximity of the TUPLE 1 probe to the *bcr*, it is likely that a discrete interstitial insertion of the *bcr* into the 9q34 as a secondary event, occurred in this patient. **Case 2**: A 47-year-old white male, with CML in blast crisis. The pretreatment karyotype was Ph-negative and abnormal: 46,XY,t(17;19)(q23;q13.1). However, FISH analyses revealed that the *bcr-abl* fusion gene was located on chromosome 22. Uniquely, an *abl* probe signal was observed on both 9q34 homologues, although one of the signals appeared smaller (?*abl* gene split). FISH analyses on a bone marrow sample after treatment, revealed a second distinct clone (33%). As with the initial clone, the *bcr-abl* fusion gene was located on chromosome 22, but unlike the initial clone, the extra *abl* signal was now interstitially located at 9q22 region, instead of 9q34 (?inversion). The exact mechanism of such a novel presentation of the fusion gene remains unclear. Further FISH and molecular studies to unravel some of these mechanisms are in progress. These cases highlight the heterogeneity with which the *bcr-abl* fusion gene may be formed and the usefulness of multicolor metaphase FISH in detecting variant *bcr-abl* translocations.

**Defects in Methylthioadenosine Phosphorylase are Associated with but not Responsible for Methionine-Dependent Tumor Cell Growth.** *B. Tang, Y.N. Li, W.D. Kruger.* Division of Population Science, Fox Chase Cancer Center, Philadelphia, PA.

A large proportion of human tumor derived cell lines and primary tumor cells show methionine-dependent growth. This phenomenon refers to the ability of cells to grow in media containing methionine but the inability to grow on media supplemented with methionines precursor, homocysteine. Methionine can be formed by two different pathways; the recycling pathway and the salvage pathway. To discover the basis for methionine-dependent growth we have analyzed twelve tumor cell lines and two non-tumor derived cell lines for defects in two key genes in different methionine synthetic pathways. We found little evidence that defects in methionine synthase (MS) expression or mutations in the MS gene are correlated with methionine-dependent growth. However, we did find a correlation between methionine-dependent growth and defects in expression of methylthioadenosine phosphorylase (MTAP), a key enzyme in the salvage pathway. Three of the four cell lines lacking detectable MTAP protein were unable to grow in homocysteine media, while all six of the MTAP positive cell lines tested showed strong growth. However, when we introduced the MTAP cDNA into MTAP deficient MCF-7 cells, the resulting cell line was still defective in growth on homocysteine, although it could now grow on the salvage pathway precursor methylthioadenosine. These findings indicate that salvage pathway defects are not causally related to methionine-dependent growth.

**Genomic Alterations in Uterine Leiomyosarcomas: Potential Markers for Clinical Diagnosis and Prognosis.** *J.*

*Hu*<sup>1,4</sup>, *V. Khanna*<sup>1</sup>, *M. Jones*<sup>2,4</sup>, *U. Surti*<sup>1,2,3,4</sup>. 1) Dept of Genetics, Magee Womens Hospital of UPMC Health System, Pittsburgh, PA; 2) Dept of Pathology, Magee Womens Hospital of UPMC Health System, Pittsburgh, PA; 3) Magee Womens Research Institute, Pittsburgh, PA; 4) University of Pittsburgh, Pittsburgh, PA.

Genomic alterations were analyzed in 21 uterine leiomyosarcomas (ULMS) by comparative genomic hybridization. DNA copy number changes were detected in all 21 tumors. The most frequent losses were 13q (16/21=76%), 10q (13/21=62%), 16q (8/21=38%), 12p (7/21=33%) and 2p (9/21=43%). The most common gains were 17p (8/21=38%), Xp(7/21=33%) and 1q (7/21=33%). High copy number gains (ratio>1.5) were identified in Xp, 1q and 17p. Loss of 13q was identified in both low grade and high-grade tumors. Inactivation of a tumor suppressor gene in 13q may be an early event in the development of leiomyosarcomas. Loss of 10q, 2p, 12p and gains of 1q as well as 17p were frequently found in high-grade tumors and recurrent tumors. Inactivation of tumor suppressor genes and activation of oncogenes in these regions may be associated with a more aggressive behavior of ULMS. Patients with just loss of 13q and without other alterations listed above had longer survival. Gains of Xp, 17p, 1q and losses of 13q, 10q, 16q, 12p and 2p have been reported in extra-uterine leiomyosarcomas. Our findings indicate that the pathogenesis of uterine leiomyosarcomas and extra-uterine leiomyosarcomas follow the same genetic pathways.

**Statistical analysis for rb-1 monoallelic deletion by FISH is crucial in multiple myeloma diagnosis.** *G. Lu, R.G. Best.* Obstetrics & Gynecology, University of South Carolina, Columbia, SC.

Multiple myeloma (MM) is a common B-cell malignancy for which activation of oncogene and loss of function of tumor suppressor genes have both been proposed. Of the tumor suppressor genes studied, loss of the retinoblastoma susceptibility gene rb-1 on 13q14 is most frequently reported with an estimated frequency as high as 52%. The loss of rb-1 gene is associated with late stage and poor prognosis of the disease. The rb-1 deletion is usually monoallelic and is often undetectable by conventional cytogenetic technique, thus requiring application of fluorescence in situ hybridization (FISH) in diagnosis. We have recently identified three cases of MM with monoallelic deletions of rb-1 with between 5% and 70% mosaicism. Of the three cases, only one showed conventional G-band deletion of 13q14 with just 2 out of 20 cells exhibiting the deletion. Rb-1 deletion by FISH was observed in only 5% of interphase cells. Rb-1 deletions in MM in the published literature are almost always monoallelic and mosaic, however, the degree of mosaicism in interphase exhibits variability from case to case, and between interphase and metaphase cells. Our findings and those reported in the literature emphasize the importance of using clearly defined statistical methods and protocols in each individual laboratory for discriminating true mosaicism from pseudomosaicism when testing interphase cells for deletions on 13q14. We discuss our protocol and its application in other laboratory settings including the use of sensitivity and specificity of the probes in determination of standards for discriminating true mosaicism from technical artifact, and the lower limits of detection of mosaicism for various interphase cell sample sizes.

**Heterogeneity of t(11;17) translocations in leukemia.** *S. Strehl*<sup>1</sup>, *M. König*<sup>1</sup>, *O.A. Haas*<sup>1, 2</sup>. 1) CCRI, Children's Cancer Research Institute, Vienna, Austria; 2) Ludwig-Boltzmann Institute for Cytogenetic Diagnosis (LBICD).

Rearrangements of the MLL gene on chromosome 11q23 account for 5-10% of acquired chromosomal aberrations in children and adults with acute lymphoblastic and myeloblastic leukemia, poorly differentiated or biphenotypic leukemias and myelodysplastic syndromes. Strikingly, involvement of at least 40 different chromosome regions in 11q23 translocations has been determined. Twenty-three fusion partner genes have been cloned and partially characterized to date. Two translocations occur at 17q21 and 17q25 each accounting for 1-1.5% of all MLL rearrangements. AF17 localized at 17q21 and MSF at 17q25 have been cloned as fusion partners of MLL. In acute promyelocytic leukemia also a variant of the more common t(15;17)(q22;q21) resulting in the chimeric PML/RARa fusion gene has been observed. In the t(11;17)(q23;q21) variant the promyelocytic leukemia zinc finger (PLZF) gene (11q23) is fused to RARa (17q21). Recently, based on FISH data also a putative fusion between MLL and RARa was suggested and still another MLL fusion partner, GAS7, is localized at 17p13. We have identified seven patients with acute leukemia carrying a t(11;17)(q23;q21-25) by cytogenetics and/or whole chromosome painting and in six of them rearrangement of the MLL gene was detected by FISH analysis using a YAC clone that spans the MLL breakpoint region. RT-PCR for the detection of the MLL/AF17 and the PLZF/RARa fusion genes was performed and surprisingly only one case was positive for MLL/AF17 suggesting involvement of other MLL partner genes. However, also RT-PCR for the MLL/MSF fusion could not detect the particular chimeric transcript at least in three of the samples. In order to further characterize the chromosomal breakpoints FISH with an MLL YAC clone and a RARa probe was performed and three different hybridization patterns were detected: (i) MLL splits and RARa remains on the der(17), (ii) MLL splits and RARa is translocated to the der(11), and (iii) MLL is translocated to the der(17) and RARa splits. These investigations will contribute to the accurate classification of distinct t(11;17) translocations and possibly lead to the detection and cloning of new MLL fusion partners.

**Gene amplification occurs via breakage-fusion-bridge cycles in oral cancer cells.** X. Huang<sup>1</sup>, M. Shuster<sup>1,2</sup>, T.E. Godfrey<sup>1,3,4</sup>, W.S. Saunders<sup>2,4</sup>, B.M. Gharaibeh<sup>1</sup>, S.M. Gollin<sup>1,4</sup>. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA; 3) Department of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Chromosomal instability is an important feature of cancer cells. Gene amplification is a common genetic alteration in tumors and is one mechanism for producing a higher level of gene product. Oral squamous cell carcinomas (OSCC) are characterized by complex, often near-triploid karyotypes with structural and numerical variations on a theme of clonal chromosomal alterations. About half of OSCC and derived cell lines express a homogeneously staining region (hsr) comprised of amplified chromosomal band 11q13. We and others have proposed that gene amplification occurs via breakage-fusion-bridge (BFB) cycles. We used FISH with probes to D11Z1, *RINI*, and cyclin D1 (*CCND1*) to examine the amplicon in our oral cancer cell lines and observed a predictable pattern of organization, an “amplification fingerprint” consistent with BFB cycles. This is characterized by an inverted duplication chromosome pattern in the region of amplification, with genes from the segment just distal to the proximal chromosomal breakpoint duplicated and flanking both sides of the amplified genes in the amplicon. In addition, FISH analysis confirmed the hypothesis by revealing the presence of the amplified *CCND1* gene in the anaphase bridges between nascent oral cancer cells. To accurately map the proximal and distal breakpoints involved in the BFB cycles, we have used quantitative microsatellite analysis (QuMA). Of the 19 OSCC cell lines with 11q13 amplification examined to date, our data show that the proximal and distal breakpoints are the same in 63% and 53%, respectively. This may indicate the presence of one or two as yet unidentified breakage hotspots or fragile sites that are responsible for 11q13 amplification by BFB cycles. These results provide the first cytological evidence that gene amplification in oral cancer cells occurs via breakage-fusion-bridge cycles.

**A highly specific and sensitive fluorescence in situ hybridization (FISH) assay for the detection of t(4;11)(q21;q23) in acute leukemias.** O.A. Haas<sup>1</sup>, S. Strehl<sup>1</sup>, M. König<sup>1</sup>, M. Reichel<sup>2</sup>, R. Marschalek<sup>2</sup>. 1) Children's Cancer Research Institute (CCRI) and Ludwig-Boltzmann Institute for Cytogenetic Diagnosis (LBICD), St Anna Children's Hosp, Vienna, Austria; 2) Department of Genetics, University of Erlangen, Germany.

The t(4;11)(q21;q23) is one of the most common 11q23 abnormalities. It occurs typically in infant leukemias and topoisomerase II inhibitor induced secondary acute leukemias. The t(4;11) fuses the *AF4* and the *MLL* genes and generates a chimeric *MLL/AF4* mRNA that is easily detectable with RT-PCR. In contrast, 11q23 abnormalities can only be detected indirectly with FISH by hybridization of clones that span or flank the *MLL* gene. Until recently, two YAC clones (13HH4 and yB22B2) were used for this purpose. They are split by translocations involving the *MLL* gene. Unfortunately, these YAC clones do not identify those approximately 20% of cases in which the 3'-*MLL* part is deleted. Therefore, new two color *MLL* probes were developed that result in the segregation of normally overlapping green- and red-labeled clones in case of translocations. Whereas such assays reliably detect all the translocations that involve *MLL*, they provide no information about the translocation partner in interphase. We therefore designed a FISH assay for the specific and sensitive detection of the t(4;11)(q23;q21) that can be applied for both interphase and metaphase analysis. Our differentially labeled *MLL* YAC (13HH4) and *AF4* PAC clones are both split in case of a t(4;11). Therefore, FISH generates two red and two green signals in normal cells, whereas in case both the reciprocal gene fusions are present in t(4;11)-positive cells, one red and one green signal occur together with two green/red co-localized signals. We evaluated the specificity and sensitivity of this FISH assay on normal controls as well as on serial dilutions of a t(4;11)-positive leukemia cell line in normal cells. To date, we have successfully studied 18 *MLL/AF4*-positive cases with varying amounts of t(4;11)-positive cells as well as unusual cases that had the der(4) chromosome either deleted or duplicated.

**Camptothecin-induced DNA damage identifies a deficiency in a double strand break repair subpathway in Ataxia-Telangiectasia which promotes multiple chromosome exchanges in probands and obligate heterozygotes.**

*R.T. Johnson, J. Schmidt, A.M. Mullinger, J.C. Leonard.* Coriell Cell Repositories, Coriell Institute for Medical Research, Camden, NJ.

A-T cells are chromosomally unstable, and are hypersensitive to ionizing radiation and other agents causing DNA double strand breaks (DSBs). Chromosome studies have suggested a defect in DSB repair, but direct measurements are less clear, and the underlying defect and basis for cell killing are uncertain. Here we use the topoisomerase I inhibitor camptothecin (CPT), which induces DSBs predominantly in replication forks, and show that A-T cells are defective in the repair of this subclass of DSBs. After CPT treatment, A-T cells pass to G2, where they remain; normal cells repair most of their DSBs and arrest briefly in G2. The frequency of CPT-induced chromosome aberrations (viewed in prematurely condensed G2 chromosomes) in each of a wide variety of A-T cells examined, including different ATM gene mutations, is abnormally high; aberrations are S-phase-derived and many are multiple illegitimate chromatid exchanges. In normal cells the aberrations are mostly chromatid breaks. Obligate A-T heterozygotes also show more aberrations than normal controls. FISH analysis using whole chromosome paints reveals the complexity and type of exchange aberrations. The data suggest that ATM, the A-T protein, recognises DSBs in active replicons and helps to suppress illegitimate S-phase recombination.

**The Role of RxFISH in the Delineation of Complex Chromosomal Abnormalities in Hematologic Disorders.** *J.H. Hersh<sup>1</sup>, M.J. Barch<sup>1</sup>, D.A. Stevens<sup>2</sup>, F.F. Yen<sup>1</sup>, E. Jusufbegovic<sup>1</sup>, B. Weisskopf<sup>1</sup>.* 1) Dept Pediatrics/CEC, Univ Louisville, Louisville, KY; 2) Nortons Hospital, Louisville, KY.

Complex karyotypes frequently are found in hematologic disorders, which are difficult to characterize by conventional banding. The development of fluorescence in situ hybridization (FISH) represented an important step in overcoming this problem, but has been limited by its inability to detect the entire genome in a single application. Cross-species color banding (RxFISH) is a new FISH technique utilizing probes from flow-sorted, differentially labeled gibbon chromosomes which overcomes this problem by examining the entire karyotype at one time. Harrison et al, Teixeira et al and Micci et al demonstrated the usefulness of RxFISH to characterize chromosomal rearrangements in patients with leukemia and solid tumors incompletely identified by G-banding. We present data comparing results of conventional banding and RxFISH on bone marrow specimens performed on 50 patients with hematologic disorders. In 14/50 (28%), a chromosomal abnormality was detected by both methods. Diagnostic entities included 8 patients with leukemia, 3 with lymphoma, 2 with thrombocytopenia and 1 with myelodysplastic syndrome. RxFISH confirmed a balanced translocation in 4 patients and deletion of a #20 chromosome and presence of a small marker chromosome in two others that had been identified by G-banding; however the origin of the marker could not be determined by either technique. In the other 8 patients, complex karyotypes were recognized on conventional banding, although complete characterization could not be achieved. RxFISH provided additional information about these abnormalities, which were confirmed by FISH studies. Our results support the previous conclusion that RxFISH provides more accurate information about complex chromosome abnormalities present in hematologic disorders and can serve as a valuable adjunct to conventional banding in the interpretation of complex karyotypes in these conditions.

**Design of an Automated Spot Counting Program for Interphase FISH on the Tissue Microarray.** *G.H. HOSTETTER<sup>1</sup>, C.L. ANDERSEN<sup>1</sup>, L. BUBENDORF<sup>1</sup>, J. KONONEN<sup>1</sup>, E. DOUGHERTY<sup>2</sup>, A. GRIGORYAN<sup>2</sup>, O. KALLIONIEMI<sup>1</sup>.* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Computer-Assisted Medical Diagnostic Imaging (CAMDI) Laboratory, Texas A&M University, College Station, TX.

Tissue microarray technology (Kononen et al. 1998) facilitates high-throughput analysis of genetic changes in cancer and other diseases. Up to 1000 tissue specimens can be placed on a single microscope slide and subjected to molecular analyses, such as FISH. Consecutive tissue microarray sections can be analyzed with probes or antibodies to perform comprehensive molecular profiling of the tissues. In the past two years, our laboratories have performed close to 20,000 FISH experiments. The most time-consuming part is the manual scoring of the FISH signals. Here, we report the development of an automated system that acquires 3-dimensional images of tissue sections, and automatically analyzes the relative copy number of target loci. A stack of 12 consecutive confocal images are acquired with a Quantix CCD camera attached to a Axioplan2 microscope equipped with a confocal CARV module. The FISH spot counting algorithm defines the signals in three dimensions, allowing separation of closely clustered signals. The program was tested on 17 images from breast cancers hybridized with HER-2 and chr 17 cen probes (Vysis Inc.). Detection of HER-2 amplification showed 94% agreement between manual and automated scoring and the correlation between the signal counts was  $r=0.468$  ( $p<0.001$ ). We then designed three adaptations: 1) Improved definition of the lower limit of size and intensity for a real FISH spot, 2) Improved analysis of tight clusters, and 3) User interaction by gating out regions of autofluorescence. In summary, development of the tissue microarray technology and automated FISH analysis have now paved the way for a high-throughput automated analysis of genetic alterations in thousands of tissues. We are now carrying out a clinical study to test the performance of the system in a large sample set of breast cancers hybridized with the HER-2 probe.

**Comparative analysis of dual versus single color *MLL* probes: Early relapse in t(4;11) leukemia detected by dual color probe only.** *J.L. Murata-Collins, P. Gaytan, G. Alvarez, M.L. Slovak.* Dept Cytogenetics, City of Hope National Med Ctr, Duarte, CA.

Accurate detection of disruptions involving the *MLL* locus, mapped to chromosome band 11q23, is critical in cancer cytogenetics, providing information necessary for both disease classification and ascertainment of prognostic risk category. After initial disease assessment and treatment, monitoring by fluorescence *in situ* hybridization (FISH) to detect minimal residual disease or early relapse is key to successful clinical intervention. Previous in-house validation studies for a single color *MLL* probe established a value <10%, for translocations, to be within background limits selected to maximize specificity [sensitivity, 91.7%, with 95% confidence intervals (CI) of 61.5%-99.8%; and specificity, 97.8%, with 95% CI of 88.2%-99.9%]. To determine whether a dual color *MLL* probe would increase sensitivity of detection, a case comparison study was performed, matching both types of *MLL* FISH probes and classic cytogenetics (CG) for 19 abnormal specimens, including translocations and deletions, and 11 normal controls. In 17 specimens, an 11q23 translocation was detected by CG in 5% - 100% of cells; eight with t(4;11), three with t(11;19), three with t(6;11), and two with t(9;11). Using a single color *MLL* probe, three t(4;11) specimens gave false negative (FN) results, under the 10% background limit. Using a dual color *MLL* probe, all translocation specimens scored positive, ranging from 10%-100%, with controls scoring between 0%-2% false positive. The three FN studies by single color probe, 0.6%, 1.4%, and 8%, scored 14.5%, 15%, and 23.5% positive, respectively, by dual color probe. In two 11q23 deletion cases, both probes gave normal signal patterns, indicating neither deletion encompassed the *MLL* locus. Despite an increased potential for false positives, due to the appearance of split signals in interphase nuclei, the dual color *MLL* probe increased both sensitivity and specificity in detecting *MLL* translocations, reducing background limits to £3% [sensitivity, 100.0%, with 95% CI of 80.5%-100.0%; and specificity, 100.0%, with 95% CI of 71.5%-100.0%].

**Duplicated 20q deletion and acute myelomonocytic leukemia (M4).** *S.L. Wenger, D. Wonsettler, W.W.L. Chang.*  
Dept Pathology, West Virginia Univ, Morgantown, WV.

A 59-year-old hypertensive white male was admitted to the hospital with shortness of breath, tightness in chest and weakness. He was found to have a pericardial effusion and underwent pericardiocentesis with placement of a drainage catheter, which continuously drained bloody fluid. He had marked leukocytosis and thrombocytopenia since surgery for a ruptured appendix 7 months ago. His leukocyte count was up to 140,000 with left shift and with 67% of atypical monocytoïd cells; the platelets were down to 23,000. Flow cytometry and smear of bone marrow aspirate were consistent with AML M4. A bone marrow aspirate showed a karyotype of 46,XY,del(20)(q11.2q13.3)[12]/47,XY,del(20)(q11.2q13.3), +del(20)(q11.2q13.3)[8]. The majority of cases with 20q deletion are associated with myeloid disorders, however, duplication of the 20q deletion has rarely been reported. The patient's hemorrhagic diathesis and cardiac tamponade aggravated and he expired 7 days after admission. Autopsy confirmed the clinical findings of AML M4. Marked cardiomegaly and extensive fibrinous pericarditis were evident. Hepatosplenomegaly was also present. Many foamy macrophages with bubbling cytoplasm in the spleen, liver, bone marrow and lymph nodes were suggestive of Niemann-Pick disease, type E. AML has not previously been reported with Niemann-Pick disease.

**Pentasony 8 in pediatric myelodysplastic syndrome.** *S. Wu*<sup>1</sup>, *W. Wong*<sup>2</sup>. 1) Division of Medical Genetics, Dept Pediatrics, Children's Hosp, Los Angeles, Los Angeles, CA; 2) Division of Hematology, Dept Pediatrics, Children's Hosp, Los Angeles.

Myelodysplastic syndrome (MDS) is a disease affecting mainly the elderly and it is rare in children. We present a case of pediatric MDS with a unique numerical chromosomal anomaly pentasony 8. To our knowledge, this is the first reported pediatric MDS with pentasony 8. The patient is a 2 year-old Hispanic male who presented with lethargy, vomiting, abdominal pain and swelling, tactile fever and a diffuse rash. Bone marrow aspirate and biopsy revealed dyserythropoiesis with marked erythroid hyperplasia, moderate megaloblastic changes and binucleated erythroid cells, irregular nuclear contours and cytoplasmic bridging. There was a marked decrease in granulocytes with 4.5% blasts and rare megakaryocytes. Karyotypic analysis showed a major clone with three additional chromosome 8s, one additional 19 and 21 with a minor clone showing an apparently normal male karyotype. The karyotype for the bone marrow cells at diagnosis was 51, XY, +8, +8, +8, +19, +21 [16]/ 46,XY [4]. FISH test using centromeric probe of Chromosome 8 demonstrated a wide range of copy number of chromosome 8 in the bone marrow cells with 0.5 % of monosomy, 39 % of disomy, 7.4 % of trisomy, 14.4 % of tetrasomy, 38.2 % of pentasony and 0.5 % of hexasony cells. The coexistence of pentasony 8, tetrasomy 8 and trisomy 8 in his marrow cells suggests that the pentasony cell line may be preceded by a tetrasomic or trisomic cell line or both, which went undetected by metaphase cytogenetics.

**Karyotype refinement in five patients with Acute Myeloid Leukemia using spectral karyotyping.** *G. Palka<sup>1,2</sup>, D. Fantasia<sup>1,2</sup>, P. Guanciali Franchi<sup>1,2</sup>, A. Spadano<sup>3</sup>, E. Morizio<sup>1,2</sup>, F. Capodiferro<sup>1,2</sup>, R. Mingarelli<sup>4</sup>, P. Di Bartolomeo<sup>5</sup>, L. Stuppia<sup>1</sup>, G. Calabrese<sup>1,2</sup>.* 1) Dept Scienze Biomediche, Univ G D'Annunzio, Chieti Scalo, Chieti, Italy; 2) Servizio di Genetica Umana, Ospedale Civile, Pescara, Italy; 3) Dipartimento di Ematologia, Ospedale Civile, Pescara, Italy; 4) CSS-IRCCS Mendel, Roma, Italy; 5) Unit di Terapia Intensiva Ematologica per il trapianto ematopoietico, Ospedale Civile di Pescara, Italy.

Cytogenetic analysis combined with different banding techniques allows to identify many chromosome rearrangements specifically associated with hematological disorders. However, poorly spreaded metaphases, chromosome fuzziness, highly rearranged karyotypes with numerous indecipherable marker chromosomes are often found in leukemia. These abnormalities are usually difficult to define using standard techniques and FISH. Recently a new technique named SKY provided additional information resulting into the precise identification of chromosome markers, complex chromosome rearrangements, and cryptic translocations. We describe 5 patients with acute myeloid leukaemia (AML) referred to the Hematology Department of Pescara Hospital. According to FAB classification, one patient, a 55 year old man, had AML-M0; the second and the third patients, two female 62 and 75 year old, respectively, had AML-M1; the fourth, a 74 year old woman, suffered of an AML-M2, and the last patient, a 34 year old woman, had AML-M4. In these 5 patients cytogenetic investigation using G-banding technique showed the presence of several complex rearrangements and indecipherable markers. For this reason SKY analysis was performed. This analysis allowed the precise definition of the karyotype in all patients by identifying 4 chromosome markers, 12 translocations and 2 insertions misidentified or undetected by standard banding technique. FISH analysis with painting and specific probes confirmed SKY results in all cases. Although at present SKY analysis has a major limitation being unable to identify chromosome breakpoints, it is of great usefulness for classifying complex rearrangements and for detecting the origin of the disease. This is a crucial point for diagnosis and prognosis assessment.

Program Nr: 323 from the 2000 ASHG Annual Meeting

**Der(Y)t(Y;1)(q12;q12) associated with myelodysplasia: Case report and review of the literature.** *M.H. Abdel-Rahman, C.E. Glasure, M.A. Caligiuri, K.S. Theil.* Department of Pathology, Divisions of Cytogenetics and Laboratory Hematology; Department of Internal Medicine, Division of Hematology-Oncology, The Ohio State University, Columbus, OH.

Cytogenetic analysis of a bone marrow aspirate from a patient with a long standing history of refractory anemia revealed a clonal 46,X,der(Y)t(Y;1)(q12;q12) karyotype. The hematological examination and bone marrow aspirate morphology were not conclusive for a diagnosis of MDS, and the presence of a clonal chromosomal abnormality was a key diagnostic feature. This abnormality has been reported previously in eleven patients, and is highly associated with myelodysplastic syndromes. The chromosomal breakpoints were confirmed to be in satellite III DNA (DYZ1) of the Y chromosome and in the satellite II/III DNA in chromosome 1 by fluorescence in situ hybridization. A literature review of the reported cases with der(Y)t(Y;1) is presented.

**Five cases with segmental amplification of 11q23 region identified by FISH in patients with AML, sAML or HIV related lymphoma and a poor prognosis.** *L. Parsons<sup>1</sup>, L. Mak<sup>1</sup>, P. Dighe<sup>2</sup>, T. Saphner<sup>3</sup>, M.K. Crow<sup>4</sup>, M. Scott<sup>5</sup>, K.S. Reddy<sup>1</sup>.* 1) Dept Cytogenetics, Quest Diagnostics Inc., San Juan Capistrano, CA; 2) Stockton Hematology Oncology Medical Group, Stockton, CA; 3) Green Bay Oncology Ltd., Wisconsin; 4) Diagnostic Clinic of Houston, TX; 5) Indian River Memorial Hospital, Vero Beach, FL .

Five cases with segmental amplifications of 11q23 region were detected by FISH. The amplification was either contiguous amplification on chromosome 11, a hsr or multiple markers of 11q23 region. These markers were derivative chromosomes, or isochromosomes involving 11q23 region. Amplification of 11q23 region was associated with a complex karyotype in all cases. 4 cases were myeloid leukemias belonging to either AML-M5a or AML-1 subtype and were resistant to treatment and the case with a hsr was an AIDS associated lymphoma. Conventional cytogenetic analysis and fluorescence in situ hybridization (FISH) studies using MLL, 11 painting, or 11 centromere probes were necessary to ascertain the segmental amplification of the 11q23 region. Amplification of the MLL gene or other genes that map to 11q23qter may be responsible for the poor prognosis in these cases.

**Detection of homogeneous staining region (hsr) in acute lymphoblastic leukemia (ALL).** *J. Xu<sup>1</sup>, F. Ling<sup>2</sup>, B. Dingle<sup>2</sup>.* 1) Pathology & Molecular Medicine, McMaster Univ, Hamilton, ON., Canada; 2) Grand River Hospital, ON., Canada.

Hsr and double minutes (dmin) are cytogenetic evidence of gene amplification and occur frequently in solid tumors, such as brain, breast and ovarian carcinomas. Detection of gene amplification in solid tumors generally predicts a poor prognosis and demands more aggressive treatment. Hsr and dmin are rare findings in hematologic malignancies and have been reported in acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS). We report a case of the presence of hsr in ALL. The patient was a 79-year-old woman who was admitted to the hospital for investigation of increasing fatigue and anemia. Her only significant past medical history was idiopathic thrombocytopenic purpura about 20 years ago. Her blood counts were as follows: Hb 101 g/L, WBC  $19 \times 10^9/L$  and platelet  $8 \times 10^9/L$ . The peripheral blood smear showed leucocytosis with 50% blasts. The bone marrow examination showed hypercellular particles with 80% blasts, confirming the diagnosis of acute leukemia. The blasts were negative for myeloperoxidase and flow cytometry showed immunophenotypic features characteristic of B-precursor lymphoblasts (TdT+, CD19+ and CD34+). The overall findings were consistent with ALL, null phenotype, L2 type under the FAB classification. The patient developed an infection and died shortly after admission. Analysis of 24 GTG banded metaphases prepared from the patient's bone marrow showed multiple numerical and structural chromosome abnormalities. The karyotype was 41~45,XX,-3[24],-5[9],del(5)(q15q34)[15],add(6)(p11.1)[24],hsr(11)(q21)[21],der(13:21)(q10:q10)[22],-14[5],inv(16)(p13q22)[15],-16[4],add(17)(p11.2)[24],-20[23],-22[19],+mar1[24],+mar2[10],+mar3[6],+mar4[3][cp24]. Among these aberrations, monosomy 22 is the only one as a common primary anomaly in ALL. The most interesting finding is the presence of a large hsr (about the size of chromosome 11) at 11q21 in ~88% (21/24) of cells examined. The origin of this hsr waits for further molecular cytogenetic studies. In AML and MDS, hsr or dmin have been reported to be a result of amplification of AML1, MLL, C-MYC, or C-ETS1. To our knowledge, this is the first report on hsr in ALL.

**Characterization of a familial RCC-associated t(2;3)(q33;q21) chromosome translocation.** *J. Podolski<sup>1,2</sup>, T. Byrski<sup>1</sup>, S. Zajaczek<sup>1</sup>, T. Druck<sup>3</sup>, D.B. Zimonjic<sup>4</sup>, N.C. Popescu<sup>4</sup>, G. Kata<sup>5</sup>, A. Borowska<sup>5</sup>, J. Gronwald<sup>1</sup>, J. Lubinski<sup>1</sup>, K. Huebner<sup>3</sup>.* 1) Hereditary Cancer Center, Dept. of Genetics and Pathology, Pomeranian Academy of Medicine, Szczecin, Poland; 2) Dept. of Human Ecology, University of Szczecin, Szczecin, Poland; 3) Kimmel Cancer Center, Jefferson Medical College, Philadelphia, PA; 4) Laboratory of Experimental Carcinogenesis, National Cancer Institute, Bethesda, MD; 5) Dept. of Urology, Postgraduate Medical Education Center, Warsaw, Poland.

We have identified a Polish family in which multifocal clear cell renal carcinoma segregates with a balanced constitutional chromosome translocation, t(2;3)(q33;q21), possibly with translocation positions similar to those of the renal cell cancer-associated t(2;3)(q35;q21) reported in a Dutch family. YAC and BAC contigs encompassing the 2q and 3q breakpoints were constructed and BACs crossing the breakpoints were partially sequenced. All known regional markers, genes and ESTs were mapped relative to the contigs, as well as to our breakpoint sequences. Two single ESTs map within the 2q breakpoint BAC, while the repeat rich 3q breakpoint region is gene poor. Physical mapping suggests that the 3q break is in 3q13, possibly near the border with 3q21 and is 10-20 megabases centromeric of the 3q21 breakpoint observed in the Dutch family with a renal cancer-associated t(2;3). Physical mapping illustrated that the 2q break is closely telomeric to the 2q31 FRA2G site, consistent with our G-band assignment. Molecular mapping data available for the Dutch 2q break was insufficient to determine similarity of the Polish and Dutch 2q breaks, although the cytogenetic data suggests different band positions. Characterization of full length cDNAs for the ESTs near the 2q break will determine if a gene(s) is altered by this familial RCC-associated chromosome translocation.

**Application of molecular cytogenetic techniques for identification of the t(8;14)(q24;q32) translocation in a new case of non-Burkitt's lymphoma associated with numerous chromosome rearrangements.** *S. Shekhter-Levin*<sup>1,2,3,4</sup>, *D. Bahler*<sup>3</sup>, *L.C. Contis*<sup>3</sup>, *J.A. Pindzola*<sup>3</sup>, *K. Cumbie*<sup>1</sup>, *M.E. Sherer*<sup>1,2</sup>, *D. Kudla*<sup>2</sup>, *U. Surti*<sup>1,2,3,4</sup>, *S.M. Gollin*<sup>1,2,3,4</sup>. 1) Pittsburgh Cytogenetics Lab, Magee Womens Hospital, Pittsburgh, PA; 2) Dept of Human Genetics, Univ of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Dept of Pathology, Univ of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Univ of Pittsburgh Cancer Institute, Pittsburgh, PA.

The patient, a 51 yr old male, presented with diffuse adenopathy, hepatosplenomegaly and blasts in blood. Cervical lymph node histology suggested diffuse large B-cell lymphoma. Bone marrow pathology was also consistent with diffuse large B-cell lymphoma. Cytogenetic analysis of G-banded bone marrow cells revealed the following chromosome pattern: 41-42,X,-Y,add(8)(?q22),?der(8)t(8;14)(q24;q32),add(9)(q34),del(12)(p11.2p13.3),add(12)(p11.2),-13,-14,?der(14)t(8;14)(q24;q32)add(14)(p11.2),-15,-16,del(17)(p11.2),der(19)t(Y;19)(q11.2;p13.3), add(20)(q13.3),-21,+1-4mar[cp12]/46,XY[11]. Similar results were obtained on G-banded cells from the lymph node biopsy. Spectral karyotyping (SKY) revealed that the add(8)(q24) consists only of chromosome 8, and therefore, represents a duplication of part of 8q. Chromosome 8 painting confirmed the SKY findings regarding dup(8q) and indicated the presence of a chromosome 8 segment on distal 14q. The use of FISH with the MYC probe revealed two MYC signals on dup(8q), which was then redesignated as dup(8)(q22q24). A third MYC signal appeared on the distal long arm of the der(14), confirming the presence of the t(8;14)(q24;q32). The t(8;14)(q24;q32) is characteristic of Burkitt's lymphoma, but also has been reported in small noncleaved cell lymphoma and in posttransplant lymphoproliferative disorder. The interpretation of this finding in our patient with diffuse large B-cell lymphoma is unclear. The MYC gene may be involved in the unusually aggressive course of this lymphoma.

**CLTC-ALK fusion in Inflammatory Myofibroblastic Tumor.** *A.S Patel<sup>1</sup>, E.J Perlman<sup>1</sup>, C.M Coffin<sup>2</sup>, C.A Griffin<sup>1</sup>.*  
1) Department of Pathology, John Hopkins University, Baltimore, MD; 2) University of Utah School of Medicine, Salt Lake City, Utah.

Inflammatory myofibroblastic tumors (IMT) are relatively rare tumors of the soft tissue occurring primarily in children and young adults. They are characterized by fascicles of myofibroblasts with a prominent inflammatory component of lymphocytes, eosinophils and plasma cells. We previously reported (*Cancer Res.*, 59, 2776) rearrangement of the Anaplastic Lymphoma Kinase (ALK) gene in 3 IMTs using a dual color FISH probe (Vysis, Inc) surrounding the ALK gene. Subsequently using FISH analysis we have observed ALK rearrangements in 47% (9/22) of IMT cases. The most common fusion partner of ALK in anaplastic large-cell lymphoma (ALCL) is the nucleoplasmin gene (NPM) on 5q35, which results in a chimeric protein localizing to the nucleus. The IMT cases that had the ALK rearrangement were also positive for ALK staining by immunohistochemistry but the staining was predominantly cytoplasmic suggesting the ALK fusion partners in IMT may be different that those observe in ALCL. Frozen tissue from one IMT was used for 5' rapid amplification of cDNA ends (5'RACE) to identify the ALK fusion partner gene. 5'RACE identified clathrin heavy chain (CLTC) on chromosome 17q23 as the fusion partner of ALK. Additional IMT cases are being analyzed to determine other ALK fusion partners. These data provide conclusive evidence for ALK gene rearrangement in IMTs.

**Spectral karyotyping (SKY) refines complex G-banded karyotypes in hematological malignancy.** *V. Sulcova, L. Parsons, A. Anguiano, B. White, K. Reddy.* Cytogenetics, Quest Diagnostics Inc., San Juan Capistrano, CA.

The bone marrow cultures from hematological malignancies frequently yield poor quality GTG-metaphases and provide only partial information for many rearrangements. Therefore, we assessed the applicability of SKY to analyze complex bone marrow cases. Among the ten hematological malignancies investigated using SKY the known indications were one patient each with thrombocytopenia, chronic lymphoproliferative leukemia, and myelodysplasia, two patients had acute myeloid leukemia and 6 patients had lymphoma. Since, SKY alone was found to be inadequate to resolve many of the clonal abnormalities in a complex lymphoma case, we resorted to test SKY as an adjunct to G-banded analysis on 10 cases with 4 or more chromosome abnormalities. In two cases, SKY was used because the poor quality of metaphases precluded G-banded analysis. Two to seven metaphases were analyzed by SKY. Of the GTG-chromosome aberrations, 23% [22/95] were confirmed, 62% [62/95] were refined (incomplete or incorrect by GTG), 11% [5 clonal and 6 in one metaphase/95] new abnormalities were identified and 3% [3/95] were not found by SKY. Some of the interesting findings following SKY were the detection of *dmin* from chromosome 8, and *der(14)t(11;14)* in a mantle cell lymphoma case which had G-banded metaphases that could not be analyzed. An *hsr* on chromosome 7 (negative for *c-MYC*, *n-MYC*, *Her-2neu*, *BCR/ABL* and *p53*) was shown by SKY and FISH with *MLL* probe to have 4 copies of *MLL-11q23* region. SKY proved to be a powerful tool to further unravel complex G-banded karyotypes in hematological malignancies. A better understanding of the chromosome abnormalities using SKY will enhance our knowledge of diagnosis, prognosis and therapeutics.

**Characterization of Askin tumor cell line, JK-GMS.** *G.J Kim<sup>1,2</sup>, S.H Park<sup>1,2</sup>, S.Y Park<sup>2</sup>, S.Y Cho<sup>3</sup>, M.J Lee<sup>3</sup>, H.S Ahn<sup>3</sup>, H.Y Shin<sup>3</sup>, J.G Chi<sup>3</sup>, C.J Kim<sup>3</sup>.* 1) Graduate School of Biotechnology, Korea University, Seoul; 2) Institute of Human Genetics, Dept. of Anatomy, Korea University College of Medicine, Seoul; 3) Dept. of Pathology and Pediatrics, Seoul National University College of Medicine, Seoul, Korea.

Askin tumor is a small round cell tumor in the thoracopulmonary region, which belongs to peripheral primitive neuroectodermal tumor (PNET) and Ewing's sarcoma (ES). PNET and ES are currently regarded as identical tumors sharing common chromosomal translocation, t(11;22)(q24;q22). TrkA mediates critical effects during human nervous system development including neural crest and also is known to modulate key biological features of brain tumors and neuroblastoma. Recently, we established Askin tumor cell line, JK-GMS, which expressed high level of trkA. For the characterization of this cell line, we analyzed the chromosomal aberrations and investigated the biological effects of trkA activity on the growth and differentiation of JK-GMS. JK-GMS had hypodiploid and showed chromosomal translocation, t(11;22)(q24;q22). Seven kinds of structural clonal aberration were effectively analyzed by cross species color banding (RxFISH) and chromosome painting. The activation of trkA induced differentiation and inhibited growth of JK-GMS, while treatment with K-252a, an inhibitor of trk tyrosine kinase, abrogated the effects of NGF on growth and differentiation of JK-GMS. These results were quite similar to those of neuroblastoma cell lines and other childhood tumor cell lines of neural crest origin. From these results, it may be suggested that JK-GMS is a good model to investigate the therapeutic target for the treatment of PNET/ES.

**Analysis of Genetic Alterations in Primary Nasopharyngeal Carcinoma by Comparative Genomic Hybridization (CGH).** *L. Sun<sup>1</sup>, Y. Fong<sup>2</sup>, J.S.T. Sham<sup>3</sup>, Y. Guo<sup>2</sup>, M. Deng<sup>2</sup>, Q. Liang<sup>2</sup>, H. Zhang<sup>4</sup>, H. Zhou<sup>4</sup>, H. Tideman<sup>1</sup>, J.M. Trent<sup>4</sup>, X.-Y. Guan<sup>3</sup>.* 1) Oral Maxillofacial Surgery, The University of Hong Kong, Hong Kong, PR China; 2) Cancer Center, Sun Yat-sen University of Medical Sciences, China; 3) Department of Clinical Oncology, The University of Hong Kong, Hong Kong; 4) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

To identify genetic alterations associated with the development and progression of human nasopharyngeal carcinoma (NPC), 57 tumors were analyzed using comparative genomic hybridization (CGH). In 47 cases chromosomal imbalances were found. Several recurrent chromosomal abnormalities were identified in the present study. The most frequently detected chromosomal gains involved chromosomes 12q (24 cases, 51%), 4q (17 cases, 36%), 3q (16 cases, 34%), 1q (15 cases, 32%), and 18q (15 cases, 32%). Common regions of gain involved 12q13-q15, 4q12-q21, and 3q21-q26. High copy number increases of chromosomal materials were detected in 4 chromosomal regions, 3q21-q26.2, 4p12-q21, 8p, and 12q14-q15. The most frequently detected loss of chromosomal materials involved chromosomes 16q (26 cases, 55%), 14q (21 cases, 45%), 1p (20 cases, 43%), 3p (20 cases, 43%), 16p (19 cases, 40%), 11q (17 cases, 36%) and 19p (16 cases, 34%). The most common regions of loss involved 14q24-qter, 1pter-p36.1, 3p22-p21.3, 11q21-qter, and the distal region of 19p respectively. Genomic alterations detected using CGH were compared and found to be largely consistent with those identified using banding analysis and loss of heterozygosity studies. However, several previously unrecognized recurrent alterations were also identified in the present study including: gain of 4q and 18q, and loss of 16q, 14q, and 19p. In addition, gain of 1q, 8q, 18q, and loss of 9q showed statistically significant association with advanced clinical stage ( $p < 0.05$ ). Identification of recurrent sites of chromosomal gain and loss identify regions of the genome that may contain oncogenes or tumor suppressor genes respectively which maybe involved in the tumorigenesis of NPC.

**Recurrent Chromosome Changes in 31 Primary Ovarian Carcinomas Detected by Comparative Genomic Hybridization.** *T.C.M. Tang<sup>1</sup>, J.S.T. Sham<sup>1</sup>, Y. Fong<sup>2</sup>, L. Sun<sup>3</sup>, L.X. Qin<sup>4</sup>, X.-Y. Guan<sup>1</sup>.* 1) Clinical Oncology, The University of Hong Kong, Hong Kong, China; 2) Cancer Center, Sun Yat-sen University of Medical Sciences, Guangzhou, China; 3) Oral Maxillofacial Surgery, The University of Hong Kong, Hong Kong; 4) Liver Cancer Institute, Zhongshan Hospital, Shanghai Medical University, Shanghai, China.

Ovarian cancer is one of the most frequent gynecological malignancies worldwide with poor prognosis. The development of new diagnostic, preventive, and treatment approaches requires good understanding of the mechanisms of the complex multi-step process of tumor pathogenesis in the ovarian cancer. Comparative genomic hybridization (CGH) has been applied to detect recurrent chromosome alterations in 31 primary ovarian carcinomas. Several nonrandom chromosomal changes including gains of 3q (17 cases, 55%) with a minimum gain region at 3q25-q26, 8q (16 cases, 52%), 19q (12 cases, 39%), Xq (11 cases, 35%), 1q (10 cases, 32%), 17q (10 cases, 32%), 12q (9 cases, 29%) with a minimum gain region at 12q12, and 20q (9 cases, 29%). High copy number gain (DNA sequence amplification) was detected in 10 cases. Amplification of 3q25-q26 and 12p11.2-q12 were detected in 4 and 3 cases, respectively. The regions most frequently lost included: 16q (9 cases, 29%), 1p (7 cases, 23%), 18q (7 cases, 23%), and 22 (7 cases, 23%). The recurrent gain and loss of chromosomal regions identified in this study provide candidate regions that may contain oncogenes or tumor suppressor genes respectively involved in the development and progression of ovarian cancer.

**Cytogenetic analyses of six neuroblastoma cell lines with cross-species color banding.** *S.Y. Park<sup>1</sup>, G.J. Kim<sup>2</sup>, K.B. Lee<sup>2</sup>, Y.H. Kang<sup>1</sup>, H. Kim<sup>1,2</sup>, Y.H. Chun<sup>1</sup>, S.H. Park<sup>1,2</sup>.* 1) Institute of Human Genetics, Dept. of Anatomy, Korea University College of Medicine, Seoul, Korea; 2) Graduate School of Biotechnology, Korea University, Seoul, Korea.

The cytogenetic analyses of chromosomal aberrations became an essential method to identify the genes involved in the pathogenesis of cancers. Recently, the chromosome painting and cross-species color banding (RxFISH) in identifying marker chromosomes became useful techniques. Neuroblastoma is a pediatric malignant neoplasm of neural crest origin. The mechanisms contributing to the development of neuroblastoma are largely unclear, but non-random chromosomal changes, such as deletion of chromosome band 1p36, aberrations of 17q, and amplification of the *MYCN* oncogene, have identified over the past years. The purpose of this study was to establish, in detail, karyotypes of six neuroblastoma cell lines (SK-N-AS, SMS-KCNR, SK-N-MC, SK-N-SH, SH-SY5Y, and IMR 32) by G-banding, RxFISH, and FISH with chromosome painting probes. Each cell line had a variable number of numerical and structural aberrations. Deletion of 1p36 and a partial gain of chromosome 17 with the breakpoint on 17q21 were observed in four cell lines each. Chromosome 6, 15, 16, and 22 were commonly involved in structural abnormalities. Homogeneously staining regions or double minute chromosomes were confirmed in three cell lines, all of which were turned out to be amplification of *MYCN*. The chromosomal aberrations of the six neuroblastoma cell lines were effectively analyzed by RxFISH and multiple chromosome painting probes. The nonrandom rearrangements suggest candidate regions for isolation of genes related to neuroblastoma.

**BRCA1 copy number in paraffin embedded cancer tissue samples of known BRCA1 and BRCA2 mutation carriers using a BRCA1 FISH probe. BRCA1 copy number in paraffin embedded cancer tissue samples of known BRCA1 and BRCA2 mutation carriers using a BRCA1 FISH probe.** *S.R. Young<sup>1</sup>, N. Kataoka<sup>1,2</sup>, Z. Wang<sup>1</sup>, H. Kato<sup>1,3</sup>, W.T. Loging<sup>1</sup>, J.R. Marks<sup>4</sup>, N. Lehman<sup>5</sup>.* 1) Dept OB/GYN, Univ South Carolina Sch Med, Columbia, SC; 2) Dept GYN/OB, Kyoto Univ JAPAN; 3) Dept OB/GYN, Nagoya City Univ Hosp, JAPAN; 4) Dept Surgery, Duke Univ Durham, NC; 5) Dept Pathology, Creighton Univ, Omaha, NE.

BRCA1 and BRCA2 genes, located on 17q and 13q, respectively, have been linked to hereditary breast cancer. Women inheriting a mutant form of either gene have up to a 70-80% lifetime risk of developing breast cancer. Both BRCA1 and BRCA2 are thought to function as tumor suppressor genes. LOH studies have shown that loss of the corresponding wild-type allele in a BRCA1 or BRCA2 mutation-carrying individual is associated with the development of malignancy. We have developed a FISH probe for the BRCA1 gene to study allele loss in archived, paraffin-embedded, tissue samples. Studies of five normal breast tissue samples, obtained during reduction mammoplasty, showed 5.8 to 11.8% of interphase cells having one BRCA1 signal. Four known BRCA1 mutation carrying malignant breast cancer tissue samples showed 30.8 to 51.4% of cells having one BRCA1 signal present in the interphase cells. In comparison, four known BRCA2 mutation carrying malignant breast cancer tissue sections revealed 25 to 30% of interphase cells as having one BRCA1 signal present. While there appears to be greater allelic loss of BRCA1 in BRCA1 cases compared to BRCA2 cases, the difference appears too small to confidently differentiate the two. A BRCA2 probe FISH study may be helpful in this regard. Numerous Southern blot studies have reported LOH at 17q in sporadic breast cancer. Our current FISH results support the concept that the BRCA1 gene, or the loss of the BRCA1 gene, is important in both hereditary and non-hereditary breast cancers. The use of FISH technology to evaluate allelic loss of BRCA1 and other tumor suppressors may prove of value in the study of other forms of cancer. It remains to be seen if FISH probes can differentiate BRCA1 and BRCA2 mutation bearing tissue samples.

**Chromosomal abnormalities in colorectal polyps.** *A.E. Rojas-Atencio, K. Urdaneta, P. Estrada, M. Soto-Alvarez, L. Borjas-Fajardo.* Unidad de Genetica, Universidad del Zulia, Maracaibo, Zulia, Venezuela.

The colorectal cancer is the second cause of death for cancer in the world, they usually begin as a benign polyp and many of them are never developed in cancer. The development of the cancer starting from a polyp you happens when it happens a mutation in the genetic code that controls the growth and repair of the cells. The objective of this work is to report the chromosomal anomalies found in 15 colorectales polyps The chromosome analysis was carried out through technical of short culture. A numeric anomaly was considered if this repeated at least 3 times and a structural one if it repeated at least 2 times. The chromosome analysis of the 15 polyps histology reported as benign adenoma, they revealed clonal chromosome aberrations in 11 of the 15 cases, seven of them presented specially lost numeric type anomalies of the chromosomes 8 and 22, other recurrent numerical change were +11 and +18, alone in a case an anomaly of structural type was observed that corresponded to a deletion of the short arm of the chromosome 7 [(del17p)]. The chromosome analysis of the polyps adenoma has been correlated by some authors with clinical and pathological parameters and the same ones could serve as a parameter suggestive presage of progression of the illness toward the metastasis.

**Karyotypic analysis of non-tumorigenic and tumorigenic, human prostatic epithelial cell lines representing a tumor progression model.** *P.D. Storto<sup>1</sup>, G. Bice<sup>1</sup>, D. Bello-DeOcampo<sup>2</sup>, S. Quader<sup>2</sup>, M.M. Webber<sup>2</sup>.* 1) Dept Pediatrics/Human Develop, Michigan State Univ, East Lansing, MI; 2) Dept Zoology Michigan State Univ, East Lansing, MI.

RWPE-1, a human prostate epithelial cell line, has been transformed with MNU (N-methyl-N-nitrosourea) to generate four new cell lines (referred to as the MNU cell lines). The four MNU cell lines have been designated WPE1-2A22, WPE1-NB14, WPE1-NB11, and WPE1-NB26, in increasing order of their malignancy. The cell lines represent different stages of tumor progression, from non-invasive to invasive, and will serve as an interesting in vitro model of prostatic neoplasia formation.

We have studied the four MNU cell lines in regards to their cytogenetic makeup, i.e. we have analyzed the specific chromosomal abnormalities present in the cell lines. The cell lines contained both common and unique aberrations; all four MNU lines had lost copies of chromosomes Y and 22, and gained entire copies of chromosomes 5 and 20. Breaks occurred at chromosomal regions 7q22, 9q11, 11q13, 11q23, 11q25, and 18q12.2. All cells lines revealed loss of material from chromosomes 7 and 18 long arms, and duplication of material from chromosomes 9 and 11 long arms. Abnormalities not common to all cell lines were a deletion of chromosome 2 long arm material and a 13q isochromosome in cell line WPE1-2A22, a deletion of chromosome 1 long arm material and loss of chromosome 13 in cell lines WPE1-NB14 and WPE1-NB26, a duplication of chromosome 19 material in cell line WPE1-NB11, a break at region 19q21 and duplication of material from the long arm of chromosome 13 in cell line WPE1-NB26, and small unidentifiable markers in cell lines WPE1-NB11 and WPE1-NB26. Overall, the more tumorigenic cell lines appeared to contain a greater number of cytogenetic rearrangements. We discuss the significance of these cytogenetic abnormalities in terms of their prevalence in prostate cancer, and in regards to the locations of tumor-suppressor genes that may be involved in the chromosomal rearrangements.

**Two unusual rearrangements in hematological disorders studied by RT-PCR and/or FISH.** *H.E. Wyandt*<sup>1,2</sup>, *R.V. Lebo*<sup>1,3</sup>, *X.-L. Huang*<sup>1</sup>, *B. Loose*<sup>1</sup>, *L. Oshry*<sup>4</sup>, *L. Weintraub*<sup>5</sup>. 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Pathology, Boston Univ Sch of Medicine, Boston, MA; 3) Pediatrics, Boston Univ Sch of Medicine, Boston, MA; 4) East Boston Neighborhood Health Center, Boston, MA; 5) Hematology/Oncology, Boston Univ Sch of Medicine, Boston, MA.

Fluorescence in situ hybridization (FISH) reveals an unusual karyotype, 46,XX,inv ins(9;22)(q34;q11.2q11.2) in bone marrow (bm) from a 56 y.o. female with chronic myelogenous leukemia (CML). Probes for bcr and abl-ass (Vysis, Downers Grove, IL) revealed 98% of interphases with a bcr/abl fusion. Metaphases showed juxtaposition of the bcr signal distal to the abl signal on der(9) and no bcr signal on der(22). Partial painting for chromosome 22 (pcp22subtel, Rainbow Scientific, Windsor, CT) revealed the subterminal region of der(22) to be intact. The bcr region of der(22) was thus inserted into der(9). RT-PCR of extracted mRNA amplified a 305 bp fragment, corresponding to a M-bcr/abl 210 kDa fusion product. In order for this product to be transcribed, both bcr and abl must be inverted. The patient had a complete hematological response and a minor cytogenetic response (reduction to 70% percent cells with bcr/abl fusion) with interferon therapy. Bm from a 49 y.o. male with acute promyelocytic leukemia (APL) and associated disseminated intravascular coagulation has the karyotype, 46,XY,t(17;15;17) (q11;q22;q25). FISH using probes for PML in 15q22 RARA in 17q22 (Oncor, Gaithersburg, MD) revealed distal 17q and RARA region of a chromosome 17 to be fused to part of the PML region on a chromosome 15. Distal 15q including the distal part of PML is translocated to the 17 homolog (breakpoint in 17q25), and distal 17q is translocated to the proximal part of the first 17. This complex rearrangement resulted in an inverted partial PML/RARA fusion on der(15), loss of RARA from der(17) and partial PML and intact RARA signals on der(17). The patient was treated with all-trans-retinoic acid, daunorubicin and cytosine arabinoside. He is now in complete hematologic and cytogenetic remission. Both patients have thus responded to treatments suggestive of typical CML and APL, respectively, despite their unusual chromosomal rearrangements.

**Cytogenetics finding in Breast Ductal Carcinoma.** *M.L. Soto-Alvarez, A. Rojas-Atencio, F. Alvarez-Nava, K. Urdaneta, L. Gonzalez, A. Boscan.* Unidad de Genetica Medica, Universidad del Zulia, Maracaibo, Zulia, Venezuela.

The feminine breast cancer it is one of the old problems of public health in our society, from the past decade an improvement in him has been observed diagnosis, as well as also in the identification of parameters prognostic that permit a better evaluation of these patients. The objective of this work is to report, the chromosomal anomalies in 32 breast ductal carcinoma (BDC) . In this report, we present the chromosomal abnormalities found in 32 primary breast ductal carcinomas. The tumor samples were studied using the technique for short-term culturing and cytogenetic analysis with G-banding. Only one tumor with normal karyotype was observed. Thirty one (99%) of the tumors had chromosomal abnormalities including 21/ (65,6 %) in which chromosome 1 was involved (trisomy, monosomy or structural abnormalities of the type t(1q;2p) and del(1q42). Other recurrent anomalies such as del(12p); del 4(p); +7; +8; -7; -3; were observed. The significance of these findings and their role in tumorogenesis will become more evident with close follow-up of women who have tumors with an abnormal karyotype.

**A “static” karyotype in epithelial cancer cell lines despite ongoing chromosomal instability.** *A.V. Roschke<sup>1</sup>, K. Stover<sup>1</sup>, G. Tonon<sup>1</sup>, A.A. Schaffer<sup>2</sup>, I.R. Kirsch<sup>1</sup>.* 1) Genetics Department, Medicine Branch, NCI, Bethesda, MD; 2) Computational Biology Branch, NCBI, Bethesda, MD.

Most human tumors and tumor cell lines exhibit numerical and structural chromosomal abnormalities. The goal of this study was to determine the ongoing rates of structural and numerical chromosomal instability in selected cancer cell lines and to investigate the consequences of these rates to karyotypic progression. Our approach was to make single cell subclones of two colorectal (HCT-116 and HT-29) and two ovarian (SKOV-3 and OVCAR-8) cell lines and to delineate rates over time of numerical and structural chromosome changes. We performed SKY, CGH and FISH with chromosome-specific centromeric probes on cell lines and their subclones. The karyotypes of all four cell lines showed evidence of genome destabilization at some previous moment or period in their history. While significant ongoing structural and/or numerical chromosomal instability could be demonstrated in all cell lines during our period of observation, there was a relative stability of the consensus karyotype over many generations. No new clonal structural chromosomal reconfigurations emerged and the few numerical changes of karyotypes were restricted to losses of abnormal chromosomes. This implies a kind of genomic optimization under the present conditions of cell culture and suggests a link between genomic stabilization and cell propagation. We have been able to support this possibility by computer modeling.

**Physical and hematopoietic transcript map of a 5q31 "critical subregion" associated with the 5q- syndrome. S.**

*Kamakari<sup>1</sup>, V. Konstantinopoulou<sup>1</sup>, N.P. Anagnostou<sup>1,2</sup>.* 1) Institute of Molecular Biology and Biotechnology; 2) University of Crete School of Medicine, Heraklion, Greece.

The 5q- syndrome represents a preleukemic state, exhibiting an acquired interstitial 5q23-31 deletion. Four critical subregions seem to be involved in leukemogenesis. To delineate the role of one of these subregions, we constructed a YAC contig between the GM-CSF/IL-3 and TCF-1 genes. Extensive PCR screening of the CEPH and ICI YAC libraries, resulted in the isolation of twelve YACs: three YACs (854G6, 679B9, 14DG10) positive for the GM-CSF/IL-3 genes, five YACs (624G4, 969H4, 969G11, 698D8, 12BE7) positive for the TCF-1 gene and four YACs (14BA6, 15AE2, 14EB12, 28CB1) positive for seven STSs (5157S1, 5250S, bac5060S, bac5177S, 5322S, 5342T and 5328S). STS content mapping of all twelve YACs resulted in the construction of the first complete YAC contig of this subregion and documented that the GM-CSF/IL-3 and TCF-1 genes are linked. The precise size of the genomic region is being investigated by generating a long-range restriction map. Furthermore, in order to develop a hematopoietic transcript map of the subregion, twenty-six chromosome 5-specific ESTs were selected, on the basis of their origin and assignment. PCR analysis and *in silico* searches, resulted in sublocalisation of nine ESTs to the identified YACs and documented their expression in a bone marrow cDNA library. Two of them, namely T77830 and W92884, mapping proximal and distal to the IL3 gene, respectively, were further analysed. Human RNA dot blot analysis of the EST T77830, exhibited expression in kidney, liver, small intestine and lung. Northern blot analysis also documented its expression in a variety of tissues, including bone marrow, with a transcript size of approximately 4 kb. Following the technique of 5' and 3' rapid amplification of cDNA ends (RACE) for this EST, using a bone marrow cDNA library as a template, two overlapping clones, covering a total length of 3.8 kb were isolated and sequenced. Characterisation of the full-length cDNA is in progress. RACE amplification of the EST W92884 resulted in a 500 bp PCR product, currently used as a probe in a bone marrow cDNA library hybridisation screening.

**Non-random X-inactivation suggests that juvenile hemangiomas are monoclonally derived.** *J.W. Walter<sup>1</sup>, P.E. North<sup>2</sup>, A. Mizeracki<sup>2</sup>, M. Waner<sup>3</sup>, D.A. Marchuk<sup>2</sup>.* 1) Department of Genetics, Duke University Medical Center, Durham, NC; 2) Department of Pathology, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Department of Otolaryngology, University of Arkansas for Medical Sciences, Little Rock, AR.

Juvenile hemangiomas are the most common tumors of infancy, and occur in as many as 10% of all births. These benign vascular lesions enlarge rapidly during the first year of life by hyperplasia of endothelial cells and attendant pericytes, then spontaneously involute over a period of years, leaving a paucicellular fibrofatty residuum. In the present study, six sporadic proliferative-phase hemangiomas were collected following surgical resection, and dissected to enrich for the endothelial cell component of each sample.

To determine if hemangiomas represent a monclonal expansion from a single progenitor cell, we assayed X-inactivation patterns for each lesion (all were obtained from female patients) using the polymorphic X-linked human androgen receptor-A (HUMARA) locus. Three of six hemangiomas, all from patients less than five months of age, demonstrate a significant degree of allele loss, in one case almost complete, following methylation-sensitive restriction digest and PCR amplification, implying a non-random X-inactivation pattern, and a monclonal origin to one or more cellular components of the lesion.

These results suggest that one or more genetic events in a single cell may contribute to hemangioma development. Eventually, accumulation of non-clonally derived cells would mask the clonal nature of these lesions. The identification of clonal, proliferative samples provides an opportunity to characterize genetic events that may precede or modulate hemangioma development, and to identify genes involved with hemangioma formation.

**Characterization of a Complex Chromosome Rearrangement involving 6q in a Melanoma Cell Line: Isolation of a Candidate Tumor Suppressor Gene Interrupted by the Breakpoint at 6q16.** *X.Y. Guan<sup>1</sup>, H. Zhou<sup>2</sup>, J.S.T. Sham<sup>1</sup>, H. Zhang<sup>2</sup>, J.M. Trent<sup>2</sup>.* 1) Dept Clinical Oncology, Univ Hong Kong, Hong Kong, China; 2) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

The incidence of human malignant melanoma has increased dramatically in many parts of the world. Deletion of 6q is one of the most frequent chromosomal alterations in malignant melanoma with a breakpoint cluster at 6p11-q21. Recently, we used G-banding analysis and micro-FISH technique to detect a complex chromosomal rearrangement involving 6q and 17p in a melanoma cell line UACC-930. The rearrangement includes an inversion involving 6q, *inv(6q;6q)(q16;q27)*, and a translocation involving the inverted 6q and 17p13. A BAC clone covering the breakpoint 6q16 was isolated by FISH screen. A novel gene (named BIM1, broken in melanoma 1) interrupted by the breakpoint was isolated by partial sequencing analysis of the BAC clone. Full-length cDNA of BIM1 with two isoforms has been isolated. Sequence analysis identified a significant similarity of BIM1 and prenyl transferase gene, which is required for the cancer-causing activity of Ras gene. Loss of BIM1 was also detected in 10/12 melanoma cell lines. Our results indicate BIM1 may play an important role in the development of malignant melanoma.

**Parental Origin of 1p36 Deletions: Does Size Matter?** *H.A. Heilstedt, W.L. Matheny, L.G. Shaffer.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

We have characterized a total of 41 patients with deletions of chromosome 1p36 using microsatellite polymorphisms and probes for fluorescence in situ hybridization (FISH). Clinical features of this syndrome include mental retardation, growth delay, hypotonia, deafness, and facial dysmorphism. The majority of deletions are maternal in origin (64%), while 28% are paternal and in 8% the parental origin could not be determined. Interestingly, the majority of patients with the largest deletions are paternal in origin. Frequent occurrence of deletions of distal chromosome 1p has been found in neuroblastoma (NB). There appears to be a distinction between the deletion size in those tumors with MYCN amplification and those without, in those tumors with MYCN amplification tend to have larger deletions of 1p. Subsequently, there is a suggestion that there are multiple tumor suppressor loci on 1p. Previously, loss of heterozygosity studies in MYCN single copy tumors have shown the lost 1p36 allele is usually of maternal origin suggesting that imprinting may play a role in the development of NB. The critical region for one of the proposed NB tumor suppressor genes is between D1S214 and D1S244 (~7cM). Of the 10 patients with deletions breakpoints proximal to D1S214, six (60%) are paternal in origin, 3 (30%) are maternal and one (10%) parental origin could not be determined. None of these patients have developed neuroblastoma. The average age of these patients is 9.3 years (range 18 mo. to 19.3 yrs.), beyond when neuroblastoma is usually diagnosed, lending further support to a possible role for imprinting. KIAA0591 is a novel kinesin-related protein, which had been mapped to this critical region by radiation hybrid mapping. It has been proposed to function as a tumor suppressor in an epigenetic manner as no mutations were found when NB tissue was examined. Using a BAC, which contains the 3' end of this gene, we have more precisely mapped KIAA0591 relative to this critical region using our panel of deletion patients and FISH. The parental origin and size of deletion are proving to be helpful tools in delineating the molecular basis of neuroblastoma.

**In Vivo Hypermutable Associated with a De Novo Interstitial Deletion Adjacent to the Glycophorin A Gene on Chromosome 4.** *S.G. Grant*<sup>1</sup>, *S.L. Wenger*<sup>2</sup>. 1) Center for Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Pathology, West Virginia University, Morgantown, WV.

Somatic mutation is a basic mechanism of carcinogenesis and aging, and is influenced by both genotoxic exposure and genetic predisposition. The human in vivo glycophorin A (GPA) assay quantitates loss of expression of one allele of the gene responsible for the MN blood type at 4q28-31.1. Elevated frequencies of GPA variants have been documented in blood samples taken from individuals exposed to ionizing radiation or genotoxic chemicals, or from patients with hereditary cancer-prone or premature aging syndromes. In this study, the frequency of GPA allele-loss variant erythrocytes was found to be unusually high in a pediatric patient with a de novo interstitial deletion of 4q25q27. The magnitude of the observed increased variant cell frequency, 30-fold over age-matched controls, would be consistent with an acute whole body dose of ionizing radiation of ~6.5 Gy, or the spontaneous variant cell frequency measured in the cancer prone syndrome Fanconi anemia. Mechanistically, these results are similar to those previously documented in a cell culture system, in which a 100-fold increase in the frequency of mutation at the CHO aprt gene was associated with translocation of an allele adjacent to an inversion breakpoint. The translocated allele was highly susceptible to spontaneous deletion, and was also found to easily undergo de novo gene inactivation, perhaps through a position effect. The possibility of unresolved genetic instability in the breakpoint regions of chromosome rearrangements has important implications both for hereditary disease in the form of contiguous gene syndromes, and for somatic disease in the form of continuing hypermutability associated with the genomic rearrangements characteristic of carcinogenesis.

**Comperative Genomic Hybridization (CGH)in peripheral blood of Polycythemia Vera and essential thrombocytosis patients.** *A. Amiel<sup>1</sup>, Y. Harishano<sup>2</sup>, M.D. Fejgin<sup>1</sup>, E. Gaber<sup>1</sup>, M. Lishner<sup>2</sup>.* 1) Genetics Unit, Meir General Hosp, Kfar-Saba, Israel; 2) Department of Medicine, Meir General Hospital.

Background- Polycythemia Vera (PV) and Essential Thrombocytosis (ET) are chronic clonal myeloproliferative diseases originating from multi-potent stem cell. Om bone marrow examination chromosomal abnormalities are encountered in 15-43% of PV patients and 5% of ET patients. However, no specific abnormality has been described. Cytogenetic abnormalities are more common in both diseases when a transformation of the disease occurs or following myelosuppressive treatment. Cytogenetic analysis in these diseases is usually done utilizing simple chromosomal karyotyping or by FISH. The aim of this research was to study cytogenetic aberrations associated with these diseases by CGH analysis. Methods- 12 PV and 8 ET patients participated in the study. Seven of the PV group were treated by phlebotomy, 12 were treated with hydroxyurea and 3 patients recieved P32 and/or Busulfan at different periods of time during their disease. All ET patients were treated with hydroxyurea. CGH analysis of the peripheral blood was performed using the method described by Kallioniemi et all (1992). Results- 3 PV patients (25%) had an abnormal karyotype: One had a gain in 11q12, one had combination of a gain in 11q12, 6p21.1-22 and 17q12-21, and another patient had a deletion 7q11.2 . Only one ET patient (12.5%) had again in 18p. Conclusion- Peripheral blood analysis by CGH in PV and ET patients did not reveale the commonly reported cytogenetic aberrations. However, other changes were observed, in particular a gain in 11q12 in treated PV patients.

**Lack of spatial preference between the der(BCR/ABL) and the der(ABL/BCR) in CML interphase cells.** *R.M. Chandra, M.J. Macera, R.S. Verma.* Department of Medicine, Wyckoff Heights Medical Center, Brooklyn-New York Hospital/Weill Medical College of Cornell Medical Center, New York, NY.

Do chromosomes involved in translocations have any special arrangement at interphase? It has been suggested that chromosomes 9 and 22 remain in close proximity in the center of interphase nuclei, a situation which enhances exchanges between them. This is of interest because of the t(9;22)(q34;q11.2) translocation, resulting in the Philadelphia (Ph) chromosome, the hallmark of CML. However, still unknown is whether, after the translocation occurs, the der(9q34) region remains closer to the Ph chromosome than the normal 9q34 region, and whether the two derivative chromosomes remain closer than the two normal chromosomes. The BCR/ABL translocation probe had been used to identify the normal BCR, the normal ABL, and the BCR/ABL rearrangement, but identification of the der(ABL) region had been difficult. Recently, a BCR/ABL probe (Vysis) became available in which the ABL label is extended 5' from exons 5-11 to an area containing sequences specific for the argininosuccinate synthetase gene (ASS). When this probe is applied to a Ph-positive CML sample, the der(9q34) can be identified as an additional red signal, smaller than the normal 9q34 signal. This probe was applied to two cases of CML which both had the t(9;22)(q34;q11.2) in 100% of analyzed metaphases. One hundred bone marrow nuclei were examined per case. The distance from the fused BCR/ABL (yellow) signal was measured to both the der(ABL) (small red) signal and the normal ABL (large red) signal and compared. Also, the distance from the normal ABL signal to the normal BCR (large green) signal was measured and compared to the distance from the BCR/ABL to the der(ABL). No preference was observed for either of the comparisons in either case. This suggests that in interphase cells, once the BCR and ABL genes have translocated to form the chimeric BCR/ABL gene, there does not appear to be further selection keeping the translocated regions closer than their normal homologues.

**HER2/neu analysis of paraffin-embedded testicular germ cell tumors using fluorescence in situ hybridization.**

*L.R. Smith<sup>1</sup>, V.C. Thurston<sup>1</sup>, J.L. Gilbert<sup>1</sup>, K. Miller<sup>2</sup>, S. Soule<sup>2</sup>, L. Einhorn<sup>2</sup>, L. Cheng<sup>3</sup>, G.H. Vance<sup>1</sup>.* 1) Dept Med & Molecular Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept Medicine, Indiana Univ Sch Medicine, Indianapolis, IN; 3) Dept Pathology, Indiana Univ Sch Medicine, Indianapolis, IN.

The HER2/neu oncogene, located on chromosome 17q, encodes a tyrosine kinase receptor which is homologous to the human epidermal growth factor receptor. Previous studies using immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH) on paraffin-embedded breast tumors have correlated HER2/neu overexpression and amplification with poor prognosis and early relapse. Recent evidence has shown a decrease in disease aggressiveness and in increase in response rate (Ross and Fletcher, 1998) in patients positive for HER2/neu amplification that were treated with the monoclonal antibody rhuMAB HER-2 (Herceptin).

The incidence of testicular germ cell tumors (TGCT) commonly found in men between the ages of 15 and 34 have more than doubled over the past four decades warranting the need for increased detection and treatment. Currently, there is an 80% survival rate for patients with newly diagnosed and treated TGCT. The remaining 20% either do not respond to treatment or are candidates for early relapse. A current IHC study on paraffin-embedded TGCT detected 15% HER2/neu protein overexpression overall. To date there are no data for HER2/neu analysis on TGCT utilizing FISH. We present preliminary FISH data from a blinded study on 64 of the same paraffin-embedded TGCT as the aforementioned IHC study. A total of forty nuclei were scored per tumor. Of the 64 tumors analyzed, 62 (96.87%) averaged 2.1 signals/nuclei (2s.d. = 1.04; 95% C.I. = 0.0089) and were considered normal. Two tumors (3.125%) exhibited HER2/neu amplification with an average of 5.9 signals/nuclei (2s.d. = 0.14; 95% C.I. = 0.006) and were scored as amplified. Future work will be twofold: to determine whether a correlation exists between HER2/neu protein overexpression (IHC) and DNA amplification (FISH) in TGCT and to determine whether this overexpression/amplification correlates to resistance to treatment and early relapse.

**Equivocal cases of Her-2 gene amplification detected by fluorescence in situ hybridization.** *F.P Espinoza<sup>1</sup>, X. Yang<sup>2</sup>, K.S. Reddy<sup>2</sup>.* 1) Dept Pathology, Quest Diagnostics, San Juan Capist, CA; 2) Dept Cytogenetics.

Her-2 gene amplification was detected using FISH on paraffin embedded tissue sections. Among 424 mammary carcinomas studied for Her-2 gene amplification, 74 (17.5%) were positive, 335 were negative and 15 [~3.5%] were equivocal using PathVysion FISH (Vysis Inc) assay. The ratio of the Her-2 signals to the centromere 17 signals (which maps to 17q11.2q12) when equal or  $>2$  was considered positive. The equivocal cases were those with a ratio  $<2$  but with a subpopulation of cells having Her-2 amplification equal or  $>2$ . Some of these cases also had chromosome 17 aneuploidy. Other cases had borderline value of 1.8-2.0. One tumor showed amplification in a restricted region and had a Her-2 ratio of 1.33. These cases were examined using immunohistochemistry (IHC) method. The FISH and IHC findings were compared. The IHC Dako antibody staining when weakly positive was scored as a 2+; and when strongly positive was a 3+;. Lack of or faint staining was considered negative (0 or 1+). Six tumors with a Her-2 gene amplification ratio  $<2$  had a subpopulation of cells (30-50%) with Her-2 ratio  $>2$ . Two such tumors with the largest population (49% and 50%) of amplified cells were 2+ positive by IHC. Four cases with a Her-2 gene ratio  $<2$  and aneuploid for chromosome 17 in the majority of cells also had a subpopulation of cells (12.5% to 40%) with  $>2$  Her-2 ratio. Two such tumors were positive (3+ or 2-3+) by IHC. Three borderline cases with a 1.8-2.0 ratio for Her-2 gene were negative 1+ by IHC. FISH evaluation of Her-2 amplification is straightforward in the majority of cases. However, it is in tumors with a Her-2 ratio  $<2$  and a mosaic pattern of amplified and normal cells that caution must be exercised by evaluating these cases with an IHC assay. In this study, 26% (4/15) of tumors with an equivocal FISH result were found to be IHC positive. If the equivocal cases were considered as negative based solely on the equal or  $<2$  Her-2 gene ratio, roughly 1 per 117 cases would have been false negative considering a 90% correlation between FISH to IHC results.

**Somatic Mutational Evidence for Tissue-specific Premature Aging in the Bone Marrow of Patients with Sickle Cell Hemoglobinopathy.** *B.M. Luccy<sup>1</sup>, L. Saglammer<sup>1</sup>, W.L. Bigbee<sup>1</sup>, J.D. Hord<sup>2</sup>, S.G. Grant<sup>1</sup>*. 1) Center for Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA; 2) Division of Hematology/Oncology, Akron Childrens Hospital, Akron, OH.

Sickle cell hemoglobinopathy is a molecularly simple genetic disorder with complex pleiotropic effects on many tissues. One of the most severely affected is the bone marrow, which must make up for constant hemolysis-induced anemia by increased processing and releasing of erythrocytes into the circulation. We have investigated whether this increased mitotic activity in the bone marrow results in higher frequencies of somatic mutation in circulating blood cells. Somatic mutation, an intrinsic factor in aging and carcinogenesis, can be measured in peripheral blood erythrocytes using a flow cytometric assay based on the glycophorin A (GPA) erythrocyte surface protein. GPA variant cell frequencies were analyzed in a group of 22 informative pediatric sickle cell patients. Mutation frequencies in the patient population were correlated with age and significantly higher than matched disease-free controls. Moreover, mutation frequencies correlated with clinical indicators of disease severity, including white blood cell count, reticulocyte count and blood hemoglobin. These results imply that the bone marrow of sickle cell patients has a somatic mutational burden characteristic of an older normal population, and that they may be at increased risk of hematopoietic malignancies. Perhaps more importantly, this data provides *in vivo* evidence that induction of cell replication (mitogenesis) directly increases the endogenous mutation frequency and/or susceptibility to genotoxic agents.

**High resolution deletion mapping defines a 3-cM region of 15q loss in human malignant mesothelioma.** A. De Rienzo<sup>1</sup>, B.R. Balsara<sup>1</sup>, S.C. Jhanwar<sup>2</sup>, J.R. Testa<sup>1</sup>. 1) Human Genetics, Fox Chase Cancer Center, Philadelphia, PA; 2) Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

Malignant mesotheliomas (MMs) are highly aggressive neoplasms that arise primarily from the surface serosal cells of the pleural, peritoneal, and pericardial cavities. Epidemiological studies have established that exposure to asbestos fibers is the primary cause of MM. The accumulation of multiple, recurrent cytogenetic deletions in most MMs suggests a multistep process in this malignancy, which is characterized by the loss and/or inactivation of several tumor suppressor genes (TSGs). Earlier karyotypic studies of MMs demonstrated frequent deletions of specific regions within chromosome arms 1p, 3p, 6q, 9p, 13q, and 22q. Recently, we reported comparative genomic hybridization analyses that enabled us to identify a new recurrent site of chromosomal loss within 15q in this malignancy (Balsara et al., *Cancer Res.* 59: 450-454, 1999). In addition, loss of heterozygosity analysis, using 8 MM cases and 16 polymorphic microsatellite markers, identified a minimal region of chromosomal loss at 15q11.1-15. To more precisely map the region of 15q deletion, we have now constructed a high-resolution map of 15q loss in 46 MM cell lines using 26 polymorphic DNA markers spanning the entire long arm. This study has defined a shortest region of overlap (SRO) within an ~3-cM region in 15q15.3. Fluorescence in situ hybridization analysis, using YACs localized to 15q15, confirmed losses from this region in several MMs with small 15q deletions. cDNA microarrays of ESTs mapped to the SRO are currently being utilized to identify candidate TSGs downregulated in MM.

**Cloning of a recurrent site of chromosome translocation in cutaneous melanoma.** *K.M. Brown<sup>1,2</sup>, D.A. Stephan<sup>1,3</sup>, J. Zhang<sup>3</sup>, M. Heiskanen<sup>3</sup>, G. Bethel<sup>4</sup>, C.R. Robbins<sup>3</sup>, C. Carder<sup>4</sup>, A. Mungall<sup>4</sup>, P.S. Meltzer<sup>3</sup>, J.M. Trent<sup>3</sup>.* 1) Res Center for Genet Medicine, CNMC, Washington, DC; 2) GWU Genetics, Washington, DC; 3) NHGRI/NIH, Bethesda, MD; 4) Sanger Centre, Cambridge, UK.

UV radiation plays a key role in the development of melanoma via the generation of photo-adducts, but the genetic mechanisms behind melanoma progression have yet to be clearly elucidated. A large body of evidence implicates chromosome 6q as a major genetic determinant for melanoma. Partial loss of 6q has been observed in the majority of malignant melanomas, while translocations in the 6q12-6q21 region have been observed in still more tumors. In addition, transfer of human chromosome 6 into melanoma cell lines has been shown to reverse the tumorigenic phenotype. This strongly argues for the presence of a tumor suppressor gene whose deletion is critical for the development or progression of melanoma.

We are currently mapping the breakpoint of a nonreciprocal translocation [t(1;6)(q21;q14)] found in the HA-A melanoma primary cell line. Previously, we identified a single YAC clone spanning the breakpoint (Zhang et al., 1995). We have since identified BAC clones by STS content from this YAC and used them for fiber-FISH on the HAL-26 cell line (contains the translocated chromosome in a rodent background) together with a chromosome 1 BAC flanking the breakpoint. The results showed a gap of ~200kb between one chromosome 6 BAC and the chromosome 1 BAC. To span the breakpoint, we end-sequenced and walked in both directions from the chromosome 6 BAC, fingerprinted it, and integrated it into the Sanger Centre chromosome 6 BAC contig. The BAC integrated into a large contig that extends >200kb in either direction from the chromosome 6 BAC. We are currently identifying the BAC clone that spans the breakpoint by fiber-FISH, end-STS content mapping, and end-STS Southern blotting in HAL-26. Identification and sequencing of the BAC that contains the gene interrupted by the translocation will hopefully identify a previously unrecognized tumor suppressor gene and allow us to better understand the molecular pathophysiology of this common malignancy.

**Low incidence of follicular lymphoma and translocation t(14;18)(q32;q21) by PCR analysis in Ecuador, South America.** *P.E. Leone<sup>1, 2</sup>, J.C. Pérez<sup>1</sup>, M.E. Sánchez<sup>1, 2</sup>, M. Arévalo<sup>1</sup>, C. Paz-y-Mino<sup>1, 2</sup>*. 1) Hum Mol Genet & Cytogen Lab., Department of Biological Sciences; 2) Medicine Faculty, Catholic University of Ecuador, Quito-Ecuador.

The chromosomal translocation t(14;18)(q32;q21) has been shown in diagnostic tissue specimens from approximately 85% of patients with follicular and 30% with diffuse non-Hodgkins lymphomas (NHL). This translocation leads to an overproduction of the Bcl-2 protein on the basis of increased Bcl-2 mRNA levels which interferes with normal apoptosis of B-lymphocytes. The breakpoints on chromosome segment 18q21 (BCL-2) have been shown to cluster at two main regions 3': approximately 70% occur within the major breakpoint region (mbr) and up to 20% are found within minor breakpoint region (mcr). There is evidence that the distribution of NHL subtypes differs by geographic region, however there is not data for Ecuador. Using PCR, we have examined the frequency of this translocation (mbr and mcr) in 65 NHL tumors samples obtained during five years in the principal hospitals of Quito-Ecuador. Of 65 NHL only 5 were follicular lymphoma, which represents an incidence of 7.7%. This incidence is quite lower than one in North America (30%). In addition, we do not find the translocation in the samples analyzed, which was confirmed by use of a control PCR; probably, then, this translocation is not common in NHL in Ecuador. These findings confirm that there are differences in the incidence of specific subtypes of NHL across some geographic areas and suggest that genetic factors may be responsible for the observed differences.

**The t(4;11)(q21;p15) - a unique recurring structural abnormality associated with ALL, AML as well as T-cell lymphomas.** *M. Thangavelu<sup>1</sup>, B. Huang<sup>1</sup>, K. Richkind<sup>2</sup>*. 1) Genzyme Genetics, Orange, CA; 2) Genzyme Genetics, Santa Fe, NM.

The t(4;11)(q21;p15) is a relatively rare rearrangement involving the same band on chromosome 4 as the t(4;11)(q21;q23), an abnormality most frequently associated with ALL in very young patients and poor prognosis. The t(4;11)(q21;p15) has been reported in ALLs (some with myeloid surface markers) a case of AML and a biphenotypic leukemia. We present a case of T-cell lymphoma and one of AML with this rearrangement. The clinical history in the latter is suggestive of a secondary leukemia. These are the first reported cases of t(4;11)(q21;p15) in a T-cell lymphoma and therapy induced secondary leukemia. One difference between the t(4;11)(q21;q23) and the t(4;11)(q21;p15) appears to be that while the former is most frequently observed in very young patients, the latter is observed in older male children and young to middle aged male patients. Our cases along with those previously reported suggest that the t(4;11)(q21;p15) may be a unique recurring structural abnormality associated with a variety of hematologic malignant disorders, both primary as well as secondary. The case of T-cell lymphoma reported here suggests that this may be the first translocation associated with ALLs, AMLs as well as lymphomas. Investigations at the molecular level are essential in determining if the breakpoint on chromosome 4 involves the AF-4 gene as in t(4;11)(q21;q23), in learning more about the sequences on 11p15 involved in this rearrangement as well as determining if the rearrangements in the various disorders, which appear similar at the microscopic level, are identical at the molecular level.

**Computational Methods for Gene Expression Based Tumor Classification.** *W. Li<sup>1,2</sup>, M. Xiong<sup>1</sup>*. 1) Human Genetics Center, University of Texas-Houston, Houston, TX; 2) Beijing Institute of Basic Medical Sciences, P.O.Box 130(3), Beijing, 100850, P.R.China.

There is increasing interests in changing the emphasis of tumor classification from morphologic to molecular. Gene expression profiles may offer more information than morphology and provide an alternative to morphology-based tumor classification systems. In this report, We have investigated the following methods: fish's linear discriminant function, neural network and support vector machine methods for gene expression based tumor classification, and we emphasize the following key issues such as feature variable selection and stability analysis. In the selection of feature variables, principal component analysis, stepwise optimization, Monte Carlo simulation and exhaustive searching methods were used. For stability analysis, the method of sample random permutation was used to get the comprehensive classification accuracy. Finally, in order to demonstrate the reliability of our method and program, the proposed tumor classification system was applied to three data sets: colon cancer data including 22 normal and 40 colon tumor tissues, breast cancer data including 14 human mammary epithelial cells and 13 breast tumors, and human acute leukemia data including 47 acute lymphoblastic leukemia (ALL) and 25 acute myeloid leukemia (AML) samples. Through these three examples, we show that using two or three genes can achieve more than 90% accuracy of classification. This result implies that after initial investigation of tumor classification using microarrays, a small number of selected genes may be used as biomarkers for tumor diagnosis. Further we also showed that stepwise optimization method based on Fisher's linear discriminant function is a practicable method for gene expression-based tumor classification.

**DIFERENTIAL GENE EXPRESSION IN COLORECTAL TUMORS.** *N.A. Pinheiro<sup>1</sup>, L.F.L. Reis<sup>1</sup>, S.J. Souza<sup>1,3</sup>, F. Soares<sup>3</sup>, S.D. Pena<sup>2,3</sup>, A.J.G Simpson<sup>1</sup>.* 1) Cancer Genetic, Ludwig Institute , Sao Paulo, SP., Brazil; 2) Departamento de Bioquimica e Imunologia, Universidade Federal de Minas Gerais, M.G., Brazil; 3) Hospital do Cancer - A.C.Camargo, Sao Paulo, S.P., Brazil.

Colon tumorigenesis is considered a complex multistep process that occurs through a series of gene mutations, leading from precursor lesions to invasive and metastatic adenocarcinoma. The development and progression of cancer and the reversal of tumorigenicity are accompanied by complex changes in patterns of gene expression. Microarrays of cDNA provide a powerful tool for studying these complex phenomena. The purpose of the present study has to determine differential gene expression in colon tumors as compared with normal tissue. We also investigated the possible variability of the gene expression among pools of microdissected colon tumors. These samples were analyzed using the Gene Discovery Array Human system (from genomesystems) that consists of two nylon membranes in a double spotted pattern at a density of 36,864 per spots per filter or 18,376 individual cDNA clones. Our preliminary results showed several differentially expressed clones between normal and tumor tissue analyzed. Our results were compared by software analysis to the patterns was found by Alon et al., 1999 using affymetrix oligonucleotide array complementary to more than 6,500 human genes tumor. When we compared our data against the results published by Alon et al, 1999 using UNIX program, 443 genes present differential expression in both analyses. Two hundred eighty were upregulate genes and 163 genes were downregulate. The majority of these genes are defined only by ESTs. Supported by: FAPESP.

**Characterization of adjacent breast tumors using cDNA microarrays.** *M.A Unger<sup>1</sup>, M. Rishi<sup>2</sup>, V. Clemmer<sup>3</sup>, B.L Weber<sup>1</sup>.* 1) Department of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Pathology, St. Francis Hospital, Wilmington, DE; 3) Department of Surgery, St. Francis Hospital, Wilmington, DE.

The clinical assessment of a patient with multiple adjacent breast tumors or an in-breast recurrence can be difficult with respect to treatment. Currently used clinical methods of tumor analysis often can not determine if the tumors have arisen from a single cancerous cell or whether the tumors have developed from distinct clones. This information may be critical for determining a treatment strategy. The recent development and commercialization of cDNA microarray technology provides a promising means by which these uncertainties can be addressed by comparing the gene expression patterns between the tumors. We have tested the capabilities of commercially available cDNA microarrays to compare the gene expression patterns of two adjacent tumors excised from the right breast of an 87 year-old woman diagnosed with invasive ductal carcinoma (IDC). Total RNA was isolated from the tumors using Trizol reagent (Life Technologies) and arrayed in duplicate on Human Genome U95A Gene Chip<sup>TM</sup> (Affymetrix, Santa Clara, CA) containing 12,000 known genes. The data generated from the microarray experiments are being analyzed using Affymetrix software. The following characteristics are being considered with the gene expression patterns of the tumors: 1) the percentage of genes with a different expression levels between duplicate microarray experiments in a tumor, 2) the percentage of genes with different expression levels between the two adjacent tumors and the types of genes that are differentially expressed. This work provides an example of the potential of microarray experiments for tumor characterization and the potential for this technology to help guide clinical treatment.

**SAGEmap: A gene expression resource for the Cancer Genome Anatomy Project.** *G.J. Riggins<sup>1</sup>, W.T. Loging<sup>1</sup>, A. Lal<sup>1</sup>, I. Siu<sup>1</sup>, C. Boon<sup>1</sup>, C. Turner<sup>1</sup>, R.L. Strausberg<sup>2</sup>*. 1) Dept. of Pathology, Duke Univ Medical Ctr, Durham, NC; 2) Cancer Genome Anatomy Project, Office of the Director, National Cancer Institute, Bethesda, MD.

The Cancer Genome Anatomy Project (CGAP) has created an on-line system, SAGEmap, for the study of gene expression in tumors, normal tissues, and model systems (<http://www.ncbi.nlm.nih.gov/SAGE/>). This public resource is based on Serial Analysis of Gene Expression (SAGE), which is used to archive the numbers of expressed transcripts in each cell population. To date 2.4 million transcripts have been assayed from 54 different mRNA samples. In addition to being able to ascertain the expression levels in malignant and normal tissues, experimental systems are being used to locate candidate genes involved in basic oncogenic functions. SAGEmap is designed to help locate the downstream targets of certain oncogenes, genes induced by hypoxia, tumor antigens, genes conferring resistance to chemotherapy, genes involved in telomere maintenance and as well as other genes with a potential role in tumor formation. As a demonstration of this approach, results on the retrieval and functional analysis of one group of genes involved in glioblastoma will be presented.

**The minimal region of CLN3 necessary for anti-apoptotic function resides at the carboxyl end.** *R.N. Boustany*<sup>1,2</sup>, *D.N Persaud*<sup>1,2</sup>, *S. Dhar*<sup>1</sup>. 1) Div Pediatric Neurology, Duke Univ Medical Ctr, Durham, NC; 2) University Program in Genetics, Duke University Medical Center, Durham, NC.

Juvenile neuronal ceroid lipofuscinosis is an autosomal recessive disease. Afflicted individuals manifest the disease as the progressive loss of vision, seizures, psychomotor disturbances and cognitive decline. The disease is caused by mutations occurring in the CLN3 gene. CLN3 consists of 15 exons and is approximately 1700 base pairs in length. The translated protein is 438 amino acids and 48 KDa. The most commonly observed mutation, affecting 80% of cases, involves a deletion of nucleotides 461-677 of the cDNA, which originates from a 1.02Kb deletion in the genomic DNA. This deletion falls within exons 7 and 8. The resulting protein is truncated and is 24 KDa. It has been shown that CLN3 is anti-apoptotic and acts by modulating ceramide generation upstream. In this study, deletion mutants were systematically generated from the 3' carboxy terminal of the gene and cloned into the pGEM (+7f) vector. Lymphoblast cell lines deficient in CLN3 were then transformed with these deletion constructs. Cell growth was then determined by thymidine incorporation and trypan blue cell counting. Restoration of the  $DY_m$ , or the mitochondrial membrane potential, of the transfectants was then assessed following treatment with etoposide using JC-1 staining. We show that exons 11-15 of the CLN3 gene provide transformed JNCL cells with protection from etoposide-induced apoptosis, and are also responsible for the correction of cell growth deficiencies. The goal of this project is to determine the motif or motifs present within this region that impart anti-apoptotic activity to CLN3. This can lead to effective drug screening for agents that can halt neurodegeneration.

**Neurofibromatosis 2 (NF2) and malignant mesothelioma.** *L.H. Pitts*<sup>1</sup>, *R.K. Jackler*<sup>1,2</sup>, *D. Altomare*<sup>3</sup>, *J.R. Testa*<sup>3</sup>, *M.E. Baser*<sup>4</sup>. 1) Department of Neurological Surgery, UC San Francisco, San Francisco, U.S.A; 2) Department of Otolaryngology, UC San Francisco, San Francisco, U.S.A; 3) Human Genetics Program, Fox Chase Cancer Center, Philadelphia, U.S.A; 4) Los Angeles, U.S.A.

NF2 tumors are caused by inactivating mutations of the *NF2* tumor suppressor gene, and somatic *NF2* mutations occur in a high proportion of malignant mesothelioma cells lines and primary tumors, but mesothelioma is not a characteristic feature of NF2. We describe a patient with NF2 and mesothelioma. Beginning at age 22, he was diagnosed with bilateral vestibular schwannomas, presenile lens opacities, and numerous spinal tumors. At age 40, he was diagnosed with a malignant peritoneal mesothelioma and he died shortly thereafter; he had worked as an automotive and jet mechanic since age 15, and the causal exposure probably occurred while working on brake systems or from reworking asbestos-containing parts. This case is consistent with Knudson's observation as to why mutations in the same tumor suppressor gene can cause different tumor types that do not each occur as part of hereditary cancer syndromes (PNAS 1995;92:10819-20). Tumors that are characteristic of hereditary cancer syndromes occur in tissues whose stem cells proliferate in utero or in adolescence (e.g., neuroectoderm-derived NF2 nervous system tumors), but proliferation of frequently-renewed tissues (e.g., malignant transformation of the mesoderm-derived peritoneum) requires an additional pathological condition. Molecular studies will include (1) *NF2* and LOH analyses, (2) comparative genomic hybridization to compare the patterns of genetic imbalances in benign and malignant tumors, and (3) molecular and immunohistochemical assays of changes in other tumor suppressor genes that often occur in mesothelioma (e.g., *p16/CDKN2A*).

**Predictors of vestibular schwannoma growth in neurofibromatosis 2 (NF2).** *D.M. Parry*<sup>1</sup>, *E. Makariou*<sup>2</sup>, *M.E. Baser*<sup>3</sup>. 1) Genetic Epidemiology Branch, National Cancer Institute, Bethesda, MD; 2) Department of Radiology, Georgetown University School of Medicine, Washington, D.C; 3) Los Angeles, CA.

We previously reported that NF2 vestibular schwannoma (VS) growth rates varied inversely with age (*Am J Hum Genet* 1998;63:[4 Suppl]A63), but others have found a direct relationship (*Laryngoscope* 1996;106:694-699). To resolve this discrepancy, we re-analyzed data from the U.S. National Institutes of Health longitudinal study of NF2, on whose patients the Laryngoscope study was also based. VS growth rates were expressed as tumor doubling times (TDTs, in years) to account for differences in baseline VS volumes. The median length of follow-up in 15 patients was five years. Fourteen patients had identified constitutional *NF2* mutations (five nonsense or frameshift mutations, six splice-site mutations, three in-frame deletions). The median TDT in patients  $\leq 30$  years old was 15 years, compared to 35 years in patients  $> 30$  years old, indicating a higher VS growth rate in younger patients. Median TDTs were similar in patients with nonsense or frameshift mutations (31 years), splice-site mutations (34 years), and in-frame deletions (37 years). TDTs were inversely associated with the number of intracranial meningiomas ( $r^2 = .35$ ,  $P = .02$ ). This finding extends other studies that have found that the number of meningiomas is an important feature of NF2 disease severity and is an independent predictor of survival in NF2.

**Human hepatocellular carcinoma is characterized by a highly consistent pattern of genomic imbalances, including frequent loss of 16q23.1-24.1.** *B.R. Balsara<sup>1</sup>, J. Pei<sup>1</sup>, A. De Rienzo<sup>1</sup>, D. Simon<sup>2</sup>, A. Tosolini<sup>1</sup>, Y.Y. Lu<sup>3</sup>, F. Shen<sup>4</sup>, X. Fan<sup>4</sup>, W.Y. Lin<sup>4</sup>, K.H. Buetow<sup>5</sup>, W.T. London<sup>1</sup>, J.R. Testa<sup>1</sup>.* 1) Div. of Population Sciences, Fox Chase Cancer Center, Philadelphia, PA; 2) MCP-Hahnemann School of Medicine, Philadelphia, PA; 3) Department of Biochemistry and Molecular Biology, Beijing Institute for Cancer Research, Beijing, P.R. China; 4) Shanghai Medical University, Haimen City Cancer Prevention Institute, Shanghai, P.R. China; 5) Laboratory of Population Genetics, National Cancer Institute, Bethesda, MD.

Comparative genomic hybridization (CGH) analysis was used to identify chromosomal imbalances in 52 human primary hepatocellular carcinomas (HCCs). The most prominent changes were gains of part or all of chromosome arms 8q (83% of cases) and 1q (73%) and loss of 16q (63%). Other commonly overrepresented sites were 5p, 7q, and Xq. Recurrent sites of DNA sequence amplification included 8q23-24 (5 cases) and 11q13-14 (4 cases). Other frequently underrepresented sites were 4q, 8p, 16p, and 17p. Taken collectively, these findings and data from other CGH studies of HCCs define a subset of chromosome segments that are consistently over- or underrepresented and highlight sites of putative oncogenes and tumor suppressor genes, respectively, involved in hepatocellular oncogenesis. Loss of heterozygosity analysis with a panel of polymorphic microsatellite markers distributed along 16q defined a minimal region of chromosomal loss at 16q23.1-24.1, suggesting that this region harbors a tumor suppressor gene whose loss/inactivation may contribute to the pathogenesis of many HCCs.

**Genotoxic effect of breast cancer patient's serum and plasma on normal blood leucocytes.** *r. narayanappa*<sup>1,2</sup>, *A. Kumar*<sup>1</sup>, *Y.R. Ahuja*<sup>2</sup>. 1) MRDG, Indian Institute of Science, Bangalore 560012, India; 2) Genetics unit, Bhagawan Mahavir Medical Research Center, 10-1-1, Mahavir marg, Hyderabad 500004, India.

Most human cancers are associated with genetic instability. Our previous studies have shown increased level of DNA damage in the peripheral blood leucocytes of cervix and breast cancer patients as compared to the controls. The presence of increased DNA damage in the leucocytes in these cancer patients which is not the target tissue is rather unexpected. According to Werkeimester et al (1980), some genotoxic agents are being released by the tumor tissue into the blood stream which might be the cause for this increased DNA damage observed in the leucocytes. To investigate the genotoxic activity of the cancer patient's blood, the genotoxic activity of the sera and plasma from breast cancer patients were evaluated comet assay. Comet assay is simple, sensitive technique used to quantitate DNA single strand breaks, double strand breaks and alkali labile sites at individual cell level. Serum and plasma were isolated from 10 untreated breast cancer patients. Normal individual's lymphocytes were treated with breast cancer patient's serum and plasma. DNA damage was evaluated by comet assay after 1hr and 2hr treatment. A significant increase in the level of mean comet tail length was observed in the normal lymphocytes treated with the breast cancer patient's serum as compared to the untreated normal lymphocytes. Similarly, a significant increase in the level of mean comet tail length was observed in the normal lymphocytes treated with the breast cancer patient's plasma as compared to untreated normal lymphocytes. This increased DNA damage in the normal lymphocytes could be due to the presence of of some genotoxic factors in the serum and the plasma of the breast cancer patients. This is a preliminary study carried out to check out on the genotoxic effect of breast cancer patient's blood. Further detailed study need to be carried out to come to reliable conclusion.

**HPV16 Integrations in Cervical Tumors Preferentially Occur within the Common Fragile Sites and Cluster at Specific Sites.** *E.C. Thorland<sup>1</sup>, S.L. Myers<sup>2</sup>, B.S. Gostout<sup>3</sup>, D.I. Smith<sup>4</sup>*. 1) Biochem & Molec Biol, Mayo Clinic, Rochester, MN; 2) Tumor Biology Program, Mayo Clinic, Rochester, MN; 3) Obstetrics and Gynecology, Mayo Clinic, Rochester, MN; 4) Division of Experimental Pathology, Mayo Clinic and Foundation, Rochester, MN.

The development of cervical cancer is highly associated with human papillomavirus (HPV) infection, and HPV integration is temporally associated with the acquisition of the malignant phenotype. A relationship between the sites of HPV16 integration and the positions of the common fragile sites (CFS) has been observed at the cytogenetic level. We explored this relationship at the molecular level. We utilized a PCR-based method to amplify the junctions between HPV sequences and the flanking genomic sequences in cervical tumor specimens. Primers based on the flanking sequences were then used to screen BAC libraries to isolate genomic clones at each integration site. These were then used as FISH probes against aphidicolin-induced metaphase chromosomes. We isolated genomic sequences flanking HPV integration sites from 20 HPV16-positive cervical tumors. Many of these integrations occur within the CFS verifying our hypothesis. The integrations from the 20 cervical tumors occurred on many chromosomes, but we have observed specific clustering of the integrations at 17q23 (the site of FRA17B), and 13q21-31 (the sites of FRA13B and FRA13C). Three integrations occurred within a 2 Mb interval on 17q23 surrounding FRA17B. Two integrations occurred within a less than 200 Kb interval on chromosome 13. Sequence analysis demonstrated that the chromosome 13 integrations occurred within the same interval as the integration previously cloned from the cervical tumor cell line, SiHa. It has been proposed that HPV integration events in cervical tumors may disrupt cellular genes at the integration sites. The observed clustering of integrations suggest that genes important in the initiation or progression of cervical cancer may be specifically disrupted by these integrations. We are currently characterizing these two regions to determine if genes contained within them have a role in cervical carcinogenesis.

**Loss of heterozygosity correlates with tumor and host response parameters in squamous cell carcinoma of the head and neck (SCCHN).** *D.L. Van Dyke*<sup>1</sup>, *J.A. Gomez*<sup>2</sup>, *A.T. Saveria*<sup>2</sup>, *B. Rybicki*<sup>3</sup>, *M.S. Benninger*<sup>4</sup>, *R.J. Zarbo*<sup>2</sup>. 1) Departments of Medical Genetics; 2) Pathology; 3) Biostatistics & Research Epidemiology, and; 4) Otolaryngology, Henry Ford Hospital, Detroit, MI.

Little is known of genotypic associations with histologic phenotypic features in SCCHN. Therefore, we evaluated the correlation between loss of heterozygosity (LOH) at several chromosomal loci and objective histopathologic characteristics. A series of 107 SCCHN were histologically typed and scored in a 4 tier scheme for histologic parameters (keratinization, nuclear grade, mitoses per high power field) and host interface characteristics (inflammation, desmoplasia, and pattern of invasion). PCR was performed on DNA isolated from paraffin tumor blocks and normal tissue for LOH at eight MSRP loci (3p13, 3p21, 5q12, 8p22, 9p21, 10p13, 18q13, 21q11). Dichotomous factors were compared by chi square test and ordinal factors by Kendall's tau, to test for associations with LOH. Of 107 patients with pathologic data, paired normal and tumor LOH data are available for 69. Tumors were classified as conventional (83%), non-keratinizing (8%), papillary squamous (3%), basaloid squamous (1%), adenosquamous (1%), conventional/non-keratinizing (1%) and conventional/ adenosquamous (1%). Statistically significant associations were noted for a poorer histologic grade and LOH at 3p21 ( $p=0.05$ ), and the data were suggestive of an association between grade and LOH at 3p13 and 5q12 ( $p=0.11$  for both). Decreasing inflammatory response was significantly associated with LOH at 3p21, 3p13, 5q12, and 9p21 ( $p=0.004$ ,  $p=0.05$ ,  $p=0.06$ , and  $p=0.04$ , respectively). Increased numbers of mitoses was significantly associated with LOH at 18q13 ( $p=0.04$ ). These findings suggest that LOH at certain loci on chromosomes 3, 5, 9, and 18 correlate with more aggressive histologic features. The present findings suggest that there are morphologic correlates of our previously reported findings of significantly poorer survival for patients whose tumors exhibit evidence of genetic loss at loci on chromosome 3, 5, and 18 (Pearlstein et al. *Genes Chrom Cancer* 21:333-339,1998, and in abstracts elsewhere.).

**Hypermethylation in the 5' region of the GSTP1 gene is a potential diagnostic index for prostate carcinoma. D.C.**

*Chu<sup>1</sup>, C.K. Chuang<sup>2</sup>, J.B. Fu<sup>1</sup>, H.H. Huang<sup>2</sup>, C.Y. Wang<sup>1</sup>.* 1) Laboratory of Molecular Diagnosis, Department of Clinical Pathology, Chang Gung Memorial Hospital, Lin-Kou, Taiwan; 2) Department of Urological Surgery, Chang Gung Memorial Hospital, Lin-Kou, Taiwan.

**Background:** Prostate cancer has been ranked as one of the top ten male cancer syndromes in Taiwan recently. A sensitive and specific biomarker is desired for diagnosis of prostate cancer. It was found that extensive methylation occurred in the 5' CpG island flanking the p-class glutathione S-transferase (GSTP1) gene in prostate cancer cells but not in normal cells. **Objective:** the purpose of this study is to investigate whether this genomic alteration could be used as a diagnostic index for prostate cancer. **Study design:** Genomic DNA was extracted from paired tissue and blood samples from prostate cancer patients. After methylation sensitive restriction enzyme Hpa II treatment, nested PCR was performed to amplify the 5' region flanking the GSTP1 gene. PCR amplicon was then analyzed qualitatively. **Results:** the preliminary data showed that of the 6 tissue samples analyzed, 6 of 6 (100 %) showed positive band patterns indicating hypermethylation in this region. However, the same band patterns were not observed when corresponding blood samples were analyzed. **Conclusions:** Hypermethylation of CpG islands in the promoter region of the GSTP1 gene appeared in high frequency in prostate cancer cells. It suggested potential application of molecular diagnosis of prostate cancer with this marker. Next, more prostate cancer samples will be analyzed to determine the detecting ability of this novel biomarker.

**Identification and characterisation of a founder mutation in the Belgian breast/ovarian cancer population. K.**

*Claes, B. Poppe, P. Scheir, M. De Vos, I. Delveaux, I. Coene, A. De Paepe, L. Messiaen.* Dept. Medical Genetics, Ghent University Hospital, Ghent, Belgium.

In order to identify the mutation spectrum of the *BRCA1/2* genes in the Belgian patient population, we perform mutation analysis for the complete coding sequence of both genes in Belgian breast and ovarian cancer patients. We finished the analysis in 73 families fulfilling our inclusion criteria (Claes et al, 1999) and in 28 patients diagnosed with breast and/or ovarian cancer before age 35. In about 30% of the families a mutation in *BRCA1* or *BRCA2* was identified. 75% of the mutations were detected in *BRCA1*. In none of the sporadic patients a mutation was found. Some mutations are novel and never reported in other populations.

In 7 unrelated families the same splice site mutation in *BRCA1* was identified: IVS5+3A>G. Haplotype analysis suggests that they share a common ancestor. This mutation was reported by Peelen et al (1997) in another Belgian family, but has not yet been identified in other populations.

All our 7 families harbouring the mutation IVS5+3A>G represent a severe phenotype: patients are often diagnosed with breast cancer at rather young age (Dx<40) and ovarian cancer is present in 4/7 families.

At the mRNA level *BRCA1* IVS5+3A>G inactivates the splice donor site of exon 5 and activates a cryptic donor (ctttAT/GTaaG) present in exon 5 leading to out of frame skipping of the last 22 nucleotides of exon 5 and a premature stop codon. Interestingly this splice variant was observed also in the lymphocytes of patients without this splice site mutation, albeit typically at low level. Additional tissues, tumors and tumor cell lines are currently investigated in order to further characterise a possible functional significance of this splice variant.

**Nibrin, the molecule mutated in Nijmegen breakage syndrome, is required for correct nuclear localization and focus formation by a DNA repair protein complex.** A. Desai-Mehta, K. Cerosaletti, P. Concannon. Virginia Mason Research Center and University of Washington School of Medicine, Seattle, WA.

Patients with the autosomal recessive disorder Nijmegen breakage syndrome (NBS) display microcephaly, growth retardation, chromosomal instability, hypersensitivity to ionizing radiation, immunodeficiency and an increased incidence of malignancies, primarily of lymphoid origin. NBS results from truncating mutations in the *NBS1* gene that encodes the protein nibrin. In normal fibroblasts, nibrin is part of a nuclear multiprotein complex that contains the DNA repair proteins Mre11 and Rad50. Upon irradiation, the nibrin/Mre11/Rad50 complex redistributes to form distinct nuclear foci that are thought to be sites of DNA repair. In cell lines from NBS patients, nibrin is truncated or absent, Mre11/Rad50 proteins lose their nuclear localization and foci fail to form upon irradiation. This suggests that the sequences in the carboxy-terminal half of nibrin are necessary for the maintenance of this protein complex. Here, we report the mapping of the sites of interaction on nibrin and Mre11, respectively, using the yeast two-hybrid system and expression of epitope-tagged constructs in normal and NBS fibroblasts. Sequences in the carboxy-terminal 101 amino acids of nibrin interacted with the amino-terminal region of Mre11. Retroviral expression vectors that produced either wild-type nibrin or a mutant form lacking the Mre11 binding site were constructed. Introduction of the wild-type nibrin expression vector into NBS cells fully complemented the phenotype including nuclear localization of complexes of nibrin, Mre11, and Rad50, formation of nuclear foci, and survival after irradiation. In contrast, the mutant nibrin displayed nuclear localization but failed to interact with or relocalize Mre11 or Rad50. Upon irradiation, the mutant nibrin formed the characteristic nuclear foci, but survival of the cells was only slightly improved. These results suggest that nibrin is necessary and sufficient to direct nuclear localization and focus formation either alone, or in a complex with Mre11 and Rad50. However, direct interaction with Mre11 is required for normal cellular survival post-irradiation.

**Screening individuals at high risk for breast or ovarian cancer by BRCA 1/2 mutation analysis: Experience from a national, comprehensive educational program.** *A.T. Bombard*<sup>1</sup>, *A.W. Cohen*<sup>2</sup>, *T.S. Frank*<sup>3</sup>, *A. Deffenbaugh*<sup>3</sup>. 1) Aetna US Healthcare; San Ramon, CA/Albert Einstein College of Medicine; Bronx, NY; 2) Aetna US Healthcare; Blue Bell, PA/Jefferson Medical College; Philadelphia, PA; 3) Myriad Genetics Laboratory; Salt Lake City, UT.

Introduction: Advances in molecular susceptibility testing provide an opportunity to effect true preventive health care by identifying women at greatest risk for familial breast/ovarian cancer *before* these cancers are clinically detectable. Once identified, at-risk individuals may utilize a variety of preventive and therapeutic options that are predicted to improve health and increase longevity. Aetna U.S. Healthcare, working with Myriad Genetic Laboratories, has developed a national, comprehensive program to educate 21,000,000 Americans and their providers about heritable breast and ovarian cancers. The project has included distribution of informational brochures to ~120,000 providers; AMA-developed CME for physicians; a simple, "Pre-Authorization" form for pre-approval coverage of testing; coverage of both medical and surgical therapies; and confidentiality (all test results are directed to the provider only). Initial AUSHC Program vs Overall Myriad Results: 1. Deleterious mutations were identified in 51/277 women (18 %, vs 16% overall); 2. Among women with no personal history of breast cancer < 50, or ovarian cancer at any age, deleterious mutations were identified in 22/277 women (8%, vs 9% overall); 3. Among women with either diagnosis, mutations were identified in 97/277 women (35%, vs 23% overall). Summary: These results show that a comprehensive, national genetics program focusing on breast and ovarian cancer risk education, screening those at greatest risk using BRCA sequencing, and coverage of current medical and/or surgical therapies can be successfully implemented. Moreover, results of this broad-based program within the general clinical provider community has achieved results comparable to those found in academic medical centers - the principal sample source in the Myriad Genetics overall laboratory experience. Specific program details and the results of the screening experience will be presented.

**The role of DNA mismatch repair defects in haematological malignancy.** *S. Andrew<sup>1</sup>, M. Campbell<sup>1</sup>, F. Jirik<sup>2</sup>, R. Coupland<sup>3</sup>*. 1) Dept Medical Genetics, Univ Alberta, Edmonton, Alberta, Canada; 2) Centre for Molecular Medicine and Therapeutics, Vancouver, BC Canada; 3) Laboratory Medicine and Pathology, Cross Cancer Institute, Univ Alberta, Edmonton, Alberta, Canada.

Germline mutations in the DNA mismatch repair (MMR) genes have been implicated in the genesis and progression of human malignancy as individuals develop hereditary non-polyposis colorectal cancer. Microsatellite instability (MSI), which can be indicative of loss of MMR, is characteristic of a variable but considerable percentage of many human malignancies, suggesting loss of MMR is an important tumorigenesis mechanism. The role of MMR in haematological malignancy has not been widely studied, however, the finding that mice homozygous for a lack of MMR activity also demonstrate a tumour-prone phenotype, especially the development of thymic lymphomas, suggested MMR may also be important in human haematological malignancy. Recent reports of a few rare children with two inherited MMR mutations that develop leukemias and lymphomas also suggested a link between loss of MMR and human haematological cancers. We chose to study loss of MMR in human T-cell lymphoblastic lymphomas (LBL), the equivalent of the murine T cell lymphomas that develop in Msh2 deficient mice. Two of ten (20%) of T-cell LBLs tested to date demonstrated a MSI+ phenotype, and loss of MSH2 by immunohistochemistry. The inactivating mutations within MSH2 are currently being sought. These MSI+ tumours can now be used to screen candidate genes postulated to be likely non-random targets for mutation in the absence of MMR. Several such genes have been identified in HNPCC or MSI+ colorectal, endometrial tumours etc. We will report on screening of TGFRII, IGFRII, BAX, PTEN, and other likely candidates for mutations in human T-LBLs as well as within the murine Msh2<sup>-/-</sup> thymic lymphoma DNA. Identification of genes involved in the proportion of lymphomas that develop along the MSI+ pathway will offer a new understanding towards the molecular nature of lymphomagenesis.

**Detection of 11 germline inactivating *TP53* mutations and absence of *TP63* and *hCHK2* mutations in 17 French families with Li-Fraumeni or Li-Fraumeni-like syndrome.** G. Bougeard<sup>1</sup>, J.M. Limacher<sup>2</sup>, C. Martin<sup>1</sup>, F.

Charbonnier<sup>1</sup>, A. Killian<sup>1</sup>, O. Delattre<sup>3</sup>, M. Longy<sup>4</sup>, P. Jonveaux<sup>5</sup>, D. Stoppa-Lyonnet<sup>3</sup>, J.M. Flaman<sup>1</sup>, T. Frébourg<sup>1</sup>. 1) INSERM EMI 9906 IFRMP, Faculté de Médecine et de Pharmacie, 22 Boulevard Gambetta, 76183 Rouen, France; 2) Hôpitaux Universitaires, 67091 Strasbourg Cedex; 3) Service de Génétique Oncologique, Institut Curie, 75248 Paris; 4) Institut Bergonié, 33076 Bordeaux Cedex; 5) Laboratoire de Génétique, Hôpitaux de Brabois, CHU de Nancy, 54511 Vandoeuvre les Nancy.

The Li-Fraumeni syndrome (LFS), affecting children and young adults, represents one of the most devastating genetic predispositions to cancers and is characterized by a wide spectrum of early-onset malignancies including bone and soft-tissue sarcomas, brain tumours, adrenocortical tumours and premenopausal breast. Germline *TP53* mutations have been detected in most of the families with LFS. Recently germline mutations of *hCHK2*, encoding a DNA damage checkpoint kinase, were identified in LFS families, indicating the genetic heterogeneity of this syndrome. We analyzed 17 French families, including 4 families fulfilling the complete criteria for LFS, and 13 the criteria for the Li-Fraumeni-like syndrome (LFL). The *TP53* functional assay in yeast and sequencing analysis of exons 2 to 11 led to the identification of 11 inactivating germline mutations in 4/4 LFS and 7/13 LFL families, including 6 unreported germline mutations. In the families without *TP53* germline mutation, we analyzed by a new functional assay and sequencing analysis the *TP53* homolog, *TP63*, which isotype  $\gamma$  is able to transactivate the *TP53* target genes, and we detected no alteration. Sequencing analysis of the entire coding region of the *hCHK2* gene within these families also identified no alteration. This study shows that the functional assay is an efficient method to detect germline *TP53* mutation since, in this series, it detected all the germline mutations, confirms that most of the LFS/LFL cases result from germline inactivation of *TP53* and indicates the involvement of other genes in the syndrome.

**Heritable versus sporadic paraganglioma: High proportion of heritable cases and high predictability of carotid body tumor diagnosis for heritable cases.**

*C.M. Drovdic<sup>1</sup>, E.N. Myers<sup>2,3</sup>, J.A. Peters<sup>1,2</sup>, B.E. Baysal<sup>1,4</sup>, D.E. Brackmann<sup>5</sup>, W.H. Slattery III<sup>5</sup>, D.B. Kameron<sup>3</sup>, B.E. Hirsch<sup>3</sup>, R.L. Carrau<sup>3</sup>, J.T. Johnson<sup>3</sup>, C.H. Snyderman<sup>3</sup>, W.S. Rubinstein<sup>1,2</sup>.* 1) Dept Human Genetics, Univ Pittsburgh Graduate School of Public Health, PA; 2) Univ Pittsburgh Cancer Inst, PA; 3) Univ Pittsburgh Eye and Ear Inst, PA; 4) Univ Pittsburgh Dept Psychiatry, PA; 5) House Ear Inst, Los Angeles, CA.

Paragangliomas (PGL) are mostly benign tumors of the head and neck that affect about 1/30,000 individuals. Reportedly, 7-50% are hereditary. A major gene responsible for these tumors, PGL1, on chromosome 11q23, was identified as succinate-ubiquinone-oxidoreductase subunit D (*SDHD*). There is evidence for a PGL2 locus on chromosome 11q13 and PGL3 locus at an unknown location. Hereditary predisposition to PGL due to PGL1 or PGL2 is inherited in an autosomal dominant fashion with maternal genomic imprinting. PGL3 does not show evidence of imprinting. Identifying heritable PGL cases reveals at-risk relatives and has medical management/genetic counseling implications. We wanted to determine the heritable proportion of PGL by detailing and classifying subjects' medical and family histories. Subjects were patients diagnosed with PGL irrespective of family history. We defined heritable as a case with a positive family history and/or bilateral or multifocal PGL. Of 60 subjects, 21 were classified as heritable. Our data suggest that approximately 35% of patients that present to an otolaryngologist with PGL have a hereditary predisposition recognizable by clinical criteria. Subjects diagnosed with a non-bilateral carotid body tumor (CBT) upon first diagnosis were 5.8 times more likely to have heritable PGL than those diagnosed with PGLs at other anatomical locations in the head and neck. Heritable subjects had non-statistically significant younger average ages of onset than non-heritable subjects, reflecting a trend in the literature. Using clinical criteria, including family history, bilaterality and multifocality, we estimate the heritability of PGL to be 35%. Our study suggests that diagnosis of CBT may also be used as a clinical criterion of heritability.

**Multiple Primary Melanoma, Family History, and Germline Mutations in CDKN2A.** A. Ganguly<sup>1</sup>, S.N Palmer<sup>1</sup>, M. Young<sup>2</sup>, R. Holmes<sup>2</sup>, L.M Schuchter<sup>2</sup>, D. Guerry<sup>2</sup>, M.A Blackwood<sup>2</sup>. 1) Department of Genetics, Univ Pennsylvania, Philadelphia, PA; 2) University of Pennsylvania Cancer Center, Philadelphia, PA.

We examined family history and germline mutations in CDKN2A gene in a cohort of 75 patients with invasive multiple primary melanomas (MPM). Family histories were collected by a genetic counselor and cancer incidences were documented by pathology report. A 3-generation pedigree was assembled for each study subject that enabled the tracking of melanoma and other cancer histories in affected families. We used polymerase chain reaction and direct DNA sequencing of the 3 coding exons of CDKN2A from genomic DNA isolated from peripheral blood lymphocytes and to identify germline mutations in the study subjects. Pedigree analysis revealed, that a small subset, 2/75(3%), of MPM subjects had a family history with the proband and more than 2 additional members affected with melanoma. Another subset, 5/75(6.6%), had at least 1 additional first degree relative with melanoma while the majority had limited family history of melanoma. Thus multiple primary melanoma commonly present without any evident genetic predisposition. Six subjects (8%) were found to have mutations in coding sequences of CDKN2A. These mutations include 4 missense mutations, and 2 deletion/insertion mutations. Of the 4 missense mutations, G23C, V28G, M53I, and G101W, the latter two have been reported in familial melanoma. The 279del14 mutation leads to a truncated protein and Ins24 gives rise to an in frame duplication of 8 amino acids at the 5'-end of the gene. Five individuals are positive for the A148T polymorphism and 12 were positive for either one of the 3-UTR polymorphisms(C540G and C580T). Family history of melanoma was documented in 3 out of the 6 CDKN2A mutation carriers. We conclude that the prevalence of CDKN2A mutations in this unselected cohort of patients with multiple primary melanomas is lower than 15% reported by Monzon et al(NEJM338: 879,1998). The presence of germline CDKN2A mutations in individuals with no family history of melanoma suggest the occurrence of de novo germline mutations in this cancer predisposing gene and/or low penetrance for the same mutations.

**Anticipation in Familial Breast Cancer.** *E. Dagan*<sup>1</sup>, *R. Gershoni-Baruch*<sup>1,2</sup>. 1) Institute of Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) Bruce Rappaport Faculty of Medicine, Technion - Institute of Technology, Haifa, Israel.

To test for evidence of anticipation in familial breast cancer we collected clinical, socio-demographic and genetic data on mother/daughter pairs with breast cancer. Eighty four Ashkenazi women with breast cancer whose mothers were diagnosed with breast cancer were genotyped in respect to their being carriers of an Ashkenazi founder mutation in either BRCA1 (185delAG, 5382insC) or BRCA2 (6174delT). The phenomenon of anticipation was then related to the presence of founder mutations in BRCA1/2. Mean age of onset was higher in the maternal generation (55.6 +/-14.3 years) than in the daughters generation (48 +/- 9.5 years) ( $t=4.1$ ;  $p<0.001$ ). Twenty seven mutation carriers were identified, 17 carried a BRCA1 mutation and 10 carried the 6174delT mutation in BRCA2. Among BRCA1 mutation carriers the mean age at diagnosis in the mothers (45.3 +/-13) did not differ from that reported in the daughters (42.4 +/- 9). Among BRCA2 mutation carriers and non-carriers the mean age at diagnosis in the daughters (41.4 +/- 7.2 and 50.7 +/- 8.8, respectively) was significantly younger than in the mothers (62.4 +/- 13 and 57.4 +/- 13.6, respectively) ( $t=-5.5$ ;  $p<0.001$  for BRCA2 carriers and  $t=-3.7$ ;  $p=0.001$  for non-BRCA1/2 carriers). In the mothers` generation carriers of BRCA1 mutations were diagnosed with breast cancer at a significantly earlier age than carriers of BRCA2 mutations and non-carriers. In the daughters` generation carriers of BRCA1 and BRCA2 mutations were diagnosed with breast cancer at a significantly earlier age than non-carriers. Our findings indicate that BRCA1 mutations predispose to breast cancer at an early age in both mothers and daughters, whereas mutations in BRCA2 are associated with significantly earlier age of onset in the second generation. This observation could be related to gene-environmental interactions causing anticipation in BRCA2 mutation carriers.

**Point mutations in PTEN in primary carcinomas and uninvolved tissue of breast, colon, endometrium, kidney, and lung.** *L. Gui*<sup>1</sup>, *C.S. Ringelberg*<sup>2</sup>, *M. Kaelbling*<sup>2</sup>. 1) Pathology; 2) Preventive Medicine, U. Mississippi Medical Center, Jackson, MS.

As part of our ongoing mutation analysis of putative tumor suppressor genes, we identified DNA sequence alterations in the lipid and protein phosphatase gene PTEN/MMAC1/TEP1 (PTEN) in 62 tumor and uninvolved tissue panels of the same patients: 11 breast, 14 colon, 13 endometrium, 12 kidney, and 12 lung. Initial studies found 10q-LOH in many glioblastoma, breast, colon, lung, prostate, and digestive tract cell lines or tumors, while point mutations or small nucleic acid sequence changes were found only in the brain tumors. Subsequently, PTEN point mutations and LOH were also found frequently in endometrial carcinoma and, less often, in malignant melanoma; liver, kidney, and thyroid carcinoma. Germline PTEN mutations were associated with juvenile hamartomatous polyposis syndromes including Cowden disease, juvenile polyposis syndrome, and Bannayan-Riley-Ruvalcaba syndrome. Most PTEN alterations occurred in exons 5 and 7, while most exon 8 sequence changes appeared to be polymorphisms.

We analyzed PTEN alterations in exons 5, 7, and 8 by SSCP and sequenced bands that differed within or between panels. Definite mutations were found in seven panels and two exons. Exon 5 yielded two missense and one frameshift mutation: R130G occurred in three endometrial tumors and one matching uninvolved tissue, N107V was on the other allele of one of these tumors; 409delG was present in a kidney tumor. Exon 7 yielded one missense, one nonsense, and one frameshift mutation: D252G occurred in a lung tumor; R233X and 739delT in different endometrial tumors. No alterations were detected in exon 8. We are now sequencing additional panels because the exon transcript sizes (262-313 bp) are somewhat large for optimal SSCP analysis.

All tumor samples contained normal stroma while some uninvolved/constitutive tissue contained a tumor focus. Of the panels, 50 were obtained from the Cooperative Human Tissue Network and 12 were collected at our institution.

**Outcomes from an enhanced cancer genetics education program for clinicians.** *K.R. Blazer, D.J. MacDonald, S. Sand, M. Grant, J.N. Weitzel.* Clinical Cancer Genetics and Nursing Research and Education, City of Hope Cancer Ctr, Duarte, CA.

Advances in understanding the genetic basis for cancer has led to new technologies for hereditary cancer risk assessment. Identification of patients and families at high risk for inherited cancer depends upon increasing primary care physicians' knowledge of the fundamentals of genetics and risk assessment. A Cancer Genetics Education Program (CGEP) was developed to educate healthcare professionals about cancer genetics and inherited cancer risk. State-of-the-art information was delivered through regular hospital-based one-hour CME seminars, four full-day regional conferences and an educational internet website. Over 5,100 allied health professionals (oncologists, surgeons and primary care physicians 71%; nurses, genetic counselors and allied health professionals 29%) participated since 1997. We used innovative approaches to garner participation by community physicians in full-day conferences, including partnering with community health organizations and inviting physicians to present cases from their practice in a highly rated practical applications segment of the conference. The website ([www.cityofhope.org/ccgp](http://www.cityofhope.org/ccgp)) received more than 1,000 queries and was also used for online registration. Scores from pre- and post-seminar questionnaires demonstrated significant improvement in cancer genetics knowledge (overall 40% average increase); increase in appropriate referrals to the *Cancer Screening & Prevention Program* by attendees reflected an impact on clinical practice. Baseline knowledge was greater among participants in full-day courses (56% correct answers), reflecting possible selection for clinicians interested in cancer genetics, compared to scores sampled from one-hour community hospital-based CME seminars (39%). Knowledge was increased in both settings (by 26% and 54%, respectively). CGEP experience to date suggests that both formats are necessary to reach a broad audience of primary care physicians, and that the full day courses may confer screening-level competence to a motivated subset. Funded in part by NCI-1R25CA75131; and project #MCHG-51, Maternal Child Health Bureau.

**Gene Expression in Prostate Cancer; Microarray Analysis of Tumor Specimens and the LNCaP Prostate Tumor Model Series.** *C.L.T. Clelland, D.M.P Morrow, C. Bancroft.* Dept Physiology & Biophysics, Mount Sinai School of Medicine, New York, NY.

Prostate cancer is the second largest cancer killer of men. In 1999, nearly 200,000 men were diagnosed with prostate cancer in the United States, with an estimated 37,000 cancer deaths in that year alone. During progression of the disease the prostate tumor loses its androgen sensitive state, becoming non-responsive to standard androgen ablation therapy. The LNCaP prostate tumor model series consists of lineage-related sublines that differ in growth abilities and recapitulate some of the major stages in the progression of this disease. For these reasons this model series has been utilized for prostate cancer research. The initial LNCaP cells have the ability to form tumors in non-castrated nude mice, but only upon co-injection of the MS bone marrow cell line. The second in the series, the C4 line, is androgen independent (and can form tumors in castrated nude mice), but the formation of tumors still requires bone cell injection. The C42 line however, has lost both androgen and bone cell dependence, while the C42B line represents the last stage of the series, with the ability to metastasize to bone.

We have used microarray analysis to identify genes differentially expressed among the individual stages of the LNCaP series. Total RNA was extracted from each cell line, in duplicate, and labeled cDNA was produced from each sample, using the NEN MicroMax<sup>TM</sup> reagents. cDNAs were then hybridized, in duplicate, to a MicroMax<sup>TM</sup> microarray slide, which contains 2400 human cDNAs obtained from 50 tissue sources, each characterized functionally on the basis of Prosite motif search results. We have employed this labeling and microarray system to repeat experiments using RNA extracted from histologically graded and Gleason scored tumor prostatectomy specimens. Following scanning and extrapolation of fluorescent signal data, computer algorithms were employed to compare expression patterns between the LNCaP series and the tumor specimens. We discuss the use of the LNCaP series in the analysis of expression patterns of prostate cancer.

**The impact of genetic counseling/testing for breast and ovarian cancer in a free and anonymous community program.** *T. Bardakjian*<sup>1,2</sup>, *N. Shields*<sup>2</sup>, *P. Gilman*<sup>2</sup>, *E. Olander*<sup>1,2</sup>, *S. Dickinson*<sup>1,2</sup>, *S. Atassi*<sup>2</sup>, *J. Mushlin*<sup>2</sup>, *A. Schneider*<sup>1</sup>, *M. Dabrow*<sup>3,2</sup>. 1) Albert Einstein Med Ctr, Philadelphia, PA; 2) Lankenau Hospital, Wynnewood, PA; 3) Jefferson Med College, Philadelphia, PA.

A program was established in 1998 to evaluate the impact of free and anonymous genetic counseling/testing for breast/ovarian cancer provided in a suburban medical center. The primary aim was to assess a woman's risk for developing these cancers and to offer those at high risk genetic counseling and testing, as appropriate. We proposed that this service would impact cancer screening and prevention methods in the study group. Women were asked to complete a brochure about their family history and personal risk factors. Based on this information, women were stratified into 3 groups: average, somewhat higher than average, or high risk. Genetic counseling was offered to all those at high risk. There were 55 women/families in this category, 33 of whom, completed the genetic counseling process. Thirty of the 33 were offered testing, and 28 (93.3%) of these underwent testing. Six individuals were found to carry a BRCA mutation. Follow-up telephone questionnaires at 12 months after disclosure evaluated screening and prevention practices and overall satisfaction with genetic testing. Six of 28 (21.4%) women tested initiated monthly self-breast exam after participation in the program, irrespective of their gene test result. All 27 women tested stated they were "mostly satisfied" with their decision to be tested. Twenty-five of 26 felt that knowing their results did not interfere with their daily activities while 1/26 felt that her positive result "somewhat interfered" with her daily living. In conclusion, risk assessment, genetic counseling and testing can have a positive impact on a woman's breast cancer surveillance, regardless of test results and without causing excess anxiety. The availability of free and anonymous genetic testing has resulted in a remarkably high acceptance rate of genetic testing. This demonstrates that gene testing in conjunction with appropriate genetic counseling and education is an important tool for women at high risk for breast/ovarian cancer.

**Breast, ovarian and other cancer penetrance estimates for BRCA1 carriers identified in a cancer risk evaluation program.** *M.S. Brose<sup>1</sup>, T.R. Rebbeck<sup>2</sup>, K.L. Nathanson<sup>1</sup>, B.L. Weber.<sup>1</sup>* 1) Dept. of Medicine, Div. of Hematology and Oncology, Hospital of the University of Pennsylvania, Philadelphia, PA; 2) Center for Clinical Epidemiology and Biostatistics, The Univ. of Penn., Philadelphia, PA.

Increasing numbers of BRCA1 mutation carriers are being identified in cancer risk evaluation programs and estimates of cancer penetrance from these clinics would be useful, as linkage families may overestimate, and population-based series may underestimate, risk. Previous lifetime penetrance estimates range from 36% to 87% for breast cancer, and 16% to 60% for ovarian cancer. We have extended our initial studies on the pedigrees of BRCA1 families identified in our cancer risk evaluation clinic to determine the risk of breast, ovarian, and other cancers in both BRCA1 positive tested individuals and obligate carriers. In 191 female BRCA1 mutation carriers the lifetime breast cancer risk was estimated at 64%, less than reported in families used for linkage analysis but much greater than estimates derived from a population selected for Tay-Sachs screening. To evaluate the bias toward testing affected women, we carried out additional analyses for 70 obligate carriers and found a lifetime penetrance of 60%. The lifetime risk of ovarian cancer in the BRCA1 tested carriers was 23% and in obligate carriers was 33%, as compared to 40-60% percent in linkage studies, and 16.5% for an Ashkenazi Jewish volunteer-based study. We have also investigated the incidence of other cancers including colon, prostate, pancreatic, and lung cancer and found that these cancers are found in greater proportion of our obligate carriers than in the tested individuals. This may be due to differences in the ages of the obligate and tested carriers or the natural bias toward breast cancer in our clinic population. Additional analyses are underway. We conclude that the risk of breast and ovarian and other cancers for BRCA1 mutation carriers identified in high risk programs is significantly different from some previous estimates. Penetrance estimates of all cancers derived directly from the population of influence may better represent the risk faced by the majority of carriers identified.

**The presence of a germ-line *BRCA* mutation is an independent poor prognostic marker in breast cancer: a two-center historical cohort study.** *W.D. Foulkes<sup>1</sup>, J.M. Satagopan<sup>2</sup>, P.O. Chappuis<sup>1</sup>, N. Wong<sup>1</sup>, L.R. Bégin<sup>1</sup>, J. Boyd<sup>2</sup>, K. Offit<sup>2</sup>, M.E. Robson<sup>2</sup>.* 1) Depts Medicine, Pathology and Oncology, SMBD-Jewish General Hospital and Montreal General Hospital, McGill University, Montreal, QC, Canada; 2) Depts Human Genetics, Epidemiology and Biostatistics, and Surgery, Memorial Sloan Kettering Cancer Center, New York, NY, USA.

The outcome following the diagnosis of invasive breast cancer in carriers of *BRCA1* or *BRCA2* mutations is an important question. We addressed this by combining data from two studies that used a similar historical cohort design, where mutation status is established independently of vital status. We tested DNA extracted from pathology blocks from 507 Ashkenazi Jewish women who were diagnosed with invasive breast cancer at Memorial Sloan-Kettering Cancer Center, New York (n=305) or Sir M.B. Davis-Jewish General Hospital, Montreal (n=202) between 1980-1995 and followed up for a median of 111 months. The patient characteristics at the 2 centers did not significantly differ, except that the Montreal series did not include women diagnosed with breast cancer older than age 64. 60 women (11.8%) carried a *BRCA* mutation (46 *BRCA1*, 15 *BRCA2*, 1 patient with both). There were 80 deaths from breast cancer, 19 of these were among *BRCA* carriers (24%). At the median follow-up, the breast cancer-specific mortality rate was 35% in *BRCA* carriers and 14% in non-carriers ( $P < .001$ ). Omitting the *BRCA2*+ cases did not significantly alter these findings ( $P < .001$ ). In a multivariate Cox model, including tumor size, nodal status and *BRCA* status, the RR for death from breast cancer for *BRCA* mutation carriers was 2.6 (95% CI: 1.5-4.6,  $P < .001$ ). Tumor size and nodal involvement also predicted outcome (RRs 2.7,  $P < .001$  and 1.8,  $P = .02$ , respectively). The results did not significantly change when we excluded women (n=87) in the New York series who were diagnosed at 65 years of age or older. These results show that the presence of a *BRCA1/2* mutation is an independent marker for a poor prognosis following breast cancer. This will be important information for women who carry a *BRCA* mutation, are currently unaffected and are considering the preventive options.

**Genetic classification of Fanconi anemia patients in the IFAR: low prevalence of complementation group F.** S.D. Batish<sup>1</sup>, H. Hanenberg<sup>2</sup>, P.C. Verlander<sup>1</sup>, R.L. Zampolin<sup>1</sup>, O. Levan<sup>1</sup>, A.D. Auerbach<sup>1</sup>. 1) Lab of Human Genetics & Hematology, Rockefeller University, New York, NY; 2) Children's Hospital, Heinrich-Heine University, Dusseldorf, Germany.

Fanconi anemia (FA) is an autosomal recessive disorder characterized by cellular hypersensitivity to DNA crosslinking agents. Cell hybridization studies have revealed extensive genetic heterogeneity in FA, with eight complementation groups reported. The genes for complementation groups FA-C (*FANCC*), FA-A (*FANCA*) FA-G (*FANCG*) and FA-F (*FANCF*) have been cloned in that order. Elucidation of the DNA sequence and molecular organization of these genes have enabled us and others to detect mutations in the DNA of FA patients and their family members. Here we used functional complementation of EBV-transformed lymphoblastoid cell lines (LCLs) by retroviral vectors containing *FANCA* or *FANCF* to identify complementation groups. IFAR patients with known mutations in *FANCA* (123 probands), *FANCC* (53 probands) and *FANCG* (40 probands) were excluded from this study. Cell lines from 109 FA patients were tested for sensitivity to the clastogenic effect of DEB. Of these, 49 cell lines were DEB-resistant while 60 cell lines were sensitive. We had previously observed that while most FA patients are uniformly sensitive to the clastogenic effect of DEB in PHA-stimulated peripheral blood lymphocytes (PBLs), some FA patients are somatic mosaics, exhibiting both DEB-sensitive and resistant PBLs. The median percentage of DEB-resistant cells on cytogenetic testing of PBLs was 28 and 4 in patients with DEB-resistant and DEB-sensitive LCLs respectively. Of a total of 50 sensitive LCLs studied with retroviral vectors containing *FANCA* or *FANCF*, 40 were in FA-A, 3 were in group F and 7 were nonFA-A/nonFA-F. The later are under further investigation. Our data on the frequency of the different complementation groups indicates that FA-A (61%), FA-C(20%) FA-G (15%) and FA-F (1.5%) together account for approximately 97% of all FA cases. Thus the remaining genes not yet identified are quite rare. Mutation screening should now be feasible for most FA families.

**The *HRAS1* minisatellite locus increases the risk of ovarian cancer in *BRCA1* carriers, but not in *BRCA2* carriers or sporadic ovarian cancer.** *W. Chu*<sup>1</sup>, *J. McLaughlin*<sup>2</sup>, *C. Phelan*<sup>1</sup>, *D. Cole*<sup>3</sup>, *H. Risch*<sup>4</sup>, *S. Narod*<sup>1</sup>. 1) Centre for Research in Women's Health, Sunnybrook and Women's College Health Sciences Centre, Toronto, ON; 2) Div. of Epidemiology and Statistics, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON; 3) Dept. of Laboratory Medicine and Pathobiology, Banting Institute, Toronto, ON; 4) Dept. of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT.

Ovarian cancer is the second most common gynecologic malignancy in women and the fifth leading cause of cancer death in North America. Approximately 10% of ovarian cancers are attributable to mutations in *BRCA1* and *BRCA2*. The rare alleles of the minisatellite *HRAS1*-variable number of tandem repeats (VNTR) locus, located 1 kilobase (kb) downstream of the *HRAS1* proto-oncogene on chromosome 11p15.5, have previously been shown to increase the risk of ovarian cancer risk 2- to 3-fold in both *BRCA1* carriers and in sporadic ovarian cancer. We conducted a population-based study of incident cases of ovarian cancer in Ontario, diagnosed between 1995-1996, to determine the impact of the presence of rare *HRAS1* alleles on ovarian cancer risk. Using a PCR-based assay we typed the DNA for the *HRAS1* alleles from 355 patients, and from 132 ethnically-matched, population-based controls. The frequency of the four common alleles (a1, a2 a3 and a4) and rare alleles in the cases was respectively 0.56, 0.10, 0.12, 0.05 and 0.17, versus 0.56, 0.12, 0.11, 0.06, and 0.15 in the controls. At least one rare *HRAS1* allele was observed in 48% of the 21 *BRCA1* mutation-positive cases (O.R.=2.42, p=0.05) and in 17% of the 12 *BRCA2* mutation-positive cases (O.R.=0.53, p=0.34). Rare *HRAS1* alleles were observed in 28% of the 322 mutation-negative cases and in 27% of the 132 controls (O.R.=1.05, p=0.46). We did not observe an association with the rare *HRAS1* alleles and the age of cancer diagnosis. The results of this study confirms our previous observations that the *HRAS1*-VNTR locus may only increase ovarian cancer risk in ovarian cancer associated with *BRCA1* mutations, but refutes findings of an association in non-hereditary cancers.

**HNPCC: Efficient diagnosis and management require a pluridisciplinary network.** *C.D. Delozier-Blanchet<sup>1</sup>, J-L. Blouin<sup>1</sup>, M.A. Brundler<sup>2</sup>, J-F. Egger<sup>1</sup>, P. Hutter<sup>3</sup>, C. Soravia<sup>4</sup>.* 1) Div Medical Genetics, Geneva Univ Hospital; 2) Div Clinical Pathology, Geneva Univ Hospital; 3) Dept. Pathology, ICHV, Sion; 4) Div Digestive Surgery, Geneva Univ Hospital, Switzerland.

**INTRODUCTION:** Some 5-10 percent of colorectal cancers are associated with dominantly-inherited mutations, mostly in genes controlling mis-match repair (MMR). The diagnosis of Hereditary Non-Polyposis Colon Cancer (HNPCC, Lynch syndrome) has prognostic and treatment implications for affected individuals as well as for early detection in at-risk relatives. **GOAL:** To implement an efficient diagnostic, counseling and management network for HNPCC. **METHODS:** Over the past 2 years a hospital-based team made up of gastroenterologists, oncologists, surgeons, pathologists, clinical and molecular geneticists has been formed to deal with management of HNPCC. Families meeting the Amsterdam/Bethesda criteria have been offered molecular analysis of hMLH1 and hMSH2 throughout the period. During the past year two additional laboratory diagnostic tests have been developed: a 5-marker search for micro-satellite instability (MSI), and the immunohistochemical determination of presence/absence/quantitative variation in the MMR proteins. We now also offer these screening tests to individuals without convincing family histories but whose young age (<50) suggests a germline mutation. **RESULTS:** Overall, 3/15 tumors have shown MSI and 7/15 have demonstrated absence or quantitative reduction of one of the MMR proteins. Germline mutations have thusfar been identified in two patients; eight first-degree relatives are at risk. Analysis of tumors from both families showed high-level MSI and absence/reduction of hMLH1 or hMSH2 proteins in tumor tissue. Surgical or chemotherapeutic management decisions may be modified in some patients in light of such laboratory results. **CONCLUSIONS:** Development of a multi-disciplinary laboratory and clinical team facilitates optimal clinical management of families with suspected Lynch syndrome. The use of MSI and IHC allows more rapid para-clinical diagnosis and renders molecular investigation more time and budge-efficient, by targeting specific families for germline mutation research.

**Estrogen receptor alpha and beta in colon cancer cells and growth effects of Raloxifene.** Z.Q. Gao<sup>1</sup>, Z.P. Gao<sup>1</sup>, T. Zhang<sup>1</sup>, A. Kairo<sup>1</sup>, S. Burkholder<sup>1</sup>, J. Fields<sup>2</sup>, S. Ehrlich<sup>1</sup>, B.M. Boman<sup>1</sup>. 1) Medical Genetics, Thomas Jefferson University, Philadelphia, PA; 2) CA\*TX inc, Gladwyne, Philadelphia, PA 19035.

Colorectal cancer is the third leading cause of cancer death in women. Epidemiological and experimental data suggest an involvement of estrogen in the development and progression of colorectal cancer. Studies on the expression of estrogen receptor (ER) in human colonic mucosa and cancer and the potential protective effect of postmenopausal hormone replacement on the incidence of colon cancer have been reported. Accordingly, we studied the expression of ER-alpha and beta mRNA in human colon cancer cells (RKO, LoVo, HT29 and HCT116) and evaluated the growth effects of the anti-estrogen agent raloxifene on these cell lines. Cells were cultured in phenol red-free medium containing charcoal-treated serum. The results from expression assay showed that four human colon cancer cell lines, RKO, LoVo, HT29 and HCT116 expressed ER-beta mRNA but not ER-alpha mRNA using reverse transcription PCR. Cell growth experiments demonstrated that raloxifene inhibited the growth of these four colon cancer cell lines, in a dose-dependent manner, as well as the growth of ER-positive human breast cancer cells MCF-7. However, these colon cancer cells were not influenced by estradiol E2. Genistein, a phytoestrogen that is similar to estradiol, has greater affinity for ER-beta than ER-alpha. Genistein at 10uM exhibited weak inhibitory effects on the growth of all these CRC cell lines, which is the same concentration that stimulated the growth of ER-alpha-positive MCF-7 breast cancer cells. These results coupled with previous studies indicate that ER-alpha and ER-beta may play different biological functions in colon cancer cells.

**Risk assessment model for HNPCC and for germline MLH1 & MSH2 mutations based on age-at-colorectal cancer (CRC) diagnosis.** *B.M. Boman<sup>1</sup>, P. Watson<sup>2</sup>, G. Fant<sup>3</sup>, J.Z. Fields<sup>4</sup>, G. Matika<sup>1</sup>.* 1) Division of Medical Oncology and Genetics, Thomas Jefferson University, Philadelphia, PA; 2) Creighton University, Omaha, NE; 3) Walter Reed Army Medical Center, Washington, DC; 4) CATX INC., Gladwyne, PA.

Currently, no risk assessment models exist to estimate the likelihood of hereditary nonpolyposis colorectal cancer (HNPCC) or of germline mismatch repair gene mutations in the individual CRC patient; the revised Amsterdam Criteria (ACII) require a positive family history of cancer. Accordingly, we developed a model using "age at CRC diagnosis" as the sole criterion to determine the relative risk of having an MSH2 or MLH1 germline mutation or of HNPCC. This model can be applied to CRC patients who do not fulfill ACII or who have an unknown family history. Calculations were based on the differential age distributions of HNPCC versus all CRC. "Early age at CRC diagnosis" had high predictive value in the CRC patient population: the relative risk (RR) for HNPCC [ $RR = (\text{Risk if age is } < \text{cutoff} / \text{Risk if age is } > \text{cutoff})$ ] peaked at age <55 with an RR = 105 (CI = 94-116). This high RR will detect many, if not most, HNPCC cases missed (by ACII) because of negative family history. To assist genetic counselors and clinicians in identifying HNPCC and to determine who should undergo genetic testing, a table was created to estimate the odds ratio (probability of disease / probability of no disease), for CRC patients at various ages, of a) HNPCC and b) MSH2 & MLH1 mutations. The table is based on modeling using estimates that MSH2 & MLH1 mutations are found in 2/3 of diagnosed HNPCC families & that overall sensitivity of ACII is ~50%. If a CRC patient is determined to be at high-risk (<55), we recommend molecular testing for microsatellite instability to eliminate false positives before DNA sequencing. Use of our "risk assessment model" will improve the clinician's ability to efficiently and cost-effectively diagnose HNPCC-affected CRC patients and their at-risk family members. This should lead to a significant reduction in cancer mortality in those carrying a germline, disease-causing mutation.

**Genetic heterogeneity in hereditary paraganglioma (PGL): SDHD is the primary locus in imprinted PGL pedigrees.** *B.E. Baysal<sup>1,2</sup>, J.E. Willett-Brozick<sup>1</sup>, E.C. Lawrence<sup>2</sup>, C.M Drovdic<sup>2</sup>, D. Myssiorek<sup>3</sup>, E.N. Myers<sup>4</sup>, R.E. Ferrell<sup>2</sup>, W.S. Rubinstein<sup>5,2</sup>.* 1) Dept Psychiatry Univ Pittsburgh Sch Med Pittsburgh PA; 2) Dept Hum Genet GSPH Univ Pittsburgh; 3) Dept Otolaryngol/Commun disorders, Long Island Jewish Med Ctr New Hyde Park NY; 4) Dept Otolaryngol Univ Pittsburgh Sch Med; 5) Pitt Cancer Inst.

PGL is characterized by the development of highly vascular, benign tumors in the head and neck. The oxygen-sensitive carotid body is the most common tumor site. PGL1 at chromosomal band 11q23 is the most common locus, although two more loci, PGL2 at 11q13 and PGL3 of unknown chromosomal location, have been implicated. PGL1 and PGL2 show exclusive paternal transmission suggesting that they are subject to genomic imprinting, whereas PGL3 shows biparental transmission. PGL1 has been recently uncovered as the SDHD gene, which encodes the small subunit of cytochrome b (cybS) in mitochondrial complex II (MTCII; succinate-ubiquinone oxidoreductase). MTCII is composed four subunits: a flavoprotein (Fp), an iron-sulfur protein (Ip), the large subunit of cytochrome b (cybL) and cybS. We assessed SDHD in nineteen "unrelated" PGL families, eighteen of which were ascertained from North America and one from Turkey. Fourteen of sixteen families that did not violate maternal imprinting (inactivation) had loss-of-function mutations in the SDHD gene. Haplotype analysis revealed eight of the thirteen American PGL families (61%) with SDHD mutations had the same P81L mutation and identical disease haplotypes (i.e., sharing a common ancestor). Three small families that violated imprinting, by showing maternal disease transmission, excluded SDHD by linkage and mutation analysis. Linkage analysis further excluded SDHA and SDHB, which encode Fp and Ip at 5pter and 1p33-35, respectively. Interestingly, all three families showed suggestive linkage to the SDHC locus, which encodes cybL at chromosomal band 1q21. However, no mutations could be detected in SDHC. These findings suggest that SDHD is the primary locus in PGL pedigrees that show maternal imprinting and that neither SDHD nor other MTCII loci are involved in families that violate maternal imprinting.

**Genetic Studies of Peutz-Jeghers Syndrome.** *C.I. Amos<sup>1</sup>, M.L. Frazier<sup>1</sup>, P.M. Lynch<sup>1</sup>, T. McGarrity<sup>2</sup>*. 1) Department of Epidemiology, U.T.Anderson Cancer Ctr HMB, Houston, TX; 2) Division of Gastroenterology, Penn State College of Medicine, Hershey, PA.

We have assembled and are studying a large cohort of families and individuals with Peutz-Jeghers syndrome. Our initial studies among the relatives of index cases indicate that the median time to onset for gastrointestinal symptoms in our cohort is 10 years of age and the time to onset for first polypectomy is 11 years of age. End to end sequencing of STK11, which has been implicated as a cause for Peutz-Jeghers syndrome, showed mutations in 69% (9/13) of individuals from families with PJS. We were unable to identify mutations in the majority of sporadic cases of Peutz-Jeghers syndrome, with only 30% (3/10) showing detectable mutations in STK11. Mutations in the first exon appeared to confer a less severe phenotype than mutations in other exons.

**A High Prevalence of *BRCA2* Mutations in Unselected Breast Cancer Patients from the Philippines.** A. Liede<sup>1</sup>, M.L. de Leon Matsuda<sup>2</sup>, A. Tan<sup>3</sup>, E. Kwan<sup>1</sup>, A. Borg<sup>4</sup>, S.A. Narod<sup>1</sup>. 1) Centre for Research in Women's Health, University of Toronto, Toronto, ON, Canada; 2) Department of Surgery, Philippine General Hospital, Manila, Philippines; 3) Department of Surgery, Davao Medical Center, Davao City, Philippines; 4) Department of Oncology, Lund University Hospital, Lund, Sweden.

Breast cancer incidence varies ten-fold throughout the world, with the highest rates in North America and Europe. The highest breast cancer rates in Asia are reported for the Manila Cancer Registry in the Philippines, with an age-standardized rate of 47.7 per 100,000 per year. The contribution of hereditary factors to these elevated rates has not been investigated. Here we report the results of *BRCA1* and *BRCA2* mutation analysis of 375 unselected breast cancer patients from the Philippines. Subjects include women undergoing examination of a breast lump at the Philippines General Hospital in Manila and at the Davao Medical Center in Davao City. The mean age of breast cancer diagnosis was 43.8 years. Molecular analysis identified 11 *BRCA2* mutations and one *BRCA1* mutation among the series of patients. The *BRCA2* 4265delCT and 4859delA were found in six unrelated breast cancer patients. Genotype analysis was performed using 7 polymorphic markers on 13q to explore the possibility of founder effects in the Philippines; the 4265delCT mutation appears to represent an independent origin from a Swedish family previously described. The age of onset of cases with identified *BRCA* mutations did not differ from that of the general case series. Five of the 12 patients with *BRCA* mutations had no family history of breast or ovarian cancer. Age and family history do not appear to be strong predictors of genetic predisposition to breast cancer in the Philippines. Our data suggest that *BRCA2* is the more significant gene for breast cancer patients in the Philippines, due in large part to the presence of two founder mutations. Because a high proportion of breast cancers in the Philippines are diagnosed in women younger than 50 years, hereditary factors may contribute to breast cancer in the Philippines to a greater degree than in North America or Europe.

**A Genetic Epidemiological Study of Carcinoma of the Fallopian Tube.** *R. Nedelcu<sup>1</sup>, S. Aziz<sup>2</sup>, G. Kuperstein<sup>4</sup>, B. Rosen<sup>3</sup>, J. McLaughlin<sup>1, 5</sup>, S.A. Narod<sup>1, 4</sup>.* 1) Familial Ovarian Cancer Clinic, Princess Margaret Hospital, Toronto, Canada; 2) Public Health Sciences, University of Toronto, Toronto, Canada; 3) Department of Obstetrics and Gynecology, The Toronto Hospital, Toronto, Canada; 4) The Centre for Research in Women's Health, Sunnybrook and Women's College Health Sciences Centre, Toronto, Canada; 5) Samuel Lunenfeld Research Institute, Toronto, Canada.

To evaluate the importance of genetic factors in the etiology of fallopian tube cancer, all pathologically-confirmed cases of fallopian tube cancer diagnosed in Ontario from 1990 to 1998 were identified from the records of the Ontario Cancer Registry. Living patients were approached to provide information about their family history and to provide a blood sample for testing for mutations in BRCA1 and BRCA2. A modest increase in the risk of ovarian cancer (relative risk (RR) = 2.2; 95% confidence interval (CI) = 0.4, 6.3) and of early-onset breast cancer (RR = 2.4; 95% CI = 0.6, 6.1) was observed in the first-degree relatives of the fallopian cancer cases. Four of the 44 cases were positive for a mutation in BRCA1 (9%) and two were positive for a BRCA2 mutation (5%). One of the six mutation carriers had a strong family history of breast and ovarian cancer, and three carriers had a modest family history. Three of the 44 cases were Jewish, and of these, two carried a founder mutation characteristic of this population. Fallopian tube carcinoma should be considered to be a clinical component of the hereditary breast-ovarian cancer syndrome, and may be associated with BRCA1 and BRCA2 mutations. Genetic evaluation should be offered to women who present with fallopian tube carcinoma. It is important to consider the risk of fallopian tube carcinoma when prophylactic oophorectomy is performed in high-risk women.

**Multiple primary cancers in south-east England: relevance to colon cancer genetic susceptibility.** *S.V. Hodgson<sup>1</sup>, H.S. Evans<sup>2</sup>, H. Møller<sup>2</sup>, D. Robinson<sup>2</sup>, C.M.J. Bell<sup>2</sup>, C.M. Lewis<sup>1</sup>.* 1) Div Medical & Molec Genetics, GKT School Medicine, London, England; 2) Thames Cancer Registry, Div Oncology, GKT School Medicine, London, England.

A number of genes have been identified in which inherited mutations can cause a predisposition to cancers at multiple sites. For example, hMSH2 and hMLH1 confer a high risk of colorectal, uterine and other cancers. This study characterises the occurrence of subsequent primary cancers in patients diagnosed with colon cancer, to explore the possibility of a common aetiology between different cancer sites and identify novel genetic associations.

Registrations of patients with a first cancer diagnosed between 1961 and 1995 were extracted from the database at Thames Cancer Registry, SE England. Expected numbers of subsequent cancers were compared with observed numbers in the study population and relative risks (RR) calculated. Analysis was stratified by sex and age at diagnosis.

Analysis of a cohort of over 80000 patients with primary colon cancer identified 4.5% with at least one subsequent tumour. Preliminary results show that women with a young onset of colon cancer (<70y) have a significantly increased risk of developing cancer of the small intestine(RR 2.9),rectum (RR 1.3),breast(RR 1.2),uterus(RR 1.8),ovary(RR 2.6) and eye(RR 3.5). Two cancer sites were significantly increased in women with a first diagnosis of colon cancer after 70: small intestine(RR 2.6) and ovary(RR 1.8). Men diagnosed with colon cancer before 65 had a significantly increased risk of developing cancer of the small intestine(RR 3.5), colon(RR 2.0) and rectum(RR 1.6). Men diagnosed with colon cancer at an older age did not show a significantly increased risk of cancer at any site.

We have shown an association between extra-colonic cancers at increased risk in HNPCC (rectum,ovary,uterus,small intestine) and some novel associations (breast,eye). These may represent genetic associations as they occur primarily after diagnosis of colon cancer at a young age.

**Multiple measures of genomic instability in a familial breast cancer patient versus a sporadic breast cancer population.** *J.J. Latimer*<sup>1,2</sup>, *W.S. Rubinstein*<sup>1,2</sup>, *V.G. Vogel*<sup>1,2</sup>, *S.G. Grant*<sup>1,2,3</sup>. 1) OB/GYN & Women's Health, Magee-Womens Research Institute, Pittsburgh, PA; 2) University of Pittsburgh Cancer Institute, Pittsburgh, PA; 3) Center for Environmental and Occupational Health, Pittsburgh, PA.

We have previously observed that newly diagnosed breast cancer patients have higher levels of somatic mutation than age matched controls and that there is a characteristic loss of Nucleotide Excision DNA Repair (NER) in the breast tumors themselves. We have begun to analyze our patient population for evidence of familial breast cancer syndromes, in order to determine whether this subset of patients has a distinctive pattern of genomic instability. The first such patient was age 54 at the time of her diagnosis and surgery. She had been diagnosed with stage II ductal carcinoma with positive nodes. The Berry-Parmigiani-Aguilar model was used to estimate the probability that she carried a germline *BRCA1* or *BRCA2* mutation. Based on her diagnosis and a mother with bilateral breast cancer at age 33 and death at age 38, the probability of germline mutation was calculated to be 76%. This patient had a bone marrow somatic mutation frequency of  $41.4 \times 10^{-6}$ , approximately twice that of a large population of disease free individuals ( $19.9 \pm 0.9 \times 10^{-6}$ ), but indistinguishable from those of our incident breast cancer population ( $47.7 \pm 14.6 \times 10^{-6}$ , N = 47). Thus, it is unlikely that our observed increase in somatic mutation in breast cancer patients is driven by the approximately 10% that are carriers of mutations in the *BRCA1* or *BRCA2* genes, despite the fact that these genes have been implicated in DNA repair processes. Direct analysis of NER capacity in primary explants of this patient's tumor tissue using the UDS assay revealed a significant loss of DNA repair retaining only 15% of normal levels, whereas the overall population of similarly staged tumors showed an average level of DNA repair of 50% normal. This is the lowest level of NER we have observed for stage II breast cancer.

**VHL gene testing: qualitative versus quantitative molecular analysis.** *M. Martella*<sup>1</sup>, *R. Polli*<sup>1</sup>, *G. Opocher*<sup>2</sup>, *A. Murgia*<sup>1</sup>. 1) PEDIATRICS, UNIVERSITY OF PADUA, PADUA, PD, ITALY; 2) MEDICAL AND SURGICAL SCIENCES, UNIVERSITY OF PADUA, PADUA, PD, ITALY.

We perform mutation scanning of the von Hippel-Lindau (VHL) disease gene with the combined use of quantitative Southern blot, and PCR-SSCP analysis of the entire coding sequence, followed by direct sequencing of altered fragments. This strategy has led to the identification of disease-causing mutations in 21 out of 22 patients with clinical von Hippel-Lindau disease. VHL germ-line mutations were detected in patients with isolated tumors and negative family history: 2/21 cases of pheochromocytoma, 2/9 patients with CNS haemangioblastoma and 1/11 cases of isolated retinal haemangioma. One intronic alteration and one apparent polymorphic variant are currently being characterized. 4 new disease-causing mutations have been also detected. We have identified one case of somatic mosaicism (Murgia et al. 2000) in which the mutation was present with a ratio of approximately 1/12-1/15 mutated versus normal cell lines. Very often direct sequencing is viewed as a more efficient and complete method if compared to other mutation-scanning techniques. In this case the mosaic alteration, visible as a very faint shifted band at the SSCP analysis was completely undetectable and would have been missed by just sequencing the amplicon. von Hippel-Lindau is a well-known monogenic disease, the protocol we use has allowed detecting mutations in 95% of the VHL patients tested. The identification of a VHL mosaic individual and the fact that the only apparently molecular negative clinically affected patient of our series is a sporadic case, suggested the need to modify the test we have been using for our molecular screening in order to increase its quantitative sensitivity and ensure the maximum possible chance to recognize the presence of low-grade mosaicisms. A complete and reliable test is essential for the correct interpretation of the clinical significance of a negative molecular result in individuals affected by VHL related tumors who do not meet strict criteria for clinical diagnosis of the disease. This work is supported by: Ricerca Sanitaria Finalizzata Regione Veneto No. 930/02/99.

**Mutations in the RUNX1/CBFA2/AML1 gene in dominant familial platelet disorder with predisposition to acute myelogenous leukaemia (FPD-AML).** *J. Michaud<sup>1</sup>, K.F. Benson<sup>2</sup>, W.H. Raskind<sup>2</sup>, C. Rossier<sup>1</sup>, S.E. Antonarakis<sup>1</sup>, M. Horwitz<sup>2</sup>, H.S. Scott<sup>1,3</sup>.* 1) Division of Medical Genetics, Geneva University Medical School, Switzerland; 2) Division of Medical Genetics, University of Washington School of Medicine, USA; 3) Genetics and Bioinformatics Group, Walter and Eliza Hall Institute, PO, Royal Melbourne Hospital, 3050, Victoria, Australia.

FPD-AML is an autosomal dominant familial platelet disorder characterized by thrombocytopenia and a propensity to develop acute myelogenous leukaemia. The identification of genes responsible for rare familial leukemias may afford insight into the mechanism underlying more common sporadic occurrences, and particularly the mechanisms initiating the multistep leukemogenic pathway. Consistent with other studies, we studied 3 families with FPD-AML showing linkage to chromosome 21q22.1. The gene for the RUNX1/AML1/CBFA2 transcription factor, previously identified as the target of translocations and somatic point mutations in sporadic AML, maps to 21q22.1. Here we describe two novel heterozygous point mutations in RUNX1/AML1/CBFA2 in 2 of 3 FPD-AML families. Both mutations are in the part of the gene encoding the DNA binding runt domain. They are; i) a missense mutation, K83E, in exon 3, a residue known to destroy DNA binding if mutated, and ii) a one-base deletion in the splice donor site of exon 4, IVS4+3delA, which results in abnormal splicing, frameshifts and prematurely truncated proteins. As all coding regions of AML1 in affected individuals from the third family are normal, a gross deletion is likely. Our studies, in agreement with 6 recently published FPD-AML mutations, indicate that haploinsufficiency of RUNX1/AML1/CBFA2 causes FPD-AML.

**Ataxia telangiectasia: a model for understanding DNA damage response.** *K. Jen, J. Watts, V.G. Cheung.*

Department of Pediatrics, University of Pennsylvania, Philadelphia, PA.

Ataxia telangiectasia (AT) is an autosomal recessive disorder resulting from mutations in the gene ataxia telangiectasia mutated (*ATM*) located on chromosome 11q22-23. AT patients develop a wide range of clinical features including cerebellar ataxia, oculocutaneous telangiectasia, predisposition to malignancies, and immune disorders. In addition, AT cells display acute sensitivity to ionizing radiation (IR) and are unable to properly activate cell cycle checkpoints in response to DNA damage resulting in overall chromosome instability.

Differential gene expression between lymphoblasts from AT patients and normal lymphoblasts was studied as a screen for genes and pathways involved in IR stress response. Approximately 2000 genes were examined through microarray analysis of which approximately 100 were chosen because of their role in DNA damage response. The basal gene expression levels of AT and normal cells along with gene expression levels of the two cell types after IR exposure at 3Gy (300rads) were analyzed and compared. Gene expression profiles were taken for 2hr, 6hr, 12hr, and 24hr post irradiation. Groups of genes identified to be significantly different in expression pattern between AT and normal cells were then confirmed by quantitative RT-PCR. Normal cellular adaptation to IR was also examined by comparing gene expression profiles of normal cells at various time points. In this presentation, we will show preliminary data from this study.

**XRCC1-R399Q, XRCC3-T241M, XPD-K751Q genotypes and DNA-adduct levels in traffic exposed workers from Florence.** *G. Matullo<sup>1</sup>, M. Peluso<sup>3</sup>, A. Russo<sup>2</sup>, S. Guarrera<sup>1</sup>, S. Carturan<sup>1</sup>, A. Munnia<sup>3</sup>, G. Masala<sup>2</sup>, C. Saieva<sup>2</sup>, S. Polidoro<sup>1</sup>, A. Piazza<sup>1</sup>, P. Vineis<sup>4</sup>, D. Palli<sup>2</sup>.* 1) Dip. di Genetica Biologia e Biochimica, Univ. Torino; 2) Epidemiology Unit, CSPO, A.O. Careggi, Florence; 3) Unit of Experimental Oncology, IST, Genoa; 4) Dipartimento di Scienze Biomediche e Oncologia Umana, Univ. Torino, Italy.

We measured DNA adducts in peripheral leukocytes in two groups of residents in Florence, who participated into the prospective study EPIC-Italy, a section of a larger European project. Overall, 13,597 volunteers, aged 35-64 years, were enrolled in the period 1993-1998: a random sample of 100 subjects was drawn from the cohort and compared with a group of 114 workers selected because exposed to vehicle traffic pollution. DNA adducts were determined in peripheral leukocytes by using <sup>32</sup>P-postlabelling technique and the following three polymorphic DNA repair genotypes were investigated by PCR methods: XPD-K751Q, XRCC1-R399Q, XRCC3-T241M. DNA adducts were detected in approximately 85.0 % of both groups. Overall, crude mean levels tended to be higher among traffic workers ( $14.0 \pm 1.3$  vs.  $11.1 \pm 1.3$  adducts per  $10^9$  normal nucleotides,  $p = 0.10$ ); differences were statistically significant among never- and light current-smokers ( $p < 0.03$ ). In both groups, urban residents tended to show higher levels than those living in the surrounding area, and a seasonal trend emerged with adduct levels being highest in summer and lowest in winter months. Two DNA repair genotypes (XRCC1-3) were not significantly related to levels of adducts. Exposed workers with at least one XPD-Gln751 allele had significantly higher levels in comparison to workers with two common alleles. A multivariate analysis showed a significant positive association between occupational exposure and higher levels of adducts (OR 2.1; 95% CI 1.1-4.2) after adjustment for several confounders. Overall, these results suggest that traffic workers and the Florence general population are both exposed to high levels of genotoxic agents related to vehicle emissions. Photochemical pollution in warmer months might be responsible for particularly elevated levels of genotoxic damage in this metropolitan area.

**The impact of breast cancer risk assessment and education for women at average and moderately increased risk.**

*E. Olander*<sup>1,2</sup>, *N. Shields*<sup>2</sup>, *M. Dabrow*<sup>3,2</sup>, *T. Bardakjian*<sup>1,2</sup>, *S. Atassi*<sup>2</sup>, *J. Mushlin*<sup>2</sup>, *A. Schneider*<sup>1</sup>, *P. Gilman*<sup>2</sup>. 1) Albert Einstein Med Ctr, Philadelphia, PA; 2) Lankenau Hospital, Wynnewood, PA; 3) Jefferson Med College, Philadelphia, PA.

A research program was established in 1998 to evaluate the impact of risk assessment for breast cancer in a suburban medical center. This program was free and anonymous and enrolled any woman interested in learning about her breast cancer risk. A woman's risk was assessed by a medical oncologist/genetic counselor/nurse educator team using reported family history, and the Gail and Claus statistical models. Women were stratified into three risk categories: average (A), somewhat higher than average (SHA), and high (H) risk. Over an 18-month period, 46 women (mean age, 48.6) were evaluated and assigned to either the A or SHA risk categories. Each woman met with a nurse educator working in an outpatient education suite for a 1 to 2 hour session to discuss her risk assessment, the appropriate guidelines for breast surveillance, and any specific concerns. Self-breast exam (SBE) was also demonstrated using models allowing the woman to practice. Pre- and post-counseling questionnaires were administered to assess breast cancer risk perception, anxiety about developing breast cancer, breast screening practices, and general knowledge about breast cancer risk. About 55% of women incorrectly assessed their risk category on the pre-test questionnaire. Consistent with previous studies, 75% of these overestimated their risk. Following counseling, 75% of all women who assessed their risk incorrectly on the pre-test questionnaire, correctly adjusted their risk as measured on the post-test questionnaire. Nearly all women reported having benefited from their participation in the program. We conclude that breast cancer risk assessment and education are useful for women at average and moderately increased risk for breast cancer, as well as for high risk women. Aside from reinforcing appropriate breast surveillance, they are effective in helping women to form a more accurate picture of their risk with the goal of reducing anxiety caused by an overestimation or lack of knowledge about their true risk.

**Age-at-colorectal-cancer-diagnosis (ACCD) correlates with microsatellite instability (MSI).** *G.L. Matika, S. Burkholder, D.G. Rose, R. Fishel, T. Edmonston, R.D. Fry, S.M. Ehrlich, B.M. Boman.* Kimmel Cancer Center, Thomas Jefferson University Hospital, Philadelphia, PA.

Identifying carriers of hereditary nonpolyposis colorectal cancer (HNPCC) traits, who account for up to 10% of all colorectal cancer (CRC) cases, can save lives & health care dollars. But, current gene testing of patients for germline HNPCC-causing mutations, DNA sequencing, is costly & time consuming. And MSI, which is found in tumors in the vast majority of HNPCC patients with germline MSH2 & MLH1 mutations is highly sensitive, but not specific, being found in 10-20% of sporadic CRCs. Clinical diagnostic tests e.g. the Amsterdam Criteria (AC), the Bethesda Criteria (BC), & other family history (FH) based criteria also have shortcomings including limited sensitivity & specificity. Only two-thirds of AC(+) patients will have a detectable germline mutation (mostly MSH2 or MLH1). Because using FH will miss many HNPCC cases, one of us (BB) developed a risk assessment model based on ACCD as the sole clinical criterion for predicting the HNPCC trait and MSH2/MLH1 germline mutations. Since MSI is a useful pretest having high sensitivity for MSH2/MLH1 mutations, in the present study we looked for a correlation between ACCD and MSI status. MSI was analyzed on 165 CRCs using the NCI-recommended panel (Cancer Res 58:5248-57) to subclassify tumors as microsatellite stable, MSI-low, or MSI-high (MSI-H). Results showed a positive correlation between MSI-H status and ACCD ( $Rho=0.67$ ;  $p=0.05$ ). MSI status of CRCs correlated variably with other criteria: AC(+) (76% MSI-H), BC(+) (28%), familial CRC (16%), & negative/unknown FH status (0%). Because young ACCD predicts MSI-H, this age criterion appears to have value for detecting HNPCC, especially if FH-based criteria fail to diagnose HNPCC. In our previous study, "ACCD < 55" was the optimal cutoff for HNPCC diagnosis in AC(-) patients. Our current series indicates that 67.5% of CRC patients <55 will not have MSI-H tumors. This shows the value of MSI as a follow up test to ACCD because among younger CRC (<55) patients there will be a substantial number of patients (67.5%) who are false positives & will not need DNA sequencing for MSH2/MLH1.

**Stem cells and colorectal cancer development: Study of crypt colonocyte changes in familial adenomatous polyposis (FAP).** *G. Kandimir*<sup>1</sup>, *J. Palazzo*<sup>2</sup>, *A. Kovatich*<sup>2</sup>, *J.Z. Fields*<sup>3</sup>, *O.A. Runquist*<sup>4</sup>, *T. Zhang*<sup>1</sup>, *B.M. Boman*<sup>1</sup>. 1) Division of Medical Genetics, Thomas Jefferson University, Philadelphia, PA; 2) Department of Pathology, Thomas Jefferson University, Philadelphia, PA; 3) CATX INC., Gladwyne, PA; 4) Department of Chemistry, Hamline University, St. Paul, MN.

The mechanism underlying the initiation of colorectal cancer (CRC) at the cellular level remains unknown even though the first genetic event (germline APC mutation) and earliest tissue change (abnormal crypt proliferation) are characterized in FAP patients. Accordingly, we developed a mathematical model of cell proliferation, differentiation and apoptosis in the colonic crypt that is based on a set of differential equations. Systematic perturbations were used to determine which model parameters could simulate the proliferative shift. Across many perturbations, only increasing the stem cell (SC) number simulated the biological FAP data (compared to healthy controls); changes in rate constants did not. This theoretical evidence suggests that APC is a regulator of SC division and that APC mutation leads to an increased number of SC located in the crypt base. To study this mechanism using biologically designed experiments, we used immunohistochemistry to analyze the expression of bcl-2, survivin, & Ki-67 as markers for crypt base cells in normal colonic epithelium and adenomas from FAP patients (n=10). In FAP adenomas the proportion of cells expressing these 3 markers was increased compared to FAP normal colonic epithelium. Given that FAP adenomas are known to have loss of the second wild-type APC allele, our immunohistochemical results are consistent with our modeling data because both findings suggest that APC mutation leads to abnormal SC division favoring SC renewal and expansion of the crypt base cell population. Overall, these findings support the idea that APC mutation in the colonic SC is the critical event for tumorigenesis and that the SC is the cell of origin for clonal expansion leading to colonic adenomas.

**Prevalence of founder *BRCA1* and *BRCA2* mutations in French Canadian women with breast cancer unselected for age or family history.** N. Hamel<sup>1</sup>, P. Ghadirian<sup>2</sup>, A-J. Paradis<sup>1,2</sup>, A. Robidoux<sup>2</sup>, C. Potvin<sup>2</sup>, J. Cantin<sup>2</sup>, G.

Kuperstein<sup>3</sup>, P.N. Tonin<sup>1</sup>, J. Deschênes<sup>1</sup>, P.O. Chappuis<sup>1</sup>, W.D. Foulkes<sup>1,2</sup>. 1) Depts Medicine, Oncology and Pathology, Montreal General and Jewish General Hospitals, McGill University, Montreal, QC, Canada; 2) CHUM-Hôtel-Dieu, University of Montreal, QC, Canada; 3) Centre for Research in Women's Health, University of Toronto, Toronto, ON, Canada.

Founder mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* have been found in selected French Canadian (FC) breast and ovarian cancer families (Am J Hum Genet 1998; 63: 1341-51). The prevalence of these mutations in unselected breast cancer diagnosed in FC women and the clinico-pathological features of these cases is currently unknown. We studied incident female first primary breast cancers diagnosed before the age of 80 years identified through the Dept of Pathology of Hôtel-Dieu, CHUM, Montreal, diagnosed between 07/96 - 04/98. The FC ethnicity was defined as having FC ancestry in at least 3 grandparents. 193 patients were eligible and 128 (66.3%) provided blood for the genetic testing. A pedigree was drawn with detailed information on the family history of cancer. Genomic DNA was screened for the 7 FC founder *BRCA1/2* mutations (*BRCA1*: C4446T, 3768insA, 2953del3+C; *BRCA2*: 8765delAG, G6085T, 2816insA, 6503delTT). Four (3.1%; 95% CI: 0.86-7.8%) women were identified as carrying a germ-line mutation, all in *BRCA2* (2x 8765delAG, 6503delTT, G6085T). The mean age at diagnosis was 51 years (range: 49-53). *BRCA2*-related breast cancers were invasive ductal (2/4) and lobular (2/4) carcinomas, of histological grade 1 or 2, axillary nodal involvement was present (3/4) despite a small tumor size (<20 mm), and ER was strongly expressed (3/3). Among these 4 cases, 2 reported a strong family history of breast cancer and 2 had unremarkable family history. The prevalence of the 7 *BRCA1/2* founder mutations screened among this series of breast cancer in unselected women of FC origin is estimated to be 3.1%, but much larger studies from different regions of Quebec will be required for more precise estimates of prevalence and penetrance of these founder mutations.

**Isolation of four novel genes from human colonic epithelial cells using bHLH transcription factor as bait in a yeast two-hybrid system.** *A. Kairo, L. Wang, Z.Q. Gao, Z.P. Gao, T. Zhang, S. Burkholder, S.M. Ehrlich, B.M. Boman.* Medical Genetics, Thomas Jefferson University, Philadelphia, PA.

Transcription factors (TFs) play a central role in regulating gene expression that is important in differentiation, development, and tumorigenic processes. For example, Id1 TF overexpression causes colonic adenoma development in murine models for colorectal cancers (CRC). The aim of this study was to isolate novel factors that interact with the basic-helix-loop-helix (bHLH) TF. The conserved domain of the bHLH binds to other TFs, modulating gene expression and cell proliferation. The importance of identifying specific TFs from colon is: 1) regulation of TFs is likely to be important in colonocyte differentiation, colon development, and disease (e.g. CRC) and 2) novel TFs might help identify biomarkers for CRC and new therapeutic targets. Proteins that interact with bHLH can be TFs themselves. We used a yeast two-hybrid screen to detect proteins that interact with bHLH. Hence, the bHLH motif (nucleotides 1528-1962), which encodes a polypeptide that attaches to the E12-box promoter region, was cloned into a pGBT9 vector. Our cDNA libraries from normal (fresh mucosa) and malignant (HCT116 line) human colonic epithelial cells (cloned in pGAD10) & the bHLH bait plasmid was co-transfected into yeast HF7c cells. Using the HCT116 library, 4 genes were isolated: CATX-11 (1800 bp); CATX-13 (620 bp); CATX-14 (1100 bp); CATX-15 (1900 bp). Full-length clones of CATX-11 & CATX-15 have been isolated. Initial homology data showed that CATX-11 shares high sequence homology with other cDNAs reported to be stage specifically expressed in the trophoblast stage during development. CATX-13 & CATX-15 showed no significant homology to any known gene, indicating that they are novel. CATX-14 showed weak homology to the mouse TLM oncogene. In pilot studies using RT-PCR, CATX-15 was not detected in the library from normal colon, whereas CATX-13 was detected. Together our data suggests that these four genes are 1) novel 2) specifically expressed in the colonic epithelial cells 3) possibly unique TFs and 4) likely to be important in colonic cell biology.

**The Bloom syndrome protein (BLM) and TopIIIa colocalize and are found together with BRCA1 and hRAD51 at telomeres in ALT pathway immortalized human cells.** *M.S. Meyn<sup>1, 2</sup>, D.J. Stavropoulos<sup>1, 2</sup>*. 1) Dept Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Molecular and Medical Genetics, Univ of Toronto, Toronto, ON, Canada.

Bloom syndrome is characterized by growth retardation, immune defects, cancer, infertility, and increased genomic instability. It is caused by mutations in the *BLM* gene, a RecQ-like DNA helicase. The *BLM* homologs, *SGS1* and *RecQ*, interact physically and functionally with topoisomerase III. As part of a study of telomere maintenance, we performed immunohistochemical analyses of BLM, TopIIIa, BRCA1 and hRAD51 proteins in human cells. These proteins localized to telomeres in immortalized cells that lack telomerase and maintain telomere length via an alternative pathway (ALT).

BLM formed nuclear foci that co-localized with telomeres in ~70% of interphase cells from two ALT fibroblast lines, WI38-VA13 and GM00847. This colocalization was not seen in a telomerase-positive fibroblast line (MRC5) or in a primary fibroblast line (WI38). TopIIIa co-localized to telomeric foci in 29-50% of cells from the two ALT lines, but colocalization was not seen in MRC5 or WI38 cells. TopIIIa co-localization with telomeres occurred only in cells in which BLM co-localized as well. We also observed colocalization of BRCA1 and hRAD51 to telomeric foci only in ALT cells. We confirmed the recently published result that BLM colocalizes to promyelocytic leukemia (PML) bodies in both telomerase positive and ALT cells. We found that TopIIIa also localized to PML bodies in a normal fibroblast cell line, MRC5, but not a *BLM*<sup>-/-</sup> cell line, GM08505B.

Our results provide direct *in vivo* evidence for an association between BLM and TopIIIa. The localization of TopIIIa to telomeres and PML bodies appears to be dependent on functional BLM. The finding that BLM, and TopIIIa colocalize with the recombination proteins BRCA1 and hRAD51 to telomeric foci only in ALT cells suggests that these proteins may be involved in the ALT pathway of telomere maintenance and provides evidence that, in human cells, the ALT pathway may involve homologous recombination.

**Frequency of glutathione-S-transferase theta (GSTT1) deletion in Mexican patients with lung cancer.** *G.M. Zuniga<sup>1</sup>, M.P. Gallegos<sup>1</sup>, J.L. Martinez<sup>2</sup>, N.P. Esquivel<sup>1</sup>, B.C. Gomez<sup>1</sup>, A.L. Zamora<sup>1</sup>, O. Torres<sup>1</sup>, J.M. Cantu<sup>1</sup>, G. Morgan<sup>2</sup>.* 1) Medicina Molecular y Genetica, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Division de Oncologia, Hospital de especialidades, CMNO, IMSS, Guadalajara, Jal. Mexico.

Glutathione-S-transferase (GST) is a dimeric isoenzyme who participated in the desactivation of carcinogen, toxic reactives such as the detoxification of several tobacco smoke derived carcinogens, and xenobiotics, and it catalized the reducing reaction of glutathione of many organic compounds to thioester. Is is thus conceivable that deficiency in GST activity due to homozygous deletion of GSTT1 gene (the null genotypes) may modulate susceptibility to smoking, inducing to lung cancer. The distribution of the GSTT1 deletion gene in healthy controls and lung cancer patients were evaluated using peripheral blood DNA from 52 samples of lung cancer patients and 178 samples of healthy controls (41 nonsmokers, 63 passive smokers and 74 smokers). Increasing lung cancer risk was related to the GSTT1 null genotype when were compared between groups, patients shown significative difference when it was compared with controls: non smokers ( $p=0.007$ ), passive smokers ( $p=0.019$ ) and smokers ( $p=0.007$ ). Our lung cancer displays the gene deletion in 21%, among population controls, the proportions are: among nonsmokers not exposed to passive smoking 2.3%, among nonsmokers who are passive smokers 6.3% and among ever smokers 5.4%. These results shown a tendency to presence the deletion GSTT1 gene among lung cancer in Mexican population when compared when were compared with healthy controls.

**The role of *ATM* heterozygosity in cancer susceptibility and genomic instability.** *S.N. Teraoka*<sup>1,2</sup>, *K.E. Malone*<sup>3</sup>, *E.A. Ostrander*<sup>3</sup>, *J.R. Daling*<sup>3</sup>, *D. Willerford*<sup>2</sup>, *M. McKay*<sup>4</sup>, *J. Bernstein*<sup>5</sup>, *P. Concannon*<sup>1,2</sup>. 1) Virginia Mason Research Ctr, Seattle, WA; 2) University of Washington School of Medicine, Seattle, WA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Peter MacCallum Cancer Institute, Melbourne, AUS; 5) Mount Sinai School of Medicine, New York, NY.

*ATM*, the gene mutated in the autosomal recessive, cancer-prone syndrome ataxia-telangiectasia, participates in the response to DNA damage caused by ionizing radiation. *ATM* is also required in processes involving joining of DNA double strand breaks, such as mitotic and meiotic recombination. A-T patients are highly susceptible to cancer, especially lymphoma and leukemia. *ATM* heterozygotes are also reported to be at increased risk for breast cancer. We screened for *ATM* mutations among breast cancer cases with early-onset (diagnosed by age 35) or family history, and observed an increased frequency of missense mutations in cases (11/142; 7.7%) versus age-matched controls (1/80; 1.2%). Three of these cases with *ATM* missense mutations also had *BRCA1* or *BRCA2* mutations. Since *ATM* has been shown to associate with and phosphorylate *BRCA1*, it is possible that mutations in these two genes in a common pathway might interact and contribute to disease susceptibility. Therefore, we are extending our studies by screening for *ATM* heterozygosity (via denaturing HPLC) in breast cancer cases with *BRCA1* or *BRCA2* mutations. We are also screening 91 lymphoma cases and an equivalent number of controls for *ATM* heterozygosity. Further, we are exploring the connection between *ATM* and radiation sensitivity in two studies. In the first, we are screening for *ATM* mutations in 70 patients who had serious complications arising from radiation therapy. The second study is a recently initiated collaborative project that will compare the *ATM* status of 700 women with contralateral breast cancer and 1400 women with unilateral breast cancer in order to examine the interaction between *ATM* status and radiation therapy on the risk of developing a contralateral breast tumor.

**Gender and Smoking Modify the Risk for Colon Cancer in the Presence of Putative Rapid NAT2 Acetylating Activity.** *A.M. Weiss, J.S. Witte, D.A. Sirko-Osadsa, M.C. MacMillen, S.D. Markowitz, G.L. Wiesner.* Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

The N-acetyltransferase 2 gene (NAT2) encodes a polymorphic enzyme in the acetylation pathway of ingested carcinogens. NAT2 genotypes encoding putative rapid acetylation activity have been associated with a 2 to 3-fold increased risk for colorectal cancer (CRC), the third most common adult malignancy. 49 sibships, with at least one affected and one unaffected sibling, from the CWRU Colon Neoplasia Sibling Study were genotyped for NAT2 by PCR-RFLP and analyzed using conditional logistic regression to determine whether putative acetylation activity was associated with colon neoplasia. Unaffected siblings were negative for adenomatous polyps or CRC on colonoscopy or flexible sigmoidoscopy. Overall, 75/164 (45.7%) siblings affected with CRC or adenomatous polyps carried a rapid NAT2 genotype. A 2-fold increased risk was found in siblings with a rapid genotype compared to siblings with a slow genotype (OR=2.24, p=0.07). Rapid NAT2 genotypes were found 6 times more often in siblings affected with CRC compared to siblings affected with adenomatous polyps (OR=5.9, p=0.10). While not statistically significant, these results are similar to those of other studies. Analysis of gender, however, showed significant differences in CRC risk. Females with a rapid genotype were more likely to be affected with colon neoplasia compared to females with a slow genotype (OR=6.25, p=0.02). This effect was not seen for male siblings (OR=1.26, p=0.78), and may reflect hormonal influences on the acetylation pathway. Our analysis also suggests a possible effect of smoking on CRC risk in the presence of a rapid NAT2 genotype. Surprisingly, non-smokers with a rapid genotype were 9 times more likely to be affected with colon neoplasia compared to smokers with a rapid genotype (OR=9.14, p=0.04). We hypothesize that gender and smoking status may modify the risk of colon neoplasia by altering the activity of the acetylation pathway. Ongoing studies of 145 affected and unaffected sibling pairs will confirm these results and help us gain an understanding of the role of NAT2 on the risk for colon neoplasia.

**BRCA1/2 Testing in Newly Diagnosed Breast Cancer Patients: Preliminary Data on Interest and Surgery Decisions.** *B.N. Peshkin, B. Brogan, C. Isaacs, C. Lerman, M. Schwartz.* Cancer Control, Georgetown University, Washington, DC.

Breast cancer (BC) patients who have a BRCA1/2 mutation have up to a 65% risk of contralateral BC, and an elevated risk of ipsilateral BC. No data exist about the most effective surgical treatment for such women, but BRCA1/2 results may allow newly diagnosed high-risk women to make more informed decisions about surgery and reconstruction. Pilot data from 75 BC patients indicated a high level of interest in genetic testing: 88% reported that they would have wanted genetic testing at the time of diagnosis and 31% would have opted for bilateral mastectomy if positive. In light of these data, the current study was undertaken to determine the following: rates and determinants of BRCA1/2 testing uptake in newly diagnosed high-risk BC patients; the impact of testing on surgical choices; the impact of pre-surgery testing on psychosocial well-being; and the cost effectiveness of such a program. Participants are newly diagnosed BC patients with at least a 10-20% probability of BRCA1/2 positivity. Genetic counseling and testing is performed free of charge. Thus far, 74 women have completed pre-surgery genetic counseling and testing. Unique issues arise in genetic counseling, including the assimilation of a new diagnosis of BC, issues related to prognosis versus implications of a positive test result, and unanticipated information such as ovarian cancer risks and risks to relatives. So far, of the women counseled, 60 (81%) received results before surgery, of whom 10 (17%) tested positive. Of these, 7 opted for breast conserving therapy (BCT) and 3 opted for bilateral mastectomies. Four women who received results after surgery had BCT and have not had further surgery (1 to 26 months f/u). It will be important to obtain larger numbers and follow these women long term to fully assess the impact of testing. While the current data are preliminary, the results of this study will help guide clinicians about the feasibility and implications of offering pre-surgery genetic counseling and testing. This information can be used to design genetic counseling protocols addressing the unique needs of new BC patients considering genetic testing. Supported by NCI RO1 CA/HG 74861.

**A study to determine the genetic basis of uterine papillary serous adenocarcinoma.** *T. Pal<sup>1</sup>, L. Elit<sup>1</sup>, R. Goshen<sup>2</sup>, W. Chu<sup>1</sup>, M. Mitchell<sup>1</sup>, S.A. Narod<sup>1</sup>.* 1) The Centre for Research in Women's Health, Sunnybrook and Women's College Health Science Centre, 790 Bay St., Toronto, Ontario; 2) Lis Maternity Hospital, Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel.

Uterine papillary serous carcinoma (UPSC) shares common pathologic, genetic and clinical features with other serous cancers of mullerian origin. The most common histologic type of ovarian cancer patients with BRCA mutations is papillary serous. To the best of our knowledge, no studies have specifically investigated genetic factors in UPSC. In order to determine how frequently UPSC is due to a hereditary factor, we conducted a hospital-based study at the Princess Margaret Hospital, Toronto, Canada. Pedigrees were obtained on 79 patients diagnosed with UPSC. Family history of cancer was obtained for all 590 first-degree relatives. A DNA specimen was collected on 56 of these patients for BRCA1 and BRCA2 mutation analysis. The observed cancer rate in relatives was compared with the expected number, based on comparison with age-standardized provincial incidence rates in order to estimate relative risks. For breast cancer, there were 23 cancers observed in relatives, compared to the 15.4 cancers expected, giving a relative risk of 1.5 (95% CI: 0.9-2.2). The relative risks for endometrial, ovarian and all cancers were not elevated. Clinical review of pedigrees did not show any clear examples of the hereditary breast-ovarian cancer syndrome, and none of the 56 patients was found to carry a BRCA1 or BRCA2 mutation. Our findings suggest that there is an association between UPSC and breast cancer but this is not related to hereditary breast ovarian cancer syndrome.

**Cyclin D1 Polymorphism and Age of Onset of Hereditary Malignant Melanoma.** A. Platz<sup>1</sup>, J. Hansson<sup>1,2</sup>, U. Ringborg<sup>1,2</sup>. 1) Cancer Centre Karolinska, Research Laboratory Radiumhemmet, Karolinska Hospital, Stockholm, Sweden; 2) Department of Oncology, Karolinska Hospital, Stockholm, Sweden.

The common A/G polymorphism in codon 224 of Cyclin D1 affects alternate splicing of exon 5. The product of the alternate spliced message lacks a sequence promoting the turnover of the protein. The relative proportion of the two possible splice products determines the level of active Cyclin D1 and variability in its expression may influence the cancer risk. We have genotyped genomic DNA from 80 individuals belonging to 80 families with Hereditary Melanoma (HMM) and from 148 normal controls for the Cyclin D1 polymorphism. The registered variant frequencies were 20% AA, 38% GG and 42% AG, in the HMM individuals, and 22% AA, 24% GG and 53% AG in the controls. We also compared genotypes with age at diagnosis for the HMM individuals and found that carriers of at least one A allele had on average a melanoma diagnosis 10 years earlier than patients homozygous for the G allele. These A allele effect may be a result of enhanced alternative splicing of the A-allele transcription product which results in a more stable Cyclin D1 lacking the PEST destruction box and is very similar to previous observations made by others on early onset of Hereditary Nonpolyposis Colorectal Cancers.

**Evidence for apparent anticipation and genetic heterogeneity in familial Hodgkin's disease and non Hodgkin's lymphoma.** *Y.Y. Shugart<sup>1</sup>, K. Hemminki<sup>2</sup>, P. Vaittinen<sup>3</sup>, A. Kingman<sup>4</sup>*. 1) Pediatrics/CIDR, Johns Hopkins University, Baltimore, MD; 2) Department of Biosciences, Karolinska Institute, Huddinge Sweden; 3) Center for Epidemiology, National Board for Health and Welfare, Stockholm, Sweden; 4) National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD.

The goal of this study is to test whether there is genetic anticipation in Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL). Using the Swedish family cancer database, we identified 18 sib-pairs (2 HD and 16 NHL) and 102 parent-child pairs (13 HD, 23 HD/NHL, 8 NHL/HD and 56 NHL/NHL). The overall mean anticipation score is 27.7 years for all 102 parent-child pairs and is 13.8, 19.8, 35.8 and 28.4 years and 13.8 years for these parent-type groups, respectively. The level of anticipation is more pronounced in the NHL pairs than in HD pairs (difference=12.6 years,  $p=0.0003$ ). These results allow us to conclude with confidence that there is apparent genetic anticipation in familial HD and NHL in the Swedish population and that HD may be associated with other types of haematopoietic malignant condition.

**Interaction of CYP3A4 genotype and benign prostatic hyperplasia (BPH) with prostate cancer (PC).** *C.M. Zeigler-Johnson, A.H. Walker, S.B. Malkowicz, T.R. Rebbeck.* U. of Pennsylvania, Philadelphia, PA.

BPH is the most common benign neoplasm in aging men, but its relationship with PC etiology remains unclear. It has been hypothesized that genetic influences on testosterone metabolism may be associated with both BPH and PC etiology. For example, CYP3A4 is a member of the cytochrome P450 family that is involved in the oxidative deactivation of testosterone. A variant in the 5' regulatory region of CYP3A4 (CYP3A4-V) has been associated with advanced stage prostate cancer. In order to examine the relationship between the variant and BPH in PC etiology, we undertook a case-control study of 253 Caucasian PC cases and 428 age matched Caucasian controls. Cases were divided into two groups: (1) those with clinically detected TNM stage 1 (T1) at diagnosis; (2) those with TNM stage 2 or higher (T2+) at diagnosis. History of BPH was determined by patient report. The results of the study demonstrated that BPH was associated with PC overall (age adjusted OR=2.35, 95%CI: 1.38-3.99). CYP3A4-V was not related significantly to BPH or PC overall. The effect of CYP3A4-V was significantly different in men with and without a history of BPH. Among BPH-negative men, CYP3A4-V was significantly less common among T2+ cases than controls (age adjusted OR=0.27 95%CI: 0.09-0.79). Among BPH-positive men, CYP3A4-V was more common among T2+ cases than controls, although this result was not statistically significant due to small sample sizes (age adjusted OR=3.11, 95%CI: 0.56-17.20). No significant differences between controls and T1 cases were observed. These results suggest that CYP3A4-V and BPH may interact in the etiology of PC, and that these two factors affect the stage of PC diagnosis.

**Hormonal regulation of smooth muscle proliferation in tuberous sclerosis complex.** *J.J. Yu, A. Astrinidis, E.P. Henske.* Dept Medical Oncology, Fox Chase Cancer Ctr, Philadelphia, PA.

Tuberous sclerosis complex (TSC) is an autosomal dominant disease characterized by seizures, mental retardation, autism, and benign tumors in multiple organs. The smooth muscle proliferation in the lungs of TSC patients, lymphangiomyomatosis (LAM), appears to be driven by hormonal stimuli, but the mechanism of this is not known. The evidence for hormonal mediation of smooth muscle cell growth in LAM includes the onset of LAM almost exclusively in pre-menopausal women and the therapeutic benefit of hormonal therapy. We recently found somatic *TSC2* mutations in patients with a non-inherited form of LAM, termed sporadic LAM (PNAS 2000; 97:6085-90). We report here the establishment and analysis of primary cultures of the abnormal pulmonary smooth muscle cells from sporadic LAM patients. LAM cells in culture had positive immunoreactivity for desmin, vimentin and muscle actin. RT-PCR analysis showed transcripts of estrogen receptor (ER $\alpha$ ) and progesterone receptor (PR). The primary cell lines were used to study the effects of estrogen and tamoxifen on the growth of LAM-derived smooth muscle cells. Estrogen at 0.01 mM stimulated cell growth to 69% and 34% of control values, and tamoxifen at 10 mM inhibited cell growth to 33% and 28% of control values, in LAM cells 635 and 650 respectively. This is, to our knowledge, the first report demonstrating an effect of steroid hormones on the proliferation of smooth muscle cells derived from LAM patients.

**Pre-symptomatic mutation testing in p16-Leiden FAMMM families.** *F.A. de Snoo<sup>1</sup>, W. Bergman<sup>2</sup>, A. van Haeringen<sup>1</sup>, M.W. Zoetewij<sup>1</sup>, H.F.A. Vasen<sup>3</sup>, N.A. Gruis<sup>2</sup>, R.R. Frants<sup>4</sup>, M.H. Breuning<sup>1</sup>.* 1) Department of Clinical Genetics, Leiden University Medical Center, Leiden, the Netherlands; 2) Department of Dermatology, Leiden University Medical Center, Leiden, the Netherlands; 3) Department of Gastro-enterology, Leiden University Medical Center, Leiden, the Netherlands; 4) Department of Human Genetics, Leiden University Medical Center, Leiden, the Netherlands.

In a number of Dutch melanoma families a specific 19 bp deletion (founder mutation) of p16 (CDKN2A) has been found, termed p16-Leiden. P16-Leiden positive family members have a life time risk of 80% of developing pancreatic carcinoma. The latter figure, together with the exceptionally low survival rate of this disease, is a new feature in the clinical oncogenetic setting.

Since the risks in these p16-Leiden families have now been well defined, we are now able to offer pre-symptomatic mutation testing. To all p16-Leiden positive family members, skin examination on an annual basis is advised to detect melanoma development at an early stage. Simultaneously, research in the high risk group will start to determine whether pancreatic carcinoma can be detected at an early stage by intensive and regular clinical examination.

The purpose of this study is to investigate the demand and impact of pre-symptomatic testing in these well defined p16-Leiden families by using a database and questionnaires. Family members of p16-Leiden positive families will be sent a letter. This letter informs the family members that they have the possibility of predictive DNA-testing.

Preliminary results show that in the first two families approximately 30% of the people who received an informative letter made an appointment at the department of Clinical Genetics for genetic counselling.

**BRCA1 and BRCA2 analysis of 268 HBOC and HBC families by DHPLC.** *T. Wagner<sup>1</sup>, R. Moeslinger<sup>1</sup>, D. Muhr<sup>1</sup>, D. Richards<sup>3</sup>, M. Schreiber<sup>1</sup>, E. Fleischmann<sup>1</sup>, Austrian Hereditary Breast and Ovarian Cancer Group<sup>1</sup>, G. Langbauer<sup>1</sup>, C. Zielinski<sup>2</sup>, L. Jin<sup>5</sup>, P. Oefner<sup>4</sup>.* 1) Dept OB/GYN, Div Senology, Univ Vienna, Vienna, Austria; 2) Division of Oncology, Dep of Medicine!, University of Vienna; 3) Department of Genetics, Stanford University; 4) Stanford DNA Sequencing and Technology Center; 5) Human Genetics Center, University of Texas, Houston.

Using denaturing high performance liquid chromatography and sequencing, the frequencies of BRCA1 and BRCA2 mutations in 268 Austrian families with hereditary breast cancer only (HBC) or breast and ovarian cancer (HBOC) were determined. In the BRCA1 gene 27 apparently disease-associated mutations were identified in 54 (20%) families. The percentage of disease-associated mutations was highest in the 60 HBOC families (40%), ranging from 23% in families with 1 BC and 1 OC to 80% with at least 3 BC and 2 OC. The overall frequency of BRCA1 mutations in the 193 HBC families was 14%, and as high as 50% in families with at least 4 BC <60 years. Nine founder mutations were detected that accounted for two thirds of all BRCA1 mutations. The two most frequently identified mutations were 1806CtoT (7 times) and 300TtoG (6 times). Additionally 10 unclassified variants were detected in the coding region of BRCA1. In the BRCA2 gene 10 apparently disease-associated mutations were identified in 17 (6%) families. One founder mutation accounted for 47% of all BRCA2 families in Austria. The percentage of disease-associated mutations was highest in families with male and female breast cancer (29%). In HBC families 5% could be explained by BRCA2 mutations, ranging from 7% in families with 3 BC cases to 25% with 4 BC < 60 years. In HBOC families only 8% BRCA2 mutations were detected. In the coding region of BRCA2 6 unclassified variants were detected. In conclusion 26% of families with HBC or HBOC can be explained by disease associated BRCA1 or BRCA2 mutations.

**Further characterization of MTR1, a novel gene from the BWS-WT2 critical region on chromosome 11p15.5 and its murine homolog.** *D. Prawitt<sup>1</sup>, T. Enklaar<sup>1</sup>, L. Brixel<sup>1</sup>, M. Thesker<sup>1</sup>, A. Langer<sup>1</sup>, C. Spangenberg<sup>1</sup>, S. Fees<sup>1</sup>, M. Higgins<sup>2</sup>, B. Weissman<sup>3</sup>, B.U. Zabel<sup>1</sup>.* 1) Molecular Genetics Lab, Children's Hosp/ Univ Mainz, Mainz, Germany; 2) Roswell Park Cancer Center, Buffalo, NY, USA; 3) Lineberger Comprehensive Cancer Center, Univ. of North Carolina, NC, USA.

Beckwith-Wiedemann syndrome (BWS) and a variety of mostly embryonal neoplasias (e.g. Wilms'tumors (WT), rhabdoid tumors and rhabdomyosarcomas) display genetic linkage to the human chromosomal region 11p15.5. By using resources of EST- and genome sequencing projects we isolated a novel transcript which shows high homologies to the transient receptor potential protein (trp) gene family. The highest homologies are observed with the human TRPC7 and with MLSN1 (a trp-related protein whose transcript is downregulated in metastatic melanomas). The novel gene was therefore named MTR1 (= MLSN1 and TRP related gene). This gene family includes mediators of ion influx into cells after stimulation with growth hormones (e.g. IGF1). Other genes related to and interacting with the trp-family encompass the grc-gene which codes for a growth factor regulated channel protein and PKD1/PKD2, integral membrane proteins, involved in polycystic kidney disease. Increased amounts of MTR1 mRNA are present in a significant proportion of WTs and rhabdomyosarcomas. We also found that MTR1 maps near a translocation-breakpoint in the rhabdoid tumor cell line TM87-16. To elucidate the function and implication of MTR1 in BWS and 11p15.5 associated tumors, we also isolated and characterized the murine homolog, which maps to the corresponding region on distal mouse chromosome 7. RT-PCR analysis of somatic cell hybrids harboring a single human chromosome 11 demonstrated exclusive expression of MTR1 in cell lines carrying a paternal chromosome 11, indicating allele-specific inactivation of the maternal copy by genomic imprinting. In contrast to this, the murine gene displays biallelic expression in all tissues and developmental stages tested. We are currently looking for mutations in BWS- and tumor materials. Further functional studies include tumor suppression experiments in G401/RD cells and search for interacting partners with a yeast two-hybrid assay.

**Mutations in the SDHD gene are not only involved in hereditary paragangliomas in the head and neck region, but also in adrenal and extra-adrenal pheochromocytomas.** *P.E. Taschner<sup>1</sup>, P.B. Douwes Dekker<sup>2,3</sup>, J.C. Jansen<sup>2</sup>, B.E. Baysal<sup>4</sup>, A. Bosch<sup>1</sup>, I.H. van Minderhout<sup>1</sup>, E.H. Rosenberg<sup>1</sup>, A.G. van der Mey<sup>2</sup>, A.H. Bröcker-Vriends<sup>1</sup>, G.J. van Ommen<sup>1</sup>, C.J. Cornelisse<sup>3</sup>, P. Devilee<sup>1,3</sup>.* 1) Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Otorhinolaryngology, Leiden University Medical Center, Leiden,; 3) Pathology, Leiden University Medical Center, Leiden,; 4) Psychiatry, The University of Pittsburgh Medical Center. Pittsburgh, PA.

Hereditary paragangliomas or glomus tumors are usually benign slow-growing tumors in the head and neck region. Occasionally, paragangliomas outside the head and neck region, such as adrenal and extra-adrenal pheochromocytomas, have been reported in patients with head and neck paragangliomas. The inheritance pattern of hereditary paraganglioma is autosomal dominant with imprinting. The occurrence of hereditary paragangliomas has been linked to two different loci, PGL1 on chromosome 11q22-q23 and PGL2 on 11q13. Most families with hereditary paraganglioma are linked to the PGL1 locus. Recently, we have identified the SDHD gene encoding subunit D of the mitochondrial respiratory chain complex II as the PGL1 gene. Two founder mutations, D92Y and L139P, account for the majority of the Dutch paraganglioma families. These two mutations were also detected among 40% of the isolated patients. Ten of these had multiple paragangliomas, and in 8 out of these 10, SDHD germline mutations were found, indicating that multicentricity is a strong predictive factor for the hereditary nature of the disorder in isolated patients. In head and neck paragangliomas from mutation-carrying patients, loss of the maternally derived wildtype SDHD allele has been observed, indicating that SDHD functions as a tumor suppressor gene. We demonstrate that loss of the maternally derived wildtype SDHD allele also occurs in adrenal and extra-adrenal pheochromocytomas in SDHD mutation carriers. This indicates that SDHD mutations are not only involved in hereditary head and neck paragangliomas, but also in adrenal and extra-adrenal pheochromocytomas. This research is supported by the Dutch Cancer Society (KWF 98-1721).

**Germ-line BRCA1 variant R1699W: A BRCT domain marker of site-specific hereditary cancer..** *J.L. Scalia<sup>1</sup>, T.S. Frank<sup>2</sup>, P.L. Weinstein<sup>1</sup>, I. Tepler<sup>1</sup>*. 1) Cancer Risk and Prevention Program, The Stamford Hospital, Stamford, CT; 2) Myriad Genetic Laboratories Inc, Salt Lake City, UT.

BRCA1 and BRCA2 germ-line mutations account for an estimated 80-90% of hereditary breast and ovarian cancer families and are present in the majority of familial epithelial ovarian carcinomas. Several recent studies have reported the nuclear localization of BRCA1 with functional evidence of DNA repair and transcriptional activation. Protein interaction with the BRCA1 C-terminal (BRCT) domain may partially account for the mediating role of transcriptional regulation as a response to DNA damage. To investigate whether the presence of a BRCT domain variant directly correlates to specific clinical expression, we analyzed the presence of the BRCA1 variant R1699W in our family TSH102-99. The variant results in the substitution of tryptophan for arginine at amino acid position 1699 of the BRCA1 protein. This exon18 missense mutation is positioned in the conserved residue of the first tandem BRCT domain. Across three generations, and four degrees of relatedness, every woman diagnosed with ovarian cancer in this family is a demonstrated or obligate carrier of this rare BRCA1 variant. There was no breast cancer in the family. This case study indicates a BRCT variant (R1699W) as a marker, and highly suggestive cause, of site-specific hereditary cancer.

**Protocols for the investigation of large, genomic alterations in the DNA mismatch repair genes MLH1, MSH2, and MSH6 by southern blot analysis.** *R.E. Pyatt<sup>1</sup>, M. Sedra<sup>1</sup>, R.W. Schafer<sup>1</sup>, A. de la Chapelle<sup>2</sup>, T.W. Prior<sup>1</sup>.* 1) Dept. of Pathology, Ohio State University, Columbus, OH; 2) Division of Human Cancer Genetics, Ohio State University, Columbus, OH.

Hereditary nonpolyposis colorectal cancer (HNPCC) is one of the most common inherited forms of colorectal (CRC) cancer and is characterized by an early age of onset, microsatellite instability (MSI), and an autosomal dominant mode of inheritance. Tumors in the HNPCC syndrome are primarily caused by inherited mutations in three of the six DNA mismatch repair (MMR) genes: MLH1, MSH2, and MSH6. While extensive research has been done identifying small types of mutations in these genes, there is little information in the literature examining the presence of large deletions and other rearrangements in them. In this study, we report the development of southern blot protocols for the complete analysis of the DNA MMR genes MLH1, MSH2, and MSH6 for large, genomic alterations. Hind III and NSI 1 restriction enzyme digestion patterns were defined using lymphocyte DNA from 150 normal controls hybridized with two cDNA probes spanning MSH6, two cDNA probes spanning MSH2, and a single MLH1 cDNA probe encompassing the entire gene. For these enzymes, no polymorphic variations in the restriction patterns were found in the control population examined. Using these protocols, lymphocyte DNA from 10 individuals with MSI+ CRC tumors and 20 individuals with MSI- CRC tumors was evaluated for the presence of junction bands and altered band intensity. In an individual with MSI+ CRC, a junction band was identified using a cDNA probe corresponding to exons 1-7 of the MSH2 gene. This junction band was further shown to be maternally inherited and, through both long PCR and exon specific quantitative PCR reactions, the exact nature of these findings are being elucidated in both individuals. The southern protocols outlined here allow for a comprehensive analysis of large, genomic alterations in the DNA MMR genes.

***SDHD* gene testing in "sporadic" paraganglioma indicates a high proportion of unrecognized heritable cases.**

*W.S. Rubinstein*<sup>1,2</sup>, *C.M. Drovdic*<sup>2</sup>, *E.N. Myers*<sup>3</sup>, *J.E. Willett-Brozick*<sup>4</sup>, *D.E. Brackmann*<sup>5</sup>, *W.H. Slattery*<sup>5</sup>, *J.A. Peters*<sup>1,2</sup>, *B.E. Baysal*<sup>2,4</sup>. 1) Cancer Genetics Program, Univ. Pittsburgh Cancer Institute, PA; 2) Dept. Human Genetics, Graduate School of Public Health, Pittsburgh, PA; 3) UPMC Eye & Ear Institute, Pittsburgh, PA; 4) Dept. Psychiatry, Pittsburgh, PA; 5) House Ear Institute, Los Angeles, CA.

Non-chromaffin paragangliomas (PGLs) are slow-growing tumors of the head and neck that cause substantial morbidity due to cranial nerve impairment. In PGL families, there is considerable potential to avert cranial nerve damage by prospective MRI. Hereditary PGL shows genetic heterogeneity with at least 3 loci. PGL1 is the succinate-ubiquinone oxidoreductase subunit D gene (*SDHD*) recently identified by our group. Inheritance is autosomal dominant with maternal imprinting in PGL1 and PGL2 families but not PGL3. The heritable proportion is widely estimated at 7-50% and is probably obscured in part by imprinting.

We assessed the heritable proportion of PGL by SSCP analysis of the 4 *SDHD* exons. We analyzed cheek swab DNA from 39 individuals with PGL ascertained in the U.S. without respect to family history or tumor multifocality. Sixteen samples showed aberrant SSCP bands. Of 8 subjects with heritable features, 7 had aberrant bands. Of the 31 apparently sporadic cases, 9 had aberrant SSCP bands and another 3 showed SSCP band shifts of uncertain significance. An aberrant band was seen in a woman affected at age 35, suggesting young age of onset alone may help to identify some heritable cases. However an aberrant band was also seen in a woman with the classical sporadic presentation, PGL diagnosis at age 82.

These data suggest that about a third of patients with a single PGL tumor and no PGL family history (as elicited by a genetic counselor) have germline *SDHD* mutations. If confirmed by DNA sequencing (in progress), this indicates that heritable PGL cannot be adequately discerned by clinical history alone. *SDHD* gene testing of apparently sporadic cases (analogous to *RET* testing for medullary thyroid cancer) may help to identify a significant proportion of people at risk for PGL tumors.

**Prevalence of germline MMR gene mutations in French kindreds with HNPCC or aggregation of colorectal cancers.** *Q. Wang*<sup>1</sup>, *C. Lasset*<sup>2</sup>, *F. Desseigne*<sup>3</sup>, *E. Ruano*<sup>1</sup>, *C. Navarro*<sup>1</sup>, *G. Montmain*<sup>1</sup>, *A. Puisieux*<sup>1</sup>. 1) Unité d'Oncologie Moléculaire; 2) Département de Santé public; 3) Département de Médecine, Centre Léon Bérard, Lyon, France.

Hereditary nonpolyposis colon cancer (HNPCC) syndrome is an autosomal dominantly inherited predisposition for early onset of colorectal cancer. It accounts for about 10% of total colorectal malignancies. This syndrome results from germline mutations of one of the MMR genes: hMLH1, hMSH2, hPMS1, hPMS2 and hMSH6. Identification of germline mutations of MMR genes has an important clinical interest in the management of HNPCC families. The aim of this study was to evaluate the involvement of MMR gene mutations in different groups of families, to study genotype and phenotype correlation, and to estimate *de novo* mutation frequency, in order to establish appropriate criteria for the selection of the families for mutation screening. We analyzed the status of hMLH1 and hMSH2 genes in 130 french patients by using a combined DNA- and RNA- based strategy. A total of 53 alterations were identified. The majority of the mutations were found in typical HNPCC families (more than 60%), whereas about 30% were identified in atypical families missing 1 or 2 Amsterdam criteria. In the absence of family history, mutations were mainly found in patients affected with multiple primary cancers. Most of the alterations were nonsense mutations and small insertions/deletions leading to the generation of prematured stop-codon. However, missense mutations were found in 19 patients, mainly in the hMLH1 gene. Our study shows 1) the use of sensitive technologies for the detection of the mutations; 2) a very low *de novo* mutation frequency in MMR genes; and 3), the requirement of appropriate criteria which should include multiple primary cancers among the guidelines for referring patients for genetic testing .

**Tumor suppressor function of the BRCA1 gene has a low threshold for mutation.** *S.R. Svojanovsky, P.K. Rogan.*  
Section Medical Genetics & Molecular Medicine, Children's Mercy Hosp, Univ Missouri-Kansas City School of Medicine.

Mutations in the *BRCA1* gene are penetrant, presumably because the tumor suppressor activity is highly susceptible to mutation. The susceptibility may be related to extensive alternative splicing in this gene, which diminishes the amount of full-length transcript produced in normal tissue. Tumor suppressor activity has been mapped to the C-terminal domain of the protein. Because of alternative splicing, we considered the possibility that tumor suppression by this gene might be susceptible to mutations that reduced, but did not abolish production of the full-length transcript. BRCA1 splice site variants reported in individuals with a history of breast cancer (n=45; Breast Cancer Information Core, NHGRI, NIH) were evaluated by individual information ( $R_i$ ) analysis. Comparison of  $R_i$  values of normal and variant splice site sequences can predict changes in levels of normally spliced mRNA that result from nucleotide substitutions. The majority of BRCA1 mutations were severe (n=33,  $DR_i > 6.6$  bits, ie. >100 fold decrease in splice site recognition), however 4 mutations were predicted only to diminish the levels of normally spliced mRNA (IVS13+6 T>C, IVS16+6 T>C, IVS22+5 G>A, and IVS23-10 C>A; between 3 and 11 fold decrease). Eight variants did not alter  $R_i$  values of the adjacent splice site and may be polymorphisms.

Nine N-terminal splicing mutations, which were predicted to be severe, remained in frame, suggesting that coding sequence deletions upstream of the C-terminal domain can also diminish tumor suppression. Surprisingly, IVS13+6 T>C, a mild mutation which also occurs upstream of the C-terminal tumor suppressor domain and maintains the reading frame, was found in a breast cancer family. Failure of this and the other leaky splicing mutations to suppress breast tumors is consistent with the possibility that a high level of normal *BRCA1* mRNA may be required to suppress tumor formation.

**Mutational analyses of BRCA1 and BRCA2 in Ashkenazi and non-Ashkenazi Jewish women with familial breast**

**and ovarian cancer.** *R. Shiri-Sverdlov<sup>1</sup>, P. Oefner<sup>3</sup>, R. Gershoni-Baruch<sup>2</sup>, L. Green<sup>1</sup>, RMW. Hofstra<sup>5</sup>, T. Wagner<sup>4</sup>, E. Friedman<sup>1</sup>.* 1) Oncogenetics Unit, Sheba Medical Center, Tel-Hashomer, Israel; 2) The Genetics Institute, Rambam Medical Center, Haifa; 3) The Department of Genetics, Stanford DNA sequencing and technology Center, Palo Alto CA; 4) Department of Obstetrics and Gynecology, Division of Senology, University of Vienna, Vienna, Austria; 5) The Department of Medical Genetics, Groningen, Netherlands.

**ABSTRACT** In Ashkenazi (East European) Jews, three predominant mutations in BRCA1 (185delAG and 5382insC) and BRCA2 (6174delT) account for the majority of germline mutations in high risk breast and/or ovarian cancer families. Among non-Ashkenazi Jews, the 185delAG, Tyr978X, and a handful of "private" mutations have anecdotally been reported within both genes. In this study we attempted to determine the spectrum of BRCA1 and BRCA2 mutations in high risk Jewish individuals, non-carriers of any of the predominant Jewish mutations. We employed multiplex PCR and denaturing gradient gel electrophoresis analysis for BRCA2, and combined denaturing high pressure liquid chromatography and protein truncation test (PTT) for BRCA1, complemented by DNA sequencing. We screened 47 high risk Jewish individuals, 26 Ashkenazis and 21 non-Ashkenazis. Overall, 13 sequence alterations in BRCA1 and 8 in BRCA2 were detected: 9 neutral polymorphisms and 12 missense mutations, including 5 novel ones. The novel missense mutations did not cosegregate with disease in BRCA1 and were detected at rates of 6.25% to 52.5%, in the general population for BRCA2. Our findings suggest that except for the predominant mutations in BRCA1 and BRCA2 in Jewish individuals, there are only a handful of pathogenic mutations within these genes. It may imply novel genes may underlie inherited susceptibility to breast/ovarian cancer in Jewish individuals.

**A diagnostic screening test for tumor microsatellite instability (MSI) using fluorescent multiplex PCR and automated fragment analysis.** *M. Rose*<sup>1,2</sup>, *T. Selander*<sup>2</sup>, *M. Redston*<sup>1,2,3</sup>, *S. Gallinger*<sup>1,2,3</sup>, *B. Bapat*<sup>1,2,3</sup>. 1) Center for Cancer Genetics, Samuel Lunenfeld Research Institute; 2) Departments of Pathology and Laboratory Medicine, and Surgery; Mount Sinai Hospital; 3) University of Toronto, Toronto, Ontario.

Microsatellite instability (MSI) is defined as the occurrence of novel alleles in tumor DNA with a frequency of at least 40% among microsatellite loci examined. Defects in mismatch repair system cause MSI, which plays an important role in the development of tumors. MSI is a hallmark of a subset of sporadic colorectal and HNPCC-associated tumors. Detection of tumors with MSI has important prognostic and treatment implications for patients. We describe the development of an efficient diagnostic test for screening of tumor MSI based on fluorescent multiplex PCR system and automated fragment analysis. The assay consists of a panel of 11 microsatellite loci including those loci (BAT25, BAT26, D2S123, D5S346 and D17S250) recommended by the National Cancer Institute (1). The microsatellite panel includes one tetranucleotide, six dinucleotide and four mononucleotide loci. DNA extracted from paraffin embedded tissue (25 ng) is amplified in two multiplex PCR reactions. The fluorescent labelled PCR amplicons (size range 65-230 bp) are analyzed using ABI377 GeneScan and Genotyper software. This diagnostic assay was validated by analyzing ten colorectal cancer cases by both fluorescent multiplex PCR and conventional radioactive labelled PCR and gel electrophoresis. The assay sensitivity was determined by MSI analysis of tumor DNA serially diluted with matched normal DNA, and was found to range from 10% for mononucleotide loci to 40% for dinucleotide loci. Overall, this diagnostic assay offers a fast, sensitive and cost-effective method of MSI detection and is most suitable for high throughput screening for mismatch-repair deficient tumors. **Insulin like growth factor I (IGF-I) polymorphism and breast cancer risk in Jewish women.** *Y. Patael-Karasik<sup>1</sup>, A. Figer<sup>2</sup>, R. Gershoni-Baruch<sup>3</sup>, A. Chetrit<sup>4</sup>, M.Z. Papa<sup>5</sup>, R. Bruchim-Bar-Sade<sup>1</sup>, E. Friedman<sup>1</sup>.* 1) Oncogenetics Unit, Sheba Medical Center, Tel-Hashomer, Israel; 2) Oncology Institute, Rabin Medical Center, Petach Tikvah; 3) The Genetics Institute, Rambam Medical Center, Haifa; 4) the Department of Clinical Epidemiology, Sheba Medical Center, Tel-Hashomer; 5) The Department of Oncological Surgery, Sheba Medical Center, Tel-Hashomer.

Background: Genes that confer mild or moderate susceptibility to breast cancer, may be involved in the pathogenesis of sporadic breast cancer, and modify the phenotypic expression of mutant BRCA1/BRCA2 alleles. An attractive candidate is the Insulin-like growth factor I (IGF-I), a known mitogen to mammary ductal cells in vivo and in vitro, whose serum levels were reportedly elevated in breast cancer patients. Methods: We analyzed allele size distribution of the polymorphic CA repeat upstream of the IGF-I gene in 412 Jewish Israeli women: 268 women with breast cancer (212 sporadic and 56 carriers of either a BRCA1 or BRCA2 mutations), and 144 controls. The methodology employed included radioactive PCR amplification of the relevant genomic region, gel size separation, and autoradiography, followed by statistical analyses of allele size distribution within the different analyzed groups. Results: Among women with breast cancer, with or without BRCA germline mutations, the 196 and 198 basepair (bp) alleles were present in 4.7% (25/536 alleles), compared with 9% (26/288) controls ( $p=0.02$ ). This difference was more pronounced and significant in the non-Ashkenazi population. Conversely, the smaller size allele (176 bp) was only present in the breast cancer group (3/536- 0.6%), and in none of the controls. Conclusion: We conclude that the IGF -I polymorphism may serve as a marker for breast cancer risk in the general Jewish population, in particular non-Ashkenazi Jews, but an extension and confirmation of these preliminary data is needed.

**Developing a regional cancer genetics network: Linking a center of excellence to the community laboratory.** *J.N. Weitzel<sup>1</sup>, D.J. MacDonald<sup>1</sup>, K.R. Blazer<sup>1</sup>, J. Choi<sup>1</sup>, R. Crane<sup>2</sup>, J. Craig<sup>3</sup>, F. Kass<sup>4</sup>.* 1) Clinical Cancer Genetics, City Hope Natl Med Ctr, Duarte, CA; 2) St. Johns Health Ctr, Santa Monica, CA; 3) St. Jude Med Ctr, Fullerton, CA; 4) Cancer Ctr of Santa Barbara, CA.

Barriers to the application of genetic cancer risk assessment (GCRA) protocols include limited access to counseling and education services that are equipped to handle the complex and rapidly evolving technological, and ethical issues.

**Objective:** Explore mechanisms for technology transfer of advanced GCRA protocols, research and education to community physicians outside the primary service area of a multidisciplinary clinical cancer genetics program at a comprehensive cancer center.

**Methods:** Identify champions in community hospitals to sponsor educational programs and provide on-site coordination of care; provide experienced personnel, GCRA protocols and opportunities for participation in clinical research; deliver CME-qualified cancer genetics education to clinicians and in public forums; use informatics to augment teaching and catalogue resources.

**Results:** The City of Hope (COH) *Cancer Screening & Prevention Program Network* (CSPPN) reaches the Santa Barbara, Orange and Los Angeles counties of Southern California (5 sites), and a new satellite site in Phoenix, AZ. Coordination of CME events and clinic opening increased both community physician knowledge and appropriate referrals (550 families to date). Two sites employ a team approach, where the oncogeneticist and the cancer risk counselor provide comprehensive services together. A solo cancer risk counselor provides initial counseling at one outlying site; these patients may travel to the COH campus to see the team for discussion of complex management issues and/or disclosure of genetic test results. Cases are reviewed in a weekly multidisciplinary conference. The CSPPN yields clinical and biologic resources for genetic epidemiology and outcomes research through an IRB-approved confidential registry. This regional cancer genetics network represents a community laboratory for the development of innovative mechanisms for delivery of GCRA protocols.

**The Homeobox gene *CDX2* in colorectal carcinomas; a genetic analysis.** *S. Sivagnanasundaram*<sup>1</sup>, *I. Islam*<sup>1</sup>, *I. Talbot*<sup>2</sup>, *F. Drummond*<sup>1</sup>, *J.R.F. Walters*<sup>3</sup>, *Y.H. Edwards*<sup>1</sup>. 1) MRC Human Biochemical Genetics Unit, Department of Biology, University College London, London; 2) Academic Department of Pathology, St Mark's Hospital, Northwick Park, London; 3) Gastroenterology Section, Division of Medicine, Imperial College School of Medicine, Hammersmith Hospital, London.

Accumulation of mutations in tumour suppressor genes and oncogenes has been proposed to underlie the initiation and progression of sporadic colorectal cancer (CRC). Evidence is accumulating to suggest that the *caudal* homeobox gene *CDX2* is implicated in the pathogenesis of CRC. The *CDX2* transcription factor is expressed in intestinal epithelium and is markedly down-regulated in colon tumours. Furthermore, *Cdx2* heterozygous null mice develop multiple intestinal tumours. In this present study, we have investigated *CDX2* as a potential candidate gene for sporadic CRC by a thorough search of all exons and exon/intron boundaries for DNA polymorphisms and rare variants in a panel of 51 CRC tumour/normal pairs. Six polymorphisms were identified and the haplotypes determined. In addition two rare variants were found, one of which was only identified in DNA from a CRC case. Loss of heterozygosity was observed in 3 out of 28 informative CRC cases. A possible association between particular haplotypes and tumour progression was also suggested by the data. In addition a preliminary analysis of the relative expression of *CDX2* alleles in tumour/normal tissue suggested some variation in the levels, however further analysis is required before any conclusions can be drawn. While *CDX2* mutations predisposing to sporadic CRC have not been identified, this study has established that loss of *CDX2* contributes towards the progression of some sporadic CRC tumours.

**MLH1 and MSH2 mutation identification from unselected patients with colorectal cancer is facilitated by the combined analysis of microsatellite instability and immunohistochemistry.** *C. Verellen-Dumoulin<sup>1</sup>, V. van Scherpenzeel Thim<sup>1</sup>, A. Kartheuser<sup>2</sup>, M. Smaers<sup>1</sup>, P. Camby<sup>3</sup>, R. Detry<sup>2</sup>, C. Sempoux<sup>3</sup>, K. Dahan<sup>1</sup>. 1) Ctr for Human Genetics, UCL, Brussels, Belgium; 2) Dpt of Surgery, UCL, Brussels; 3) Dpt of Pathology, UCL, Brussels.*

Colorectal cancer (CRC) morbidity and mortality can be dramatically reduced by appropriate management of patients with hereditary non polyposis colorectal cancer (HNPCC) and by surveillance of at-risk individuals. The aim is to find a approach to identify HNPCC patients on a large scale in a sensitive and efficient manner. **PATIENTS AND METHODS:** From 1998 until 2000, CRC specimens from consecutively new patients were studied for microsatellite instability (MSI) and expression of MLH1 and MSH2 proteins. HNPCC germline mutation search was carried out for MSI(+) individuals according to the immunohistochemistry results. **RESULTS:** Among 225 CRC, 45 (20%) were MSI high associated with lack of immunostaining in 32: 25 for *MLH1* and 7 for *MSH2*. Among these, until now, we have found 8 (3.5 % of all CRC) disease-causing germline mutations, 5 in *MLH1* and 3 in *MSH2*. Seven are new ones. The functional consequences result from 2 frameshifts leading to stop codons, 2 splice defects and 4 missenses. Among these 8 patients, 4 were older than 50 years, 7 had at least 1 first-degree relative with CRC or endometrial cancer and 1 had a Turcot syndrome. **CONCLUSION:** A systematic MSI study associated to immunohistochemistry is an efficient strategy to identify HNPCC patients from an unselected cohort of patients with CRC. This approach allowed us to make the diagnosis of HNPCC in 8 as yet unrecognized patients and to start a predictive HNPCC screening in their family.

**Cellular localization of nonfunctional BLM protein in cells from persons with Bloom's syndrome (BS) who have inherited missense mutations.** *M.M. Sanz<sup>1</sup>, N.A. Ellis<sup>2</sup>, J. German<sup>1</sup>*. 1) Laboratory of Human Genetics, Dept. of Pediatrics, Cornell Univ. Medical College; 2) Laboratory of Cancer Susceptibility, Dept. of Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

In cells from normal persons examined by immunofluorescence microscopy employing antiBLM antibody, BLM is detectable in the nucleus of all except very early G1 cells, distributed fairly diffusely and usually also concentrated focally in tiny speckles, large dots, and large patches. Earlier we demonstrated a total lack of BLM protein in cells from persons with BS caused by either homozygosity or compound heterozygosity for protein-truncating mutations at BLM [AJHG 65(Suppl.):A320,1999]. Among the 65 mutations in BLM detected in persons followed in the Bloom's Syndrome Registry, protein-truncating mutations are the commonest class, but 10 are missense mutations. In the analysis of three of the persons with BS who inherited either one or two missense mutations, BLM has been found in what on preliminary examination appears to be a normal distribution. The present report is of (i) the amount and cellular distribution of BLM encoded by the various BS-causing missense mutations detected comparing homozygotes, genetic compounds with two different missense mutations, and genetic compounds with one missense and one truncating mutation; and (ii) significant phenotype correlations between the mutation, the nuclear distribution of BLM, the BS clinical and cytogenetic (SCE) phenotypes, and the development of cancers.

***De novo BRCA2 mutation in a patient with early-onset breast cancer.*** M. Robson, L. Scheuer, R. Baum, J. Hull, D. McDermott, H. Pierce, K. Nafa, N. Ellis, K. Offit. Dept Human Genetics, Mem Sloan-Kettering Cancer Ctr, New York, NY.

To date there is no published report of a *de novo BRCA2* mutation. We report a patient with a *de novo BRCA2* mutation, 7260insA, previously undescribed in the Breast Information Core database. The proband was a 41 year old female diagnosed with synchronous bilateral breast cancer at age 35. Family history was significant for a primary gastric cancer diagnosed in her brother at age 47, metachronous diagnoses of colorectal and gastric cancer in her father at ages 57 and 62, and a diagnosis of pancreatic cancer in a paternal grandfather in his sixties. All affected family members were deceased. Of note, the patient had 10 other siblings (5 brothers and 5 sisters), none of whom had cancer diagnoses. Following informed consent, sequencing of *BRCA1* and *BRCA2* was performed on the proband's leukocyte-derived DNA, which revealed a frameshift mutation, *BRCA2* 7260insA, which causes premature termination at codon 2359. The proband's mother and five sisters all underwent testing for the 7260insA mutation by direct, single amplicon sequencing. The mutation was not present in any of their samples. In an attempt to detect the 7260insA mutation in the father, who is deceased, a colon tumor block was acquired. After extraction of DNA from the paraffin-embedded tissue, DNA sequencing analysis was performed, and the mutation was not present. DNA genotyping analysis at informative microsatellite loci supported the paternity of the father. The frequency of *de novo* mutations of *BRCA1* and *BRCA2* has not yet been determined. Given the large size of *BRCA2* (27 exons distributed over approximately 70kb of genomic DNA) and evidence of mutational "hot spots," it is not surprising that *de novo* mutations exist. Failure to consider the occurrence of *de novo* mutations will result in an underestimate of penetrance estimates derived from models that are based on genotyping of probands with incomplete or no genotyping of parents. The existence of *de novo* mutations must be considered in counseling individuals with early onset breast and/or ovarian cancer.

**The APC/b-Catenin/Tcf-4 (ACT) signaling pathway, survivin expression, and apoptosis in normal and malignant human colonic epithelial cells.** *T. Zhang, T. Otevrel, Z.Q. Gao, Z.P. Gao, A. Kairo, S. Burkholder, S. Ehrlich, B.M. Boman.* Division of Medical Genetics, Thomas Jefferson University, Philadelphia, PA.

Survivin is an anti-apoptotic gene that is expressed in cells during embryological development or after malignant transformation, but its expression is suppressed in differentiated cells. Indeed, we have shown in normal human colonic crypts that survivin is preferentially expressed in the proliferative compartment as compared to the compartment containing differentiated colonocytes. The ability of survivin to inhibit apoptosis is thought to be important in tumorigenesis. However, cellular factors that normally regulate survivin gene expression and that are involved in dysregulation of its expression during cancer development are unknown. Because ACT signaling modulates transcription of a number of target genes and APC mutation causes development of colorectal cancer (CRC), we investigated a possible role of ACT signaling in the regulation of survivin gene expression in a CRC cell line (HT-29). In one experimental approach, we used a recombinant HT-29 cell line, HT29-APC, which contains a wild type (wt) APC construct with a zinc inducible promoter. Zinc induction of wt-APC causes apoptosis in this recombinant cell line. Upon zinc induction, a significant decrease in the level of survivin expression was observed using immunocytochemistry and RT-PCR as well as a marked increase in cell death. In another experimental approach, we attempted to inhibit tcf-4 mediated activation of gene transcription by using a dominant negative tcf-4 gene construct. In an initial pilot study, this construct was transiently transfected into HT-29 cells. We observed, using RT-PCR, that survivin expression decreased within 24 hours and the suppression of survivin expression correlated with the amount of tcf-4 construct transfected. These two experimental findings are consistent with each other and suggest a tumorigenic mechanism whereby APC mutation and tcf-4 activation leads to constitutive expression of survivin, thereby preventing apoptosis and contributing to the development of malignant colon cells.

**Two separate regions of functional tumor suppressor activity on chromosome 10p involved in prostate cancer.**  
*P.E. Wong, M.M. Lovell, A.M. Killary.* Dept Pathology & Lab Med, Univ Texas MD Anderson CA Ctr, Houston, TX.

A major goal of our laboratory's research is to use a functional genomic approach to define and isolate tumor suppressor genes involved in prostatic adenocarcinoma. Previously, we have defined a novel tumor suppressor locus *PAC-1* within chromosome 10p. Introduction of the short arm of chromosome 10 into a prostatic adenocarcinoma cell line PC-3H resulted in dramatic tumor suppression and restoration of a programmed cell death pathway. To functionally dissect the region within 10p containing *PAC-1*, we developed the novel strategy of serial microcell fusion, a technology that would allow the transfer of defined fragments of chromosome 10p into PC-3H and the rapid *in vivo* assay for functional tumor suppressor activity. Serial microcell fusion was used to transfer defined 10p fragments into a mouse A9 fibrosarcoma cell line. Once characterized by FISH and microsatellite analyses, the 10p fragments were subsequently transferred into PC-3H to generate a panel of microcell hybrid clones containing overlapping deletions of chromosome 10p. *In vivo* and microsatellite analyses of these PC hybrids identified four clones that limited a region of functional tumor suppressor activity to 10p11 and flanking a region of LOH demonstrated in prostate cancer. In addition, these clones further limited a second unique region within 10p15 distinct from two regions identified by LOH in different histologic neoplasms. These studies demonstrate the utility of this approach as a powerful tool to limit regions of functional tumor suppressor activity. Furthermore, these data used in conjunction with data generated by the Human Genome Project will lend a focused approach to identify candidate tumor suppressor genes involved in prostate cancer.

**Risk-reducing surgery outcomes among a series of *BRCA* heterozygotes.** *L.M. Scheuer*<sup>1</sup>, *M. Robson*<sup>1,3</sup>, *R. Baum*<sup>1</sup>, *M. Capasso*<sup>1</sup>, *C. Duteau-Buck*<sup>1</sup>, *J. Hull*<sup>1</sup>, *B. Kelly*<sup>1</sup>, *D. McDermott*<sup>1</sup>, *H. Pierce*<sup>1</sup>, *M. Pinto*<sup>1</sup>, *C. Schulz*<sup>1</sup>, *R. Barakat*<sup>2</sup>, *P. Borgen*<sup>2</sup>, *C. Hudis*<sup>3</sup>, *L. Norton*<sup>3</sup>, *K. Offit*<sup>1,3</sup>. 1) Dept. of Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Dept. of Surgery, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Dept. of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY.

Women with mutations in *BRCA1* and *BRCA2* are at increased risk to develop breast and ovarian cancers. Some of these women decide to undergo risk-reducing salpingo-oophorectomy (RRSO) and/or risk reducing mastectomy (RRM). We have obtained follow-up data from 2 months to 5 years after genetic testing on 169 women with pathogenic *BRCA* mutations. Eighty-five of the 169 women (50.3%) underwent RRSO, the vast majority (74/85 or 87.1%) after receiving genetic test results. Of the remaining women, 16 underwent oophorectomy for treatment of ovarian/fallopian tube/ or peritoneal cancers (14 diagnosed clinically and 2 diagnosed after surgery for an abnormal screening ultrasound), 9 for other gynecologic reasons, and 3 for abnormal screening findings proven not to be malignant at surgery. Fifty-six *BRCA* heterozygotes had their ovaries intact at follow-up. Four of the 85 women (4.7%) who underwent RRSO were diagnosed with clinically occult cancers. This includes 2 women diagnosed with ovarian cancers at ages 38 and 52, 1 with a fallopian tube cancer at age 47, and 1 with pathology pending at age 48. The mean age at RRSO among those without occult cancers was 46.4 years.

Forty-two women (24.9%) underwent RRM, including 31 with and 11 without breast cancer. Of 41 women who underwent RRM, 25 (61.0%) did so after receiving genetic test results and 16 (39.0%) prior to receiving results. The mean age at RRM was 41.7 years. The majority, 35/41 (85.4%) of women underwent reconstruction. One woman (2.4%) was diagnosed with an unsuspected intraductal cancer at age 50.

Among our series of *BRCA* heterozygotes, a significant proportion have chosen to undergo risk-reducing surgeries. Four women (4.7%) who underwent RRSO and 1 (2.4%) who underwent RRM were detected to have early-stage cancers at the time of these procedures.

**High-resolution analysis of gene copy number changes across the genome in hundreds of tumors: CGH on cDNA microarrays followed by FISH analysis on tissue microarrays identify genes involved in DNA amplifications at 17q23 in breast cancer.** *A.H. Kallioniemi<sup>1</sup>, O.M. Monni<sup>1</sup>, J. Kononen<sup>1</sup>, M. Barlund<sup>2</sup>, S. Mousses<sup>1</sup>, J.D. Weaver<sup>1</sup>, M.*

*Bittner<sup>1</sup>, Y. Chen<sup>1</sup>, J. Torhorst<sup>3</sup>, G. Sauter<sup>3</sup>, O-P. Kallioniemi<sup>1</sup>.* 1) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Institute of Medical Technology, University of Tampere and Tampere University Hospital, Finland; 3) Institute of Pathology, University of Basel, Switzerland.

Due to the limited resolution of classical chromosomal CGH, microarray-based CGH methods have been developed for high-resolution analysis of chromosomal changes in cancer and other diseases (Pinkel, 1998, Pollack et al. 1999, and Heiskanen et al. 2000). However, informative breakpoints for copy number changes are often rare, requiring analysis of hundreds of specimens, which is not easy to achieve with such DNA chip based approaches. Here, we present a novel strategy for genome-wide high-resolution mapping of copy number changes in hundreds of tumors based on combination of CGH microarray analysis with hundreds of mapped cDNA clones, followed by assembly of a high-resolution panel of BAC probes for tissue microarray-based FISH analysis on hundreds of tumors. In order to identify genes involved in DNA amplifications taking place along 17q in breast cancer, we constructed a chromosome-specific cDNA microarray, covering RH-mapped known genes and Unigenes. Breast cancer cell lines with high-level DNA amplifications at 17q23 by chromosomal CGH revealed a region of high-level copy number at cR 372 to 385. In order to explore this site in more detail, a set of 10 BAC probes for this interval was generated, and applied in FISH analysis of 372 primary breast cancers placed in a tissue microarray. This analysis was able to narrow down the region of involvement, from which a novel overexpressed, and rearranged MB-17A gene was found. In summary, this study illustrates a powerful high-throughput CGH-microarray and tissue microarray-based strategy to utilize the genomic sequence and resources to identify target genes for chromosomal rearrangements in cancer.

**Comparison of Neural Network Modeling and Logistic Regression for Predicting *BRCA1* and *BRCA2* Mutations in Women with Ovarian Cancer.** *M.-P. Dube<sup>1</sup>, J.-S. Brunet<sup>1</sup>, R. Moslehi<sup>1, 2</sup>, S.A. Narod<sup>1</sup>.* 1) Public Health Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Department of Medical Genetics, University of British Columbia, British Columbia, Canada.

The goal of this study is to develop an accurate model for predicting the presence of a *BRCA1* and *BRCA2* founder mutation among Jewish women with ovarian cancer. We performed genetic testing for two mutations in *BRCA1* (185delAG and 5382insC) and one mutation in *BRCA2* (6174delT) in 208 Jewish women with ovarian cancer. A total of 86 mutations were identified. We then designed prediction models for the presence of a mutation, which incorporate information on the age of onset of the ovarian cancer, the histology, stage and grade of the tumor, and the patient's family history of ovarian and breast cancer. The models included logistic regression and a three-layer back propagation neural network.

The prediction models were designed using 75% of the available data (156 cases), and were then tested using the remaining 25% of the cases (52 cases). The two models performed equally well for a test with one output variable (carrier versus non-carrier). The logistic regression model correctly predicted the mutation status for 40 of the 52 patients in the test group, including 63.2% of the carriers and 84.8% of the non-carriers. The neural network model correctly predicted the status of 41 of the 52 carriers in the test group, including 78.9% of the mutation carriers and 78.8% of the non-carriers.

In a second approach, we attempted to predict the mutation status at *BRCA1* and *BRCA2* concurrently, using polytomous logistic regression and using a three-layer neural network model with two outputs in its outer layer. The neural network performed better than the polytomous logistic regression in predicting mutation status at both genes. The polytomous logistic regression predicted 28.6% of the *BRCA1* carriers, 0% of the *BRCA2* carriers and 84.3% of the non-carriers. The two outputs neural network model predicted 71.4% of *BRCA1* carriers, 40.0% of *BRCA2* carriers, and 66.7% of non-carriers.

**Familial Cancer Database: an example of low-cost world-wide electronic distribution of genetics software.** *R.H. Sijmons<sup>1</sup>, G.T.N. Burger<sup>2</sup>, W. Weber<sup>3</sup>.* 1) Medical Genetics, Univ Groningen, Groningen, Netherlands; 2) Dept. of Pathology, Sazinson Foundation, Hooegeveen, Netherlands; 3) Chair UICC Familial Cancer and Prevention Project, Basel, Switzerland.

The Familial Cancer Database (FaCD) is free software to support differential diagnostics in clinical cancer genetics. The program has been released as part of the Familial Cancer and Prevention Project of the UICC (International Union against Cancer; <http://www.uicc.org/programmes/epid/familial.shtml>). Out of necessity to keep the distribution costs of FaCD low, the software is distributed by our organisation exclusively through the Internet, although individual users are free to distribute the software non-commercially to other health care professionals on CD-ROM's or diskettes. We have tried to draw attention to the FaCD web site (<http://facd.uicc.org>), which opened February 1st 2000, by submitting announcements to genetics and oncology journals as well as to medical web sites, by (poster) presentations and a journal article. However, we questioned whether such an approach and distribution system is indeed suitable for a project which aims at reaching potential users globally. We have therefore analyzed user-registration information, which includes country of residence and field of medical expertise. Results from such an analysis might also be useful for similar projects which aim at low cost distribution of genetics software (or information in general) to a global professional community.

By June 6th (5 months from the start), registrations for the software had been received from a total of 61 countries, including all Western-European and North-American countries as well as a wide range of countries from South-America, Eastern-Europe, Asia and Africa. Details on that range and on the fields of expertise of the users will be presented. We conclude that low cost distribution of oncogenetics software through the Internet may indeed reach potential users world-wide.

**Cloning of a replicative senescence gene for immortal tumor cells.** *G.P. Kaur, D.E. Reddy, R.S. Athwal.* Fels Cancer Research Inst, Temple Univ Sch Medicine, Philadelphia, PA.

Escape from senescence has been postulated to be a prerequisite for progressive tumor growth. Cells cultured from many tumors can proliferate indefinitely, while normal diploid cells become senescent after defined number of generations. Cellular senescence is expressed as a dominant phenotype over immortal cell growth. We have applied a functional-positional approach to map and isolate human genes that induce senescence in immortal tumor cell lines. A cell senescence gene, SEN16, identified on chromosome 16 by microcell mediated chromosome transfer into immortal mammary tumor cells, has been mapped within a genetic interval of 3-7cM at 16q24.3 (Reddy et al.1999, Oncogene 18:5100-5107). Six yeast artificial clones corresponding to candidate locus were identified and tested for functional complementation of immortal phenotype by introducing into mammary tumor cells. These studies led to the identification of a 360 kb YAC (Reddy et al. 2000, Oncogene 19:217-222) In order to construct a high-resolution map of the candidate region carrying the senescence gene, a human BAC library was screened with DNA markers to obtain relevant BAC clones, which were assembled in a contig based upon PCR analysis. Some selected BAC clones were retrofitted with a selectable marker and introduced into human and rat mammary tumor cells for functional complementation. These results identified a 85 kb BAC clone that carries the senescence gene. In following experiments, we isolated expressed sequences from the complementing BAC clone by exon trapping. Twelve exons were identified and their sequence comparison with databases has identified few partial cDNA clones. Experiments are in progress to determine the expression of these clones in tumor cell lines. In conclusion, we have mapped a senescence gene to a 85kb genomic clone and identified expressed sequences from this clone.

**Construction of a BAC contig across the *NRC-1* region of chromosomal band 3p12.** *J.M. McDonald<sup>1</sup>, S.T. Lott<sup>1</sup>, M. Lovell<sup>1</sup>, S. Naylor<sup>2</sup>, A.M. Killary<sup>1</sup>.* 1) Experimental Lab. Medicine, Unit Texas MD Anderson CA Ctr, Houston, TX; 2) Dept. of Cellular and Structural Biology, University of Texas Health Science Center at San Antonio.

Renal cell carcinoma (RCC) is the most common adult kidney neoplasm, and has a 5-year survival rate of less than 50%. Aberrations of chromosome 3 are found in more than 80% of RCC patients, and there is evidence for four different regions of 3p that could contain tumor suppressor genes. Evidence for one of these regions includes functional studies involving the introduction of 3p centric fragments into a RCC line SN12C.19. Subcutaneous injection of SN12C.19 into athymic nude mice resulted in the formation of tumors. Similar injections of microcell hybrids that retained the subchromosomal region of 3p14-q11 caused suppression of tumor growth, based on the comparison of average tumor volume of the microcell hybrids (350-600mm<sup>3</sup>) to that observed from injection of the SN12C.19 parent cell line (900mm<sup>3</sup>). In contrast, other microcell hybrids that retained 3p12-q24 failed to suppress tumor growth. These experiments identified the region 3p14-p12 to contain the tumor suppressor locus nonpapillary renal carcinoma (*NRC-1*). Microsatellite analysis of the microcell hybrids and refinement of the physical map for chromosome 3 placed *NRC-1* within chromosomal band 3p12.

One of the major objectives of this project is to identify candidate loci for *NRC-1*. Sequencing of 3p12 is underway as part of the Human Genome Project, and BAC contigs for 3p12 are available. In order to construct a BAC contig that spans the region of *NRC-1*, a primary hybridization screen of the RPCI-11 BAC clone library was performed by using 12 markers from the *NRC-1* region. BAC contigs generated by this approach in combination with BAC contigs available through Washington University's fingerprint database will establish a minimal tiling path contig across the *NRC-1* critical region. BACs will be mapped by FISH onto the suppressed and unsuppressed hybrid clones as well as transfected into SN12C.19 using a functional genomic approach to identify candidates for *NRC-1*.

**Screening of 20q13 Candidate Genes in Familial Prostate Cancer.** *L. Wang<sup>1</sup>, R.S. Berry<sup>1</sup>, J.M. Cunningham<sup>1</sup>, D.J. Schaid<sup>2</sup>, S.N. Thibodeau<sup>1</sup>.* 1) Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic, Rochester, MN.

Prostate cancer (PC) is one of the most human cancers, occurring in as many as 15% of men in the United States. Recent studies suggest that hereditary PC is a complex disease, involving multiple susceptibility genes and variable phenotypic expression. Previously, four presumed PC susceptibility loci (HPC1, PCAP, CAPB, HPCX) have been identified through linkage studies. While conducting a genome-wide search on 162 North American families with 33 members affected with PC, we found evidence for linkage to chromosome 20q13 with the largest 2-point LOD score of 2.8 for marker D20S196. The maximum multiple NPL score was 3.02 at D20S887. In an effort to clone PC susceptibility genes in this region, we constructed a physical and transcript map around this region covering 25.8cM from D20S119 to D20S149 with D20S196 in the middle. This map includes more than 104 BAC/PAC clones, 47 known genes, 17 genes for hypothetical proteins and 156 unigenes or ESTs. Based on their function and location on this map, we have selectively screened 13 known genes using conformation-sensitive gel electrophoresis (CSGE) in 60 patients from 30 families with the highest NPL score. These genes include STK15, UBE2V1, PD1, SNAI1, KIAA0784, KIAA0978, MOCS3, KIAA0939, DPM1, AIB1, KCNB1 and EYA2. No truncation type mutation (nonsense, frameshift, splice) was identified. However, numerous single nucleotide polymorphisms were identified in coding region of these genes. Specifically, the frequency of two polymorphisms in the STK15 gene tend to be different among familial PC, sporadic PC and normal controls. Currently, we are analyzing additional PC families to determine whether these polymorphisms contribute to familial prostate cancer. Additionally, we are continuing to screen other candidate genes in this region.

**A prospective study on risk factors for hereditary breast cancer in a hospital-based series of breast cancer patients.** *M.G.E.M. Ausems<sup>1</sup>, R.B. van der Luijt<sup>1</sup>, V.C.M Koot<sup>2</sup>, C.J.M. van der Sijs-Bos<sup>1</sup>, H.F.A. Vasen<sup>3</sup>, R.P. van Helvoirt<sup>4</sup>, C.C. Warlam-Rodenhuis<sup>4</sup>.* 1) Dept Medical Genetics, Univ Medical Ctr Utrecht, Utrecht, Netherlands; 2) Comprehensive Cancer Ctr Utrecht, Netherlands; 3) Dept of Internal Medicine, Univ Medical Ctr Utrecht, Utrecht, Netherlands; 4) Dept of Radiotherapy, Univ Medical Ctr Utrecht, Utrecht, Netherlands.

To determine the prevalence of presumed risk factors for hereditary breast cancer, we performed a prospective study in 1000 breast cancer patients, and offered genetic counselling and mutation analysis of the BRCA1 and BRCA2 genes to a sub-group of patients. All patients had primary invasive breast cancer and received adjuvant radiotherapy between 1997 and 1999. For patient selection a check list with 8 risk factors was used. If patients had one or more risk factors, a pedigree was composed. Patients fulfilling the criteria for referral to the Family Cancer Clinic (FCC), were offered genetic counselling and DNA analysis. Selected regions of the BRCA1 and BRCA2 gene were analyzed. Risk factors for hereditary breast cancer were present in 515 of 1,000 patients. Less than half of the patients at risk for hereditary breast cancer were interested in genetic counselling. In total, 188 of 237 selected patients agreed with referral to the FCC. 164 patients (87%) came from families with breast cancer only; 18 (10%) from families with breast and ovarian cancer and 6 (3%) came from families with breast and ovarian cancer in one patient. Mutation analysis will be performed in 124 patients. To date, 6 BRCA1 mutations and 1 BRCA2 mutation have been identified in 105 tested patients. The frequency of mutations is low (7%) compared with breast cancer patients referred outside this study. The potential benefit of clinical genetics is not fully utilized as most of the patients would not have been referred outside this study.

**The Needs of Male *BRCA1* and *BRCA2* Mutation Carriers.** *D.E. Hanna<sup>1</sup>, A. Liede<sup>1</sup>, K. Metcalfe<sup>1</sup>, E. Hoodfar<sup>1</sup>, C. Snyder<sup>2</sup>, C. Durham<sup>2</sup>, H. Lynch<sup>2</sup>, S.A. Narod<sup>1</sup>.* 1) Women's College Hospital, Toronto, Canada; 2) Department of Preventive Medicine and Public Health, Creighton University, 2500 California Plaza, Omaha, NE.

The concerns of men at risk of inheriting a *BRCA1* or *BRCA2* mutation have received little attention. It was assumed that few men would be interested in predictive testing. However, men are likely to be affected emotionally by their female relatives diagnoses and they may harbor fears of developing cancer. Male *BRCA* carriers are at significantly increased risk of developing several cancers, including prostate, pancreatic and breast cancer. In addition, *BRCA2* carriers are at increased risk of gall bladder, bile duct cancer and cutaneous malignant melanoma. We have surveyed 57 of 67 eligible male *BRCA1* or *BRCA2* carriers from the University of Toronto and Creighton University. The men were asked about their motivations for seeking testing, involvement in family discussions of breast and ovarian cancer, change in cancer screening practices and overall satisfaction with the genetic counseling process. A range of emotions were reported in response to receiving a positive test result, including concerns for self (4%) and children/daughters (19%), feelings of sadness and fear (14%) and acceptance and relief (38%). Over half the subjects (53%) stated that the primary motivation for seeking genetic testing was for their children or family. The majority (88%) were included in past family discussions of breast and ovarian cancer risk but a smaller proportion (46%) was involved in family conversations about prophylactic surgery. Twelve percent stated that their family relationships were strengthened by this information, with an increased appreciation for their female relatives' experience. Almost one-third of respondents indicated that they would be interested in taking part in an information/support group. Over half of the men (56%) indicated that they thought about their risk of developing cancer (29% of these regularly or daily). Half of the men stated that their cancer screening practices had changed as a result of learning their carrier status, two-thirds having regular PSA for prostate cancer surveillance. Overall, high levels of satisfaction with genetic counseling were reported.

**Over-representation of a germline variant in *GFRA1*, encoding a RET co-receptor, but not *GFRA2* and *GFRA3* in patients with sporadic medullary thyroid carcinoma.** *O. Gimm*<sup>1</sup>, *H. Dziema*<sup>1</sup>, *J. Brown*<sup>1</sup>, *C. Hoang-Vu*<sup>2</sup>, *R.*

*Hinze*<sup>3</sup>, *L. Mulligan*<sup>4</sup>, *H. Dralle*<sup>2</sup>, *C. Eng*<sup>1</sup>. 1) Human Cancer Genetics Program, The Ohio State University, Columbus, OH, USA; 2) Dept. of General Surgery, Martin-Luther-University, Halle, Germany; 3) Institute of Pathology, Martin-Luther-University, Halle, Germany; 4) Dept. of Pathology and Paediatrics, Queens University, Kingston, ON, Canada.

In contrast to hereditary MTC, little is known about the etiology of sporadic MTC. Somatic gain-of-function mutations of RET are found in an average of 40%. Mutation analysis of GDNF, encoding one of the ligands of RET, has not revealed any mutations. We analyzed 31 sporadic MTC for somatic and germline variants in *GFRA1*, *2*, and *3*, encoding RET co-receptors. Although there were no somatic mutations in all three genes, a rare polymorphic sequence variant (193C>G) in the 5-UTR of *GFRA1* was found in 15% of MTC alleles. Three patients were heterozygous (het), another 3 homozygous (hom) for the G variant. We did not find this variant in any of 62 alleles from a region-matched control group ( $p < 0.05$ ). Since this variant lies within a CpG-rich region, we analyzed this region for methylation. We found various degrees of methylation in germline and tumor DNA. Interestingly, methylation in tumor DNA was higher than in the corresponding peripheral leucocyte DNA ( $p < 0.01$ ). No association between methylation status and expression of *GFRA1* at the transcript level could be identified. However, tumors harboring the rare G variant seemed to have higher expression of *GFRA1* transcript ( $p = 0.065$ ). Immunostaining for GFRA1 was suggestive of overall stronger cytoplasmic staining intensity in het patients and stronger nuclear staining intensity in hom patients as compared to tumors from patients without the rare G variant. In conclusion, mutation analysis of *GFRA1*, *2*, and *3* revealed over-representation of a rare germline sequence variant in *GFRA1*, which showed a trend towards association with differential expression levels and patterns at both transcript and protein levels. Whether this or other mechanisms contribute towards low penetrance susceptibility remains to be fully worked out.

**Somatic and occult germline mutations in *SDHD*, a mitochondrial complex II gene, in apparently sporadic pheochromocytoma.** *M. Armanios*<sup>1</sup>, *O. Gimm*<sup>1</sup>, *H. Dziema*<sup>1</sup>, *H.P.H. Neumann*<sup>2</sup>, *C. Eng*<sup>1</sup>. 1) Human Cancer Genetics Program, Ohio State Univ, Columbus, OH; 2) Dept. of Medicine, Albert-Ludwigs-University, Freiburg, Germany.

Most pheochromocytomas, also known as adrenal paragangliomas, are sporadic but about 10% are associated with inherited syndromes. While the etiology of most familial pheochromocytomas is well known, little is known about the genetic basis of the more common sporadic type. Recently, germline mutations of *SDHD* were found in patients with hereditary paragangliomas, most often found in the carotid body. We therefore sought to determine the role of *SDHD* in the development of sporadic pheochromocytomas. We analyzed the coding sequence of *SDHD* as well as flanking markers (D11S1347, D11S1986) for LOH. Among 18 samples, we identified four heterozygous sequence variants (3 germline, 1 somatic). One germline mutation, IVS1+2T>G (absent among 78 control alleles), is predicted to cause aberrant splicing and is likely of functional significance. In addition, this patient had recently been diagnosed with a tumor of the carotid body, a probable paraganglioma. The second germline mutation (c.112C>T) was found in a patient with extra-adrenal pheochromocytoma, resulting in a nonsense alteration (R38X) which predicts a likely dysfunctional peptide. Another patient with malignant, extra-adrenal pheochromocytoma was found to have germline missense mutation c.34G>A (G12S). However, this sequence variant was also found in 1 of 78 control alleles. The only somatic mutation, c.242C>T (P81L), was found resulting in a change of a highly conserved proline residue among four eukaryotic multicellular organisms. This mutation is identical to germline mutations described in two families with hereditary paraganglioma. Overall, LOH in at least one of the two markers was found in 13 tumors (72%). All tumors already harboring intragenic *SDHD* mutations also showed LOH. Our results indicate that *SDHD* plays a role in the pathogenesis of pheochromocytoma. Given the 17% germline mutation frequency in this set of apparently sporadic pheochromocytoma cases, our observations might suggest that all such patients should be routinely subjected to *SDHD* mutation analysis.

**Knockout of the Mouse Men1 Gene Gives a Lethal Phenotype in the Heterozygous Chimera.** *J.S. Crabtree<sup>1</sup>, P.C. Scacheri<sup>1</sup>, E.A. Novotny<sup>1</sup>, L. Garrett-Beal<sup>1</sup>, A. Chen<sup>1</sup>, K.A. Edgemon<sup>2</sup>, S.J. Marx<sup>2</sup>, A.M. Spiegel<sup>2</sup>, S.C. Chandrasekharappa<sup>1</sup>, F.S. Collins<sup>1</sup>.* 1) NHGRI/NIH, Bethesda, MD; 2) NIDDK/NIH, Bethesda MD.

Multiple Endocrine Neoplasia, type 1 (MEN1) is an autosomal dominant familial disorder characterized by tumors of the parathyroid, gastrointestinal endocrine tissues and the anterior pituitary. Germline, heterozygous loss-of-function mutation followed by somatic loss of the normal allele leads to tumor formation in subjects with MEN1. This suggests that the MEN1 gene is a tumor suppressor, but the specific function of the nuclear protein, menin, encoded by the gene is unknown. To elucidate the function of menin, a conventional mouse knockout model was developed. To our surprise, the Men1 conventional knock out was lethal in heterozygous, chimeric animals. Removal of embryos revealed late gestational lethality, due to omphalocele, in what appeared to be a dose dependent manner based on the degree of chimerism. Southern analysis of embryo DNA indicated the homologous recombination was specific and did not affect the primary structure of neighboring genes. Northern analysis of conventionally targeted embryonic stem cell RNA revealed the presence of an abundant, novel transcript of 2.1kb. Wildtype transcripts are 2.7kb and 3.1kb, and the small size of this aberrant transcript suggests bidirectional activity from the PGK promoter (used to drive neomycin for ES cell selection) in the antisense orientation. RT-PCR data supports this postulated bidirectional activity of the PGK promoter. While as yet we have not been able to detect an aberrant protein on Western blots from targeted ES cells, we hypothesize that the PGK-driven transcript is producing a dominant negative effect through the production of an amino-terminal truncated protein product.

**Identification of Human Papillomavirus DNA sequences in paraffin-embedded Retinoblastoma tissue. H.**

*Montoya-Fuentes<sup>1</sup>, M.P. Ramirez-Munoz<sup>1</sup>, J.M. Ornelas-Aguirre<sup>2</sup>, M.C. Moran-Moguel<sup>1</sup>, M.P. Gallegos-Arreola<sup>1</sup>, G. Vazquez-Camacho<sup>2</sup>, B. Ibarra<sup>3</sup>, J.M. Cantu<sup>3</sup>, J. Sanchez-Corona<sup>1</sup>.* 1) Division de Medicina Molecular, C.I.B.O., I.M.S.S., Guadalajara, Jalisco, Mexico; 2) Departamento de Anatomia Patologica, Hospital de Especialidades, I.M.S.S., Guadalajara, Jalisco, Mexico; 3) Division de Genetica, C.I.B.O., I.M.S.S. Guadalajara, Jalisco, Mexico.

Retinoblastoma is the most frequent intraocular tumor in children and the main cause of enucleation. The etiology is diverse and includes mitotic nondisjunction and duplication of the mutated gene or loss of the wild-type chromosome, mitotic recombination between the RB1 locus and the centromere or punctual mutations. Although there are no antecedents of Human Papillomavirus (HPV) infection and Retinoblastoma, there are data about the transmission of HPV DNA from the sperm cells to the embryo, which can possibly dysregulate the retinal cells, causing Retinoblastoma. The purpose of this study was to investigate the presence of the HPV DNA in paraffin-embedded Retinoblastoma tissue. 56 samples in a period of time of 10 years (1987-1997) were obtained. The analysis by means of Polymerase Chain Reaction with consensus primers showed 44 positive samples (78.5%) and 12 negative (21.5%). We also tested specific amplification of HPV 16 and 18 in the positive samples, resulting negative for both. Our results suggest that the HPV could be involved in some cases of Retinoblastoma. Further studies remain in order to establish the types of HPV involved in this tissue sample preliminary survey (possibly low or medium-risk HPVs, because of the absence of High-risk HPV) as well as to define the role of HPV in the etiology of Retinoblastoma.

**An interaction of alcohol intake and family history on breast cancer risk?** *C.M. Vachon, J.R. Cerhan, R.A. Vierkant, T.M. Therneau, T.A. Sellers.* Health Sciences Research and Mayo Clinic Cancer Center, Mayo Foundation, Rochester, MN.

There is significant heterogeneity in studies of alcohol consumption and breast cancer. One explanation for the variability in results could be the presence of effect modifiers, such as a family history of cancer. We examined the association of alcohol and breast cancer risk within a cohort of 426 multigenerational families who were ascertained through a breast cancer proband at the University of Minnesota Hospital and Clinic between 1944 and 1952. We evaluated whether alcohol use among sisters, daughters, nieces and granddaughters of breast cancer probands was a stronger risk factor than among women who married into these families. Lifetime frequency of usual alcohol intake (daily, weekly, < weekly, never drinker), breast cancer risk factors, and medical history information were collected through a telephone interview between 1991 and 1995 with either a living individual or a surrogate. Relative risks (RR) and 95% confidence intervals were estimated through Cox proportional hazards models using each woman's age as her own timescale for the baseline risk. Analyses were adjusted for smoking status, birth cohort and type of information (surrogate or self-report). A total of 9032 blood relatives and marry-ins with 558 cases of breast cancer were available for analysis. In the entire 426 families, there was a suggestion of an interaction of relationship to the proband and frequency of alcohol consumption on breast cancer risk ( $p_{\text{intx}}=0.14$ ). Among first- and second-degree relatives of the proband, daily drinkers had an increased risk of breast cancer compared to never drinkers (RR for daily vs. never drinkers among 1st degree relatives=2.45(1.20,5.02); RR for 2nd degree=1.27(0.73,2.20)), but this increase was not evident in marry-ins reporting daily use of alcohol (RR=0.90 (0.42,1.90)). The findings based on the subset of 132 high-risk families with 3 or more breast and/or ovarian cancers were similar to analyses based on all 426 families ( $p_{\text{intx}}=0.07$ ). Thus, alcohol associated risks of breast cancer may be increased among women with a family history.

**Evidence for a morphological continuum in inherited breast cancer: Implications for genetic testing.** *M.J.*

*Worsham<sup>1</sup>, U. Raju<sup>1</sup>, C. Young<sup>1</sup>, R. Nanavati<sup>1</sup>, H. Mao<sup>1</sup>, S.R. Wolman<sup>2</sup>, G. Pals<sup>3</sup>.* 1) Dept Pathology, Henry Ford Hosp, Detroit, MI; 2) Uniformed Services University of the Health Sciences, Bethesda, MD; 3) University Hospital Vrije Universiteit, Amsterdam, The Netherlands.

In testing for hereditary breast cancer susceptibility, only women with invasive breast or ovarian cancer are presumed to be gene carriers. Currently, neither in-situ breast cancer nor atypical hyperplasias are considered as clinical evidence of breast-ovarian syndrome, nor are these diagnoses used to predict carrier status within at-risk families. This reflects lack of evidence that breast cancer develops along a recognized morphological continuum from precursor lesions. We analyzed malignant breast cancer tissue and potentially preneoplastic lesions (PPL) from three individuals bearing BRCA1 mutations for p53 mutations. We used immunohistochemistry for p53 protein, followed by mutational analysis of exons 2-11 of the p53 gene using the Affymetrix p53 gene chip assay. In addition to normal and malignant breast tissue from the three patients, the PPL included hyperplasia and papilloma in a 2178 C->T BRCA1 mutant (case 1); papilloma in a 3519 G->T BRCA1 mutant (case 2); and hyperplasia and apocrine metaplasia in a 4154 delA BRCA1 mutant (case 3). Breast tumors from all three cases had unique disease-associated exon 6 p53 mutations. In case 1, the p53 mutation observed in the tumor was also present in the papilloma but not in the hyperplasia; in case 2, the papilloma and the tumor had the same mutation; and in case 3, areas of apocrine metaplasia from two separate tissue blocks (one adjacent to tumor, and one without tumor) showed the same p53 mutation as that in the tumor. These results indicate that p53 mutations occur early in the evolution from proliferative breast lesions to malignancy, and that clonal molecular alterations provide evidence for an evolutionary continuum of those tissue changes in BRCA1 mutation-bearing women. We suggest that in high-risk families without a previously identified BRCA1 mutation and lacking available affected family members with breast or ovarian cancer, women with proliferative breast lesions may qualify as candidates for carrier testing.*BRCA1*.

**Risk of other cancers among French Canadians family members of BRCA1 and BRCA2 gene carriers. P.**

*Ghadirian<sup>1</sup>, S. Narod<sup>2</sup>, J.S. Brunet<sup>2</sup>, C. Perret<sup>1</sup>, W. Foulkes<sup>3</sup>, P. Tonin<sup>3</sup>.* 1) Epid Res Unit, Res Ctr, HDM, Univ Montreal Fac Medicine, Montreal, PQ., Canada; 2) Breast Cancer Research, Women's College Hospital, Toronto, ON., Canada; 3) Department of Medecine & Human Genetics, McGill University, Montreal, PQ., Canada.

Several studies have suggested an increased risk of some cancer sites, other than breast and ovarian among the blood relatives of BRCA1 and BRCA2 gene carriers. We have carried out a preliminary analysis of 41 mutation positive French Canadian families (including 1001 first degree relatives and 220 probands) in Quebec, Canada and found an excess of cancers other than breast and ovarian such as: [any cancer: SMR=1.23; 95% CI (1.01-1.49); P=0.046 for male and SMR=1.74; 95% CI (1.32-2.25); P=0.00013 for female] prostate cancer with a SMR of 1.61; 95% CI (1.01-2.45); P=0.045; colorectal cancer SMR = 1.92; 95% CI (1.14-3.04)., P=0.016 in males and SMR=2.58; 95% CI (1.50-4.12), P=0.011 in females. The SMR for thyroid cancer in male relatives was 9.98 with a 95% CI of (2.72-25.57), P=0.002. We also observed significantly higher risk of cervical cancer among female relatives of gene carriers, SMR=3.43, 95% CI (1.11-8.01), P=0.03. Lymphoma-Hodgkins disease was also higher among gene female relatives of gene carriers, indicating a SMR=5.35; 95% CI (1.46-13.70), P=0.016. The preliminary results of our study suggests, higher frequency of certain types of cancer (other than breast and ovarian) among BRCA1 and BRCA2 gene carriers.

**Linkage analysis of 173 prostate cancer families using markers that span the region of 20q containing the novel prostate cancer susceptibility locus HPC20.** *C.H. Bock<sup>1</sup>, J.M. Cunningham<sup>2</sup>, S.K. McDonnell<sup>2</sup>, E.M. Lange<sup>1</sup>, D.J. Schaid<sup>2</sup>, B.J. Peterson<sup>2</sup>, K. Brierley<sup>1</sup>, R. Pavlic<sup>1</sup>, J. Schroeder<sup>2</sup>, J. Klein<sup>2</sup>, A. French<sup>2</sup>, A. Marks<sup>2</sup>, S.N. Thibodeau<sup>2</sup>, K.A. Cooney<sup>1</sup>.* 1) Departments of Epidemiology, Biostatistics, Internal Medicine and Surgery, University of Michigan, Ann Arbor, MI; 2) Departments of Laboratory Medicine and Pathology and Health Sciences Research, Mayo Clinic/Foundation, Rochester, MN.

Four prostate cancer predisposition genes have been identified through family-based linkage approaches: HPC1, PCAP, CAPB and HPCX. A recent linkage study of 162 Caucasian prostate cancer families described evidence for a previously unreported prostate cancer predisposition gene termed HPC20 on 20q13. To confirm the potential contribution of this locus to prostate cancer susceptibility, we studied 173 unrelated prostate cancer families participating in the University of Michigan Prostate Cancer Genetics Project. These families have at least three prostate cancer diagnosed members or two prostate cancer diagnosed members under age 55 years. 582 DNA samples were genotyped using a panel of 17 polymorphic markers spanning 98.5 cM and containing the HPC20 candidate region. Data were analyzed using both model-free (NPL) and parametric linkage methods with GENEHUNTER. Analysis of all 173 families resulted in a maximal NPL Z-score of 0.63 with a corresponding one-sided p-value of 0.26 at marker D20S171. Stratification analysis revealed increased evidence for linkage in the subset of 18 families without male-to-male transmission, <5 affected members, and age at onset > 66 years (NPL Z-score of 1.27, p-value 0.11 at marker D20S889). In the original report by Berry et al. (*Am J Hum Genet.* vol. 67, p.82-91, 2000) the strongest evidence for linkage occurred in an identically defined subset. Highest evidence for linkage in our study was seen in the subset of 17 African-American families (NPL Z-score of 1.95, p-value 0.03, at marker D20S893). Overall, our linkage study provides support for the existence of a prostate cancer susceptibility gene at 20q13, although genetic complexity will likely require further confirmation, perhaps by a meta-analysis.

**Genome-wide scan of high-risk prostate cancer families with breast cancer reveals novel prostate-breast loci.** *J.L. Stanford*<sup>1</sup>, *M.D. Badzioch*<sup>2</sup>, *S. Kolb*<sup>1</sup>, *M. Peters*<sup>1</sup>, *M. Janer*<sup>3</sup>, *E.L. Goode*<sup>2</sup>, *M. Gibbs*<sup>1</sup>, *L. Hood*<sup>3</sup>, *E.A. Ostrander*<sup>1</sup>, *G.P. Jarvik*<sup>2</sup>. 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) University of Washington, Seattle, WA; 3) Institute for Systems Biology, Seattle, WA.

Hereditary prostate cancer (PC) is a complex disease that may be associated with other cancers in some families. Epidemiological and genetic studies have reported familial clustering of prostate and breast cancers. As part of a genome search for prostate cancer genes, we performed linkage analyses in 27 families with 3 or more affected men with PC who had at least 1 first-degree relative with breast cancer (BC). To maximize homogeneity, these families were stratified by the pattern of BC (1 case, n=14 families; <sup>3</sup> 2 cases, n=6; any ovarian cancer, n=7). Families were stratified into early (<66 yrs.) or later (<sup>3</sup>66 yrs.) onset PC based on median age at diagnosis. GENEHUNTER was used to compute multipoint NPL scores for PC linkage using 380 genomic scan markers. Stratified analyses revealed 3 chromosomal regions with NPL scores <sup>3</sup> 3.0: 1) chr. 7q, NPL=3.98 (p=0.002) for markers D7S1826 through D7S1805 in later-onset PC families with BC and ovarian cancer; 2) chr. 12q, NPL=3.00 (p=0.010) at marker D12S392 in all families with more than one relative with BC; and 3) chr. 14q, NPL=3.09 (p=0.006) at marker D14S306 in early-onset PC families with one first-degree relative with BC. None of these groups had significant evidence of linkage of PC to chr. 13 or chr. 17. These data provide evidence for loci on chromosomes 7q, 12q, and 14q that may be involved in both prostate cancer and breast cancer susceptibility.

**Genes within the common fragile sites are down-regulated in ovarian cancer.** *M.J Ferber<sup>1</sup>, S.R. Denison<sup>2</sup>, N.A. Becker<sup>2</sup>, J. Lee<sup>3</sup>, J. Lillie<sup>3</sup>, L.C. Hartmann<sup>4</sup>, V. Shridhar<sup>2</sup>, D.I Smith<sup>2</sup>.* 1) Biochemistry/Molecular Biology, Mayo Foundation, Rochester, MN; 2) Division of Experimental Pathology, Mayo Foundation, Rochester, MN; 3) Millenium Predictive Medicine, Cambridge, MA; 4) Division of Oncology, Mayo Foundation, Rochester, MN.

We have been using transcriptional profiling to analyze gene expression in primary ovarian tumors. Using a 25,000 gene microarray filter from Millenium Predictive Medicine, we analyzed 15 primary ovarian tumors to identify genes that were aberrantly regulated relative to uncultured ovarian epithelial cells. Many genes were found to be consistently aberrantly regulated in the ovarian tumors. An analysis of genes that were down-regulated at least 5 fold in most of the ovarian tumors profiled revealed that many of these genes were derived from chromosomal bands known to contain common fragile sites. We chose ten genes down-regulated in the ovarian tumors that were derived from chromosomal bands known to contain common fragile sites and first confirmed their expression using RT-PCR and Northern Blot analysis. To determine if the verified genes were actually derived from within a common fragile site, we isolated bacterial artificial chromosomes (BACs) spanning these genes and used these as probes for FISH analysis with aphidicolin-induced metaphase chromosomes. BAC clones spanning 6 of the 10 genes analyzed were found to span previously uncloned common fragile sites. We have fully characterized three of these new common fragile sites and determined their size and the position of the down-regulated gene relative to aphidicolin-induced breakage in these regions. We are currently analyzing an additional 10 genes to determine if they also reside on common fragile sites. This has therefore proven to be a powerful technique to quickly localize previously uncloned common fragile sites. A more important question is whether or not many of the genes residing within common fragile sites are inactivated during the development of ovarian, and possibly other, cancers.

**High-throughput gene copy number analysis in 4700 tumors: FISH analysis on tissue microarrays identifies multiple tumor types with amplification of the MB-17A gene, a novel amplified gene originally found in breast cancer.** C.L. Andersen<sup>1, 2</sup>, O.M. Monni<sup>1</sup>, J. Kononen<sup>1</sup>, M. Barlund<sup>3</sup>, C. Bucher<sup>4</sup>, P. Hass<sup>4</sup>, A. Nocicito<sup>4</sup>, H. Bissig<sup>4</sup>, G. Sauter<sup>4</sup>, O-P. Kallioniemi<sup>1</sup>, A. Kallioniemi<sup>1</sup>. 1) Cancer genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Danish Cancer Society, Århus, Denmark; 3) Institute of Medical Technology, University of Tampere and Tampere University Hospital, Finland; 4) Institute of Pathology, University of Basel, Switzerland.

We recently developed a novel technique for high density arraying of hundreds of 0.6 mm diameter tissue cylinders (Kononen et al, Nat Med 4: 844, 1998). Consecutive sections cut from such a tissue microarray (TMA) on a microscope slide provide a template for a high-throughput analysis of multiple DNA, RNA and protein targets in each of the hundreds of tissue specimens on the array. Here we constructed a set of TMAs for high throughput analysis of interesting genes in specimens from many different tumor types. Four thousand seven hundred tumor specimens, representing 135 different tumor types were arrayed into ten TMA blocks. Sections from these blocks provide a template for a systematic screening of most malignant tumor types. The MB-17A gene was recently identified by cDNA microarray experiments to be amplified, overexpressed and rearranged in breast cancer (see ASHG abstracts Monni et al. and Kallioniemi et al. 2000). In order to study the importance of this gene in cancer development, across all tumor types, we performed FISH with a MB-17A gene probe on the multi-tumor TMA. As expected, we found high-level amplification of MB-17A most often in breast cancer, with a frequency of 13/129 (10%). Other tumor types with MB-17A amplification included cancers of the endometrium, ovary, thyroid, parathyroid, urinary bladder and squamous cell carcinoma of the skin and melanoma. In summary, our results indicate that MB-17A maybe involved in the development of multiple different tumor types. High-throughput tissue microarray technology allows screening of thousands of tumors at a time and thereby facilitates rapid translation of gene discoveries to clinical and diagnostic applications.

**A search for germline APC mutations in early onset colorectal cancer or familial colorectal cancer with normal DNA mismatch repair APC.** *L.A. Boardman<sup>1</sup>, S. Schmidt<sup>3</sup>, N.M. Lindor<sup>2</sup>, L.J. Burgart<sup>3</sup>, J.M. Cunningham<sup>3</sup>, T.L. Price-Troska<sup>3</sup>, K. Snow<sup>3</sup>, D.A. Ahlquist<sup>1</sup>, S.N. Thibodeau<sup>3</sup>.* 1) Department of Internal Medicine, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN 55905; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic Rochester, MN 55905.

Twenty percent of colorectal cancers (CRC) arise in people who have a family history of CRC in at least one other relative. Though a fraction of these are explained by two well-described autosomal dominant syndromes-5% by hereditary nonpolyposis colorectal cancer (HNPCC) and 1% by familial adenomatous polyposis (FAP), the cause of the remaining 14% of familial aggregates of CRC is unknown. Many cases of HNPCC are due to germline mutations in DNA mismatch repair genes, leading to the tumor phenotype of microsatellite instability (MSI), and most cases of FAP are caused by germline APC mutations. To date, non-FAP familial CRC aggregates have not been evaluated for germline APC mutations. In this study, we examined the involvement of germline APC mutations in 79 individuals with CRC who had either early age onset of their cancer (age <50 years) and/or a family history of CRC. Cases with FAP or HNPCC due to defective mismatch repair were excluded from the study. Using conformation sensitive gel electrophoresis (CSGE) and the protein truncation test (PTT) as the screening methods, functionally significant germline mutations were not detected for any of the cases. An apparently silent polymorphism resulting in a one base pair alteration of A>G (Proline> Proline) in exon 4 was observed. Additionally, four intervening sequence (IVS) alterations were detected: 1) IVS2 (-53) t>c in 3 cases; 2) IVS4 in 3 cases (-17) ins T; 3) IVS5 (+32) t>c in 16 cases and 4) and IVS 5(+33) g>a in 1 case. All appeared to be polymorphisms present in similar proportions in an average risk population. We conclude that germline APC mutations do not account for familial MSS CRC associated with few synchronous polyps.

**Imbalance in wild-type hMSH2:hMLH1 protein ratio in lymphocytes identifies colorectal cancer (CRC) patients with hereditary nonpolyposis colon cancer (HNPCC) traits.** Z.P. Gao<sup>1</sup>, Z.Q. Gao<sup>1</sup>, S. Burkholder<sup>1</sup>, T. Zhang<sup>1</sup>, J.Z. Fields<sup>2</sup>, A. Kairo<sup>1</sup>, S. Ehrlich<sup>1</sup>, B.M. Boman<sup>1</sup>. 1) Medical Genetics, thomas jefferson university, philadelphia, PA; 2) CA\*TX Inc., Gladwyne, Philadelphia, PA 19035.

Identifying carriers of HNPCC traits can save lives and health care dollars. However, current genetics tests for HNPCC is costly and time consuming. Therefore, the need is to develop a more feasible assay to detect a germline HNPCC-causing mutation, particularly one that is sensitive, rapid, easy & inexpensive. Our approach to the problem of detecting HNPCC was to develop a quantitative immunoassay for wild-type DNA mismatch repair (MMR) protein levels (hMSH2 and hMLH1). Mutations in hMSH2 and hMLH1 account for the vast majority (>90%) of detectable germline mutations in HNPCC kindreds. And most (>70%) germline hMSH2 and hMLH1 mutations lead to a truncated protein product. We hypothesized that cells carrying a germline, truncation-causing, hMSH2 or hMLH1 mutation will have a 50% reduction in the corresponding full-length protein product. To test proof of principle for our assay, we used western blot analysis to estimate hMSH2 and hMLH1 protein levels in lymphoblastoid cell (WBC) lines from CRC patients. We tested 42 WBC lines established from CRC patients in our Familial Colorectal Cancer Registry and 8 WBC lines from healthy, unaffected individuals. Western blots were done using antibodies against the carboxyl end of both hMSH2 and hMLH1 proteins. All of the samples from healthy unaffected individuals had, on western blots, a) clearly identifiable bands for hMSH2 and for hMLH1 and b) nearly identical hMSH2/hMLH1 ratios. In 7 of the 42 WBC lines from CRC patients, we found decreased expression of hMSH2 or hMLH1 on western blot analysis and all 7 of these, subsequently, showed evidence of a mutation in corresponding MMR gene. Moreover, where DNA was available from fresh lymphocytes(5 of the 7), we found evidence for the mutation. Together these data demonstrate i) that our assay can be used to identify individuals with the HNPCC trait and ii) that this can be done practically and inexpensively.

**Identification and characterisation of the familial cylindromatosis gene.** *G.R. Bignell<sup>1</sup>, W. Warren<sup>2</sup>, S. Seal<sup>2</sup>, M. Takahashi<sup>2</sup>, E. Rapley<sup>2</sup>, R. Barfoot<sup>2</sup>, P. Biggs<sup>2</sup>, A. Ashworth<sup>2</sup>, M. Stratton<sup>2</sup>.* 1) Team 78, The Sanger Centre, Hinxton, Cambridgeshire, UK; 2) Cancer Genetics Section, Institute of Cancer Research, Sutton, Surrey, UK.

We report the cloning of the gene for Familial Cylindromatosis (*CYLD*). Familial Cylindromatosis is an autosomal dominant genetic predisposition to multiple tumours of the skin appendages. The susceptibility gene has previously been localised to chromosome 16q12-q13 and has the genetic attributes of a tumour suppressor gene/recessive oncogene. The critical evidence for involvement of the *CYLD* gene in familial cylindromatosis is the identification of 21 germline mutations. We have also identified six somatic mutations, five from familial cylindromas and one from a sporadic cylindroma. All of the germline and somatic mutation are predicted to cause early protein termination. The *CYLD* gene has also been screened through a bank of other tumours, however, no mutations were detected from this set. Analysis of the protein sequence reveals three regions with homology to Cytoskeletal Associated Protein-Glycine conserved (CAP-GLY) domains, found in proteins that co-ordinate the attachment of organelles to microtubules, and homology to the catalytic domain of Ubiquitin Carboxy-terminal Hydrolase type 2.

**Functional evidence for multiple tumor suppressor genes on the short arm of chromosome 8.** *G. Chenevix-Trench*<sup>1</sup>, *J. Arnold*<sup>1</sup>, *P. Wilson*<sup>1</sup>, *D. Trott*<sup>2</sup>, *A. Cuthbert*<sup>2</sup>, *R. Neubold*<sup>2</sup>. 1) Queensland Inst Medical Res, Brisbane, Australia; 2) Brunel University, Uxbridge, UK.

The short arm of chromosome 8 frequently undergoes loss of heterozygosity in many different solid tumors, and homozygous deletions have been reported in prostate and squamous cell carcinomas. We have previously provided functional evidence of a tumor suppressor gene on this chromosome by the transfer of chromosome 8 into colorectal cancer cell lines by microcell fusion. Spontaneous deletions of the donor chromosome allowed us to map the location of the putative tumor suppressor region to a 5.2 Mb region at 8p22-23. We have now transferred chromosome 8 into ovarian (HEY) and breast (21MT and T47-D) cancer cell lines. HEY/8 hybrids containing all of the donor chromosome 8 grew normally in vitro but showed significantly reduced tumor formation in athymic mice compared to those that only contained the long arm of the donor chromosome. Analysis of hybrids containing only part of the donated 8p have allowed us to map two regions of suppression at 8p12-21 and 8p23. We have also obtained 17 21MT/8 and 5 T47-D/8 hybrids. All of these hybrids share in common the exclusion of several regions on the short arm of the donor chromosome. This suggests that they might contain tumor suppressor genes that convey a strong selective disadvantage in vitro. These data suggest that there are several tumor suppressor genes on the short arm of chromosome 8 and efforts are underway to narrow down their location prior to gene identification.

**Towards identification of a senescence-associated gene / tumor suppressor gene (TSG) in the NRC-2 locus in human chromosome band 3p14.** *B. Opalka<sup>1</sup>, W. Bardenheuer<sup>1</sup>, G. Marquitan<sup>1</sup>, N. Werner<sup>1</sup>, K. Juelicher<sup>1</sup>, H. Topal<sup>1</sup>, I. Horikawa<sup>2</sup>, J.C. Barrett<sup>2</sup>, J. Schuette<sup>1</sup>.* 1) Innere Klinik (Tumorforschung), Universitaet (GH) Essen, Essen, NW, Germany; 2) NIEHS, Research Triangle Park.

Chromosomal alterations in human chromosome region 3p14 have been found in numerous tumor entities including lung cancer (LC) and renal cell carcinoma (RCC). Results of functional investigations as well as data concerning structural aberrations suggest the presence of at least one TSG in 3p14. The FHIT gene in 3p14.2 and the WNT5A gene in 3p14.3-21 have been shown to reveal TSG function in vitro and/or in animal models while mutations of these genes have been rarely detected in LC or RCC. We have previously established functional complementation assays using a YAC contig covering chromosomal band 3p14 and neighboring regions. Following retrofitting of YACs for the introduction of a mammalian selectable marker we established the YAC transfer by spheroplast fusion into a human RCC line showing a cytogenetically detectable deletion within 3p13-23. Using this approach we identified a 530 kb YAC clone within 3p14.2 which induced cellular senescence in vitro and reveals sustained suppression of tumorigenicity of transduced RCC cells in nude mice. This activity which maps differently from the FHIT gene and the WNT5A gene defines a novel TSG locus, NRC-2, in 3p14. Genomic sequencing was performed using PAC clones. Including data from the human genome project 60-80% of the entire YAC sequence are available now. Primers were synthesized corresponding to 6 ESTs and 15 predicted exon sequences as well as for 8 exon sequences identified in exon trapper experiments and are currently used to screen different cDNA libraries. These efforts should allow the isolation of the gene(s) responsible for the NRC-2 locus activity. Supported by Deutsche Forschungsgemeinschaft and foundation VerUm.

**Two deletions in regions 6q22-23 and 6q25-27 are associated with immortalization of SV40 transformed cells.** *J. Liu, A.K. Sandhu, N. Rane, R.S. Athwal.* Department Of Pathology, Fels institute, Temple University School of Med. Philadelphia, PA.

We have applied a 'Functional-Potential' approach to identify cell senescence genes on human chromosomes. Microcell mediated transfer of a gpt tagged intact human chromosome 6 or a part of the long arm(6q14-qter) restored senescence in human (Sandhu et al. 1994, PNAS 91: 5498-5502) and mouse SV40 immortalized fibroblasts. Segregation of the transferred chromosome 6, with the loss of gpt tag, led to the resumption of indefinite cell proliferation. While microcell hybrids were maintained in the MX selection medium, for the retention of the donor chromosome, immortal revertant clones arose among senescent cells. Reversion to immortal growth could result from the loss of the expression of the senescence gene due to a mutation or a deletion. Analysis of the revertant clones for the loss of the DNA markers, mapped in the region 6q22-qter, identified two deletions in the region 6q22-27. The results of this study revealed two independent deletions located at 6q22-23 and 6q25-27, suggesting the location of two senescence genes on the long arm of chromosome 6. In order to further define the position of the senescence gene(s), we have identified YAC and BAC clones corresponding to the deleted markers, by human genome data base search. A high resolution physical map of the region containing the senescence gene has been developed. Candidate BAC clones will be tested for the restoration of senescence by introduction into SV40 immortalized human and rodent cells.

**BRCA2 mutations in African Americans.** *Y.M. Kanaan<sup>1</sup>, E. Kpenu<sup>1</sup>, K. Utley<sup>1</sup>, L.C. Brody<sup>2</sup>, G.M. Dunston<sup>1</sup>, C. Whitfield-Broome<sup>1</sup>.* 1) Howard University College of Medicine, Departments Microbiol., Biochem.& Mol. Biol.; Cancer Center, Human Genome Center, Washington, DC.20059; 2) National Human Genome Res. Inst., Bethesda MD 20892-4442.

Since the identification of the BRCA2 breast-ovarian cancer susceptibility gene, mutation analyses have been carried out in various populations revealing ethnic-specific mutations. In order to identify BRCA2 mutations in African Americans, seventy-five breast cancer patients from families at high risk of hereditary breast cancer were studied. The entire coding regions and flanking introns of BRCA2 have been screened for germline mutations by single stranded conformational polymorphism or the protein truncation test, followed by DNA sequencing. Eight protein truncating, pathogenic mutations have been detected. Four (1991delATAA, 1993delAA, 2001delTTAT, 8643delAT) of the eight pathogenic mutations observed in African Americans have not been previously described. Therefore, half of the pathogenic mutations observed are unique to African Americans. The other four pathogenic mutations (1882delT, 2816insA, 4075delGT, 4088delA) detected in African Americans have been previously reported in Caucasians. Two of the pathogenic mutations, 1991delATAA and 2816insA, were detected in male breast cancer patients, consistent with previous studies showing an association of BRCA2 with male breast cancer. One-half of the pathogenic mutations were identified in women diagnosed with breast cancer under the age of 40 with or without a family history of the disease. One rare missense variant of unknown functional significance was detected. Numerous polymorphisms and non-coding variants were observed. Considering our work and that of others, many different pathogenic mutations and many variants of unknown significance are observed in African Americans; therefore, BRCA2 genetic testing in high risk African American families needs to involve the entire coding and flanking sequences of the gene. This work was supported by the U.S. Army Medical Research and Materiel Command under DAMD17-98-1-8106 and in part by the Komen Found.

**Genome wide variation in LD : Insights for association studies.** *P.E. Bonnen<sup>1</sup>, D. Triikka<sup>1</sup>, Z. Fang<sup>1</sup>, M.M. Weil<sup>4</sup>, M. Kimmel<sup>2</sup>, R. Chakraborty<sup>3</sup>, D.L. Nelson<sup>1</sup>.* 1) Baylor Coll of Med, Houston, TX; 2) Rice Univ, Houston, TX; 3) Univ of Texas Health Science Ctr, Houston, TX; 4) MD Anderson Cancer Ctr, Houston, TX.

Polymorphisms in the human population may lead to functional variants of genes that lend increased or decreased risks for cancer. Our strategy for detecting such risk is to develop haplotypes for genomic regions (130-180kb) containing candidate cancer genes and to perform association studies in cancer populations. We used a resequencing approach to uncover SNPs (8-14) spanning the length of each locus of interest (ATM, BLM, WRN, and RECQL). We then genotyped an ethnically defined control population (~300) for these SNPs and using an EM algorithm predicted haplotypes and their frequencies for each locus. A striking difference between genes was immediately apparent with ATM having 22 haplotypes while BLM, WRN, and RECQL had 50, 56, and 47 respectively. Investigation with the four gamete test revealed reduced recombination at the ATM locus. The most extreme case of which was found in the ATM Caucasian population where there was no evidence for recombination in the entire 140 kb covered by these haplotypes. Examination of LD across these loci followed the same trend with ATM showing extensive LD. To investigate the utility of these haplotypes for association studies we ventured three model studies. First, we established the ability of our BLM haplotypes to detect a founder mutation (blmAsh) for Bloom Syndrome in the Ashkenazi Jewish population. Interrogation of nine Bloom Syndrome patients revealed the mutation occurred strictly on BLM haplotype 25. Next, we demonstrated the efficacy of the ATM haplotypes for detecting polymorphisms by simulating an association study with coding SNPs (cSNPs) in the ATM gene. We genotyped samples known to have one of three particular cSNPs as our "case" population (n= 84) and samples without the cSNPs as controls (~500). Each cSNP was detected by association with an ATM haplotype. A similar study was done with the WRN gene haplotypes and six cSNPs. No haplotype associations were found. Frequency of mutation and haplotype, strength of association as well as extent of LD influence the ability to ascertain risk through association studies.

**Association of 5-alpha-reductase gene (SRD5A2) with prostate cancer.** *N. Mononen<sup>1</sup>, P.A. Koivisto<sup>1</sup>, T. Ikonen<sup>1</sup>, K. Syrjäkoski<sup>1</sup>, J. Schleutker<sup>1</sup>, E. Hyytinen<sup>1</sup>, T.L.J. Tammela<sup>2</sup>, O.-P. Kallioniemi<sup>1</sup>.* 1) Dept Cancer Genetics, Inst Medical Technology, Tampere, Finland; 2) Division of Urology, Tampere University Hospital, Tampere, Finland.

The molecular mechanisms underlying prostate cancer development are incompletely understood. However, androgens are suspected to play a critical role. Human 5-alpha-reductase (SRD5A2) gene encodes for a key enzyme catalyzing the intra-prostatic conversion of testosterone to a more potent 5-alpha-dihydrotestosterone. Recently, A49T substitution of the SRD5A2 was described, leading to a variant enzyme with a Vmax five times that of the wild type. A49T was shown to be strongly associated with prostate cancer. Here, we performed a large-scale population-based study of 563 prostate cancer patients to explore the significance of the A49T variant. We also used PCR-SSCP to screen for novel SRD5A2 germline alterations in 50 prostate cancer patients. The A49T substitution was found in 6.0% of the 516 population controls, in 5.7% of 472 unselected prostate cancer patients (RR=0.97, 95% CI 0.73-1.29, P=0.89), and in 5.5% of patients with hereditary prostate cancer (RR=0.92, 95% CI 0.40-2.13, P=1.00). Therefore, in contrast to the previous report, no association of the A49T variant with prostate cancer could be demonstrated. In the PCR-SSCP analysis, no significant novel coding region mutations or SNPs were detected among 20 patients with a strong positive family history of prostate cancer, nor among 8 patients who developed prostate cancer during treatment of benign prostate cancer with finasteride. Therefore, our studies do not support the significance of genetic variation at the SRD5A2 gene locus in prostate cancer causation.

**Detection of Single-nucleotide Polymorphism and Expression Analysis using Microspheres Encoded with Quantum Dot Semiconductor Nanocrystals.** *E.Y. Wong<sup>1</sup>, T.T. Le<sup>1</sup>, M.P. Bruchez<sup>1</sup>, V.E. Phillips<sup>1</sup>, Y. Jiang<sup>2</sup>, G.C. Gooden<sup>2</sup>, J.A. Treadway<sup>1</sup>, J.P. Larson<sup>1</sup>, J.H. Lai<sup>1</sup>, M.L. Bittner<sup>2</sup>.* 1) Quantum Dot Corporation, Palo Alto, CA 94303; 2) Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Semiconductor nanocrystals (Qdot Nanocrystals) represent a new class of multi-color, highly fluorescent materials that circumvent many problems associated with the organic dyes used in biological applications. The physical and optical characteristics of nanocrystals such as high sensitivity, low cross talk and single wavelength excitation made them an ideal for use in encoding microsphere (Qbead microspheres). We have developed a method using Qdot nanocrystals to encode microspheres. These Qbead microspheres are functionalized for biological applications. We will present detection of single nucleotide polymorphisms and expression analysis using molecular beacons immobilized on Qbead microspheres.

**Measuring Mutation Load in Human Cells From Paraffin Embedded Human Tissues.** *S.S. Sommer, E. Heinmoller, G. Schlake, X. Li, K. Hill, Q. Liu.* Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA.

Somatic mutations can compromise the integrity of the human genome. If one could find and analyze gene mutations within single cells, individuals with a high mutation load (i.e. high mutation frequency) in normal tissues could be identified. These individuals may be at increase for cancer. Since the pattern of mutation can vary dramatically with the type of mutagenic insult or the defective repair system, the pattern of mutation elucidated by the mutation load assay can serve as a clue for identifying the nature of the causative factor. The p53 gene was used as a model, because it has two advantageous properties for the immunohistochemical assay of mutation load: i.) p53 is stabilized by missense mutation in exons 5 through 9; and ii.) mutations in the p53 gene can alter normal transcriptional regulation, thereby distinguishing cells with mutant p53 gene from the background of cells with stabilized wildtype p53 gene. To measure mutation load, slides from ethanol fixed, paraffin embedded cells were immunostained with p53 and PCNA antibodies. Single cells that stain positively for p53 with altered PCNA levels were microdissected and DNA amplified by PCR. Specific mutations were then identified by sequence analysis of exons 5 to 9. A robust method requires reproducible double immunohistochemical staining, efficient microdissection of single cells under conditions that preserve the integrity of genomic DNA, and the efficient amplification of the p53 gene from single cells (70% of efficiency). These milestones have been achieved and point mutations were detected in single cell from normal colon.

**Different frequencies of mutation types in HNPCC versus HNPCC-suspected families.** *R.M.W. Hofstra<sup>1</sup>, Y. Wu<sup>1</sup>, M.J.W. Berends<sup>2</sup>, R.G.J. Mensink<sup>1</sup>, R.H. Sijmons<sup>1</sup>, A.G.J. van der Zee<sup>3</sup>, J.H. Kleibeuker<sup>2</sup>, C.H.C.M. Buys<sup>1</sup>.* 1) Medical Genetics, Univ Groningen, Groningen, Netherlands; 2) Gastroenterology, Univ Groningen, Groningen, Netherlands; 3) Gynaecology, Univ Groningen, Groningen, Netherlands.

Current data in HNPCC families indicate that MMR gene mutation carriers have a cumulative lifetime risk of 80% of colorectal cancer (CRC), 50% risk of endometrial cancer, and a substantially increased risk for a number of other tumors. Germline mutations in MSH2, MLH1 or MSH6 occur in 50-75% of HNPCC families fulfilling the Amsterdam criteria. In families not completely fulfilling the Amsterdam criteria (HNPCC-suspected) the detection rate of germline MMR gene mutations drops to less than 30%. To investigate whether the type of MMR gene germline mutations differs between HNPCC and HNPCC-suspected families, we screened 32 HNPCC and 199 HNPCC-suspected families for mutations in MLH1, MSH2 and MSH6. In the 32 HNPCC families we detected 15 truncating mutations and 4 possibly causative missense mutations or small in-frame insertions or deletions. In the HNPCC-suspected group we identified 15 truncating and 13 possibly causative mutations. We tentatively postulate that these missense and small in-frame deletion/insertion mutations may have a lower penetrance, and are therefore found more often in the HNPCC-suspected group.

**Genotype-phenotype analysis of endometrial cancer in sardinian patients: fine mapping of a new minimal LOH region at chromosome 10q25-q26.** *G. Palmieri<sup>1</sup>, A. Manca<sup>1</sup>, A. Cossu<sup>2</sup>, P. Baldinu<sup>1</sup>, R. Muresu<sup>1</sup>, S. Tore<sup>1</sup>, M. Pisano<sup>1</sup>, M. Casula<sup>1</sup>, G. Ruiu<sup>3</sup>, S. Dessole<sup>3</sup>, A. Pintus<sup>2</sup>, G. Massarelli<sup>2</sup>, F. Tanda<sup>2</sup>, M. Pirastu<sup>1</sup>.* 1) Istituto Genetica Molecolare CNR, Alghero (SS), Italy; 2) Istituto di Anatomia Patologica, Università di Sassari, Italy; 3) Dipart. Ginecologia ed Ostetricia, Università di Sassari, Italy.

Large number of molecular studies have revealed loss of heterozygosity (LOH) at variable frequency within different genomic regions in endometrial cancer (EC). However, deletion mapping studies suggested the presence of tumor suppressor gene(s) involved in EC at chromosome 10q25-q26. In addition, microsatellite instability (MSI) has been demonstrated higher in EC than in other common malignancy, mostly due to defective DNA mismatch repair. To further evaluate the role of the 10q25-q26 region in EC pathogenesis, we screened EC cases from Sardinia, whose population is genetically homogeneous and helpful in defining the molecular basis of complex diseases like cancer. Paired normal and tumor samples from 157 Sardinian patients with EC at various stages of disease were screened by PCR-based analysis using microsatellite markers spanning about 14-cM at 10q25-q26. Three subsets of tumors were identified: one, negative for genetic alterations within the 10q25-q26 region; the second, with prevalence of MSI (suggesting the presence of a "mutator" phenotype); and the third, carrying a specific allelic deletion. This latter group was further analyzed by increasing the marker density within the candidate region. Since two discreet LOH regions were previously described at 10q25-q26 in EC patients from Japan and North America, the region we identified could represent the third one. All these mapping data might be due to the presence of different tumor suppressor genes at 10q25-q26 or, more intriguing, to differences associated to patients' origin. As additional feature, we found a significant correlation between MSI and the disease stage; its role as prognostic factor is under evaluation. We have actually restricted the minimal consensus region of LOH to a genomic fragment of about 200 kb, and two candidate EST clusters are being analyzed.

**Site of a putative TSG at 17p13.1 in Barrett's Oesophageal Adenocarcinoma.** *J.R. Dunn<sup>1</sup>, J. Garde<sup>1</sup>, J.R. Gosney<sup>2</sup>, B.C. Oates<sup>1</sup>, A.J.M. Watson<sup>3</sup>, J.K. Field<sup>1</sup>.* 1) Clinical Dental Sciences, University of Liverpool, Liverpool, UK; 2) Department of Pathology, University of Liverpool, Liverpool, UK; 3) Department of Medicine, University of Liverpool, Liverpool, UK.

We have previously identified thirteen common minimally deleted regions (MRs I-XIII) on chromosome 17 in twelve Barrett's Oesophageal Adenocarcinoma (BOA) specimens using 41 precisely mapped microsatellite markers. The aim of the present study has been to identify the earliest sites of loss on this chromosome that arise and persist during the progression to BOA. This has been undertaken by the analysis of multiple carefully microdissected tissue samples from each of five oesophagectomy specimens, several of which contained identifiable pre-malignant tissue. An LOH profile was constructed for each specimen using loss data generated from tissue histotypes ranging from normal epithelium to adenocarcinoma. Our data demonstrates a stepwise accumulation of loss in each specimen, consistent with a single clonal pathway in four specimens and several co-existing pathways in one specimen. Within extensively deleted regions of the tumour (seen in three specimens), small deletions were detected in pre-malignant tissue predominantly at the site of our identified minimal regions, and these losses were seen to expand and merge during the progression to BOA. Clonal losses at minimal regions were first detected in tissue showing early changes histologically, including Barrett's intestinal metaplasia and intermediate grade dysplasia. In particular, LOH at minimal region III (MRIII) occurred in the earliest tissue in all five specimens. MRIII is a novel region situated at 17p13.1 and is approximately 500 kb in size. We have confirmed that MRIII is separate from p53 and now propose to further investigate this region as the site of a putative tumour suppressor gene involved in BOA. This work was sponsored by the North West Cancer Research Fund.

**Gene expression profile of malignant mesothelioma cell lines using cDNA microarrays.** *S. Apostolou*<sup>1</sup>, *A. De Rienzo*<sup>1</sup>, *S.S. Murthy*<sup>1</sup>, *C. Patriotis*<sup>2</sup>, *J.R. Testa*<sup>1</sup>. 1) Human Genetics, Fox Chase Cancer Center, Philadelphia, PA; 2) Molecular Oncology, Fox Chase Cancer Center, Philadelphia, PA.

Malignant mesothelioma (MM) is a highly aggressive mesodermal neoplasm characterized by a long latency following exposure to asbestos. The length of the latent period suggests that multiple somatic genetic alterations may be required for tumorigenic conversion of a mesothelial cell. To identify genes relevant to MM, we compared normal mesothelial cells with 4 MM cell lines using Atlas human cancer cDNA array membranes (CLONTECH). We identified 6 upregulated and 8 downregulated genes common to all 4 MM cell lines relative to the normal mesothelial cells. Most of these genes are located in chromosomal regions previously shown by comparative genomic hybridization to be gained or lost, respectively, in MM. Several of the overexpressed genes encoded products involved in DNA replication control and apoptosis, rho GDP dissociation inhibitors, and intermediate filament markers. The underexpressed genes encoded receptors, cell adhesion molecules, cytokines, and invasion regulators. The downregulated procollagen alpha subunit precursors, COL1A2 and COL3A1, and the metalloproteinase inhibitor precursors, TIMP1 and TIMP3 have not previously been shown to be involved in the pathogenesis of MM. In addition, the upregulated, rho GDP dissociation inhibitor, ARHGDIA, has not been implicated in this malignancy. RT-PCR is underway to verify the expression levels of the up- and down-regulated genes. If differential expression is confirmed, the genes will be further characterized to determine their role in MM. *COL1A2 COL3A1 TIMP1 TIMP3 ARHGDIA*.

**Expression screening to identify target genes of chromosomal alterations: cDNA microarray reveals a novel amplified, overexpressed and rearranged gene MB-17A at 17q23 in breast cancer.** *O.M. Monni<sup>1</sup>, M. Barlund<sup>2</sup>, J. Kononen<sup>1</sup>, S. Mousses<sup>1</sup>, J.D. Weaver<sup>1</sup>, M. Bittner<sup>1</sup>, Y. Chen<sup>1</sup>, J. Torhorst<sup>3</sup>, G. Sauter<sup>3</sup>, O-P. Kallioniemi<sup>1</sup>, A. Kallioniemi<sup>1</sup>.* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Institute of Medical Technology, University of Tampere and Tampere University Hospital, Finland; 3) Institute of Pathology, University of Basel, Switzerland.

Identification of target genes for chromosomal rearrangements by traditional methods involves substantial amount of work, especially if the regions of involvement are large. Here, we developed a new strategy to identify target genes for DNA amplifications, based on cDNA microarray analysis of all known transcripts from the region of involvement. A custom-made cDNA microarray of 615 transcripts was generated to cover all known genes from chromosome 17, as well as full regional representation of two amplicons: 17q12 (HER-2 amplicon), and 17q23-q24, another common amplification site in breast cancer. In breast cancer cell lines with 17q12 amplification, HER-2 was the most highly overexpressed gene, thereby validating this expression based screening strategy in the identification of target genes. The most highly overexpressed transcript in the 17q23 amplified cell lines was a novel EST, which was cloned and predicted to encode a 913 aa protein with no homologies to any other known proteins. High-level amplification of this MB-17A gene was verified by FISH in all breast cancer cell lines with 17q23 amplification and in 24 of 280 primary breast cancers (8.6%) based on a tissue microarray analysis. In breast cancer cell lines with 17q23 amplification, Northern blotting showed overexpression, in some cases of a structurally rearranged gene. The results suggest that MB-17A may be a genomic target for chromosomal rearrangements at 17q23 and play a critical role in breast cancer progression. In summary, with the completion of the human genome sequence, cDNA microarrays with full representation of all transcripts from a chromosomal region can be constructed and applied to systematically uncover the molecular consequences of chromosomal rearrangements in cancer.

**Classification of Renal Cell Carcinoma with cDNA Microarray.** *K. Zhang<sup>1</sup>, M. Xiong<sup>1</sup>, L. Jin<sup>1</sup>, L. Rogers<sup>2</sup>, R. Amato<sup>2</sup>, A. Killary<sup>2</sup>, S. Lott<sup>3</sup>.* 1) Human Genetics Center, UT-Houston, Houston, TX; 2) MD Anderson Cancer Center, University of Texas, Houston, TX; 3) NEN Life Science Products, Inc., Boston, MA.

With the ability to simultaneously monitor the expression level of thousands of genes, microarrays have become a powerful tool for tumor classification. However, the most popularly used direct labeling methods require large quantities of RNA, which are often unattainable from tissue samples collected from residual surgical specimens. To overcome this obstacle, we utilized NENs MICROMAX TSA (tyramide signal amplification) microarray system, from which we were able to measure gene expression profiles from only 100 mg of available tissue. Twenty-two pairs of renal cell carcinoma and adjacent normal kidney tissues were collected from patients undergoing primary nephrectomy with no prior history of chemo/immunotherapy. Expression levels of 2400 genes were simultaneously measured using labeled cDNA and TSA detection. A novel application of Fishers linear discriminant analysis was used to rank genes according to their ability to classify tumor and normal tissues. Candidate genes for classification were then selected based on their ranking scores. Our preliminary data based on ten pairs of samples suggests that, with the expression profile of only 26 genes, the tissue samples can be perfectly classified by a hierarchical clustering method. Several of these genes are known to have a biological function during tumor initiation and progression, such as the VHL binding protein and 14-3-3 epsilon. Additional genes that have possible functions in transcription regulation and cell growth regulation were identified, including HLH basic phosphoprotein(G0S8) and Cellular growth-regulating protein (L10844). In comparison, classification with expression profiles of all genes leads to poor cluster results and no genes with biological significance could be easily identified. A comprehensive analysis using the full set of gene expression data, in combination with the patients clinical information, is in progress to confirm these results.

**Defining the unique expression pattern for Barrett's-associated oesophageal adenocarcinoma (BA) by comparing pooled normal versus disease oligonucleotide array data.** *A.J. Williams<sup>1</sup>, J.F. Boland<sup>1</sup>, R.V. Lord<sup>2</sup>, C. Alvares<sup>1</sup>, J.C. Wetzel<sup>1</sup>, U. Scherf<sup>1</sup>, J.G. Vockley<sup>1</sup>.* 1) Gene Logic INC., Gaithersburg, MD 20878; 2) Department of Surgery, University of Southern California Keck School of Medicine, Los Angeles, CA 90033.

To fully understand the genetic basis of a given disease, it is necessary to identify all essential genes that reliably exhibit abnormal expression values in a wide variety of patients. We have refined a strategy that systematically examines normal and diseased tissue samples to determine the patterns of gene expression that are unique to disease. This approach was tested by performing oligonucleotide array studies and pooling the data for individual normal oesophagus and Barrett's-associated oesophageal adenocarcinoma (BA) samples. We first identified all genes from the normal or diseased samples that were either commonly expressed or commonly not expressed. Next, we revealed the unique pattern of genes over-expressed in the disease by determining those genes that were expressed in BA, but not expressed in normal oesophagus. Similarly, the unique pattern of genes under-expressed in disease was found by identifying genes that were expressed in normal oesophagus, but not expressed in BA. These results were combined with fold change analysis to rapidly discover a subset of key disease-related genes. The identified genes were used as signposts pointing to significant gene clusters in hierarchical clustering analysis. Our approach should be useful for the relatively quick and systematic identification of potential therapeutic and diagnostic targets for a wide variety of diseases.

**Somatic and/or germline mosaicism for recurrent APC gene mutations.** *E. Bakker, E.C. Bik, Y.M.C. Hendriks, R.H.A.M. Vossen, C.M.J. Tops.* Department of Human and Clinical Genetics, Leiden University Medical Center, Wassenaarseweg 72, 2333AL Leiden, Netherlands.

Familial adenomatous polyposis (FAP [MIM 175100]) is an autosomal dominant disorder caused by germ-line mutations in the APC gene (M74088 [GenBank]). Scanning of the APC gene in 530 Dutch FAP and 'FAP-like'; patients has resulted in the identification of 130 pathogenic mutations. These mutations are scattered along a large part of the gene, with some recurrent mutations. Somatic mosaicism was evident in 5 of the 130 Dutch pathogenic mutations, with an apparent preference for a nonsense mutation in exon 8. The presence of low (10-20%) mosaicism of the exon 8 mutation was detected by DGGE and/or SSCP scanning of sporadic cases of clinical evident polypsis coli. In one family there was a woman (85 years, healthy) with an apparent isolated gonadal mosaicism, since the mutation was transmitted twice to the next generation on the maternal haplotype, whereas the mutation was not detectable in the maternal lymphocytes or skin-fibroblasts. Since the APC de novo mutation rate is estimated to be in the order of 25% (Bisgaard et al. *Hum Mutat*, 1994, 3:121-5), germline and/or somatic mosaicism could account for a substantial portion of the solitary FAP or 'FAP-like'; cases and a mutation scanning directed towards identifying a low-abundant mutated APC allele should be considered in the non-familial cases. New detection techniques like pyrosequencing (Ahmadian et al. *Anal Biochem*, 2000, 10:103-10) are currently evaluated as a method to detect low level mosaics.

**Association of the aromatase gene (Cyp19) and endometrial cancer -- Testing for Hardy-Weinberg disequilibrium in cancer patients.** *C.C. Gu<sup>1</sup>, D.G. Mutch<sup>2</sup>, P.J. Goodfellow<sup>3</sup>*. 1) Div Biostatistics,; 2) Dept. of Obstetrics and Gynecology; 3) Dept. of Surgery, Washington Univ Sch Medicine, St Louis, MO.

Estrogen is a potent risk factor for the development of a variety of cancers, including endometrial carcinoma. Siegelmann-Danieli and Buetow (S&B, 1999) recently reported an association between constitutional variation in the aromatase (estrogen synthetase) gene, CYP19, and breast cancer risk. In a case-control study, they investigated an intron 4 tetranucleotide repeat polymorphism and saw an over-representation of a specific allele in breast cancer cases. We undertook a study to determine whether CYP19 variation is associated with endometrial cancer risk. We genotyped 222 endometrial cancer patients for the intron 4 tetranucleotide repeat marker and assessed marker-disease association by testing for Hardy-Weinberg disequilibrium (HWD) in cancer cases. The overall allelic distribution in our cases is similar to that reported by S&B (1999) in breast cancer patients, although in our study the distribution in white patients is significantly different from that in blacks. We carried out analyses of HWD in patient subgroups stratified according to ethnicity, age at cancer presentation and tumor histologic subtype. The average age of onset differs by 5 years between patients with type I (endometrioid) and type II (nonendometrioid) cancers. In the type I cases, HWD is detected by Fisher's exact test with a p-value of 0.03 (N=18) in blacks (p=0.24 in whites with N=166). Tests for HWD in type II cases were nonsignificant in both ethnic groups (p=0.143 in whites with N=22; p=0.90 in blacks with N=16). These preliminary results suggest that CYP19 variation may be a contributing risk factor in type I endometrial cancer patients. We found that while the high-risk allele (171bp) reported by S&B (1999) is more frequent in cases of younger age of onset (<55 yr.), the test for HWD is nonsignificant in this subgroup. A case-control study extending findings reported here is underway to further define the role of aromatase and to quantify contributions of constitutional genetic variation of other estrogen-related genes to the development of endometrial cancer.

**A genome-wide scan of 94 prostate cancer families stratified by clinical features identifies loci of interest.** *E.A. Ostrander<sup>1</sup>, E.L. Goode<sup>2</sup>, S. Kolb<sup>1</sup>, M. Janer<sup>3</sup>, M. Badziach<sup>2</sup>, M. Peters<sup>1</sup>, M. Gibbs<sup>1</sup>, J.L. Stanford<sup>1</sup>, G.P. Jarvik<sup>2</sup>, L. Hood<sup>2,3</sup>.* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) University of Washington, Seattle, WA; 3) Institute for Systems Biology, Seattle WA.

A 10 cM genome-wide scan of 94 prostate cancer families, including 432 affected men, is being analyzed to identify prostate cancer susceptibility loci. Fifty families are classified as early-onset (median age at diagnosis <66 years); 44 as later-onset (> or = 66 years) and 11 as earliest onset (<61 years). When the entire data set was considered previously, regions of interest were identified on chromosomes 8, 10, 12, and 14. Stratification by tumor stage and grade provide additional support for findings on 8, 10 and 14, and highlights additional regions of interest on chromosomes 6, 20 and X. GENEHUNTER was used to compute multipoint NPL scores for linkage in the stratified data sets. We observe an NPL score of 2.58 ( $p = 0.014$ ) for marker D10S1213 in families in the <61 group with local/regional disease, and an NPL of 2.24 ( $p = 0.026$ ) at D14S587 in the <66 group in families with at least one member with advanced stage disease. We also observe an NPL of 2.82 ( $p = 0.006$ ) at D8S1130 in later-onset families with at least one case with high grade disease. For chromosomes 8 and 10, multipoint Lod scores >2.0 were observed in the same regions in our initial genome scan of all 94 families. An additional region of interest in the stratified screen is identified by an NPL of 2.55, ( $p = 0.015$ ) at D6S474 in the <61 families who have at least one prostate case with advanced stage disease, suggesting a locus that predisposes to a more severe form of familial prostate cancer. Finally, we observed significant results at two previously described loci: D20S478 (NPL = 3.32,  $p = .003$ ) in the HPC20 region in families > or = 66 with at least one case of advanced stage disease, and at the HPCX locus with marker DXS984 (NPL = 2.11,  $p = 0.023$ ) in families with local/regional disease. In aggregate, these data suggest the existence of several prostate cancer susceptibility loci, and that analysis of data by a variety of criteria is needed to fully understand genetic susceptibility to the disease.

**An exploration of the role of family history of cancer among four rare types of cancer.** *H.H. McDuffie, P. Pahwa, S. Fincham, J.J. Spinelli, J.R. McLaughlin, J.A. Dosman, D. Robson.* Ctr Agric Med, Royal Univ Hosp, Univ Saskatchewan, Saskatoon, SK., Canada.

A positive family history of cancer can reflect both environmental exposures and genetic susceptibility. Hodgkin's Disease (HD), Multiple Myeloma (MM), non-Hodgkin's Lymphoma (NHL) and Soft Tissue Sarcoma (STS) have several putative etiologies and risk factors in common. The risk factors include a positive history of cancer among first degree relatives, perturbed immune function, occupational exposure to specific pesticides, to viruses and chromosomal instability. Simultaneously and using identical methodology, we obtained cancer history information on the first degree relatives of male incident cases (316 HD, 347 MM, 517 NHL, 365 STS and 1506 sex, age 2 year and province of residence matched controls using postal questionnaires. Family history of cancer included relationship to the proband, the types of tumours diagnosed among relatives, the year and province of diagnosis. We conducted conditional logistic regression analyses adjusted for age and province of residence and report adjusted odds ratios (OR) and 95% confidence intervals (95% CI). Proband was excluded from all statistical analyses. We found (a) that most families are cancer free (excluding probands)(range 52% MM to 67%; controls); (b) few families have two or more affected first degree relatives (range 5.7% HD to 18.7% MM);(c) HD cases had fewer siblings and children compared to other case groups and to controls;(d) adjusted for family size, HD, MM and NHL families have significantly higher risks of affected siblings compared to control families;(e) among all cases and controls; cancers of the trachea, bronchus, lung and of the female breast are first or second in frequency among relatives. Lymphoid leukemia ranked third or fourth in frequency among relatives of HD, NHL and STS cases; (f) leukemia, lymphoma and multiple myeloma occur in excess in families of HD cases (OR (95% CI) 3.61 (1.65, 7.86) compared to controls adjusted for pesticide exposure. Conclusions:(a) a positive family history of cancer is an independent risk factor for HD,MM and NHL. b)the evidence is strongest for HD, followed by MM and NHL.

**Effect of stratifying by linkage at known loci in assessing a genome-wide scan of familial prostate cancer.** *M.D. Badzioch<sup>1</sup>, J.L. Stanford<sup>2</sup>, M. Gibbs<sup>2</sup>, M. Janer<sup>3</sup>, E.L. Goode<sup>1</sup>, M. Peters<sup>2</sup>, S. Kolb<sup>2</sup>, L. Hood<sup>3</sup>, G.P. Jarvik<sup>1</sup>, E.A. Ostrander<sup>2</sup>.* 1) Division of Medical Genetics, University of Washington; 2) Fred Hutchinson Cancer Research Center; 3) Institute for Systems Biology, Seattle, WA.

Five putative familial prostate cancer (FPC) high-risk loci, HPC1, PCAP, HPCX, CAPB, and recently, HPC20 (chr. 20q13) have been reported to date. To increase genetic homogeneity of analysis groups, most genome scan studies stratify by average age at diagnosis, number and distribution of affected individuals, and clinical characteristics, but linkages to putative high-risk loci have not yet been used for this purpose. We present the effects of stratifying by multipoint NPL scores at putative high-risk loci in assessing a 10 cM scan of 94 FPC families. Classified by age alone, the highest linkage scores were at CAPB (NPL=2.28, avg. age at diagnosis <61 years) and on chrs. 4 (NPL=2.06, <66), 8 (NPL=2.02, <sup>3</sup>66), and 15 (NPL=2.04, <sup>3</sup>66). By HOMOGM, we estimated the percentages of families showing some evidence of linkage to the first 4 candidate regions to be 12.5, 10.3, 7.1, and 18.2, respectively, leaving 51.9% without such evidence. We split all families into 2 groups of roughly equal size by assuming true linkage to any of the 4 regions if an NPL score was <sup>3</sup>0.7. We then resurveyed the genome using sets of families defined by median age of diagnosis and prior linkage status. The highest NPL scores now occurred chr. 4 (NPL=2.68, p=0.006) in early-onset families having no evidence of prior linkage. In the subset with evidence of prior linkage, peaks were found on chr.10 (NPL=2.49, p=0.014) in early-onset and on chr. 20 (NPL=2.76, p=0.005) in late-onset FPC. Since the result on chr. 20 was consistent with HPC20 we maximized the NPL score to 4.20 by increasing the cutoff NPL at other loci to <sup>3</sup>1.10. These results suggest that prior linkages, in addition to clinical and family data, may identify more homogenous subgroups for scan analysis. Although caution should be taken when testing multiple strata, the fifth putative FPC locus, HPC20, appeared in this dataset after partitioning on prior linkages. These results support the existence of multiple FPC loci and suggest the possibility of locus interaction.

**CYP17 promoter polymorphism and breast cancer in Australian women under forty years of age.** *A.B. Spurdle<sup>1</sup>, X. Chen<sup>1</sup>, J. Hopper<sup>2</sup>, D. Easton<sup>5</sup>, G. Dite<sup>2</sup>, J. Cui<sup>2</sup>, M. McCredie<sup>3</sup>, M. Southey<sup>4</sup>, D. Venter<sup>4</sup>, G. Chenevix-Trench<sup>1</sup>.* 1) Queensland Inst Med Res, Brisbane, Queensland, Australia; 2) University of Melbourne, Victoria; 3) New South Wales Cancer Council, Sydney; 4) Peter MacCallum Cancer Institute, Melbourne; 5) Strangeways Research Laboratory, Cambridge, UK.

We conducted a population-based, case-control-family study to assess the relationship between the cytochrome P450c17a (CYP17) 5' promotor region T to C polymorphism and early-onset breast cancer. CYP17 genotype was determined in 369 cases under 40 years, 284 controls and 91 relatives. Genotype distributions were compared by logistic regression, and cumulative risk estimated by a modified segregation analysis. The TC genotype was not associated with risk ( $P = .7$ ). Compared to TT and TC, the CC genotype was associated with a relative risk (95% confidence interval) of 1.81 (1.15-2.86) before, and 1.63 (1.00-2.64) after adjustment ( $P = .01$  and  $.05$ , respectively). There was an excess of CC genotypes in cases with at least one affected first- or second-degree relative (23% compared with 11% in controls;  $P = .002$ ), and these cases were at a 3- to 4-fold risk compared with other groups. Analysis of breast cancer in first- and second-degree relatives of CC cases, excluding two known carriers of a deleterious mutation in BRCA1 or BRCA2, gave a relative hazard in CC women of 3.48 (1.13-10.74) ( $P = 0.04$ ), equivalent to a cumulative risk of 16% to age 70. This finding is currently being extended to a larger case-control-family study from the Cooperative Family Registry for Breast Cancer Studies of women diagnosed before and after age 40.

**Detection of high-order interactions among estrogen metabolism genes in sporadic breast cancer.** *M.D. Ritchie, N. Roodi, L.R. Bailey, W.D. Dupont, W.D. Plummer, L.W. Hahn, F.F. Parl, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

Mammary metabolism of estrogen to carcinogenic catechol estrogens is thought to increase the risk of sporadic breast cancer. An important question is whether breast cancer risk can be predicted by knowledge about variation in genes from the estrogen metabolism pathway. Previous studies by our group and others suggest that genes from this pathway do not have main or independent effects. The goal of this study was to determine whether interactions among variations in genes from this pathway are associated with sporadic breast cancer.

Our sample included 414 age-matched Caucasian women: 207 cases and 207 controls. We measured eight polymorphisms in five genes from the estrogen metabolism pathway: *CYP1A1*, *CYP1B1*, *COMT*, *GSTM1*, and *GSTT1*. We employed a multifactor data reduction method to evaluate each of the possible interactions among the eight polymorphisms. For each particular combination of loci, we identified multilocus genotypes that are more common in cases than controls and pooled these into a single group. This reduces the dimensionality of the data to one. We estimated the prediction error or misclassification rate of each combination of loci and their optimal multilocus genotype grouping using nine-fold cross validation.

The best model included five polymorphisms, one from each of the five estrogen metabolism genes. Permutation testing indicated the probability of observing the misclassification rate for this model, given the null hypothesis of no association, was less than 0.05. This study illustrates the importance of considering high-order genetic interactions in studies of complex diseases such as sporadic breast cancer when there are no main or independent genetic effects.

**Denaturing high performance liquid chromatography (DHPLC) used in the detection of mutation in hMLH1 and hMSH2 genes.** *S. Pawar*<sup>1</sup>, *S. Ciocci*<sup>2</sup>, *A. Markowitz*<sup>2</sup>, *S. Jhanwar*<sup>2</sup>, *N. Ellis*<sup>2</sup>. 1) IMPATH, New York, NY; 2) Memorial Sloan-Kettering Cancer Center New York, NY.

Hereditary nonpolyposis colorectal cancer (HNPCC) is the most common genetic condition that determines susceptibility to colorectal cancer. Studies for this disease have revealed it to be a simple mendelian disease involving five mismatch repair genes: hMLH1 and hMSH2 being the major ones. Rapid and accurate identification of DNA sequence heterogeneity is being recognized as of major importance in disease management. In this study we have used Denaturing high performance liquid chromatography (DHPLC) as a method of screening for germ line mutation in the hMSH2 and hMLH1 genes. The method is based on differential separation and detection of mismatched heteroduplexes formed after re-annealing of normal and mutant DNA strands. Analysis of all the exons and the exon-intron borders of hMSH2 and hMLH1 genes in 16 unrelated HNPCC kindreds was done. Optimization of DHPLC analysis of each exon was carried out by design of primers with minimum variation in the melting temperature of the amplicon, and titration of both elution gradient and temperature. To confirm the validity of DHPLC analysis all the 560 amplicons corresponding to 16 fragments for hMSH2 gene and 19 fragments for hMLH1 gene for each DNA sample were directly sequenced. All but 2 patients tested showed at least one heterozygous DHPLC profile in either hMLH1 or hMSH2 gene. A total of 18 unique DNA sequence variants were identified. Sequencing of the variant amplicons detected one novel and four previously reported pathogenic mutations, as well as seven novel and six known polymorphisms or unique sequence variants that are probably of no clinical significance. The amplicons that were observed to have a normal homozygous DHPLC profile detected no sequence variation in cycle sequencing. Therefore under our DHPLC conditions 100% of the sequence variation in hMLH1 and hMSH2 genes for the 16 individuals were correctly identified. Our results demonstrate that DHPLC is a highly sensitive, specific and inexpensive method to screen for mutations.

**Caveolin-1 gene promoter methylation in prostate cancer.** *J. Cui*<sup>1</sup>, *L.R. Rhor*<sup>2</sup>, *G. Swanson*<sup>3</sup>, *V.O. Speights*<sup>4</sup>, *M. Powers*<sup>1</sup>, *T.M. Maxwell*<sup>1</sup>, *A.R. Brothman*<sup>1</sup>. 1) Dept. of Pediatrics and Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept. of Pathology, University of Utah, Salt Lake City, UT; 3) Cancer Care Northwest, Spokane, WA; 4) Dept. of Pathology, Scott & White Hospital, Texas A & M University, Temple, TX.

Hypermethylation of CpG islands in the promoter regions of tumor suppressor genes appears to be a common mechanism of tumorigenesis. Caveolin-1 (Cav-1), a gene coding for the structural component of cellular caveolae, is involved in cell signaling and has been proposed as a tumor suppressor gene in several malignancies. We analyzed the methylation status of CpG sites in the Cav-1 promoter region on 26 primary prostate tumor samples. Genomic DNA from both tumor and normal specimens was obtained from paraffin-embedded prostate sections by laser capture microdissection (LCM) and was bisulfite modified and PCR amplified to evaluate 24 CpG sites at the 5' promoter region of exon 1 of Cav-1 by bisulfite genomic sequencing. Immunohistochemistry staining with a caveolin-1 specific antibody was also performed to evaluate the expression of the gene. Twenty out of the 22 (91%) informative cases showed promoter hypermethylation in the tumor cell population when compared with adjacent normal prostate cells ( $p=0.0001$ ). An elevated immunoreactivity was observed in tumor cells from 7 of 22 prostate samples tested but this did not correlate with Gleason grade or PSA failure. While no association with Gleason grade was found, overall increased methylation correlated with PSA failure ( $p=0.016$ ), which may predict clinical recurrence of the disease. These findings support the notion that Caveolin-1 functions as a tumor suppressor gene in prostate cancer and suggest that methylation status of this gene may be a marker predictive of outcome. Supported by NIH grant R01CA46269 and a grant from the University of Utah.

**Overexpression of proline oxidase, a late p53-induced-apoptosis gene (PIG6), induces apoptosis in cancer cells.**

*C.A. Hu<sup>1</sup>, J. Yu<sup>2</sup>, W.-W. Lin<sup>2</sup>, S.P. Donald<sup>3</sup>, X.Y. Sun<sup>3</sup>, S. Almashanu<sup>4</sup>, G. Steel<sup>4</sup>, J. Phang<sup>3</sup>, D. Valle<sup>1,4</sup>.* 1) Institute of Genetic Medicine; 2) Predoctoral Training Program in Human Genetics, JHMI; 3) BRL, NCI-FCRDC, NIH; 4) HHMI, JHMI, Baltimore, MD.

Mutations in p53 are a major contributor to malignancy and have profound effects on cell cycle regulation, DNA repair and apoptosis. In particular, cells lacking p53 have defective apoptosis but the role played by p53 in this complex process is only now being elucidated. In a SAGE study of p53-induced apoptosis in a colorectal cancer cell line (DLD-1), the expression of only 14 of 72,02 genes (0.19%) was found to be induced >10X. Of these, 3 were early (~3 hr) and 11 were late (>12 hr). One of the late p53-induced genes, proline oxidase (POX), a mitochondrial inner-membrane protein catalyzes the oxidation of proline to pyrroline-5-carboxylate. Expression of POX was increased 12-fold following p53 overexpression. A number of aspects of POX make it an interesting candidate for playing a role in apoptosis. These include its location in the inner-mitochondrial membrane; the potential for the POX reaction to influence the intramitochondrial redox ratio; and the use by POX of cytochrome C (cyt. C) as an electron acceptor. To study the possible role of POX in apoptosis, we established several DLD-1 lines harboring an inducible POX gene using the tet-off system. We showed that DLD-1 cells expressing high POX activity undergo a proline-dependent apoptotic response. The effect is apparent at 0.5 mM and maximal at 5 mM proline. Normal plasma proline concentrations (mean 160 mM; range 50 to 280 mM) approach these concentrations. Under induction conditions, apoptosis of the DLD-1 cells peaks at six days with massive cell death associated with release of cyt. C from mitochondria, caspase-9 activation, and chromatin condensation. Additionally, ROS in the POX-overexpressing cells were increased by 150 to 200% above controls. We conclude that POX induction in the presence of proline is sufficient to induce classical apoptosis perhaps through generation of ROS or alteration of cyt. C. The relation of these observations to the *in vivo* role of p53 in apoptosis remains to be determined.

**Molecular and Cellular Pathology of Benign Neurofibromas.** *E. Serra*<sup>1</sup>, *E. Ars*<sup>1</sup>, *M. Nadal*<sup>1</sup>, *A. Sanchez*<sup>2</sup>, *A. Ravella*<sup>3</sup>, *T. Rosenbaum*<sup>4</sup>, *X. Estivill*<sup>1</sup>, *C. Lazaro*<sup>1</sup>. 1) Medical and Molecular Genetics, IRO, Hospitalet Llob, Barcelona, Spain; 2) Genetics Service, Hospital Clinic, Barcelona, Spain; 3) Dermatology Service, Hospital Creu Roja, Barcelona, Spain; 4) Department of Neuropediatrics, Heinrich-Heine-University, Dusseldorf, Germany.

Neurofibromas, benign tumours that originate from the peripheral nerve sheath, represent a hallmark of Neurofibromatosis type 1 (NF1). Although their unicellular origin has been confirmed they are difficult to study due to their multicellular composition. Several studies suggested and our group recently demonstrated that Schwann cells are the NF1(-/-) cells in this type of tumour. Although different LOH studies indicated that inactivation of both copies of the NF1 gene is a common feature in neurofibromas, the presence of the two hits in the NF1 gene has only been reported in few neurofibromas. In this work our group presents the widest mutational study of the NF1 gene in a large number of neurofibromas by using several methods including SSCP/HD analysis and LOH studies. In total we have identified 42 somatic NF1 mutations from a pool of 123 neurofibromas. LOH is presented in 25% of the studied neurofibromas. We differentiate two types of LOH: one being true deletions of part or the whole NF1 gene, and a second type of LOH affecting the whole long arm of chromosome 17, which arose through a mitotic recombination event. By cDNA-SSCP/HD analysis we have detected 13 NF1 somatic point mutations, being nonsense mutations, small deletions, mutations in the consensus splice site or nonsense mutations producing exon skipping, and mutations causing the introduction of cryptic exons. As we have previously demonstrated in the study of germline NF1 mutations somatic point mutations causing splicing alterations are also common. The analysis of various neurofibromas from patients with sporadic NF1 can facilitate the identification of their germline mutation. The demonstration that somatic and germline mutations are in the two NF1 copies, corroborates the "double hit" model for the NF1 gene in the generation of these benign neoplasias, and also shows that both mutated alleles can be expressed in neurofibroma tumoural cells.

**Molecular genetic analysis on the BRCA1 gene in thirty Chilean families with breast cancer.** *M. Gallardo<sup>1</sup>, L. Egana<sup>1</sup>, D. Austin<sup>1</sup>, H. Paredes<sup>2</sup>, M. Rodriguez<sup>3</sup>, T. Walsh<sup>4</sup>, K. Gordon<sup>4</sup>, C. Rousseau<sup>4</sup>, M-C. King<sup>4</sup>, M.P. Carvallo<sup>1</sup>.* 1) Depto de Biología Celular y Molecular, Fac.Cs.Biologicas,P.Universidad Catolica de Chile, and (formerly) Facultad de Medicina, Universidad de Chile, Santiago, CHILE; 2) Instituto Nacional del Cancer, Santiago,CHILE; 3) Hospital Barros Luco, Santiago, CHILE; 4) University of Washington, Seattle,USA.

Several studies involving the molecular analysis of BRCA1 and BRCA2 genes in families affected of breast cancer, from worldwide populations, have been developed. The results describe a variable frequency for BRCA1 and BRCA2 mutations, depending on the ethnic origin of the population analyzed. Thirty Chilean families were evaluated for inherited mutations in BRCA1. Families were selected by any of the following criteria: three cases of breast cancer in first degree relatives; or two cases of breast cancer in first degree relatives, one diagnosed before age 40; or one breast cancer and one ovarian cancer in first degree relatives. The 23 exons encoding the BRCA1 gene were PCR amplified and analyzed by SSCP and DNA sequencing. Two mutations were identified, both novel. Family 5 includes mother, daughter and maternal cousin diagnosed with breast cancer at ages 67, 43, and 37, respectively. Frameshift mutation 308insA was identified in BRCA1 exon 5 in the surviving affected mother and daughter. An unaffected 69-year-old aunt is an obligate carrier of the mutation. Family 14 includes 7 cases of breast cancer, 5 cases of prostatic cancer, 1 case of uterine cancer, and 1 case of stomach cancer. Nonsense mutation 3936 C->T, causing a stop at codon 1273, was identified in BRCA1 exon 11. In addition to the breast cancer cases, at least 3 of the prostatic cancer cases and both women with uterine and stomach cancer, are obligate carriers of the mutation. In order to find mutations in the remaining families, we will test BRCA1 with additional approaches, such as PTT and direct sequencing of some exons, and also screen BRCA2. It is of particular interest to know whether BRCA1 and BRCA2 mutations may manifest as cancers other than breast or ovary in Chilean families. Supported by NIH-FIRCA grant R03 TW008.

**Analysis of p16 protein expression in familial melanoma patients: correlation with germline status.** *P. Ghiorzo*<sup>1</sup>, *B. Villaggio*<sup>2</sup>, *N. Hayward*<sup>3</sup>, *G. Bianchi-Scarra*<sup>1</sup>. 1) Department of Oncology, Biology & Genetics, Univ Genova, Genova, Italy; 2) Department of Internal Medicine, Univ Genova, Genova, Italy; 3) Queensland Institute of Medical Research, Brisbane, Australia.

The CDKN2A gene, which encodes the p16<sup>ink4</sup> cell-cycle inhibitor, is the major melanoma suppressor gene. It is frequently deleted, mutated or rearranged in sporadic melanoma and in the germline of approximately 20 to 40% of familial melanoma patients. Its location on 9p21, a chromosomal region whose cytogenetic and molecular alterations correlate with clinical stages of melanoma progression, suggests that dysfunction of this gene could be critical to the evolution of melanoma. Loss of p16 expression has been found to correlate with tumor progression in sporadic melanoma, confirming this hypothesis. In this study we looked at p16 expression by immunohistochemistry in familial melanoma patients that had been characterized for p16 germline status. We collected specimens from lesions representing all stages in the progression of melanoma from patients belonging to 10 families carrying wildtype p16 and mutated p16 (G101W, in 5 families). In some cases we were able to analyse multiple lesions from the same patient. To improve interpretation of results and avoid confounding nonspecific signal, we performed the analysis with 3 different antibodies. Results of digital image analysis revealed correlation of a progressive loss of p16 expression with melanoma progression, and in some cases p16 loss was observed at an early stage of tumor progression. Moreover, the pattern of p16 localization, which was both nuclear and cytoplasmic in lesions from p16 wildtype patients, was predominantly nuclear in G101W (p16-mutated) patients, suggesting that a feature of the mutant protein is that it affects intracellular localization. This would confirm *in vivo* what has been previously observed in functional re-assessment of this p16 variant, which also detected a predominantly nuclear localization of the mutant protein by immunofluorescence.

**Are Mutations in the von Hippel Lindau Gene Involved in Renal Carcinogenesis in Tuberous Sclerosis Complex Patients?** *K.A. Duffy*<sup>1</sup>, *T. Al-Saleem*<sup>2</sup>, *E. Petri Henske*<sup>1</sup>. 1) Department of Medical Oncology, Fox Chase Cancer Center, Philadelphia, PA; 2) Department of Pathology, Fox Chase Cancer Center, Philadelphia, PA.

Tuberous sclerosis complex (TSC) is a tumor suppressor gene disorder characterized by seizures, mental retardation, and tumors of the brain, heart, skin, and kidney. The cellular pathways leading to renal cancer in TSC patients have not been characterized. Renal cell carcinomas occur in children as well as in adults with TSC and are pathologically heterogeneous, including clear cell, chromophobe, and papillary subtypes. This heterogeneity is in contrast to von Hippel Lindau (VHL) patients who develop almost exclusively clear cell renal cell carcinomas. We have previously found loss of heterozygosity in the *VHL* region of chromosome 3p in some TSC renal cell carcinomas. In addition, the majority of sporadic clear cell carcinomas have *VHL* mutations. Therefore, mutations in *VHL* could be downstream genetic events in some TSC-associated renal cell carcinomas, particularly those with clear cell morphology.

We analyzed renal cell carcinomas from seven TSC patients for mutations in the *VHL* gene. All tumors were clear cell in subtype. The age range of the patients was 7-68, with an average age of 41 years. The *VHL* gene was examined by direct sequencing of tumor DNA from paraffin embedded tissues. To date, we have not identified mutations in any of the three exons of the *VHL* gene. This is, to our knowledge, the first indication that clear cell renal cell carcinomas in TSC develop in the absence of *VHL* mutations. This may have biological and clinical relevance to the cellular pathways leading to renal cancer in the general population.

**Screening B cell lymphomas for mutations in the Nijmegen Breakage Syndrome gene (NBS1).** *K.M. Cerosaletti<sup>1,2</sup>, A. Morrison<sup>1</sup>, D. Willerford<sup>2</sup>, P. Concannon<sup>1,2</sup>*. 1) Molecular Genetics, Virginia Mason Res Ctr, Seattle, WA; 2) University of Washington School of Medicine, Seattle, WA.

Nijmegen Breakage Syndrome (NBS) is a rare autosomal recessive disorder characterized by chromosomal instability, radiation sensitivity, immunodeficiency, and a high incidence of cancers. Among NBS patients with malignancies, 73% were B cell lymphomas. The gene mutated in NBS patients (NBS1) encodes a novel 85 kD protein (nibrin). All NBS patients have truncating mutations in NBS1 and do not produce full-length protein. Nibrin appears to play a role in maintaining genomic integrity, since it forms a complex with the Mre11/Rad50 proteins, involved in the repair of DNA double strand breaks, and may be the primary target of phosphorylation by ATM in response to ionizing radiation. To determine if the NBS1 gene is mutated in sporadic cases of non-Hodgkins B cell lymphoma (NHL), we screened 91 NHL cases and 154 normal controls from the Seattle area. DNA was extracted from paraffin blocks of lymphoma samples and PBL of normal controls, and was screened for mutations in the NBS1 gene by SSCP. We found one null mutation, the founder mutation 657del5, in one of the NHL DNAs (1.1% incidence, 95% CI 0.03%-6%) but not in the normal controls (0% incidence, 95% CI 0%-1.9%). One other variant was identified in a NHL DNA which altered an amino acid, 628G/T > V/F210. This variant was not found in the controls. A different variant, 643C/T > R/W215, was identified in a control. The effect of these amino acid changes on nibrin structure or function is unknown. The remaining sequence variants identified included five common polymorphisms, 102G/A, 553G/C > E/Q185, IVS9+18C/T, 1197 T/C, and 2016A/G. Five rare variants that do not alter the amino acid sequence of nibrin were also identified. The frequency of these polymorphisms did not differ significantly between cases and controls. Given the low incidence of NBS reported in North America, < 1 in 10 million, identification of a NBS1 mutation in a small sample of NHL cases suggests that carriers may be at increased risk for NHL. However, mutations in the NBS1 gene do not appear to be a major contributor to NHL susceptibility in the U.S. population.

**MOLECULAR STUDY OF WT1, IGF2, H19 Y P57KIP2 GENES IN MEXICAN CHILDREN WITH WILMS' TUMOR** <sup>KIP2</sup>. A. Cervantes<sup>1</sup>, F. Salamanca-Gomez<sup>1</sup>, C. Barrientos-Salcedo<sup>1</sup>, R. Pealoza<sup>1</sup>, D. Arenas<sup>1</sup>, J. Vazquez<sup>2</sup>, G. Sciordia<sup>3</sup>, J. Velazquez<sup>4</sup>. 1) Unit of Medical Investigation in Human Genetics, Children Hospital, Medical Center S. XXI,IMSS; 2) Department of Oncological Surgery, Children Hospital,Medical Center S XXI,IMSS; 3) Department of Pathology, Children Hospital,Medical Center S XXI,IMSS; 4) Department of Pediatric Surgery, General Hospital, Mediactal Center La Raza,IMSS.

MOLECULAR STUDY OF WT1, IGF2, H19 AND P57KIP2 GENES IN MEXICAN CHILDREN WITH WILMS TUMOR Barrientos C, Pealoza R, Arenas D, Palma V, Vzquez J, Velzquez J, Sciordia G, Salamanca F. Wilms Tumor is a kidney embrionary neoplasia, which in Mexico constitutes 5.5 percent of all childhood malignancy neoplasia. It has been associated to mutations in WT1 gene (Little, et al.,1995), and alterations in expression of genes that show genetic imprinting: H19, IGF2 and P57KIP2 (Taniguchi et al.,1995; Baird et al.,1997). We studied by PCR-SSCP and sequencing techniques, the mutations in the zinc finger region of WT1 gene in 25 Mexican children with sporadic Wilms tumor. Four different mutations were found. One of them no previously reported (insA1002 Y334Stop) was present in four blastemal cellular type tumors. Other mutation guanine for cytosine was change in intron 9 located at 160 bp upstream of beginning of 10 exon present in three tumors. The G1296C V432L mutation was present in two patients and the last one was C1041G that change H347N. The differential expression of parental alleles of H19, IGF2 and P57 KIP2 genes was also studied in four patients with Beckwith-Wiedemann syndrome and Wilms tumor by RT-PCR and CFLPs techniques using MspI for H19, ApaI for IGF2 and Cfo II for P57 KIP2. Our results indicated no expression of H19 in three patients and loss of imprinting (LOI) of IGF2 in two case and P57KIP2 of an another two patients. These results show genetic heterogeneity of WT1 gene but a novel mutation highly prevalent in the Mexican population. These findings also support the roll of genetic imprinting in the carcinogenic process.

**P53 Gene Mutations in Russian Patients with Breast Cancer Detected by Chemical Cleavage of Mismatch. A.**

*Lambrinakos<sup>1</sup>, M. Yakubovskaya<sup>2</sup>, J.J. Babon<sup>1</sup>, A.A. Neschastnova<sup>2</sup>, Ya.V. Vishnevskaya<sup>2</sup>, G. D'Cuhna<sup>1</sup>, R.G.H. Cotton<sup>1</sup>.* 1) Mutation Research Centre, St. Vincent's Hospital, Melbourne, VIC, Australia; 2) Institute of Carcinogenesis, Russian Academy of Medical Sciences, Moscow, Russia.

Mutations in the tumor-suppressor p53 gene are frequent and seen in most human cancers including breast cancer. A new solid phase chemical cleavage of mismatch method (CCM) involving silica beads made it possible for rapid and efficient screening of 89 different fluorescently labeled PCR products amplified from DNA samples extracted from tumors of breast cancer patients. Single tube CCM was incorporated and effectively utilized on silica beads. The potassium permanganate/tetraethylammonium chloride (KMnO<sub>4</sub>/TEAC) and hydroxylamine (NH<sub>2</sub>OH) reactions occur sequentially in a single tube. Mutation analysis involved pairing and forming heteroduplexes with the 89 different samples and screening the p53 gene from exons five to nine with the solid phase silica beads CCM. Forty-eight signals were evident in the 89 pairs of samples. Five signals were present in exons five and nine. Ten in exon six, thirteen in exon eight and fifteen signals detected in exon seven. Of the 48 CCM signals eight mutations were confirmed and identified by sequencing. The three novel mutations detected are R213L, N200K (2 patients), and L201V (2 patients). The mutations T253I, G244C and delT256 have not been reported in breast cancer but have been recorded in other tumor organs. A putative 47bp deletion at codon position 198 was detected and never reported. A mutation H179Y previously reported in breast cancer was also detected. These mutations presumably contributed to the carcinogenesis in the breast. Forty signals were not identified as a sequence change. As no false positive signals have been detected with CCM, these signals indicated CCM is more sensitive in detecting mutations in mixed mutant and wild type compared to sequencing.

**Intronic *BRCA1* mutations in two highly affected kindreds.** *I.M. Kedar-Barnes*<sup>1</sup>, *P. Devilee*<sup>2</sup>, *H. Meijers-Heijboer*<sup>3</sup>, *J. Klijn*<sup>3</sup>, *S.E. Plon*<sup>1</sup>. 1) Baylor College of Medicine, Houston, TX; 2) Leiden University Medical Center, Netherlands; 3) Erasmus University Medical Center, Rotterdam, Netherlands.

Germline mutations in the *BRCA1* and *BRCA2* genes have been extensively studied in Caucasian populations including the Ashkenazi Jewish population. However, less is known about mutations in these genes in other population groups. In addition, most deleterious mutations interrupt the coding portion of the gene or the flanking 3' and 5' splice sites. We would like to report 2 new mutations at the same intronic residue, which have been identified in very highly affected African American and Dutch/Belgian families.

Family 1: The proband was a 44 years old African American woman diagnosed with breast cancer at age 27. Her family history was remarkable for 4 sisters with early-onset breast cancer with the age of diagnosis ranging from age 24-32 years old and a mother who had died of breast cancer at age 35. Her maternal grandmother had postmenopausal breast cancer. There were no cases of ovarian cancer. Her brother had colon cancer diagnosed at age 35. Full sequence analysis of *BRCA1* and *BRCA2* at the Myriad Genetic Laboratories Inc., revealed an intronic mutation in the *BRCA1* gene: IVS22+5G>T. She also had a known variant I3412V in the carboxy terminus of *BRCA2*.

Family 2: A Dutch/Belgian family highly affected with breast and ovarian cancer was studied. The proband was diagnosed at age 41 with breast cancer. Her family history included: 3 first degree relatives with early-onset breast cancer and 10 other relatives with early-onset breast and ovarian cancer. The age of diagnosis for breast cancer was from 30-45 years old. Analysis at the University of Leiden revealed the proband and a cousin carried a IVS22+5G>A mutation in the *BRCA1* gene which segregated with cancer in the family. cDNA analysis confirmed deletion of exon 22 which results in truncation of the protein.

This data suggests that mutation at IVS22+5 disrupts splicing at exon 22 in *BRCA1* and results in a high risk of very early-onset breast and ovarian cancer.

**Analysis of MLL septin-like fusion (*MSF*) in breast cancers as a candidate 17q25 tumor suppressor gene.** *L.M. Kalikin, C.K. Neeley, E.M. Petty.* Dept Internal Medicine, Univ Michigan, Ann Arbor, MI 48109-0638.

We cloned a novel 17q25 septin-like gene from a 300 kb breast tumor suppressor gene candidate interval that we defined by allelic imbalance studies. Interestingly, this gene was also identified as a fusion partner with *MLL* on 11q23 in acute myeloid leukemia patients and was named MLL septin-like fusion (*MSF*). Septins belong to a highly conserved GTPase subfamily, bind to membrane phospholipids, polymerize into filaments, and coordinate cell cycle progression. Yeast septins localize to the cleavage furrow and, when mutated, result in elongated buds, delayed mitosis, and multinucleated cells. Mammalian septins localize to the contractile ring with mutations leading to multinucleated cells. We have identified 3 alternatively spliced 5' exons that predict 3 amino-terminal distinct *MSF* protein isoforms. Other results predict two additional carboxy-terminal distinct isoforms. RNA expression studies using a probe common to all isoforms show differential expression of 3.0 kb and 4.0 kb *MSF* transcripts in all fetal and adult tissues tested.

Given that septins appear to play an integral role in the cell cycle, including cell division, signal transduction and cytoskeletal scaffolding, we hypothesize that altered *MSF* expression could contribute to carcinogenesis. Therefore we further investigated *MSF* as a positional candidate for the 17q25 suppressor gene. Northern blot analyses of breast tumor cell lines revealed 8 of 22 lanes with variable sized transcript bands not found in 5 normal breast cell lines. However, only silent polymorphisms were identified in the coding region of the 8 lines. Similarly no functionally significant nucleotide alterations were found in the coding region of 7 paraffin embedded breast tumors with minimal 17q25 allelic imbalance. These initial results do not support a direct role for *MSF* mutations in breast tumorigenesis. However, a role for alternatively spliced transcript expression has not been excluded. Further *MSF* expression and functional analyses are underway as well as characterization of other novel transcripts in the interval.

**Loss of heterozygosity and RB1 mutations associated with retinoblastoma in Mexican patients.** *L. Orozco*<sup>1,2,3</sup>, *A. Atkinson*<sup>2</sup>, *M. Macias*<sup>1</sup>, *F. Garcia*<sup>1,3</sup>, *C. Ridaura*<sup>1</sup>, *M. Dean*<sup>2</sup>. 1) Human Genetics and Pathology Departments, Instituto Nacional de Pediatría. Mexico, DF., Mexico; 2) Laboratory of Genomic Diversity, National Cancer Institute-FCRDC, Frederick, MD; 3) Interinstitutional Program of Molecular Biomedicine. CICATA-IPN. Mexico City, Mexico.

Retinoblastoma (RB) results from mutations or inactivation of both alleles of the RB1 gene. Approximately 40% of all cases are hereditary. Children with heritable RB are usually diagnosed within the first year of age, and develop bilateral or multiple tumors. Fifteen percent of unilateral RB cases are heritable. Children with nonhereditary RB tend to develop unilateral tumors at a later age than do children with the hereditary form of the disease. In Mexico, RB is the third most frequent cause of cancer in children and 56% develop the tumor during the first year of age. Although RB is usually recognized clinically, some forms of the disease can elude diagnosis. Here we report the results of a mutational analysis of blood samples and paraffin embedded RB tumors from 34 unrelated Mexican patients. Using SSCP and sequencing we identified 11 different RB1 mutations (33%), six of them have not been previously reported by the RB1-gene mutation database. We also characterized three novel polymorphisms. In two unilateral cases a RB1 mutation also was detected in peripheral blood DNA. Somatic mosaicism was suggested in one bilateral case without a detectable mutation in peripheral blood. A mutation was found in a mother without RB, revealing a non-penetrance case. Screening for BamHI and XbaI intragenic polymorphisms is underway. Our initial results show that loss of heterozygosity (LOH) at both loci might be less frequent among tumors where mutations were not detected. Our results suggest that the detection of RB1 mutations and LOH in Mexican population is lower than that observed in other populations mainly from developed countries.

**BRCA1 mutation analysis in Greek breast cancer families.** *A.C. Schofield<sup>1</sup>, L. Ioannidou-Mouzaka<sup>2</sup>, N.E. Haites<sup>1</sup>.* 1) Medical Genetics, Univ Aberdeen, Aberdeen, Scotland; 2) Univ Athens, Greece.

Inherited predisposition to breast and ovarian cancer, which accounts for about 5-10% of these cancers, has been associated with mutations in the BRCA1 and BRCA2 genes. At present, the prevalence of BRCA1 mutations in Greek breast cancer families is unknown. We have identified 25 breast cancer families in the Greek population for BRCA1 mutation analysis. Of these, 6 families contain 1 breast cancer only (diagnosed under 35 years), 13 families with 2 breast cancer cases, 4 families with 3 breast cancer cases and 2 families with breast and ovarian cancer. The heterozygote risk of carrying an inherited predisposition breast cancer gene ranges from 6.7%-93.5%. The BRCA1 gene was screened for mutations by SSCP analysis. SSCP variants were further characterised by direct DNA sequencing. Our results to date have identified the presence of 5382insC mutation in 3/24 families (12.5%). In addition, a novel missense mutation, Pro1856Ser, has been identified in one case. Furthermore, a number of different sequence variants have been found in intronic and coding regions. Most of these represent polymorphisms, and studies are underway to determine the frequency of these variants in the Greek population. Our initial results suggest that the 5382insC mutation may represent a common founder mutation in the Greek population.

**Characterization of functional mutations in the human estrogen receptor gene in breast cancer.** *S.G. Roth<sup>1</sup>, S.M. Gollin<sup>1,2</sup>, M.D. Nichols<sup>2,3</sup>*. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) University of Pittsburgh Cancer Institute, Pittsburgh, PA; 3) Department of Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh, PA.

The human estrogen receptor (ER) acts as a transcription factor for estrogen-responsive genes in reproductive organs. The normal ER responds when bound by a ligand, which may either repress or activate genes depending on the conformation of the ER protein. The presence or absence of the ER in human breast cancer is utilized widely as a laboratory indicator for treatment approaches. Studies have suggested that tumors expressing the ER respond to tamoxifen, an anti-hormone drug. An abnormal conformational change results when the ER is bound by tamoxifen, thereby hindering the transcriptional activity of ER protein on estrogen-responsive genes. In certain ER-positive breast tumors, the response to tamoxifen does not repress transcription, instead activates it. In these tumors, perhaps a mutation in the gene coding for the ER results in abnormal protein function. Identifying mutations will help in understanding the role of an altered ER protein in breast cancer. A number of assays were used in this study to determine the genetic basis of ER dysfunction. Human breast tumors at various stages of disease were collected to recover RNA for ER cloning. A qualitative analysis examined how recovered human ER from tumors responds to a series of hormones and antihormones, using a fusion protein of the ER with a site-specific recombinant enzyme, FLP. Activation of the FLP-ER fusion protein complex led to excision of genetic markers. The assay indicated the presence of ER mutations through color changes after the FLP-ER complex was activated. Direct sequence analysis characterized mutations in altered ER clones, which revealed deletions and base pair mutations within the ligand binding domain of the ER that changed the amino acid sequence. These results confirm that certain deletion and point mutations in the gene coding for the ER in human breast tumors alter the conformational properties and subsequent activities of the ER protein.

**Comprehensive mutational analysis of the ATM gene by denaturing HPLC.** *Y.R. Thorstenson<sup>1</sup>, P.J. Oefner<sup>1</sup>, V. Goss<sup>2</sup>, R.W. Davis<sup>1</sup>, R.A. Gatti<sup>3</sup>, G. Chu<sup>2</sup>.* 1) Stanford Genome Tech Ctr, Palo Alto, CA; 2) Stanford Univ Medical Ctr, Stanford, CA; 3) UCLA Medical Ctr, Los Angeles, CA.

ATM is the gene mutated in the autosomal recessive disease Ataxia-telangiectasia (A-T). ATM is a complex gene with 66 exons and 9168 base pairs of coding sequence in a genomic region of 150,000 base pairs. A worldwide effort to identify all of the mutations responsible for A-T has been hindered by the large size of the gene, as well as the heterogeneity of the causative mutations. Furthermore, most A-T patients are compound heterozygotes - a challenging situation even for conventional dideoxy sequencing protocols. Given these difficulties, it may not be surprising that published reports indicated a detection rate of only about 75%. Here, a new mutation detection strategy using denaturing HPLC (DHPLC), is compared with conventional protein truncation test (PTT), and single-strand conformation polymorphism analysis (SSCP). A set of 60 genomic DNA samples from 55 A-T patients and 5 obligate carriers was blinded to the DHPLC operator. The samples included mutations that had proven difficult to detect; only 69 out of 115 expected alleles had been identified previously (60%). DHPLC analysis confirmed all 69 and added 27 more alleles, for a total of 96 alleles (83%). Given that the sensitivity of DHPLC is close to 100%, it is likely that the remaining 19 alleles involve intron or flanking sequences in the ATM gene. The 96 alleles included 65 unique disease-causing mutations, including 23 not reported before. Of 19 unique mutations that were detected only by DHPLC, one was a single base pair insertion, and 18 were single nucleotide changes, clearly demonstrating a bias for detection of insertion and deletion mutations using conventional methods. Furthermore, the 18 newly detected single base pair changes were functionally relevant, including five premature stops, six non-conservative amino acid changes at residues conserved in the mouse ATM homolog, three alterations at canonical splice donor or acceptor sites, and four disruptions of potential splice enhancer motifs. Hence, many more of the previously undetected mutations in A-T patients may be caused by single base pair changes.

**Sequence variation of the ARA24 gene and prostate cancer in African Americans.** *R.K. Panguluri<sup>1</sup>, W. Chen<sup>1</sup>, C. Ahaghotu<sup>2,3</sup>, W. Isaacs<sup>4</sup>, G.M. Dunston<sup>1,3</sup>, R.A. Kittles<sup>1,2,3</sup>*. 1) National Human Genome Center at Howard University; 2) Division of Urology, Howard University Hospital; 3) Howard University Cancer Center, Washington, DC; 4) Johns Hopkins Medical Institutions, Baltimore, MD.

ARA24 is an androgen receptor associated protein that has been shown to interact with the androgen receptor's (AR) N-terminal polyglutamine tract and enhances coactivation of the AR. In Kennedy's disease, ARA24 interacts weakly with longer AR polyglutamine tracts producing a weaker coactivation of the AR. Shorter polyglutamine tracts in the AR are more common among populations of African descent than other ethnic groups. The prevalence of prostate cancer is higher in African Americans compared to any other ethnic group and this may be attributed to the shorter AR polyglutamine repeats. Genetic variation of the ARA24 gene may increase or decrease coactivation of the AR leading to higher or lower activity of the AR. The purpose of this study was to screen the ARA24 gene for single nucleotide polymorphisms (SNPs) that may contribute to greater coactivation of ARA24 with smaller polyglutamine tracts of the AR in African Americans. African American prostate cancer cases and matched controls were screened for ARA24 SNPs by DHPLC and direct sequencing. The ARA24 gene has a single open reading frame of 651 bases that encodes a protein of 216 amino acids. We observed that the ARA24 gene sequence data in published databases such as NCBI contained many discrepancies in the sequence. A consensus sequence of the ARA24 gene was obtained by using African American, European, and Asian samples. Screening of the ARA24 gene revealed 5 non-synonymous mutations (T25P; V27M; E105D; L163W; S181A) and 1 synonymous mutation (G103G). One of these variants V27M was genotyped in prostate cancer cases (n=97) and controls (n=91). The frequencies of this allele are 0.07 and 0.06 in cases and controls, respectively. No association between prostate cancer and this variant was observed (p=0.8). The discovery of these novel SNPs will provide the opportunity to test for haplotype associations as well as genotype-genotype interactions with other androgen related genes influential in the etiology of prostate cancer.

**A tumor suppressor gene for the development of cervical cancer has been localized to a region of 400 kb that contains 8 potential transcripts.** *D.S. Gerhard<sup>1</sup>, T.L. Nguyen<sup>1</sup>, Y. Li<sup>2</sup>, P. Huettner<sup>3</sup>, A. Mungall<sup>4</sup>, J.S. Rader<sup>2</sup>.* 1) Dept Genetics, 8232, Washington Univ Sch Medicine, St Louis, MO; 2) Dept. of Obstetrics & Gynecology, Washington University SOM, St. Louis; 3) Dept. of Pathology, Washington University SOM, St. Louis; 4) 4Sanger Centre, Hinxton, England.

There are ~400,000 new cases of invasive cervical cancer (ICC) each year. A number of factors increase the risk of tumor development, but the most consistent risk factor is human papillomavirus (HPV) infection. HPV infection alone is not sufficient for the development of ICC since most infected women do not have tumors. We have previously determined that a large number of cervical tumors have lost all or part of 6p, suggesting that a TSG is localized there. We have also found deletions of 6p in the precursor lesion. About 50% of 139 invasive tumors, of all stages and histologic types, lost at least 6p21-6p23; some deletions were larger. A number of tumors have overlapping interstitial deletions of 6p23 and the composite information indicates that the boundary of the candidate region is defined by the markers D6S429 and D6S1578. This region of ~1 cM or ~1.4 Mb is covered by a contig of BACs and PACs. The contig allowed us to order 3 known, but unlocalized polymorphisms and from the recently generated sequence we developed 2 additional polymorphic loci. With these new markers we were able to identify one tumor whose deletion appears to be about 400 kb. Homology search of the 400 kb genomic sequence against the dbEST revealed the presence of at least 11 distinct clones. However, a careful examination of the EST versus genomic sequence revealed that at least 3 of the clones are genomic contaminants. We sequenced both 5 and 3 ends from the remaining 8 clones and found that 4 has an IVS, while the rest do not. One clone has only 600 bp, but does not have an orf. It is present in the cervix by RT-PCR and in situ hybridization. The expression of this gene in tumors is under investigation. Preliminary data show it to be overexpressed in ovarian carcinoma. Experiments are ongoing to determine its function in cervical cancer. Experiments are also underway to investigate the other transcripts mapped to the candidate region.

**Biochemical Characterization of the Mismatch Repair Protein MED1 (MBD4).** A. Bellacosa<sup>1,2</sup>, F. Petronzelli<sup>1,2</sup>, A. Riccio<sup>1</sup>, G.D. Markham<sup>1</sup>, S.H. Seeholzer<sup>1</sup>, J. Stoerker<sup>3</sup>, M. Genuardi<sup>2</sup>, A.T. Yeung<sup>1</sup>, Y. Matsumoto<sup>1</sup>. 1) Human Genetics Program, Fox Chase Cancer Center, Philadelphia, PA; 2) Department of Medical Genetics, Catholic University Medical School, Rome, Italy; 3) Bruker Daltonics, Billerica, MA.

We recently isolated the human protein MED1 (also known as MBD4) in a two-hybrid screening using the mismatch repair protein MLH1 as a bait, and reported that MED1 has homology to bacterial base excision repair DNA N-glycosylases/lyases (Bellacosa, A. et al. *Proc. Natl. Acad. Sci. U.S.A.*, 1999). Via its 5-methylcytosine binding domain (MBD), MED1 binds to methylated DNA; this suggests that DNA methylation may affect MED1 repair processes. The MED1 (MBD4) gene is frequently mutated in human carcinomas exhibiting microsatellite instability (Riccio et al. *Nature Genet.*, 1999; Bader et al. *Oncogene*, 1999). In colorectal cancer specimens, we also detected loss of heterozygosity at the MED1 (MBD4) locus, suggesting that this gene may act as a tumor suppressor. Here we show that MED1 functions as a mismatch-specific DNA N-glycosylase active on thymine, uracil, 5-fluorouracil and, weakly, on the mutagenic adduct 3,N4-ethenocytosine, when these bases are opposite to guanine. The glycosylase activity of MED1 prefers substrates that contain a G:T mismatch within a methylated or unmethylated CpG site. Since G:T mismatches can originate via deamination of 5-methylcytosine to thymine, these findings indicate that MED1 may act as a caretaker of genomic fidelity at CpG sites. In order to gain insight in the molecular mechanisms of action of MED1, we conducted a kinetic analysis of the glycosylase reaction. This analysis revealed that MED1 displays a fast first cleavage reaction followed by slower subsequent reactions, resulting in biphasic time course. This is due to the tight binding of MED1 to the AP site reaction product rather than a consequence of enzyme inactivation. Comparison of kinetic profiles revealed that the MBD and methylation of the mismatched CpG site are not required for efficient catalysis, indicating that the roles of cytosine methylation and of the MBD in DNA repair by MED1 are independent of glycosylase activity.

**A conserved gene antisense to the proto-oncogene *c-RAF* encodes a multi-zinc-finger protein, MAKORIN2.** T.A. Gray<sup>1</sup>, K. Azama<sup>2</sup>, K. Whitmore<sup>1</sup>, A. Min<sup>1</sup>, S. Abe<sup>2</sup>, R.D. Nicholls<sup>1</sup>. 1) Dept Genetics, Case Western Reserve Univ, Cleveland, OH; 2) Faculty of Agriculture, Ehime Univ., Matsuyama, Japan.

High levels of *c-RAF* proto-oncogene expression occur in some human lung cancers, and recent studies have shown that over-expression of wildtype *c-Raf* in a mouse model leads to an increased incidence of lung tumorigenesis. The *c-RAF* proto-oncogene can be downregulated by antisense oligonucleotide therapy, culminating in a reduced growth rate for treated cells. Combined, the data suggest that regulation of *c-RAF* expression is an important factor in some cancers. Here, we describe a novel gene, MAKORIN RING zinc-finger 2 (*MKRN2*), that overlaps and is antisense to *c-RAF*. Northern blot analyses show that human and mouse *MKRN2* and *c-RAF* are concurrently transcribed, suggesting that the mRNA products may form RNA duplexes. We have also identified *MKRN2* orthologs in fish and birds, placing the gene duplication event that gave rise to this locus early in vertebrate evolution, at least 450 million years ago. All MAKORIN2 orthologs are well-conserved (56%-93% amino acid identity) and retain the hallmark RING and C3H zinc-finger composition of the MAKORIN protein family. While the function of MAKORIN2 is unknown, RING and C3H zinc-fingers suggest macromolecular and ribonucleoprotein roles, respectively, and poxviral derivatives homologous to the MAKORIN protein family circumvent apoptotic pathways. Taken together, our data identify a conserved vertebrate *MKRN2* gene that overlaps the *c-RAF* locus in a tail-to-tail orientation. The conservation of this arrangement implies that it is evolutionarily advantageous, possibly due to co-regulation of the *MKRN2* and *c-RAF* antisense mRNA and/or protein products. Present studies are examining a functional link between *MKRN2* and *c-RAF*, and evaluating *MKRN2* for disruption in human cancers.

**An expression microarray for investigation of genes involved in loss of heterozygosity on chromosome 16 in breast cancer.** *A.M. Cleton-Jansen<sup>1,2</sup>, T. Van Wezel<sup>1</sup>, E. Hogenhout<sup>1</sup>, H.M. Van Beerendonk<sup>1</sup>, M. Van den Berg<sup>2</sup>, J. Den Dunnen<sup>2</sup>, G.J.B. Van Ommen<sup>2</sup>, C.J. Cornelisse<sup>1</sup>.* 1) Pathology , LUMC, Leiden, The Netherlands; 2) Human and Clinical Genetics, LUMC, Leiden, The Netherlands.

Molecular-genetic as well cytogenetic studies have revealed that loss of heterozygosity (LOH) at the long arm of chromosome 16 (16q) belongs to the most frequent genetic alterations occurring in breast cancer. In a previous study we identified two separate smallest regions of overlap (SRO) involved in LOH at 16q22.1 and 16q24.3. A detailed investigation of genes in the SRO at 16q24.3 has so far not led to the identification of the gene targeted by LOH. We now want to use a different approach that will lead to the identification of the tumour suppressor gene(s) thereby making use of the wealth of data generated by the human genome project and the novel technique of cDNA expression arrays. Microarray construction and scanning is performed at the Leiden Genome Technology Centre. We are constructing a microarray containing partial cDNA clones of genes and ESTs (expressed sequence tags) that are mapping to the region which is most frequently involved in LOH, i.e. 16q22.1-qter. Information on the presence of transcribed sequences at this locus is obtained from the public databases such as Genemap '99, and from the large scale sequencing efforts. Special effort is put into obtaining the genes from the two SROs at 16q22.1 and 16q24.3. Genes and ESTs are PCR-amplified from a 40,000 clone library constructed by the I.M.A.G.E. consortium and PCR products are spotted onto microscope glass slides in an arrayed fashion. The microarrays are hybridized with labeled RNA from normal mammary epithelium versus breast cancer cells obtained from cultured cells or primary tumours. The result shows which genes are expressed in mammary epithelial cells, both normal and tumour cells. Furthermore it is anticipated that in a subset of the tumours a gene shows repeatedly decreased transcription. This microarray analysis will facilitate the selection of potential candidate genes, which will be further investigated in tumours showing LOH at chromosome 16.

**A microcell hybrid based approach to identify chromosome 3p genes that antagonize tumor growth. I.D. Kholodnyuk, A. Szeles, M. Kost-Alimova, V. Kashuba, Y. Yang, G. Klein, S. Imreh.** MTC, Karolinska Institute, Stockholm, Sweden.

We have previously shown that inoculation of human chr3/A9 mouse fibrosarcoma microcell hybrids (MCHs) into SCID mice was followed by the regular elimination of some 3p regions (Imreh et al., 1994). Using this approach, referred to as the elimination test (Et), we have defined a common eliminated region (CER) at 3p21.3 and an eliminated region (ER) at 3p21.1-p14.2 (Kholodnyuk et al., 1997). ER partially overlaps the FHIT gene, considered as a putative TSG. In the present work, the new MCHs and 13 derived SCID tumors, were analyzed by FISH and by PCR using 83 chr3-specific markers. Nine tumors generated from 3 MCHs remained PCR-positive for all chr3 markers tested ("PCR+" tumors). FISH showed normal intact chr3 in 65-98 % of MCHs cells and in 16-75% of tumor cells. Although FISH reverse painting (FISH-RP) has indicated losses over 3p26-3p25, 3p24, 3p22, 3p21 and 3p14. The "PCR+" tumors were examined by RT-PCR for the expression of 23 human genes: 5 genes within CER1 (LIMD1, CCR1, CCR2, CCR3, CCR5), 7 genes located within regions that were homozygously deleted in a variety of carcinomas (ITGA4L, SEMA4, GNAI2, LUCA1, PTPRG, FHIT, DUTT1), and 11 other genes in chr3p. We have found that VHL, MLH1, ITGA4L, NKTR, CTNBN1, LIMD1, UNPH, TCTA, APEH, UBE1L, SEMA4, LUCA1, PTPRG and DUTT1 were expressed in the SCID tumors as well as in the MCH lines in vitro. FHIT was expressed in vitro in 5 out of 7 MCH lines. Nine of 13 derived tumors had no FHIT transcript. The remaining 4 expressed a truncated mRNA. We have previously found that FHIT was deleted at the DNA level in 21 tumors derived from 4 MCHs. Our compiled data show that FHIT was either physically or functionally impaired in all 34/34 analyzed tumors. This suggests that the expression of the human FHIT gene in mouse fibrosarcoma cells impairs the growth potential of the cells in SCID mice. Interestingly that the transcript of the murine homologue of FHIT was lost also from the MCHs after growth in SCID mice. Comparative duplex RT-PCR revealed also significant reduction of the amount of GNAI2 transcript and DLEC1 transcript in SCID tumors versus the MCH lines in vitro.

**Identification of Novel Tumor-Associated Genes in 11q12-q23.** *R.A. Kuner, E. Dahl, C. Pilarsky, T. Specht, A.O. Schmitt, B. Hinzmann, B. Weber, M. Choschzick, E. Staub, A. Buss, B. Petschke, A. Rosenthal.* metaGen GmbH, Berlin, Germany.

Tumor development is characterized by chromosomal disorders which may lead to activation of oncogenes or loss of tumor suppressor genes. In gynecological tumors, genetic information within chromosomal region 11q12-q23 is often amplified or lost. Assuming that chromosomal rearrangements in tumors cause changes in gene expression, four million ESTs available in public and proprietary EST databases were subjected to in silico expression analysis using assembled cDNA sequences (Schmitt et al., 1999). In this first approach 600 candidate genes were identified which are associated with sporadic forms of gynecological tumors (Dahl et al., in preparation). Chromosomal assignment of these 600 genes localized 15 genes within 11q12-q23. To achieve an even higher coverage of tumor-associated genes for this critical chromosomal region we analyzed 968 STS-markers between RH13699 (11q12) and RH27416 (11q23) for expression analysis as aforementioned. Using this strategy we identified a total of 69 genes which are significantly differentially expressed in gynecological tumors. 47 of these genes have been described previously, whereas 22 are novel. Verifying these in silico data by Northern blot technique, RNA in situ hybridization and RT-PCR, we identified one novel gene in 11q14.1 which may represent a tumor suppressor gene.

**Suppression of prostate cancer tumorigenicity by chromosome 18.** *T.L. Johnson-Pais<sup>1</sup>, S.S. Padalecki<sup>2</sup>, K. Weldon<sup>3</sup>, A.M. Killary<sup>4</sup>, R.J. Leach<sup>1,3</sup>.* 1) Dept Pediatrics, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Dept Medicine, Univ Texas Health Sci Ctr, San Antonio, TX; 3) Dept Cellular & Structural Biology, Univ Texas Health Sci Ctr, San Antonio, TX; 4) Div of Laboratory Medicine, Univ Texas M.D. Anderson Cancer Ctr, Houston, TX.

Our recent studies of 32 metastatic prostate tumor samples have identified two non-overlapping regions of allelic imbalance on chromosome 18 that are associated with the progression of prostate cancer. We have also analyzed DNA obtained from the human prostate cancer cell lines DU-145 and TSU-PR1 for significant stretches of homozygosity using highly polymorphic markers from chromosome 18. Both of these lines exhibit an apparent loss of heterozygosity on the long arm of chromosome 18. DU-145 appears to have lost both regions, while TSU-PR1 appears to have lost only the more distal region at 18q22-q23. In an effort to identify putative tumor suppressor genes located within these regions on chromosome 18 that are involved in prostate cancer, we have used microcell-mediated chromosome transfer to introduce an intact chromosome 18 and chromosome 8 into TSU-PR1 cells. We have also introduced an intact chromosome 18 into DU-145 cells. While introduction of an intact chromosome 8 had no effect on the in vitro growth properties or the in vivo tumorigenicity of TSU-PR1 cells, microcell hybrids containing an introduced chromosome 18 exhibited a longer population doubling time, retarded growth in soft agar and slowed tumor growth in vivo. Introduction of chromosome 18 into DU-145 cells also had a profound effect on the in vitro growth of the hybrids, which precluded isolation of hybrid cells for further analysis. These experiments provide functional evidence for the presence of at least one tumor suppressor gene on human chromosome 18 involved in prostate cancer.

**The *RET* proto-oncogene and its ligand *GDNF* are expressed in human head and neck tumors.** *M.A. Nagai*<sup>1</sup>, *L.P. Kowalski*<sup>2</sup>, *L.M. Mulligan*<sup>3</sup>. 1) Disciplina de Oncologia, Depto de Radiologia, Fac de Medicina da USP, Sao Paulo, Brazil; 2) Fundacao Antonio Prudente, Sao Paulo; 3) Department of Pathology, Queen's University, Kingston Canada.

Germline mutations in the *RET* proto-oncogene are associated with multiple endocrine neoplasia (MEN) type 2 syndromes and Hirschsprung disease. In addition to that, somatic mutations in the *RET* gene have been demonstrated in human thyroid carcinomas. To date, there have been no reports describing the involvement of this proto-oncogene in human tumors from other anatomic sites of the head and neck. In the present study, using RT-PCR, we have examined the expression of *RET* proto-oncogene and *GDNF* transcripts in RNA samples from both tumor and normal tissue from 15 patients with head and neck carcinomas (oral cavity, 14 cases; larynx, 1 case). We have consistently detected *RET* and *GDNF* expression in the samples analyzed. Moreover, 4 out of the 15 tumors analyzed showed increased levels of *RET* transcripts. Further, using PCR-SSCP we have examined exons 10, 11, 13, 14, 15 and 16 of the *RET* proto-oncogene for the presence of mutations in these tumours which could be associated with the disease phenotype. These exons represent the sites of mutations previously associated with tumorigenesis. So far polymorphisms have been observed in exons 11, 13 and 15 but we have found no evidence of disease associated mutations. Here we show for the first time that transcripts of the *RET* proto-oncogene and its ligand *GDNF* are expressed in head and neck cancer. Further studies will be needed to clarify the role of the *RET* proto-oncogene in the initiation or progression of tumorigenesis in head and neck tumors. Supported by: PADCT/CNPq.

**GFRa-3 variants in human lung carcinoma.** *C.I. Onochie<sup>1</sup>, Y. Shi<sup>1</sup>, J.B. VanHorne<sup>1</sup>, R.M.W. Hofstra<sup>2</sup>, L.M. Mulligan<sup>1</sup>.* 1) Departments of Paediatrics and Pathology, Queen's University, Kingston, ON., Canada; 2) Department of Medical Genetics, University of Groningen, Groningen, The Netherlands.

GDNF family receptor a-3 (GFRa-3) is a co-receptor required for the activation of the RET receptor tyrosine kinase by its circulating ligand artemin. GFRa-3 is most highly expressed in the peripheral nervous system, heart, lung and neuroendocrine cell types. Using RT-PCR, we have shown that GFRa-3 is expressed in a series of small cell (SCLC) and non-small cell (NSCLC) lung carcinoma cell lines. We have previously shown that RET is also transcribed in these lines, suggesting that autocrine or paracrine activation of this system might play a role in tumour progression. To investigate such a role, we performed SSCP analyses of the *GFRa-3* gene in a panel of SCLC and NSCLC tumours. We have not detected mutations or variants of the coding sequence of the *GFRa-3* gene in this population, however, we have identified polymorphisms in introns 4 (IVS4-30A>G) and 7 (IVS7+4insGG) of the gene. The frequency of the intron 4 variant was similar in our tumour lines and control population (7%). However, we found that the IVS7+4insGG insertion was significantly over-represented in a panel of 52 SCLC and NSCLC lines (6%) as compared to our controls population (0.6%;  $p < 0.005$ ). The IVS7+4insGG variant lies within the consensus splice donor site downstream of exon 7, changing it from a GTAGGGCC to GTAGGGGG, and thus has the potential for disrupting splicing of the *GFRa-3* transcripts. We are currently investigating the effect of this variant on *GFRa-3* transcription. The *GFRa-3* gene has been mapped to 5q31, a region of frequent allelic loss in SCLC. Our data suggest that, either *GFRa-3* or a locus linked to it within this region, may have a role in lung tumour development.

**Identification of expression changes of prognostic and therapeutic value in metastasizing medulloblastoma.** T.

MacDonald<sup>1</sup>, K.M. Brown<sup>1,2</sup>, P.H. Cogen<sup>1</sup>, Y.-W. Chen<sup>1</sup>, B. Rood<sup>1</sup>, R.J. Packer<sup>1</sup>, D.A. Stephan<sup>1,3</sup>. 1) Childrens National Medical Center, Washington, DC; 2) George Washington University Genetics, Washington, DC; 3) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Medulloblastoma is a highly malignant cerebellar tumor of children and, less frequently, of adults, with a tendency to early recurrence and dissemination. Despite recent advances in patient survival, the quality of life for survivors is poor due to neurocognitive, neuroendocrine, and hearing deficits as a direct result of the whole brain and spine radiation required for prevention of metastatic disease. Using global expression profiling, we identified genes prognostic of tumor metastasis that may also serve as new therapeutic targets. An initial expression scan was done using a pooling approach, assuming that genetic heterogeneity would not be a significant confounding factor. We isolated total RNA from six metastasizing and six-non metastatic tumors, made biotinylated cRNA, and pooled samples from the two clinical groups in equimolar amounts. Gene expression profiles were generated using Affymetrix HuGeneFL Gene Chips (5600 genes). 266 genes showed differential expression greater than two-fold. The 58 genes expressed at least five-fold more or less between groups were selected for further analysis. 21/30 genes with *increased* expression in metastatic tumors have been implicated in promoting: invasion/metastasis (14), cell growth (4), and angiogenesis (3). 12/28 genes with *decreased* expression in metastatic tumors have been implicated in inhibiting: invasion/metastasis (5), cell differentiation (6), and cell growth (1). Expression of each gene is being characterized via immunostaining (45/58 have available antibodies) and qRT-PCR using 48 frozen and 130 paraffin embedded tumors, and correlated with clinical and pathological data. This study has identified historically valid candidate genes involved in metastatic medulloblastoma, and has shown that a pooling strategy can be utilized effectively to identify candidate genes without complex statistical analysis, as long as validation studies are part of the study design.

**Molecular genetic and mutational analysis of CDKN2A (p14/p16) in 260 human neuroblastomas.** *P.M. Thompson, J.M. Maris, M.D. Hogarty, G.M. Brodeur, P.S. White.* Division of Oncology, Children's Hospital of Philadelphia, Philadelphia, PA.

Neuroblastoma (NB) is a common pediatric tumor arising from post-ganglionic sympathetic neuroblasts. Loss of heterozygosity (LOH) for several specific genomic regions, including 1p36, is frequently observed in NB tumors and cell lines. A panel of 46 NB cell lines was used to search for homozygous deletions (HD) within 1p36 and at 21 known tumor suppressor gene loci. HD was detected only at CDKN2A, in 4 cell lines. The CDKN2A locus encodes two overlapping proteins, p16 and p14, which are involved in cell cycle regulation and are inactivated in many human malignancies. HD was also detected in corresponding tumor specimens, but not in constitutional DNA samples, in two of the three cell lines for which tumor tissue was available. All four exons encoding p16 and/or p14 were homozygously deleted in three cell lines, while the fourth cell line had HD of only 104 bp of CDKN2A exon 2. To determine the extent of CDKN2A deletions in primary NBs, LOH analysis was performed upon 214 NB tumor and constitutional DNA pairs using four 9p21 polymorphisms flanking CDKN2A. Allelic loss of all four loci was present in 20 tumors and LOH for only a subset of informative markers was evident in 10 additional tumors (14% 9p21 LOH). Analysis of the deletion breakpoints for the 10 tumors with partial LOH showed 2 non-overlapping SROs: one region mapping proximal to D9S171 and including CDKN2A, and a second, more distal 9p21 region between D9S259 and D9S169. Five of 46 NB cell lines (11%) were homozygous for 4/4 markers within 9p21, suggesting allelic deletion of the entire region in these cell lines. Sequencing of CDKN2A exon 2 (shared by p16 and p14) and exon 1 (unique to p14) in 30 primary tumors with LOH of CDKN2A found no mutations. LOH for 9p21 was correlated with 1p LOH ( $p < 0.05$ ) and 14q LOH ( $p < 0.01$ ) but not with MYCN amplification, tumor stage, patient age, histopathology, or 11q LOH. These results suggest that biallelic inactivation of CDKN2A may contribute to tumorigenicity in a subset of NBs, and that two or more tumor suppressor loci involved in NB tumorigenesis may be located in proximal 9p.

**Adenoviral transfer of the FHIT gene in cancer cell lines results in apoptosis and activation of the caspase-8 pathway.** *L. Roz<sup>1</sup>, M. Gramegna<sup>1</sup>, P. Accornero<sup>1</sup>, H. Ishii<sup>2</sup>, C.M. Croce<sup>2</sup>, G. Sozzi<sup>1</sup>.* 1) Dept Experimental Oncology, Ist Nazionale Tumori, Via Venezian 1, 20133, Milano, Italy; 2) Kimmel Cancer Center, Jefferson Medical College, Philadelphia, Pennsylvania 19107.

Although the inactivation of the FHIT tumor suppressor gene seems to play an important role in different types of human cancer, the mechanism of action responsible for the oncosuppressive properties of the protein is still unknown. In the present study we have used an adenoviral vector to express the Fhit protein in 7 lung and 3 cervical cancer cell lines with low or undetectable level of endogenous protein and analysed the effect on the cell cycle and on apoptosis as measured by TUNEL assay. High levels of expression of the transgene could be achieved in all the cell lines tested and the efficiency of transduction was also confirmed by experiments done with control adenoviral vectors expressing lacZ or GFP. The levels of apoptosis induced by the reintroduction of Fhit expression ranged from 15% to 55% depending on the cell line and on the culture conditions: serum deprivation seemed to increase the pro-apoptotic effect of Fhit. Both lung and cervical cancer cell lines were susceptible to Fhit mediated apoptosis with as low as 10% of cells remaining viable 5 days after gene transfer. Analysis of the cell cycle at different time points after transduction showed a progressive block in the cycling properties of the cells with accumulation in the S-phase before massive cell death. In vitro transduced H460 cells also lost their ability to induce tumor growth in vivo in nude mice. Finally, in Fhit transduced cells we could consistently detect activation of caspase-8, suggesting the involvement of this signalling pathway in Fhit induced apoptosis. In accordance with this observation treatment of H460 cells stably transfected with a Fhit expression plasmid with agonistic anti-Fas antibody resulted in high apoptotic rate confirming that cells expressing high levels of Fhit might be particularly susceptible to caspase-8 mediated apoptosis. In conclusion, our results show high apoptotic activity and anti-tumorigenic properties of the Fhit protein, possibly mediated by interaction with the caspase-8 pathway.

**VNTR polymorphism of HRAS1 gene in breast cancer patients in Tomsk region of Russia.** *I.V. Tereschenko<sup>1</sup>, M.V. Goloubenko<sup>2</sup>, V. Saviouk<sup>2</sup>.* 1) Prevention Department, Cancer Research Institute, Tomsk, Russia; 2) Population Genetics Lab, Institute of Medical Genetics, Tomsk, Russia.

Recent studies failed to support an association of rare VNTR alleles of HRAS1 gene with susceptibility to neither hereditary nor early-onset breast cancer. However, numerous previous investigations with the use of PDRF analysis showed the link of that polymorphism with increased risk of breast cancer. To investigate whether the breast cancer risk is associated with rare HRAS1 alleles we conducted a population based research of VNTR polymorphism of this locus using the PCR-based technique. We have genotyped 73 women with breast cancer from Tomsk region, Russia. The control consisted of 181 healthy individuals from Tomsk region. Mean age of the individuals from the group with breast cancer was 45,6 (29-68) years, that of control - 47,6 (32-82). Genomic DNA was extracted from blood samples and amplified using the protocol of Phelan et al. (1996). Amplified products were resolved by electrophoresis on 2% agarose gel (2,5 v/cm, 10 hours). Gels were stained with ethidium bromide. The allele frequencies for a1, a2, a3, a4 were 0.071, 0.011, 0.006, 0.001 in case subjects and 0.079, 0.008, 0.004 and 0.001 in control. The frequency of the rare alleles was 0.009 and 0.006, respectively. That difference was not significant (chi-square=1.16, p=0.28). In multiple cancer patients with primary tumor in breast (n=9) the frequency of rare alleles was 0.017 (chi-square=2.86, p=0.09). In group of patients with two or more first-degree relatives affected with breast cancer (n=8) 0.019 (chi-square=3.68, p=0.05).

**Mutator phenotype at *Aprt* and *Hprt* loci in normal tissues of mice deficient in *Pms2*.** C. Shao<sup>1</sup>, M. Yin<sup>2</sup>, L. Deng<sup>1</sup>, R.M. Liskay<sup>3</sup>, T.C. Doetschman<sup>2</sup>, P.J. Stambrook<sup>2</sup>, J.A. Tischfield<sup>1</sup>. 1) Rutgers Univ, Piscataway, NJ; 2) Univ. of Cincinnati College of Medicine, Cincinnati, OH; 3) Oregon Health Sciences Univ, Portland, OR.

The DNA mismatch repair (MMR) gene *Pms2* has been implicated in hereditary non-polyposis colon cancer. *Pms2* knockout mice exhibit predisposition to lymphoma, microsatellite repeat instability, and failure of spermatogenesis. To study the effects of *Pms2* deficiency on genomic integrity in somatic cells *in vivo*, we analyzed point mutation and loss of heterozygosity (LOH) at *Aprt* locus in T lymphocytes and fibroblasts of *Pms2*<sup>-/-</sup>*Aprt*<sup>+/-</sup> mice. The frequency of DAP-resistant (DAP<sup>r</sup>) T lymphocyte clones, due to point mutation or LOH of *Aprt*, was about three fold higher in *Pms2*<sup>-/-</sup> mice than in wild-type mice. While the majority (80%) of the DAP<sup>r</sup> clones were caused by mitotic recombination in wild-type mice, point mutation was nearly as common as mitotic recombination in mutant T cell clones from *Pms2*<sup>-/-</sup> mice. Also, the frequency of 6-TG-resistant (6-TG<sup>r</sup>) T cell clones, due to mutation of *Hprt*, was increased about sixty-fold in *Pms2*<sup>-/-</sup> mice. The point mutations were predominantly caused by T:A to C:G transition. The frequency and mutational spectrum of DAP<sup>r</sup> fibroblasts in *Pms2*<sup>-/-</sup> mice was not significantly different from those in *Pms2*<sup>+/+</sup>, though 6-TG<sup>r</sup> fibroblasts were more common in *Pms2*<sup>-/-</sup> mice. The mutator phenotype as a consequence of MMR deficiency may play a role in initiating and/or accelerating carcinogenesis.

**Identification of differentially expressed genes in early and late stage primary ovarian tumors by the construction of suppression subtraction hybridization cDNA libraries.** *D.I. Smith<sup>1</sup>, A. Sen<sup>2</sup>, R. Avula<sup>1</sup>, J. Staub<sup>1</sup>, J. Lee<sup>2</sup>, L. Hartmann<sup>3</sup>, J. Lillie<sup>2</sup>, V. Shridhar<sup>1</sup>.* 1) Dept Experimental Pathology, Mayo Clinic & Foundation, Rochester, MN; 2) Millenium Predictive Medicine Cambridge, MA; 3) Division of Oncology, Mayo Clinic & Foundation, Rochester, MN.

Each year 16,000 American women succumb to ovarian cancer, the deadliest of gynecologic cancers. Ovarian cancer is frequently asymptomatic in its early stages, thus 75% of patients have advanced stage disease at the time of diagnosis. The anticipated 5-year survival for patients with advanced stage disease is less than 20%, while early stage disease is highly curable. In order to identify genes that are differentially expressed in early versus late stage ovarian cancer, we generated up and down suppression subtraction hybridization cDNA libraries from early and late stage primary ovarian tumors subtracted against normal ovarian epithelial cell brushings. Approximately 3000-4000 successful sequences were generated from each library. We analyzed the differentially expressed down regulated clones obtained from two individual early stage tumor libraries and compared them to clones from libraries generated from two individual late stage tumors. This analysis revealed that while there were specific genes that were unique to each library, the majority of the genes were common between the different libraries. Some of the genes that were down regulated in both early and late stage tumors included SPARC, osteoblast specific factor, caveolin 1, IGF2, glutathione transferase A2, HSP90, fibronectin, transferrin receptor, integral membrane protein 2A, and C7 complement factor. The differential expression of these genes were confirmed by semiquantitative RT-PCR with GAPDH as control in a panel of 15 stage I tumors and 25 stage III tumors of different histologies. Cadherin13, MMP2 and IL8 were only isolated from libraries generated from stage III/IV tumors and were not isolated from tumors generated from early stage tumors. We are in the process of characterizing novel clones that were isolated from these libraries to test them as potential candidate tumor suppressor genes that may be involved in the pathology of this malignant disease.

**Post-translational modifications of OVCA1 contribute to ovarian carcinogenesis.** *A.H. Prowse, W. Bruening, A.K. Godwin.* Fox Chase Cancer Ctr, Philadelphia, PA.

*OVCA1* is a candidate tumor suppressor gene which maps to a region of frequent allelic loss in ovarian cancer at 17p13.3. *OVCA1* is mutated in some ovarian tumor cell lines and its protein levels are decreased or lost in nearly 40% of ovarian adenocarcinomas. Expression of low levels of exogenous *OVCA1* results in dramatic growth suppression and decreased levels of cyclin D1 (Bruening *et al* 1999). *OVCA1* codes for a highly conserved protein with no known function, but the C-terminal region of *OVCA1* interacts with an RNA binding motif protein named RBM8A (Salicioni *et al* 2000). We have recently found that *OVCA1* exists in at least two forms: a 48 kDa and a 50 kDa protein. Subcellular fractionation studies indicate that p50<sup>*OVCA1*</sup> localizes to the cytoplasm whereas p48<sup>*OVCA1*</sup> is predominantly found in the organelle fraction with some in the nuclear fraction. Immunohistochemical analysis of normal ovaries and ovarian tumors using p50<sup>*OVCA1*</sup> or p48<sup>*OVCA1*</sup> specific antibodies demonstrated strong nuclear and cytoplasmic staining in the epithelial cells of the normal ovaries and borderline tumors for both antibodies. In contrast, p50<sup>*OVCA1*</sup> was observed primarily in the nucleus, with little or no cytoplasmic staining in the vast majority of malignant ovarian tumor cells. Interestingly, no nuclear or cytoplasmic staining was detected in these adenocarcinomas using antibodies for p48<sup>*OVCA1*</sup>. Furthermore, there was not apparent correlation with *OVCA1* expression and cellular proliferation (as determined by ki67 staining) and *BRCA1* levels in these tumors. 2-D gel western blotting revealed that *OVCA1* is extensively modified post-translationally in tumor cells leading to a dramatic shift in pI from ~9 to ~7. These aberrant modifications result in the p50<sup>*OVCA1*</sup> form and loss of immunoreactive p48<sup>*OVCA1*</sup>. Studies of the molecular mechanisms regulating *OVCA1* expression and localization, and its interaction with RBM8A are underway. Our studies indicate that altered expression and/or post-translational modifications of *OVCA1* is associated with the development of malignant ovarian tumors and suggest a potentially new mechanism for the inactivation of tumor suppressors in ovarian adenocarcinomas.

**Identifying Downstream Events Associated with Thy-1 Expression.** *J. Xu, H.R. Abeyasinghe, N. Wang.* Dept Pathology & Lab Med, Univ Rochester Medical Ctr, Rochester, NY.

Previous studies with transfection and xenographic analysis in our laboratory have demonstrated that Thy-1, a membrane glycoprotein, is a putative tumor suppressor gene for ovarian cancer. Transfection of Thy-1 into SKOV-3, a tumorigenic human ovarian carcinoma cell line, resulted in reductions in tumor growth compared to their null counterparts while abolishing Thy-1 expression from 11(c)9-8, a non-tumorigenic hybrid derived from SKOV-3, restored tumorigenicity. In this study we performed reciprocal cDNA subtractions between SKOV-3-Thy-1 and SKOV-3-Null to identify the downstream effects of the Thy-1 gene. The cDNA pool generated from the reciprocal cDNA subtractions were then subjected to gene discovery array screening and to PCR-based differential display (DD-PCR) using four arbitrary primers. The array analysis revealed that 15 ESTs plus 33 known genes were up-regulated and 42 ESTs plus 61 known genes were down-regulated in SKOV-3-Thy-1 vs. SKOV-3-Null. Various tumorigenicity related known genes were found affected by Thy-1. Among the up-regulated genes, acid ceramidase, which has been confirmed by DD-PCR as well, is known to be involved with the induction of apoptosis and has been characterized as an anti-oncogene. Of the down-regulated genes, Cyclin D1 has been identified by both DD-PCR and microarray screening amplification and over expression of Cyclin D1 has been identified in a variety of tumor cells including breast, colon, and small cell lung cancers. The data obtained from this study provides some insight into the downstream genes that may have been affected by Thy-1 in the tumorigenic ovarian carcinoma cells and the possible mechanisms of Thy-1 in ovarian tumor suppression.

**Genes up- and down-regulated by Thy-1 in an ovarian cancer doxycyclin Thy-1 inducible system.** *N. Wang<sup>1</sup>, W. Kao<sup>2</sup>, K. Peck<sup>2</sup>, J. Xu<sup>1</sup>, H.R. Abeyasinghe<sup>1</sup>.* 1) Dept Pathology, Univ Rochester Sch Medicine, Rochester, NY; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, ROC.

A Thy-1 inducible expression system was established by co-transfection of two plasmids pTEP4m and pUHD172-neo into human carcinoma cell line SKOV-3. Three hours post doxycyclin exposure, Thy-1 expression is detectable. To identify the downstream gene expression of Thy-1, mRNA was extracted from the cells at 0, 3, and 6 hrs post doxycyclin exposure. cDNA was generated from various time points and then subjected to a high-density cDNA microarray analysis. The genes which expressed more than a 2 fold increase from both 0 to 3 hrs as well as 3 to 6 hrs were classified as up-regulated genes. These include homosapions immunoglobulin heavy chanin variable region (VH4), alanine aminotransferase, adenosine deaminase, and B-cell CLL/lymphoma 7b, etc. The genes which expressed 2 fold decreased from both 0 to 3 hrs as well as 3 to 6 hrs were classified as down-regulated genes. These include protein phosphatase type IVA, involucrin, protein phosphatase 1, catalytic subunit, gamma isoform, and transporter 2, ABC (ATP banding cassette). In addition, there are genes that fit the criteria between 0 to 3 hrs but not between 3 to 6 hrs which may indicate early events immediately post Thy-1 induction.

**5qNCA, a candidate for the chromosome 5 leukemia tumor suppressor gene, is a novel nuclear receptor coactivator.** *C.A. Westbrook<sup>1</sup>, Z. Arbieva<sup>1</sup>, J. Kravarusic<sup>1</sup>, B. Chyna<sup>1</sup>, Z. Hu<sup>1</sup>, S. Edassery<sup>1</sup>, S.K. Horrigan<sup>2</sup>.* 1) Department of Medicine, University of Illinois at Chicago, Chicago, IL; 2) Department of Pediatrics, Georgetown University Medical Center, Washington, D.C.

Loss or interstitial deletion of the long arm of chromosome 5, del(5q) or 5q-, is a consistent finding in acute myeloid leukemia (AML) or myelodysplasia (MDS), especially those that arise after previous chemotherapy. We and others have proposed the presence of a tumor suppressor gene (TSG) within the consistently-deleted region, which centers at 5q31. We report a novel gene at 5q31, 5qNCA, as a candidate for this TSG. 5qNCA produces a 7.4-kb transcript with a 5,286-bp open reading frame that is ubiquitously expressed and is present in CD34+ cells and AML cell lines. The gene spans 23 exons and contains a signature motif for a nuclear receptor co-activator, a novel zinc finger motif, and a highly-conserved C-terminus with putative transcriptional regulatory activity. It is homologous to TRIP8, human/murine hairless, KIAA0742, and drosophila CG815 in the zinc finger and transactivation domains. The zinc finger has the unique spacing CysX2-Cys-X7-His-X2-Cys-X2-Cys-X4-Cys-X2-Cys, which may define a new family, resembling both LIM and PHD zinc finger domains, which are known to regulate chromatin structure and are often involved in leukemia. Sequencing of KG-1, an AML cell line with del(5q), shows an apparent mutation in exon 6 resulting in a THR to ALA substitution which is not seen in >40 normal alleles. KG-1 thus demonstrates the loss of one allele and mutation of the residual allele, as expected for a TSG. Additional sequencing is in progress in clinical del(5q) samples. We propose 5qNCA as a likely candidate for the del(5q) TSG based on its protein homologies, expression, and mutation.

***EPHX1, GSTM1, GSTT1 and GSTP1* gene polymorphisms in patients with mouth and throat neoplasias.** A.G. Amador<sup>1,2</sup>, P.D. Righi<sup>2</sup>, S. Radpour<sup>2,3</sup>, E.T. Everett<sup>1,2</sup>, E. Weisberger<sup>2</sup>, M. Langer<sup>2</sup>, G.J. Eckert<sup>2</sup>, A.G. Christen<sup>1</sup>, S. Campbell, Jr.<sup>1,3</sup>, D-J. Summerlin<sup>1</sup>, J.K. Hartsfield, Jr.<sup>1,2</sup>. 1) Indiana University School of Dentistry, Indianapolis, IN; 2) Indiana University School of Medicine, Indianapolis, IN; 3) Roudebush Veterans Administration Medical Center, Indianapolis, IN.

Xenobiotic metabolizing enzymes have been implicated in the carcinogenesis of tobacco-related neoplasias. Since polymorphisms are known to occur in genes coding for some of these enzymes, a search to determine representation of these polymorphisms in patients with mouth or throat cancer compared to a population sample was undertaken. Subjects included 120 ever-smokers, 15 never-smokers and 99 random controls. Polymorphisms were determined in genomic DNA using PCR followed by RFLP analysis for *GSTP1* and *EPHX1*, and by allele specific multiplex PCR for *GSTM1* and *GSTT1*. At *EPHX1* codon 113, a significant over-representation of the reportedly greater *in vitro* specific activity phenotype (Tyr/Tyr) was observed when compared to controls. This was observed for male ever-smokers (P=0.012) and for all ever-smokers (P=0.001), as well as in never-smokers (P=0.006). A less dramatic but significant over-representation of the Tyr/Tyr phenotype was observed in female never-smokers (P=0.042). There was an over-representation of homozygosity for the *GSTT1* null allele (but not for the *GSTM1* null allele) in ever-smokers in general, when compared to controls (21.45% vs. 10.10% P=0.027). Analysis of polymorphisms at the *GSTP1* locus did not show differences versus controls. However never-smokers, with a history of mouth or throat cancer had a 3.5 times higher incidence of the low activity producing phenotype B/B compared to ever-smokers (P=0.043) with a history of cancer. The *EPHX1* codon 113-Tyr/Tyr variant as well as homozygosity for *GSTT1* null have a role in, and/or are possible predisposing markers for carcinogenesis in the mouth and/or throat. Supported by grants NIH HD0737 (AGA) and NIH R29DE11280 (JKH).

**The evolution of breast and ovarian cancer gene research: a bibliometric study.** *L. Bouchard<sup>1</sup>, R. Dalpé<sup>1,2</sup>, D. Ducharme<sup>1,3</sup>.* 1) CIRST, Univ De Quebec Montreal, Montreal, Quebec, Canada; 2) Political Sciences Department, Univ Montreal, Montreal, PQ, Canada; 3) Sociology Department, Univ Montreal, Montreal, PQ, Canada.

The main objective of this paper is to describe, using a bibliometric approach, the nature of scientific production in the field of cancer genetics, specifically with respect to the localization and identification of the BRCA genes (breast and ovarian cancer genes). Method: The Data were extracted from the Science Citation Index (SCI), the Social Science Citation Index (SSCI) and the Arts and Humanities Citation Index (AHCI). The search strategy consisted in choosing all papers that included "BRCA" in their titles. About 800 papers were retained, running from 1993, when the label was first introduced, to 1998. The extracted information included citations, quotations and authors (by countries and institutions), but excluded patents. This method allowed us to define research profiles by identifying the organizations involved in the research, the topics of investigation and the dynamics of scientific development. Results: The results revealed, among other findings, a steady increase in the number of articles related to BRCA genes: from 45 articles in 1993-94 to over 500 in 1997-98. These articles were published in specialized journals in three research domains: human genetics, oncology and medicine. The database contained mainly biomedical articles (97%) and relatively very few articles dealing with the psychosocial aspects of genetic screening (3%). About 15 articles were cited more than 100 times and a dozen of which generated at least two commentary, which gives an indication of the controversy surrounding this research area. American researchers accounted for about half of the international BRCA genes research community and were followed by English, Canadian and French researchers. The largest organizations involved were academic research centers, although private firms, like Myriad Genetics in Salt Lake City, played a very important role. Conclusion: The results allow us to portray the evolution and constitution of research groups and the configuration of research practices in terms of two major models: the "Republic of Science" and the privatization of fundamental knowledge.

**Genotypic distribution of glutathione-S-transferase (GSTM1) in healthy subjects and in lung cancer patients in mexican population.** *B.C. Gomez<sup>1</sup>, M.P. Gallegos<sup>1</sup>, J.I. Martinez<sup>2</sup>, G. Morgan<sup>2</sup>, A.L. Zamora<sup>1</sup>, O. Torres<sup>1</sup>, G.M. Zuniga<sup>1</sup>.* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Division de Oncologia, Hospital de especialidades, CMNO, IMSS, Guadalajara, Jalisco. Mexico.

The enzymes GSTM1 belong to the isoenzymes family who participate in the desactivation of toxic compounds. Previous studies correlate the deletion of the GSTM1 gene with the increase to develop cancer, specially lung and bladder cancer in different world populations. The objective of this study was, determine the genotypic distribution of GSTM1 in healthy subjects and lung cancer patients in mexican population. 120 controls were study (52 smokers, 38 nonsmokers and 30 passive smokers) and 40 lung cancer patients, in order to take a peripheral blood sample (5 ml) for the DNA extraction. Using PCR, a segment of 271 bp, part of the exon 4 in the GSTM1 gene, was amplified with the primer G1 and G2 who coamplified with a 93 pb fragment in the exon 10 of Cystic fibrosis used as a internal control. The results of the genotypic distribution of the patients with lung cancer was 63.75 % for the allele present (+), and the 36.25 % for the null genotype when were compared between groups; no smokers 62% 38%; passive smokers 53%, and 47%, and smokers 63%, and 37% of the present and null genotypes respectively. The not shown difference statistical significance, but in the passive smokers group a tendency of GSTM1 null genotype were observed, showing the harmful effect of tobacco in that group.

**Cytochrome *P450-1B1* genetic polymorphism, alcohol consumption and breast cancer risk.** *A.C. Deitz<sup>1</sup>, R. Sachdeva<sup>2</sup>, J. Swoyer<sup>1</sup>, S. Gunasegaram<sup>1</sup>, T.R. Rebbeck<sup>1</sup>*. 1) Center for Clinical Epidemiology & Biostatistics, Univ. of Pennsylvania, Philadelphia, PA; 2) Dept. of Pathology & Laboratory Medicine, Univ. of Pennsylvania-VA Health Care System, Philadelphia, PA.

Breast cancer etiology is multifactorial and complex. Factors associated with breast cancer risk include genetic susceptibility and exposure to estrogens. Alcohol consumption is thought to influence estrogen levels, which in turn may affect breast cancer risk. CYP1B1, a member of the cytochrome P-450 family, is involved in the metabolism of estrogens. We hypothesized that alcohol exposure and inherited genotypes at CYP1B1 may act synergistically to influence endogenous estrogen metabolism, and therefore affect breast cancer risk. To evaluate whether CYP1B1 interacts with alcohol consumption in breast cancer etiology, we designed a case-case study of peri- and post-menopausal breast cancer cases (n=227), 50-80 years of age. CYP1B1 genotypes were determined by PCR-based methods and alcohol consumption information was collected using a standardized questionnaire. For women with at least one variant allele at codon 432 (Val@Leu) consuming moderate to high levels of wine and hard liquor, we found an interaction odds ratio (OR) of 2.16 (95% CI=1.09-4.32). In addition, we found an interaction OR of 3.18 (95% CI=1.32-7.65) for women with two variant alleles who consume moderate to high levels of wine and hard liquor. These results suggest that a gene-environment interaction exists between alcohol consumption and CYP1B1, and that factors affecting endogenous estrogen metabolism may influence post-menopausal breast cancer risk.

**Association between polymorphisms of the *GPXI* gene and multiple primary tumours (MPT).** *S. Jefferies*<sup>1</sup>, *Z. Kote-Jarai*<sup>1</sup>, *R. Houlston*<sup>1</sup>, *M-J. Fraser-Williams*<sup>1</sup>, *R. A'Hern*<sup>1</sup>, *W.D. Foulkes*<sup>3</sup>, *D. Goldgar*<sup>4</sup>, *R.A. Eeles*<sup>1,2</sup>. 1) Cancer Genetics, Inst. of Cancer Research, London, England; 2) The Royal Marsden Hospital Trust, Downs Rd, Sutton, Surrey, SM2 5PT; 3) McGill University, Montreal, Canada; 4) IARC, Lyon, France.

Head and neck cancer is a common cancer. There is some preliminary evidence that there may be a genetic component to SCCHN. Individuals who have had an index SCCHN have a 10-20% chance of developing MPT. There is an increased risk of cancer in first-degree relatives of individuals with SCCHN and this risk rises markedly when the individual has MPT. Individual susceptibility to cancer development may be contributed to by differences in metabolism of carcinogens. The *GPXI* gene is a selenium-dependent enzyme that maps to chromosome 3p21, an area frequently showing loss of heterozygosity on SCCHN. There are three *GPXI* alleles characterized by the number of GCG triplet nucleotide repeats encoding for alanine in a polyalanine tract in exon 1. These alleles are identical except for the length of the polyalanine polymorphism. The *GPXI/ALA6* also has a leucine for proline substitution at codon 198, a T for C substitution at +2 and a G for A substitution at -592<sup>1</sup>. The effect on function of the *GPXI* gene is not known. We investigated the association between polymorphisms in the *GPXI* gene and patients with index SCCHN and MPT compared with population controls. The genotypes were determined for 63 cases of MPT and 259 controls using a PCR technique with a fluorescent-labelled primer. The PCR products were analysed using an ABI automated fluorescent DNA sequencer. The associations between specific genotypes and the development of MPT were examined by the Chi-square test. We found a significantly increased frequency of the *GPXI/ALA6/GPXI/ALA7* genotype in the MPT cases versus controls ( $p=0.04$ ). The findings of this study suggest that certain *GPXI* genotypes may be associated with an increased risk of developing MPT. Identification of such genotypic markers may be of value in the future for targeting chemoprevention.<sup>1</sup> *Moscow et al Carcinogenesis*; 15:2769-2773, 1994.

**SNP Identification and Haplotype Studies at BRCA2.** *S.H. Jones, D.L. Nelson.* Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX.

This project seeks to identify functional variants of genes involved in familial cancers. These genes may play a role in increased or decreased risk for cancer predisposition in the general population due to their roles in DNA replication, repair or general cell maintenance. We have carried out SNP identification for BRCA2 and its surrounding genomic sequence, and defined haplotypes using ten CEPH families as well as individuals representing the four major ethnic groups from the U.S. (Asians, Caucasians, African Americans, Hispanics). The genomic region spanning approximately 180 kb was contained in two clones with a 3kb gap in between. A total of 10 non-coding SNPs were found, and seven of those, along with two previously reported (*Wagner et al.*, 1999) were used to type 321 individuals and to define haplotypes. We used the software package EMHAPFRE based on a maximum likelihood algorithm to infer haplotypes. EMHAPFRE analysis on the nine SNPs revealed 83 haplotypes when all samples were considered together. Two of the SNPs were located in the second clone containing the last three exons of BRCA2, and these loci appeared to be in equilibrium with the more proximal markers. This was further supported by EMHAPFRE analysis on the remaining seven loci, which decreased the total number of haplotypes to 50. Recombination and linkage disequilibrium analyses suggest historical recombination events to have taken place between the clones. DNA recombination and linkage disequilibrium was assessed using DNASP. These findings are relevant to the selection of markers to be used for association studies based on SNPs.

**The ATM variant D1853N in BRCA1 mutation carriers.** *R.A Omaruddin<sup>1</sup>, K.L Nathanson<sup>1</sup>, T.R Rebbeck<sup>3</sup>, B.L Weber<sup>1,2</sup>.* 1) Department of Medicine, Univ of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, Univ of Pennsylvania, Philadelphia, PA; 3) Department of Biostatistics & Epidemiology, Univ of Pennsylvania, Philadelphia, PA.

Mutations in BRCA1 confer a greatly increased risk of breast cancer. However, the breast cancer risk due to mutations in BRCA1 varies from 40-85%, depending on the population ascertained. Therefore it has been hypothesized that the mutation alone does not explain the observed pattern of cancer, but that other factors, including variants in genes other than BRCA1 and BRCA2, influence the development of breast cancer in BRCA1 mutation carriers. As ATM phosphorylates BRCA1 and both proteins participate in regulation of the DNA damage response, variants in ATM are candidates to modify BRCA1 penetrance. In addition, various studies have demonstrated an increased risk of breast cancer in female ATM heterozygotes. We have preliminarily investigated the G→A variant at nucleotide 5557 (D1853N) in 150 BRCA1 mutation carriers using PCR-RFLP analysis. The date of birth of the BRCA1 mutation carriers ranged from 1899 to 1977; 96 had developed breast cancer and 25 had developed ovarian cancer. In the BRCA1 mutation carriers, we were unable to find a statistically significant association between breast cancer ( $p=0.611$ ) or ovarian cancer ( $p=0.571$ ) and the ATM D1853N variant. Despite the lack of evidence for an association of this polymorphism and breast or ovarian cancer risk, the present analysis may have had limited statistical power to detect an association, and further evaluation of the ATM D1853N variant in an expanded set of BRCA1 and BRCA2 mutation carriers may be required.

**Improved PCR-Genescan Genotyping of Mononucleotide Repeat (BAT) Loci.** *S. Rao, W. Bloch.* Dept Sci & Technology, PE Biosystems, Foster City, CA.

The A-repeat BAT loci are useful in studying microsatellite instability (MSI), which correlates with certain cancers. They also represent a ubiquitous class of genetic polymorphism, possibly more common than either microsatellites with longer repeat units or SNPs. PCR-sizing methods are limited in resolving closely spaced mononucleotide-repeat alleles by two PCR artifacts, stutter and the terminal transferase side reaction exhibited by non-proof-reading enzymes. In the MSI field, BAT loci have been described as pseudomonomorphic, indicating that their natural size polymorphism lies close to the resolution limit of PCR-sizing methods. The present research provides increased control of PCR artifacts to improve confidence in mononucleotide-repeat genotyping, specifically at loci with high heterozygosity. The data shown here confirm that BAT loci are naturally polymorphic and provide allele distributions for several of these loci in a single population. Improved analysis of BAT-locus polymorphism should increase discrimination of acquired MSI. In addition, loss of heterozygosity correlated with cancer should become easier to detect for BAT loci. Finally, improved PCR-Genescan resolution of mononucleotide repeats increases their value as mapping and identification tools when more commonly used loci are insufficiently informative.

**Lack of association between  $HER2^{V655}$  and breast cancer in a US population.** C. Keshava<sup>1</sup>, E.C. McCannlies<sup>1</sup>, M.S. Wolff<sup>2</sup>, A. Weston<sup>1</sup>. 1) National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, Morgantown, WV; 2) Mount Sinai Medical Center, New York, NY.

A recent study in a population of Chinese women revealed an association between inheritance of a moderately common polymorphism (0.10-0.15) of  $HER2$  (I655V) and excess risk of breast cancer (OR = 12.7, 95% CI = 1.6-99.5) (Xie *et al.*, *J. Natl. Cancer Inst.*, 92:412-417, 2000). Also, a stronger relationship was claimed in younger women (adjusted OR = 1.7, 95% CI = 1.1-2.6). We tested this hypothesis in a population of US women enrolled in a hospital based case control study in New York City (n = 137 cases and 291 controls, matched 1:2 on age and self-reported race/ethnicity). No evidence was found to support an association between inheritance of the 655-valine variant of  $HER2$  and excess breast cancer risk. Our population consisted of African-Americans (n = 34 cases/58 controls), Caucasians (n = 77/162) and Latinas (26/71). Genotypic distributions for all groups were consistent with Hardy-Weinburg population laws (all p-values fell within the range 0.16-0.91). Interestingly,  $HER2^{V655}$  allelic frequencies were found to vary with race (African-Americans 0.05, Caucasians 0.16, Latinas 0.15), differences between African-Americans and Caucasians and African-Americans and Latinas were significant (p-values = 0.002 and 0.001, respectively). No association was found between inheritance of  $HER2^{V655}$  and breast cancer, either in the group as a whole (carriers OR = 1.2, 0.8-1.9 or homozygotes OR = 1.2, 0.4-4.2) or when considered by racial groups or when limited to younger women (<54 years:carriers OR = 1.4, 0.7-2.6 or homozygotes OR = 3.1, 0.7-14.3).

**A polymorphism in the human MSH2 gene associated with increased susceptibility to lymphomas.** C. Paz-y-Mino<sup>1, 2</sup>, J.C. Pérez<sup>1</sup>, P.E. Leone<sup>1, 2</sup>. 1) Hum Mol Genet & Cytogen Lab., Department of Biological Sciences; 2) Medicine Faculty, Catholic University of Ecuador, Quito-Ecuador.

Infrequent genetic variants include the primary causes of rare genetic diseases, nevertheless, some authors have suggested that the common variants may contribute significantly to genetic risk for common diseases. The central aim of all genetics, therefore, is to correlate specific molecular variation with phenotypic changes. Because of its biological function in mismatch repair, functionally significant hMSH2 gene polymorphisms are candidates for influencing cancer susceptibility and overall genetic stability. We screened for polymorphic variants in the exon 13 of the hMSH2 mismatch repair gene in 72 individuals (50 normal individuals and 22 non-Hodgkins lymphomas) to determine their prevalence in the Ecuadorian population and their probable association with development of lymphomas. The polymorphism screening was realized by Single Strand Conformation Polymorphism (SSCP) analysis. Optimal conditions for SSCP were established and nine samples displaying mobility shifts were identified. These samples were subjected to DNA sequencing. We found a single nucleotide polymorphism: a T to C substitution at the 6 intronic splice acceptor site of exon 13. In the normal individuals group (they have neither disorders nor cancer) the polymorphism frequency was 0.05 (4 individuals, 3 heterozygotes and 1 homozygote), and in the group of lymphomas was 0.11 ( $p < 0,01$ ) (5 heterozygotes). These results suggest that probably the polymorphism is associated with an increased risk to develop non-Hodgkins lymphomas. Because of a former study reported that this allele could also predispose to colon cancer, probably it is associated with susceptibility to different cancers.

**Identification and Characterization of Novel Polymorphisms/Mutations in the Glycine N-methyltransferase Gene in Liver Cancer.** *T.-L. Tseng<sup>1</sup>, Y.-M.A. Chen<sup>2</sup>, J.P. Struewing<sup>1</sup>, K. Buetow<sup>1</sup>*. 1) Laboratory of Population Genetics, Division of Cancer Epidemiology and Genetic, NCI, Bethesda, MD.20892, USA; 2) Division of Preventive Medicine, Institute of Public Health, School of Medicine, National Yang-Ming University, Taipei, Taiwan 112, R.O.C.

Glycine N-methyltransferase (GNMT) is an enzyme participating in the detoxification pathway, and has been shown to down-regulate cytochrome p4501A1 activity and decrease the DNA adducts formation. Therefore, the expression of GNMT has a protective effect against the exposure of carcinogens. Moreover, GNMT was shown to be diminished in human hepatocellular carcinoma (HCC). We are investigating the GNMT gene for liver cancer predisposition by genotypic and phenotypic characterization of the gene in Taiwanese population and liver cancer cell lines. So far, we have identified several novel mutations and at least five new polymorphisms, including two short tandem repeat polymorphisms and three single nucleotide polymorphisms (SNPs) around flanking region of exon 1. Interestingly, we have identified a novel alternative splice product, skipping exon 1 and its 5'end boundary containing SNPs. Although the allele frequencies are similar in normal individuals and hepatoma patients, the observed frequencies of heterozygosity are significantly different from the expected. We also characterized the genotypes of the GNMT gene in 60 pairs of HCCs. The genotypic distribution between DNA from normal and tumorous liver tissues are the same, however, it is very different in blood and liver DNA. Furthermore, the observed heterozygosity of 2 of the SNPs is dramatically decreased in liver DNA compared with the observed in blood DNA, from 0.31 to 0.09 and 0.5 to 0.15, respectively ( $p$  value  $< 0.005$ ). This may result from the high loss of heterozygosity (LOH) rate within the GNMT gene in liver. Such alterations within the GNMT gene in the liver tissues imply its role in liver cancer development, and the same genotypic alterations in normal and tumorous tissues may suggest evidence of a field effect associated with this locus.

**Identification of Lung Cancer Susceptibility Genes After Adjusting for Population Stratification.** *Y.-Y. Tsai<sup>1</sup>, K.A. McGlynn<sup>1</sup>, A.B. Cassidy<sup>2</sup>, Y. Hu<sup>1</sup>, J. Arnold<sup>2</sup>, P.F. Engstrom<sup>2</sup>, K.H. Buetow<sup>1</sup>.* 1) DCEG/NCI, Bethesda, MD; 2) Fox Chase Cancer Center, Philadelphia, PA.

Population stratification or recent admixture of populations in case-control studies can lead to spurious associations between a phenotype and unlinked candidate loci. We propose an alternative method to account for population stratification by applying nine unlinked, high-heterozygosity STRP markers to assess background relationship among study subjects, and build up logistic regression models to address the effects of candidate cancer susceptibility genes after adjusting for population stratification. A total of 756 smoking individuals, including 462 lung cancer cases and 294 controls, were recruited. Nine microsatellite markers, frequently used in genetic profiling (PE-Biosystems AmpFISTR Profiler Plus), were used as the background information of each subjects. Fifteen genes involved in Phase II metabolism were evaluated. These genes can be categorized into: 1) Epoxide hydrolases; 2) Glutathione S-transferases (GST); 3) N-acetyl transferases; 4) NAD(P)H:quinone oxidoreductase gene. Variants used were either previously described in the literature, or obtained through data mining publicly available sequence data utilizing the SNP pipeline of the NCI's CGAP Genetic Annotation Initiative. To address possibility of population stratification, logistic regression models were performed to evaluate the main effect of 9 markers of DNA profiles between cases and controls, and to examine the independent effect of polymorphisms on cancer susceptibility genes after adjusting for the background. None of the 9 markers of DNA profiles has shown significant differences between cases and controls. After adding susceptibility genes into the model, GST Theta and GSTA4 were significantly associated with lung cancer, with p values of 0.002 and 0.022, respectively. Using logistic regression, we have demonstrated that population stratification was not a serious issue in our data. After adjusting for background markers, we have found that patients who carried both alleles 2 of GSTA4 and those who did not carry any of allele 2 of GST Theta had a significantly increased risk of developing lung cancer.

**An association between genetic polymorphisms in the ileal sodium-dependent bile acid transporter gene and the risk of colorectal adenomas**<sup>1s</sup>. *W. Wang*<sup>1</sup>, *S. Xue*<sup>1</sup>, *Q. Chen*<sup>1</sup>, *A.T. Diep*<sup>1</sup>, *A. Stolz*<sup>2</sup>, *H. Frankl*<sup>3</sup>, *R.W. Haile*<sup>1</sup>. 1) Department of Preventive Medicine, Univ Southern California, Los Angeles, CA; 2) Department of Medicine, Univ Southern California, Los Angeles, CA; 3) Kaiser Permanente Sunset, Los Angeles, CA.

Epidemiological and experimental studies have implicated bile acids (particularly, secondary bile acids) as important factors in the development of colorectal cancer. The ileal sodium- dependent bile acid transporter (ISBT) is a crucial player in the enterohepatic circulation of bile acids. Genetic defects in ISBT may result in malabsorption of bile acids and a loss of bile acids into the large intestine, with a resultant increase in the cytotoxic secondary bile acids in the colon produced by bacterial biotransformation. In a case-control study, we investigated the association between two sequence variations in SLC10A2, the gene encoding ISBT, and colorectal adenomas, a precursor lesion of colorectal cancer. The frequency of the missense mutation in codon 171 of exon 3 (a nucleotide transversion from G to T, resulting in an alanine to serine substitution) was not significantly different between cases and controls. However, we found an 85% increased risk of colorectal adenomas associated with a C-> T nucleotide transition in codon 169 of exon 3 (OR=1.85, 95% CI: 1.01-3.37). Logistic regression analysis using A171S/C169T haplotypes as the allelic markers showed that only the haplotype with a T allele at the amino acid position 169 was associated with the increased risk (OR=2.45, 95% CI: 1.28-4.70). The finding of an association between a polymorphism in the SLC10A2 gene and the risk of colorectal adenomatous polyps supports the role of bile acids in the carcinogenesis of colorectal cancer.

**BRCA1/2 Testing - Psychological Implications of Informative Vs. Non-Informative Test Results.** *S. Eisenberg<sup>1</sup>, P. Mor<sup>1</sup>, J.S.B. Guedalia<sup>2</sup>, P. Renbaum<sup>1</sup>, L. Peled<sup>1</sup>, A. Lahad<sup>3</sup>, E. Levy-Lahad<sup>1</sup>.* 1) Medical Genetics, Shaare Zedek Medical Center, Jerusalem, ISRAEL; 2) Neuropsychology Unit, Shaare Zedek Medical Center, Jerusalem, ISRAEL; 3) Department of Family Medicine, Hebrew University, Jerusalem, ISRAEL.

Genetic testing for BRCA1/2 mutations in healthy subjects, has various psychological implications for carriers and non-carriers. For non-carriers, it is important to distinguish between individuals whose familial mutation is known, and those in which the genetic test was non-informative (high risk families where a mutation cannot be identified). For the latter group there is little information on the psychological effects. However, there is a concern that these women may be falsely reassured by negative test results. We examined the anxiety levels and medical behavior (surveillance/preventive actions), in 58 healthy women from high risk families, who received genetic counseling and BRCA1/2 testing, 6 months or more after receiving test results. Women were tested for the three common mutations in Ashkenazi Jews. They were classified into three groups: 1. Carriers. 2. Non-carriers from families with a known mutation. 3. Non-carriers with non-informative test result. We assessed anxiety levels with the Spielbergers State Trait Anxiety Inventory questionnaire, and medical surveillance behavior by a 35-item questionnaire. Multiple regression analysis was used to compare the levels of anxiety between the groups, with group 1 as the reference. Rates of high anxiety were similarly high in groups 1 and 3 (61%), significantly higher than in group 2 (30%,  $P=.007$ ;  $OR=.0877$ ). Interestingly, despite lower anxiety levels, many group 2 subjects continued to follow excessive surveillance routines. Our results show that uninformative negative test results are an independent predictor of anxiety. Levels of anxiety in subjects with non-informative results are as high as those of carriers, and significantly higher than in definite non-carriers. This indicates that these women perceive their risk correctly. In addition, family history influenced medical behavior more than genetic status in many definite non-carriers.

**Does genetic counseling for breast cancer predisposition increase knowledge?** *K. Brown<sup>1</sup>, H. Valdimarsdottir<sup>2</sup>, J. Erlich<sup>2</sup>, D. Amareld<sup>3</sup>, L. Scheuer<sup>3</sup>, J. Hull<sup>3</sup>, D. McDermott<sup>3</sup>, D. Bovbjerg<sup>2</sup>, K. Hurley<sup>2</sup>, K. Offit<sup>3</sup>.* 1) Dept Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Cancer Prevention and Control, Mount Sinai School of Medicine, New York, NY; 3) Dept Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

An important goal of genetic counseling for cancer predisposition is to improve knowledge about a range of topics, including principles of genetics and oncology, risks for cancer, and options for screening and primary prevention. However, there are little published data on knowledge and comprehension following genetic counseling for breast cancer. Therefore, the major aims of the present study were: 1) to examine the effectiveness of genetic counseling in improving general knowledge about breast cancer/genetics; and 2) to determine if the effectiveness of counseling is related to demographic and psychosocial factors. Participants were 107 women attending individual genetic counseling sessions for breast cancer susceptibility at Memorial Sloan-Kettering Cancer Center in New York. Approximately one week prior to their counseling session, the women completed measures of: 1) breast cancer knowledge (a 27-item questionnaire); 2) cancer specific distress (Impact of Events Scale); and 3) general distress (Profile of Mood States). Approximately one week following their counseling session, the women again completed the knowledge questionnaire. There was a significant increase in knowledge from before to after the genetic counseling session ( $p=.0001$ ). However, there was a wide variability among the women, with no improvement in knowledge among some women. The counseling was less effective for minority women ( $p=.007$ ), less educated women ( $p=.05$ ), and women with high levels of general distress ( $p=.003$ ). When all of these variables were entered together into the equation, ethnicity and general distress remained significant while education was no longer significant. These findings suggest that some women may require different counseling protocols if genetic counseling is to be effective in educating them about their risks and options.

**Detection and comparison of telomerase activity in oral squamous cell carcinoma, normal and PHA induced lymphocytes.** A.A DELDAR<sup>1</sup>, F. MAJIDFAR<sup>1</sup>, B. ESLAMI<sup>3</sup>, H. NAJMABADI<sup>2</sup>, N. MAGHSOODI<sup>1</sup>. 1) GENETIC ENGINEERING, RES. CENT. OF SCI. AND BIOTECH, TEHRAN, TEHRAN, IRAN; 2) GENETIC RESEARCH CENTRE, WELFARE AND REHABILITATION UNIV. TEHRAN, IRAN,; 3) DEPARTMENT OF PATHOLOGY, DENTISTRY FACULTY, SHAHID BEHESHTI MEDICAL UNIV., TEHRAN, IRAN,.

Telomerase is an enzyme that maintains telomeres at the end of eukaryotic chromosomes. Activation of this enzyme causes repetition of TTAGGG hexamer which is associated with cell immortalization. Recently the role of telomerase has been considered in human cancers. In this study, activity of telomerase in oral S.C.C. was evaluated and would be followed by detection of telomerase activity in normal and PHA induced lymphocytes. Our research performed on 10 oral S.C.C. paraffin embedded samples out of 200 individuals that refer to our pathology department. We estimate telomeric ends length by PCR that relatively indicate the rate of telomerase activity. In initial report results shown existence of telomeric tails in these abnormal cells. In the malignant cells DNA breaks is observed and seems cells with these changes tend to malignancy. On the other hand telomerase can elongate single strand oligonucleotides whose termini are not complementary to the RNA template sequence 5'-CAACCCCAA-3'. By these data we suggest that presence of variant length of telomeric repeats in cell and PCR products may predict malignancy of these cells.

**Simultaneous identification of sequence changes in the p53 tumor suppressor gene and HPV typing using multiplex base excision sequence scanning (M-BESS).** *F.W. Hyde, J.T. Schanke.* Epicentre Technologies, Madison, WI.

Recent studies in assessing risk for development of cervical cancer have focused on a mutation in the p53 tumor suppressor gene and its role in the pathogenesis of human papillomavirus (HPV) type 16. Women who have this mutation and are infected with HPV type 16 have been reported to have a higher risk of cervical cancer than those who do not. This finding is the subject of controversy as the results of other studies do not support this conclusion. We examined this correlation with Multiplex Base Excision Sequence Scanning (M-BESS), which allows simultaneous sequence analysis of at least two DNA fragments amplified by PCR. In this method, two DNA fragments are amplified using two different primer pairs labeled with distinguishable fluorescent dyes. The differentially-labeled PCR products are treated with BESS-T and BESS-G Base Reader reagent systems and analyzed using an automated DNA sequencer. We demonstrate the utility of this application in determining the correlation between human papillomavirus (HPV) type and the existence of a specific mutation in codon 72 of the p53 tumor suppressor gene in a single reaction. We demonstrate that M-BESS can simultaneously detect the mutation in codon 72 and type the strain of HPV present.

**Completed BRCA1/BRCA2 Mutation Analysis Reveals a Low Rate of Germline Mutation in At-risk African-American Families.** L. Gayol<sup>1</sup>, H. Basterrechea<sup>1</sup>, T. Scholl<sup>2</sup>, E. Perera<sup>1</sup>, S. Smith<sup>1</sup>, J.F. Arena<sup>1</sup>, L. Baumbach<sup>1</sup>. 1) Univ Miami Med Sch, Miami, FL; 2) Myriad Genetics, Salt Lake City, UT.

The incidence of *BRCA1* germ-line mutations in at-risk individuals is controversial. In Caucasians, the detection of *BRCA1* mutations varies from 5-40%. Even more controversial is the incidence of *BRCA1* mutations and genetic variants in at-risk African-Americans (AA), which has been reported as ranging from very low to incidences equaling those in Caucasians. We report our results of completed *BRCA1* and *BRCA2* analyses in 20 AA families at-risk for breast/ovarian cancer. Families were ascertained based on a history of breast cancer or breast/ovarian cancer and subdivided into three categories: high-risk (HR; three affected 1st degree relatives; 10 families), moderate-risk (MR; two affected 1st degree relatives, 7 families) and undetermined risk (UR; single affected with medical information being updated, 3 families). *BRCA1* and *BRCA2* germ-line alterations were detected first using a series of exon-specific PCR primers for SSCP analysis, followed by DNA sequencing of SSCP variants. A limited number of *BRCA1* polymorphic intronic variants detected as a result of these studies were also analyzed for their effect on *BRCA1* mRNA splicing via an assay developed by Myriad Genetics. In this cohort, only one protein-truncating mutation was detected in either *BRCA1* or *BRCA2* (1/20; 5%). However, splice mutations, missense mutations, and a number of polymorphic variants were detected in both *BRCA1* and *BRCA2*, with a higher frequency occurring in *BRCA2*. Many of these variants were both novel, and specific to AA patients, as well as present in the absence of another disease-causing mutation. Moreover, a novel *BRCA1* missense mutation [exon 19(W1718C)] in one of the HR families appears to co-segregate with breast cancer. The relative frequencies of these *BRCA1* and *BRCA2* variants in patient and control populations will be reported. In summary, these results agree with previous observations that deleterious mutations in *BRCA1* or *BRCA2* are uncommon in at-risk AA patients, and suggest that more benign variants should be further evaluated for their potential role in the disease process in AA patients.

**Germline *BRCA2* mutations were detected in individuals from high risk breast cancer kindreds using a novel enzyme mutation detection method.** *B.A. Bove, J. Schick, A.T. Yeung, J. Costalas, M.B. Daly, A.K. Godwin.* Fox Chase Cancer Ctr, Philadelphia, PA.

Mutations in the *BRCA2* gene are associated with the development of breast cancer and to a lesser extent ovarian cancer. We have previously reported a highly sensitive enzymatic mutation detection (EMD) method, which relies on a novel plant endonuclease, referred to as CEL I (Oleykowski et al., 1998). CEL I recognizes DNA distortions and cleaves mismatches on the 3-side of the mismatch site in one of the two DNA strands in a heteroduplex. The fluorescent-labeled fragments are resolved by gel electrophoresis and any EMD variants are verified by direct sequencing. We selected 37 females from breast and/or breast/ovarian cancer families attending our Family Risk Assessment Program. Thirty of the individuals selected for screening were diagnosed with breast cancer (29 to 72 yr.), one with ovarian cancer (70 yr.), one with bladder cancer (63 yr.), and five were unaffected. All had previously tested negative for a mutation in *BRCA1* and each reported a family history of at least one first- and/or second-degree relative diagnosed with cancers other than breast and/or ovarian at the following sites: colon (18), stomach (14), lung (13), skin (12), prostate (11), hematopoietic (10), bladder (9), pancreas (7), throat (5), esophagus (5), abdomen (4), bone (4), brain (4), liver (4), kidney (3), rectum (2), gall bladder (2), cervix (1), and oral cavity (1). All 27 exons and intron/exon boundaries of *BRCA2* were evaluated by EMD and mutations were found in 10 of the 37 patients (27%), including six previously unreported mutations. Eight of these mutations were deletions or insertions, one was a splicing variant, and one was a novel missense mutation. Interestingly, all ten *BRCA2* mutation carriers had extensive family histories of cancers in addition to breast and/or ovary. Our results indicate that EMD is a highly sensitive and cost effective method for detecting missense and frameshift mutations in expansive genes such as *BRCA2* and that the incidence of other cancers appears to be elevated in many *BRCA2* mutant kindreds.

**Analysis of gene expression patterns in breast cancer by microarray technology.** *N. Gokgoz<sup>1</sup>, J. Woodget<sup>2</sup>, X. Sun<sup>2</sup>, S. Bull<sup>1</sup>, I.L. Andrulis<sup>1</sup>.* 1) Samuel Lunenfeld Research Inst, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Ontario Cancer Institute, Princess Margaret Hospital, Toronto, Ontario, Canada.

Although alterations in several specific genes have been implicated in breast cancer progression, greater understanding of the molecular basis of the disease may benefit from the evaluation of global gene expression patterns using microarray technology. To identify patterns of gene expression that are of prognostic importance in axillary node-negative (ANN) breast cancer, we are taking advantage of a large cohort of ANN patients. Before using the limited RNA from these specimens, we performed pilot studies designed to evaluate the feasibility of using the technology on a larger scale. For this purpose, we studied gene expression in 4 different breast cancer cell-lines (T47D, MDA231, SKBR3 and BT474) using cDNA microarrays containing 1700 and 19000 sequence-verified human cDNAs produced by the microarray facility at the Ontario Cancer Institute, Toronto (<http://www.oci.utoronto.ca/services/microarray>). Each hybridization compared Cy5 labeled cDNA from one of the cell lines with Cy3 labeled cDNA from a reference sample (MCF12A: a normal breast cell line). We also performed reciprocal labeling with subsequent hybridization to demonstrate the consistency and the reproducibility of the technology. In addition, different amounts of RNA (50ug, 25ug and 10ug) from the same cell lines were labeled to determine the sensitivity of the system. We have been able to devise a system that can now be applied to primary breast tumors. After expression analysis, biostatistical modelling will be used to detect clusters of genes that are coordinately expressed and/or repressed. These clusters are likely to represent common pathways of genes involved in breast carcinogenesis.

**Absence of MLH3 coding sequence germline mutations in HNPCC families.** *S.M. Lipkin<sup>1</sup>, V. Wang<sup>1</sup>, I. Kirsch<sup>2</sup>, D. Hadley<sup>1</sup>, H. Lynch<sup>3</sup>, F. Collins<sup>1</sup>.* 1) GMBB, MSC 4442, NIH/NHGRI, Bethesda, MD; 2) National Cancer Institute, Bethesda, MD; 3) Creighton University, Omaha NE.

DNA mismatch repair is of considerable scientific and medical importance because of its essential role in maintaining genomic integrity, and its association with Hereditary Non-Polyposis Colon Cancer (HNPCC). Linkage analyses originally led to the identification of MLH1 and MSH2 mutations in highly penetrant HNPCC pedigrees. 60-70% of HNPCC families HAVE identifiable mutations in these genes. Subsequently, <1% of HNPCC pedigrees have been found to have PMS2 mutations, and to date only a single PMS1 mutation has been described in one individual from a pedigree with familial cancer clustering. We have recently cloned MLH3, a novel mammalian homologue of yeast DNA mismatch repair gene MLH3p, that appears to be highly expressed in bowel epithelium. In order to evaluate whether MLH3 mutations might underlie unexplained HNPCC, we screened affected probands from more than 40 HNPCC families without identifiable germline mutations in the known candidate genes for MLH3 coding sequence mutations using denaturing HPLC. In no case were we able to identify coding sequence mutations in MLH3 in these probands. Ongoing studies are examining MSI+ colorectal tumors for somatic MLH3 mutations. Although we cannot exclude the existence of rare HNPCC families with underlying mutations, our results suggest MLH3 germline mutations are not frequently associated with HNPCC susceptibility.

**Comparison of fluorescence in situ hybridization (FISH) with immunohistochemistry (IHC) for detection of HER2/neu amplification/overexpression in breast cancer.** *G. Sun, J.S. Morales, S. Wilz, C. McKee, J. Amberson, S. Gersen.* DIANON Systems, Inc., Stratford, CT.

Adding to its prognostic/predictive value, HER-2/neu is also an indicator for specific therapeutic regimens. However, whether to use immunohistochemistry (IHC) or fluorescence in situ hybridization (FISH) or both to assess HER-2/neu status is still a debatable issue. To determine the correlation of IHC and FISH results and thus potentially determine a preferable testing method, 110 consecutive formalin-fixed paraffin-embedded tissue sections of ductal breast carcinoma were studied using the PathVysion FISH assay (Vysis) and the HercepTest IHC assay (DAKO). With the FISH assay, a HER-2/neu to chromosome 17 copy number ratio of 2 or greater was considered positive for gene amplification. With IHC, results of 0 and 1+ did not represent overexpression of HER-2/neu, while 2+ and 3+ were considered positive. Using the FISH assay, HER-2/neu was amplified in 17.3% of samples, while 46.4% demonstrated overexpression with IHC. Seventeen FISH-positive cases had an IHC result of 3+, but three other 3+ cases were negative with FISH. Of 59 IHC-negative cases, only one was positive with FISH. The greatest discordance was encountered in the IHC 2+ patients, where only one of 31 IHC-positive cases was positive with FISH. Conclusions and discussion: 1) Strong (3+) HER-2/neu immunostaining correlates well with gene amplification. 2) FISH is a highly specific and reproducible test for gene amplification. 3) IHC is more cost-effective, and may detect a subset of positive cases that are negative with FISH. 4) Using a mean copy number of HER-2/neu rather than a HER-2/neu to chromosome 17 ratio may reduce the possibility of under-representation of detectable amplified cases. 5) Additional studies are needed for possible improvement of methodology and clinical correlation in IHC 2+ cases.

**Extension of the Two-hit Hypothesis in Neurofibromatosis 2 (NF2): Effects of the Mutant Allele and Prediction of the Age of Onset for Both Vestibular Schwannomas.** *R.R. Woods<sup>1,2</sup>, H. Joe<sup>1,2</sup>, D.G.R. Evans<sup>4</sup>, M.E. Baser<sup>5</sup>, J.M. Friedman<sup>1,3</sup>.* 1) University of British Columbia, Vancouver, BC, Canada; 2) Department of Statistics; 3) Department of Medical Genetics; 4) St. Mary's Hospital, Manchester, U.K; 5) Los Angeles, U.S.A.

Molecular and epidemiological data are consistent with the application of Knudson's two-hit model for development of vestibular schwannomas (VS) in patients with NF2, but this model does not predict the occurrence of genotype-phenotype correlations or the age at onset of the second tumour in an affected individual. Here we propose some simple extensions to the two-hit models of Moolgavkar and Venzon (Math Biosci 1979; 47; 55-77) and provide an application of these to incidence data for VS in NF2 patients. Our first model, which incorporates an effect of the mutant NF2 allele, was fit to data on 68 NF2 probands with bilateral VS and identified mutation type. Patients were stratified into those with protein truncating mutations (40 patients) and those with other identified mutation types (28 patients). Model-predicted incidence curves for age at onset of hearing loss differed significantly between strata and fit the empirical incidence curves very well for both strata. Our second model combines the techniques used for classical two-hit models with methodology for paired survival data in an effort to predict incidence curves for the ages at onset of both the first and second VS in NF2 patients. Data on the ages at onset for left and right VS for 144 NF2 probands were used to fit the model. Predicted incidence curves from this model fit the empirical incidence curves for the ages of onset for both the first and second VS (See <http://mendel.medgen.ubc.ca/friedmanlab/2hit.html> for plots). A parameter representing the relationship between the ages at onset of the two VS in each patient is estimated in this model and shows a very strong association (Kendall's Tau ~ 0.90).

**Audiological phenotype of patients with mitochondrial DNA mutation 3243A>G.** *K. Majamaa<sup>1,3</sup>, S. Uimonen<sup>2</sup>, J.S. Moilanen<sup>1</sup>, M. Sorri<sup>2</sup>, I.E. Hassinen<sup>3</sup>*. 1) Department of Neurology, University of Oulu, Oulu, Finland; 2) Department of Otorhinolaryngology, University of Oulu, Oulu, Finland; 3) Department of Medical Biochemistry, University of Oulu, Oulu, Finland.

The relationship between the phenotype and the genotype is complex in diseases caused by mutations in mitochondrial DNA (mtDNA). The 3243A>G mutation in mtDNA leads frequently to sensorineural hearing impairment (HI), a phenotype that can be measured in severity by audiometry, and consecutive audiograms can give an estimate on the rate of HI progression. We examined the audiological phenotype of 38 patients (14 men, 24 women) with 3243A>G that belonged to the population-based cohort ascertained in the province of Northern Ostrobothnia, Finland. The subjects went through an extensive otorhinolaryngologic examination, including audiometry. Factors modulating the severity of HI were analyzed, and the rate of HI progression was calculated. Better ear hearing level at frequencies 0.5, 1, 2 and 4 kHz (BEHL/0.5-4kHz) was > 20 dB in 28 patients (74 %). A good correlation ( $r = 0.550$ ,  $p = 0.001$ ) was found between BEHL/0.5-4kHz and the degree of the mutant heteroplasmy. BEHL/0.5-4kHz was higher in men than in women, and women outnumbered men among patients with normal hearing or mild HI. In addition, 181 consecutive audiograms were reviewed from 24 patients with HI. The rate of HI progression was calculated to be 2.9 dB/year in men and 1.5 dB/year in women being 5-6 -fold faster compared to the rates that have been observed in the corresponding age group in the general population. High degree of mutant heteroplasmy and male gender were found to increase the severity of HI and its rate of progression. Phenotypic difference by gender may thus be a more universal phenomenon in mitochondrial diseases and not only associated with Leber hereditary optic neuropathy. Furthermore, this study provides the first estimate on the rate of disease progression among patients with the 3243A>G mutation.

**RESULTS OF A SCREENING PROGRAM FOR WAARDENBURG SYNDROME IN COLOMBIA. M.L.**

*Tamayo, M.C. Lattig, M. Rodríguez, N. Gelvez, J.C. Prieto.* Instituto de Genética Humana, Universidad Javeriana, Bogotá, Colombia.

Waardenburg syndrome (WS) is an autosomal dominant disorder characterized by sensorineural hearing loss and pigment abnormalities (white forelock, premature graying, heterochromia irides and skin hypopigmentation). The syndrome is clinically and genetically heterogeneous, and has been divided into four principal types. We search for individuals with Waardenburg Syndrome in the institutions for the deaf in the main cities of our country. Genetic, otological and ophthalmological studies were performed in 1542 individuals with hearing loss, finding a clinical diagnosis of WS in 80 of them (5,2%). A complete medical history and physical examination was performed in all of them and were tested for WI (W Index), cytogenetic examination and molecular screening for the most common mutations. In accordance with our clinical classification we found 45% WS1 and 55% WS2. No WS3 and WS4 were observed. We analyzed 32 WS individuals with high resolution cariotype, showing abnormalities in 4 of them (12.5%). We found: t(13,21)(13pter,13q21::21q22.1-21qter;21pter-21q22.1::1+H25 in one girl, and two different mosaicisms: Normal(60%);t(15q,18ter)(40%) and Normal(96%);t(10,19);10q22.1;19Pter(4%). We also identified a centromeric duplication of chromosome 16 in another girl. As regard of our screening for mutations, we have identified for PAX3 gene 5 mutations: 3 on exon 2, 1 on exon 5 and 1 on exon 6; for MITF gene 3 different mutations on exon 5. Our goal is complete the screening for mutations causing WS, and establish genotype/phenotype correlation in our deaf Colombian population.

**Neurological presentation of a congenital disorder of glycosylation CDG Ia : implications for diagnosis and genetic counseling.** *V. Drouin-Garraud<sup>1</sup>, M. Belgrand<sup>1</sup>, S. Grünewald<sup>2</sup>, N. Seta<sup>3</sup>, J.N. Dacher<sup>4</sup>, A. Hénocq<sup>1</sup>, G. Matthijs<sup>2</sup>, V. Cormier-Daire<sup>5</sup>, T. Frébourg<sup>1</sup>, P. Saugier-veber<sup>1</sup>.* 1) Service de Génétique, CHU de Rouen, 76031 Rouen, France; 2) Center for Human Genetics, University of Leuven, B 3000 Belgium; 3) Laboratoire de Biochimie, CHU Bichat-Claude Bernard, 75877 Paris; 4) Service de Radiologie, CHU de Rouen, 76031 Rouen; 5) Département de Génétique, Hôpital Necker Enfants-Malades, 75743 Paris, France.

The congenital disorders of glycosylation type I (CDG I) are rare autosomal recessive disorders characterised by a defective glycosylation of complex glycoconjugates. CDG Ia, the most frequent type, is a multisystemic disorder affecting the nervous system and numerous organs including liver, kidney, heart, adipose tissue, bone and genitalia. A phosphomannomutase (PMM) deficiency has been identified in CDG Ia patients and numerous mutations within the *PMM2* gene, located on chromosome 16p13, have been recently identified in patients with PMM deficiency. We report here a French family including 3 affected sibs, with an unusual presentation of CDG Ia remarkable by (i) the neurological presentation of the disease and, (ii) the dissociation between a subnormal PMM activity in fibroblasts and a decreased PMM activity in leukocytes. This case report shows that the diagnosis of CDG Ia must be considered in patients with non-regressive early-onset encephalopathy with cerebellar atrophy and that intermediate values of PMM activity in fibroblasts do not exclude the diagnosis of CDG Ia.

**A Korean patient with Fanconi-Bickel syndrome(FBS) presenting with transient neonatal diabetes mellitus and galactosemia.** *J.W. Cheong<sup>1</sup>, G.H. Kim<sup>2</sup>, E.J. Seo<sup>2</sup>, H.W. Yoo<sup>2</sup>.* 1) Asan Institute for Life Sciences, Asan Medical Center, Seoul, Korea; 2) Medical Genetics Clinic & Laboratory, Asan Medical Center, Ulsan University College of Medicine, Seoul, Korea.

Fanconi-Bickel Syndrome(FBS) is a rare autosomal recessive disorder of carbohydrate metabolism recently demonstrated to be caused by mutations in GLUT2, the gene for the glucose transporter protein 2 expressed in liver, pancreas, intestine and kidney. This disease is characterized by hepatorenal glycogen accumulation, both fasting hypoglycemia as well as postprandial hyperglycemia and hypergalactosemia, and generalized proximal renal tubular dysfunctions. We report the first Korean patient with FBS diagnosed based on clinical manifestations and identification of novel mutation in the GLUT2 gene. She was the first full term product born to normal healthy parents with non-consanguineous marriage. She was initially diagnosed as having a neonatal diabetes mellitus due to hyperglycemia and glycosuria at 3 days after birth. Newborn screening for galactosemia also revealed hypergalactosemia. Galactose-1-phosphate uridylyltransferase activity was within normal range. Thereafter, she has been managed with lactose free milk, insulin therapy. However, she failed to grow and her liver has been progressively enlarged. Her cheeks were chubby, and her abdomen was protruded. Laboratory tests indicated she had generalized proximal renal tubular dysfunction; renal tubular acidosis, hypophosphatemic rickets, generalized aminoaciduria. Given aforementioned findings, the diagnosis of FBS was entertained at age of 2 months. Her genomic DNA was isolated from peripheral leucocytes. The nucleotide sequencing of the GLUT2 gene from the patient revealed a novel mutation; K5X/K5X.

**Evidence for a novel X-linked adrenal insufficiency with salt wasting.** *E.Robert Wassman<sup>1</sup>, M. Moline<sup>1,2</sup>, S. Clark<sup>2</sup>, M. Ibrahim<sup>3</sup>, J. Siegel-Bartelt,<sup>1</sup>* 1) PAMG, Pasadena, CA; 2) Pomona Valley Hospital; 3) San Antonio Community Hospital.

Genetic heterogeneity is reported for many conditions. We report novel X-linked inheritance of congenital adrenal insufficiency with salt wasting in a family with 3 affected males originally thought to have 21 hydroxylase deficiency. Three obligate carrier females are two maternal half sisters and their mother. The family resides in a large metropolitan area, and there is no consanguinity. The oldest affected child is a now 16 year old male who was found to have dehydration, hyperpigmentation, and salt wasting at 2 weeks of age. He carries a diagnosis of 21 hydroxylase deficiency, and is maintained on hydrocortisone and florinef. Commercial molecular analysis of the steroid 21-hydroxylase gene (HACHapman Institute) revealed no G mutation, nor 8bp mutation characteristic of a gene deletion in the CAH gene or pseudogene conversion, nor point mutations M239K, V281L, Q318X and R356W. Case 2 is a now 4 year boy born to the proband's maternal half sister. He also presented at 12 days with dehydration and salt-wasting, and is being maintained on Cortef and Florinef. His course has been complicated by hypertension, and he has an elevated 11-deoxycortisol. Case 3 is a one year old male with similar presentation born to another maternal half sister to the proband. This pedigree is highly suggestive of previously undescribed X-linked inheritance of congenital adrenal hyperplasia with salt wasting, as the odds of 3 unrelated carriers marrying into the family is low. We speculate that an X-linked factor modifies this steroid synthesis pathway. Genetic counseling in families with males probands should include this possibility of genetic heterogeneity.

**Proximal 1q deletion syndrome: A patient with del(1)(q24.2-q25.3).** *M. Descartes*<sup>1</sup>, *J. Zenger-Hain*<sup>2</sup>, *M. Conklin*<sup>3</sup>, *A. Carroll*<sup>1</sup>. 1) Dept Human Genetics, Univ Alabama, Birmingham, AL; 2) Oakwood Hospital, Dearborn, MI; 3) Pediatric-Orthopedic Children's Hospital, Univ. of AL, Birmingham, AL.

Patients with deletion 1q21-q25 have characteristic features that have allowed the delineation of a syndrome, proximal 1q deletion syndrome.<sup>1</sup> Based on 11 reported cases, the features include growth retardation, microbrachycephaly, psychomotor retardation, hypertelorism, abnormal ears, bulbous nose, micrognathia, cleft lip/palate, small hands/feet, 5th finger clinodactyly, dysplastic nails, hernias, genital and cardiac anomalies.<sup>1-5</sup> We report on a 13 year old female patient with a smaller deletion than previously described. Her karyotype was 46,XX,del(1)(q24.2-q25.3) *de novo*. Our patient had many of the previously described features as well as, partial growth hormone deficiency, small optic nerves, and hearing loss. The later features have been described in patients with more distal deletions, i.e. del(1)(q24q32).<sup>6-7</sup> Her physical examination revealed microcephaly, short forehead, flared eyebrows, bulbous nose, flared nares and broad columella, posteriorly rotated ears, full lips and small chin. In addition, bilateral pes cavus, bowing and shortening of the forearms with Madelung's deformity, limited pronation and flexion of wrists and elbows, short fingers and toes, broad thumbs, and 5th finger clinodactyly were noted. The patient attends an educable mentally impaired school program. Radiographic examination revealed: 11 pairs of ribs; relative ulnar shortening and subluxation; shortened/broadened phalanges; 4-5th metacarpals with abnormal shape; fusion of the distal phalanges; short 3-5th metatarsals. She did not have cleft lip/palate, genital or cardiac defects. This case narrows the critical region for the proximal 1q deletion syndrome, and a possible candidate is T-box19 which maps to 1q23q24.<sup>8</sup> Mutations in other genes in the T-box family have been implicated in multiple malformation syndromes in which skeletal anomalies are the features such as Ulnar-Mammary syndrome (TBX3)<sup>9</sup> and Holt-Oram syndrome (TBX5).<sup>10</sup>

**A Lethal Skeletal Dysplasia - Distinct from Neu-Laxova Syndrome.** *A.M. Elliott<sup>1</sup>, J. Hoeffel<sup>2</sup>, M. Gonzales<sup>3</sup>, R.S. Lachman<sup>1</sup>.* 1) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Hôpital Jeanne d'Arc, Toul Cedex, France; 3) Hôpital St-Antoine, Paris, France.

Neu-Laxova Syndrome (NLS) is a severe disorder with intrauterine growth retardation, edema and characteristic facies (including microcephaly with receding forehead, protuberant eyes, a flattened nose, deformed ears, cleft palate and micrognathia). Ichthyosis is often present. Limb anomalies include hypoplastic fingers and syndactyly of fingers and toes. Patients are usually stillborn or die shortly after birth. We report two unrelated patients with clinical findings suggestive of Neu-Laxova syndrome, but with anomalies not usually seen in this disorder. These patients likely represent a distinct lethal skeletal dysplasia. Both patients were stillbirths. Patient 1 was a stillbirth at 24 weeks gestation and is of North African descent. Radiographic evaluation of patient 1 revealed vertebral body deficiency with a short trunk. The clavicles were elongated. There appeared to be 11 pairs of ribs which were proportionately thickened. The skull was large. There was rhizo-, meso- and acromelia. There was hypoplasia of the metacarpals and phalanges. The feet were similarly affected. The ilia were tall and narrow and the sacrosiatic notches were widened. The ischia were vertical. The long bones showed diaphyseal widening which spared the metaphyses and was more pronounced in the lower extremities. Patient 2 showed similar radiographic changes with a large skull, short trunk, tall and narrow ilia and vertical ischia. The hips were dislocated and the acetabular region never formed. The diaphyseal bony overgrowth primarily involved the lower extremities. Clinically, there was macrocephaly, short limbs with hypoplastic digits and generalized edema. Scott et al., (*Am J Med Genet* 9:165-175, 1981) described 2 patients with Neu-Laxova syndrome with radiographic and clinical findings similar to the 2 patients reported here. Scott's patients were described as having short-limbs, large heads, short necks and hypoplastic/absent digits and generalized edema. These 4 unrelated patients lack the typical findings of NLS, and likely represent a distinct lethal skeletal dysplasia.

**Bone mineral metabolism in Satoyoshi syndrome associated with autoimmune thyroiditis.** *V. del Castillo*<sup>1</sup>, *N. Altamirano*<sup>1</sup>, *A. Rasmussen*<sup>2</sup>, *C. Esmer*<sup>1</sup>, *M. Ruiz*<sup>1</sup>. 1) Inst Nacional Pediatria, SSA, Mexico, DF; 2) Inst Nacional de Neurologia y Neurocirugia, SSA, Mexico, DF.

Satoyoshi syndrome is a rare disorder characterized by progressive muscle spasms, alopecia, diarrhea, skeletal abnormalities and endocrine disorders. The frequency and severity of spasms slowly increases causing skeletal damage secondary to repeated traumas, manifested as metaphyseal lesions, slipping of epiphyses, cystic lesions, acro-ostelolysis, bone fragmentation, fatigue fractures and early osteoarthritis. Other common features are: amenorrhea, mild microcytic anemia, short stature and impaired glucose tolerance. Although etiology is unknown, an autoimmune mechanism has been proposed. We report on a 14-year-old female that experienced painful muscle spasms in the lower limbs at age 6 years with progressive involvement of the upper limbs, trunk, neck and masticatory muscles, with articular deformity that led to difficult walking. Soon after, she had alopecia involving scalp hair, eyebrows and eyelashes, and intermittent diarrhea. Her radiologic findings are those typically described in the syndrome. Femoral neck and lumbar spine L1-L4 bone density was decreased and biochemical markers of bone turnover (serum Ca, P, Mg, alkaline phosphatase and Ca/Cr ratio) were within normal limits. She was responsive to dantrolene and biphosphonate administration during 20 months in which autoimmune thyroiditis was diagnosed and managed with thyroid hormones. Dantrolene was suspended one year ago. At the present time, antithyroid antibodies are negative, bone density has improved, new hair has grown and the muscle spasms have decreased in frequency and intensity, she has Tanner 3 breast development, but menarche is still absent. To our knowlegde this is the first case who shows abnormal bone density succesfully treated with biphosphonates. Also is the first in which thyroiditis is described, this finding provides support to the autoimmune theory.

**Pre-Expression Evaluation of Spondyloepiphyseal Dysplasia Tarda By Sedlin Gene Analysis.** *G.S. Gottesman*<sup>1,2</sup>, *S. Mumm*<sup>3</sup>, *X. Zhang*<sup>3</sup>, *W.H. McAlister*<sup>4</sup>, *M.N. Podgornik*<sup>1</sup>, *M.P. Whyte*<sup>1,3</sup>. 1) Metabolic Research Unit, Shriners Hosp Children, St Louis, MO; 2) Div Medical Genetics, Saint Louis Univ Sch Medicine, St Louis, MO; 3) Div Bone Mineral Diseases, Wash Univ Sch Med, St Louis, MO; 4) Dept Radiology, St Louis Childrens Hosp, St Louis, MO.

Spondyloepiphyseal dysplasia tarda (SEDТ) is a X-linked recessive disorder that presents during childhood with back pain and short stature in boys. As we have reported (*Medicine* 78:9-25,1999), heterozygous women can manifest subtle radiographic changes. However, skeletal radiographs of affected (hemizygous) boys are normal during infancy and early childhood. In 1999, 2 bp deletions were identified in a gene designated Sedlin in 3 Australian families with SEDТ (*Nat Genet* 22:4, 400-404 1999). Although there is no established medical treatment for this condition, pre-expression diagnosis by sedlin gene analysis could be beneficial, allowing appropriate counseling against physical activities injurious to the spine and the joints, especially those of the lower limbs.

After an orthopedist referred a 15-year-old young man (proband) with dysplastic changes of the spine, we established a diagnosis of SEDТ. He was from a large kindred with previously undiagnosed SEDТ involving at least 5 generations. A unique 2 bp deletion in exon 5 was found on molecular analysis by PCR amplification and sequencing of all the coding exons. We then studied a nuclear family from within the kindred (proband's maternal aunt and her 3 sons). The woman was a potential carrier. Subtle shaping abnormalities of her pelvis and knees on skeletal radiographs supported this possibility. Radiographs of the spine and pelvis of the 2 younger boys (ages 2 and 5) showed no changes of SEDТ, but those of the eldest son (age 8) had clear-cut evidence of the disorder. Molecular testing demonstrated the mother and only her eldest son had the same 2 bp deletion in exon 5. Molecular testing for Sedlin gene abnormalities enables pre-symptomatic diagnosis prior to radiographic demonstration of the disorder. Perhaps, cautions early on to minimize physical strain to the spine and joints will ameliorate the eventual manifestations of the disorder.

**Ophthalmoplegia, severe scoliosis and brain stem hypoplasia: A recognized autosomal recessive syndrome.** *B. Lo<sup>1</sup>, S. Blazer<sup>2</sup>, B. Banwell<sup>3</sup>, N. Quercia<sup>1</sup>, A. Teebi<sup>1</sup>.* 1) Division of Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Diagnostic Imaging, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Neurology, Hospital for Sick Children, Toronto, Ontario, Canada.

Congenital horizontal gaze palsy associated with early onset severe scoliosis is a rare disorder that has been hypothesized to be due to brainstem maldevelopment. In families previously ascertained, however, brain imaging studies have not uncovered any brainstem abnormalities, and intelligence has been reported as normal or borderline. We describe here a consanguineous family in which three of five siblings have congenital horizontal gaze palsy and early onset severe scoliosis. The affected siblings exhibit complete ophthalmoparesis of the medial and lateral recti muscles bilaterally with relatively well preserved superior and downward gaze, and scoliosis of the thoracolumbar spine requiring either surgical repair or bracing. In two of the affected siblings, a brother and sister, there was also significant cognitive delay. Interestingly, MRI scans revealed brainstem hypoplasia in these two individuals with cognitive delay. MRI on the sister, age 12, demonstrated a prominent midline raphe of the medulla and an abnormal flattened configuration of the pons. Visual and auditory evoked potentials, EMG and nerve conduction studies performed on the brother, age 6, were all within normal limits. A muscle biopsy taken from the sister did not provide any evidence for a mitochondrial or structural myopathy and karyotyping of the brother was unremarkable. The siblings did not exhibit any significant dysmorphic features. The MRI results in this family provide support for the theory that the maldevelopment of neurons in the abducens nuclei and caudal longitudinal fascicle is the cause for this rare syndrome of horizontal gaze paralysis and kyphoscoliosis.

**A female case of osteopathia striata with cranial sclerosis associated with markedly skewed X-chromosome inactivation: Implication of an X-linked trait.** *Y. Nozaki<sup>1</sup>, T. Kubota<sup>2</sup>, Y. Fukushima<sup>2</sup>, T. Yamagata<sup>1</sup>, M. Mizuguchi<sup>1</sup>, M.Y. Momoi<sup>1</sup>, G. Nishimura<sup>3</sup>.* 1) Pediatrics, Jichi Medical School, Minamikawachi, Tochigi, Japan; 2) Department of Hygiene and Medical Genetics, Shinshu University School of Medicine, Nagano, Japan; 3) Department of Radiology, Nasu-Chuo Hospital, Tochigi, Japan.

Osteopathia striata with cranial sclerosis (OS-CS) is a sclerosing bone dysplasia associated with a variety of dysmorphic features and mental retardation. OS-CS has been considered to be dominantly inherited. However, female preponderance and male severity in OS-CS have raised a question as to whether this entity is transmitted as an autosomal dominant or X-linked trait. We report here a female patient with OS-CS with some additional features. The parents of the patient were healthy, and the mother had two miscarriages. The clinical manifestation of the patient consisted of macrocephaly with frontal bossing, hypertelorism, broad nasal bridge, cleft palate, cataract, and severe mental retardation. The radiologic manifestations of the patient, including longitudinal striation of the metaphyses of long bones and sclerosis of cranial bones, warranted a diagnosis of OS-CS. In addition, she had severe conspicuous brachydactyly, scoliosis, features rarely described in OS-CS. To elucidate the pathogenesis of OS-CS in this female patient, we studied the inactivation pattern of X-chromosomes on lymphocytes by methylation-specific PCR. The DNA of the patient and parents was treated with sodium bisulfite that converts all unmethylated, but not methylated, cytosines to uracil. PCR primers were designed to detect active and inactive X chromosomes separately by utilizing repeat length polymorphism of PCR products. The patient had a 213 bp band from the father and a 195 bp band from the mother with as much as 97% activation of the mother-derived X-chromosome. These results suggest that in this patient OS-CS had been inherited in an X-linked fashion and became manifest due to extremely skewed inactivation of X chromosomes.

**Neonatal demise in an infant with a molecular diagnosis of osteogenesis imperfecta Type I.** *V. Loik Ramey<sup>1</sup>, J.G. Habecker-Green<sup>1</sup>, G. Markenson<sup>2</sup>, S. Pflueger<sup>3</sup>, G.M. Cohn<sup>1</sup>.* 1) Clinical Genetics, Baystate Medical Center, Springfield, MA; 2) Maternal-Fetal-Medicine, Baystate Medical Center, Springfield, MA; 3) Pathology, Baystate Medical Center, Springfield, MA.

Osteogenesis imperfecta Type I is the mildest form of OI and is not typically associated with neonatal demise. We present a female infant with a molecular diagnosis of OI Type I who had multiple congenital anomalies and expired at 22 hours after birth.

The infant was diagnosed prenatally with an isolated congenital heart defect of undefined type. The pregnancy was significant for poorly controlled diabetes. The parents were maternal first cousins as were their maternal grandparents. The infant, born at 33 weeks gestation, sustained a femur fracture during delivery. Postnatally, she sustained a humeral fracture without trauma. The evaluation of the infant was notable for markedly redundant and hyperextensible skin. Dysmorphic features included: a bulbous nasal tip, retrognathia, anomalous ears, ambiguous genitalia, dorsiflexed left foot with hyperflexion of toes, and clenched fists. A skeletal survey revealed multiple prenatal rib fractures with otherwise unremarkable ribs and long bones. The skull was significant for wormian bones, undermineralization, and calvarian fractures. The infant expired 22 hours after birth secondary to cardiorespiratory failure. Autopsy revealed a hypoplastic transverse aortic arch and main pulmonary artery dilation with elongated tortuous right and left pulmonary arteries. Collagen studies revealed a functional null allele for COL1A1 consistent with a clinical diagnosis of OI Type I. Heterozygosity studies ruled out a microdeletion of chromosome 17q.

There have been no reports in the literature describing a case of OI type I with the severity of clinical symptoms seen in this infant. Whether this case represents a severe form of isolated OI Type I or OI Type I in combination with another disorder remains a question. As the parents were multiply consanguineous, we hypothesize that this infant may have also had another autosomal recessive connective tissue disorder.

**A new connective tissue disorder with features overlapping those of Ehlers-Danlos, Marfan and Stickler syndromes.** *H.P. Levy<sup>1</sup>, J.J. Johnston<sup>1</sup>, J. Davis<sup>1</sup>, J. Balog<sup>1</sup>, P.S. Rose<sup>1,2</sup>, A. Schäffer<sup>1</sup>, H. Dietz<sup>2</sup>, C.A. Francomano<sup>1</sup>.*  
1) NHGRI, National Institutes of Health, Bethesda, MD; 2) Johns Hopkins University School of Medicine, Baltimore, MD.

A family with manifestations overlapping Ehlers-Danlos, Marfan and Stickler syndromes originally came to medical attention when a 58 year old mother and 32 year old son both died from spontaneous aortic dissection. The mother's father and two uncles also died from vascular dissections (two cerebral and one abdominal aneurysm). We have examined thirteen living relatives (nine affected). Common features among affected individuals include joint laxity and mild skeletal abnormalities, which are nonspecific for a particular connective tissue disorder. Vascular dilatation and dissection are most consistent with a diagnosis of Marfan syndrome. Findings suggestive of Ehlers-Danlos syndrome include soft, fragile skin and a bleeding diathesis. Many individuals also have characteristics typical of Stickler syndrome, including premature osteoarthritis, bifid uvula (a form fruste of cleft palate), hearing loss, and vitreoretinal degeneration. In addition, there may be progressive microretrognathia, similar to but more severe than that seen in Marfan and Stickler syndromes, and profoundly simple auricular helices. Peripheral blood karyotype and biochemical analysis of types I and III procollagen and collagen from fibroblasts were normal. A full genome scan was performed using a linkage set with 10 centimorgan spacing. LOD scores for markers surrounding COL11A2 exceeded -2 and were negative for markers flanking FBN1, FBN2, COL1A1, COL1A2, COL2A1, COL3A1, COL5A1 and COL5A2. Power was too low to confirm linkage to any particular region, and efforts are underway to include additional family members and analyze additional markers.

In summary, we describe a new autosomal dominant connective tissue disorder with features overlapping those of Ehlers-Danlos, Marfan and Stickler syndromes. No single defined heritable disorder of connective tissue reconciles all of the manifestations, and preliminary data appear to exclude the majority of genes associated with these disorders.

**A man who inherited SRY and Leri-Weill dyschondrosteosis from his mother and neurofibromatosis from his father.** *F. Wei<sup>1</sup>, S. Chheng<sup>1</sup>, F.F.B. Elder<sup>1</sup>, C.I. Scott Jr.<sup>2</sup>, L. Nicholson<sup>2</sup>, J.L. Ross<sup>3</sup>, A.R. Zinn<sup>3</sup>.* 1) McDermott Center for Human Growth and Development, University of Texas Southwestern Medical School, Dallas, TX; 2) Alfred I. duPont Hospital for Children, Wilmington, DE; 3) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

**CASE REPORT:** We studied a 29 year old man with Leri-Weil dyschondrosteosis (LWD) and neurofibromatosis (NF). He was 146 cm. tall (-4.6 SD) and had Madelung's deformity, mesomelia, café au lait spots and neurofibromata. His father was 162 cm. tall (-2.3 SD) and had NF. His mother was 142 cm. tall (-3.4 SD) and had Madelung's deformity, mesomelia, high arched palate, bicuspid aortic valve, aortic stenosis, and premature ovarian failure at age 40 after two successful pregnancies. A male sibling had NF but not LWD.

**RESULTS:** Karyotype of the mother for suspicion of Turner syndrome showed mos 45,X[17 cells]/46,X,dic(X;Y)(p22.3;p11.32)[3 cells].ish dic(X;Y)(DXZ1+,DYZ1+). The proband's karyotype was 46,X,dic(X;Y)(p22.3;p11.32). Additional studies showed that the dic(X;Y) chromosome was PABY+, SRY+, DYZ5+, and SHOX<sup>-</sup>. The dic(X;Y) chromosome was also positive for a marker < 300 kb distal to PABX, suggesting that the translocation deleted only pseudoautosomal sequences, including SHOX.

**DISCUSSION:** Haploinsufficiency of SHOX explained LWD in the proband and his mother. Her female phenotype could be due to 45,X mosaicism, SRY silencing by X-inactivation, or both. X-inactivation studies of the proband and his mother are in progress. The proband was normally virilized; detailed andrologic evaluation is planned. Prophylactic oophorectomy was recommended for the mother because of the risk of gonadoblastoma. This family segregating multiple Mendelian and chromosomal disorders demonstrates remarkable sex chromosome variation compatible with grossly normal male and female sexual differentiation. The case also highlights the importance of a karyotype for differentiating Turner syndrome and LWD, especially in patients with findings that are not explained by SHOX haploinsufficiency, such as premature ovarian failure or aortic abnormalities.

**The "Marshall Chronicles:" Splicing mutation of 54-bp exon in the COL11A1 gene not found in four generation family with Marshall syndrome (MS)(MIM 154780).** *A.L. Shanske<sup>1</sup>, J. Korkko<sup>2</sup>, R. Marion<sup>1</sup>.* 1) Ctr Congenital Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 2) Center for Gene Therapy, MCP Hahnemann University, Philadelphia, PA.

In 1958, Marshall described 7 members in 3 generations of a family who were affected with a form of "ectodermal dysplasia" comprising ocular abnormalities, minor facial anomalies and hearing loss. The author emphasized the ectodermal and ocular abnormalities. Since the original description, there have been only 8 additional families including our own (Shanske, 1997). Since then, nosologic relationships among MS, Stickler Syndrome (SS) and a number of related disorders have been debated. The recognition of molecular defects in patients with SS has revealed genetic heterogeneity but has not resolved the molecular basis of MS.

**Clinical Reports:** The propositus, EM is a 21 year old woman with midfacial hypoplasia, telecanthus, broad flat nasal bridge, sparse scalp hair, lashes and brows and normal sweating. She has myopia, exotropia and embryotoxin. She underwent craniofacial reconstruction consisting of orbital translocation, cranial bone graft, first stage nasal reconstruction and medial and lateral canthopexy. FM is the 18 year old brother of EM with the identical craniofacial and ectodermal findings and has also undergone craniofacial correction of hypertelorism. He has high myopia and bilateral amblyopia. NM is their 14 year old brother who also underwent a craniotomy to repair third degree hypertelorism. He has myopic astigmatism and exotropia. EM's mother, maternal grandfather and 2 of her 3 children have the same phenotype.

PCR amplification of the exons and the exon-intron boundaries of the 54 exons of COL2A1 and the 67 exons of COL11A1 was followed by screening of the PCR products by the technique of confirmation gel electrophoresis. No unusual sequence variations were identified in NM. We conclude that neither a splicing mutation of 54-bp exon in the C-terminal region of COL11A1 nor the several mutations identified in COL2A1 in patients with the MS/SS phenotype are the molecular basis of MS in this family.

**Presumed AR ulna/fibula dysplasia with cleft lip: a third reported family.** *J. Siegel-Bartelt*<sup>1,2</sup>, *M. Chung*<sup>3</sup>, *E.R. Wassman*<sup>1,2</sup>, *G.R. DeVore*<sup>1</sup>. 1) Alfigen, The Genetics Inst, Pasadena, CA; 2) Perinatal Alliance Medical Group; 3) Glendale Adventist Hospital.

We report a sibship with 3 affected children with ulna/fibula dysplasia similar to the families previously reported by Pfeiffer, RA (1988) and Fuhrmann, W (1980.) This supports a rare autosomal recessive etiology for the ulna/fibula developmental field. The limb anomalies in the proband were seen at 26 weeks on ultrasound. The term AGA male had poor respiratory effort, and died at 9 hours. There were short angulated forearms, with ulnar clubbing of the hands. The ulna was markedly hypoplastic, 4 metacarpals were present, and 4 digits. The thumbs were also smaller than usual. The lower leg was slender with a short fibula, 4 metatarsals, and 4 digits with 1,2 syndactyly. The face showed hypertelorism, incomplete left cleft lip, small mouth with trismus, and small lowset ears. The chest was broad, with partial superior duplication of the nipple. The genitalia were hypoplastic. Chest Xray showed an enlarged heart. Chromosome analysis was normal, 46,XY. The family history revealed normal parents (not known to be consanguineous but from adjacent rural villages.) The first affected child was a female who died at 6 days. She had 3 digits on the hands and feet, and a mouth that did not open. The second child in the family is a male with 4 digits on each extremity. He is alive at 6 years with developmental handicap (walked at 3 years.) He had prolonged gastrostomy feeding, and had infant heart surgery. His facies are similar to the proband, with hypertelorism, lowset cupped ears, and mild retrognathia. The ulna/fibula developmental field is most frequently affected in sporadic birth defects, such as Femur-fibula-ulnar syndrome. However, it is also affected in a few autosomal dominant conditions, such as Schinzel ulnar-mammary syndrome due to TBX3 at 12q24, and Weyer acrodistal dysostosis due to EVC gene at 4p16. Kaplan fibulo-ulnar aplasia with renal anomalies is also presumed to be autosomal recessive. This case report supports the concept of a fibulo-ulnar developmental field with heterogeneous etiologies.

**Additional Skeletal Features in Pallister-Hall Syndrome.** *T. Roscioli<sup>1</sup>, D. Kennedy<sup>2</sup>, G.F. Watson<sup>3</sup>, B. Fonseca<sup>4</sup>, J. Pereira<sup>5</sup>, D. Mowat<sup>1</sup>.* 1) Dept Medical Genetics, Sydney Children's Hospital, Sydney, Australia; 2) Central Sydney Clinical Genetics Service; 3) Department of Anatomical Pathology, Royal Prince Alfred Hospital; 4) St. George Hospital Paediatric Unit; 5) Department of Radiology, Sydney Children's Hospital.

Pallister-Hall Syndrome (PHS) is a dominant condition comprising insertional polydactyly, hypothalamic hamartoma and anogenital abnormalities. Mutations of the GLI3 zinc finger protein have been found in PHS, Greigs Cephalopolysyndactyly and Polydactyly type A. We present two isolated cases of PHS; one a fetus and one a neonate. In the former, routine 18 week antenatal ultrasound showed 3-4 finger syndactyly, shortening of both lower limbs with fibular hypoplasia and asymmetrical radio-ulnar shortening. Examination post mid-trimester induction showed a female fetus with bilateral postaxial and insertional polydactyly, left 3-4 syndactyly, a bifid right middle finger and short, bowed forearms. Bilateral foot post-axial polysyndactyly, mesomelic lower limb shortening and an imperforate anus was present. An autopsy showed a rectovaginal fistula, vaginal atresia and a hypothalamic hamartoblastoma. X-rays showed mesomelic changes in the ulna, tibia and fibula with blunted metaphyses and decreased epiphyseal ossification. The second case was diagnosed after birth with bilateral lower limb acromesomelia, bilateral brachydactyly, insertional left third toe polydactyly, variable syndactyly, digital nail hypoplasia, and an anteriorly placed anus with stenosis. Investigations confirmed the presence of a hypothalamic tumour, growth hormone deficiency, bilateral renal dysplasia, a laryngeal cleft, epiglottal hypoplasia and a vascular ring. X-Ray findings included bilateral hip dysplasia, shortened tibias, proximal syndactyly of the left 3-4 metacarpals and insertional polydactyly of the left 2nd and 4th toes. These two cases have classical features of PHS as well as a generalised skeletal dysplasia with acromesomelic limb shortening not highlighted in previous reports. PHS should be included in the differential diagnosis of antenatally ascertained mesomelic limb shortening particularly in the presence of polysyndactyly.

**Female-to-male transmission of isolated Periventricular Nodular Heterotopia, cosegregating with the Xq28 region.** *M. Gerard-Blanluet*<sup>1</sup>, *K. Machinis*<sup>2</sup>, *C. Danan*<sup>1</sup>, *J. Patkai*<sup>1</sup>, *A.S. Trentesaux*<sup>1</sup>, *M. Benani*<sup>1</sup>, *M. Sinico*<sup>1</sup>, *F. Encha-Razavi*<sup>1</sup>, *C. Walsh*<sup>3</sup>, *P. Brugieres*<sup>4</sup>, *M. Goossens*<sup>2</sup>, *J.C. Janaud*<sup>1</sup>, *S. Amselem*<sup>2</sup>. 1) CHIC Creteil, France; 2) Genetique Moleculaire, Hopital Henri Mondor, Creteil, France; 3) Neurology, Harvard Medical School, Boston USA; 4) Neuroradiologie, Hopital Henri Mondor, Creteil, France.

We report the first female-to-male transmission of periventricular nodular heterotopia. Periventricular heterotopia is an OMIM listed genetic disease (OMIM number 300049), described in 1993. The disorder, which is usually transmitted as an X-linked dominant trait, is lethal in males. MRI images can mimic Bourneville syndrome, but clinical features show no mental retardation, no depigmented skin patches, and partial seizures, occurring usually in late infancy. The Filamin-1 gene is located at Xq28, spans 47 exons, and was proved to be responsible for this disorder. Two dizygotic diamniotic twin boys were born prematurely at 26 weeks because of chorioamniotic infection. The mother is 23 and the father is 41 years old. There is no family history of epilepsy, nor abnormal spontaneous abortions. The twin boys were eutrophic, without external malformations. They both have large anterior fontanels. Periventricular wall irregularities were noted in each twin, the first day of life. MRI, done at three months of age for both, revealed multiple periventricular nodular heterotopia. EEGs were normal. Developmental milestones seemed normal. Maternal MRI showed asymptomatic nodular periventricular heterotopia. Cytogenetic analysis, done with a peculiar attention at the Xq28 region, was normal, as metabolic screening. Molecular analysis demonstrated that the twins are dizygotic. Each has inherited a different X chromosome. They share the same Xq28 locus, spanning the Filamin-1 region, because one of the twin had a recombined X chromosome. Mutations in Filamin-1 gene are then actively searched for. As far as we are aware, this observation demonstrates the first female-to-male transmission of periventricular nodular heterotopia, possibly linked to the Filamin-1 gene. A mild Filamin-1 mutation may explain the viability in males.

**CUTIS LAXA, CHARACTERISTIC FACIAL DYSMORPHISM, CLEFT PALATE AND MENTAL RETARDATION: A NEW SYNDROME?** *D. Genevieve<sup>1</sup>, L. Faivre<sup>1</sup>, C. Baumann<sup>2</sup>, D. Sanlaville<sup>1</sup>, S. Jacquemont<sup>1</sup>, C. Bodemer<sup>3</sup>, S. Lyonnet<sup>1</sup>, A. Munnich<sup>1</sup>, V. Cormier-Daire<sup>1</sup>.* 1) Departement de Genetique, Hopital Necker Enfants malades, Paris, FRANCE; 2) Service de Neonatologie, Hopital Robert Debre, Paris, FRANCE; 3) Service de Dermatologie, Hopital Necker Enfants Malades, Paris, FRANCE.

We report on the association of cutis laxa, facial dysmorphism, cleft palate and moderate mental retardation in 3/7 children born to first cousin healthy parents. Two girls and a boy presented with cutis laxa, increased joint laxity and facial dysmorphism including flat and round face, very short nose, sagging cheeks, blue sclerae, hypertelorism and small chin. Additional features were hygroma in early pregnancy (2/3), hard cleft palate (2/3) and ventricular septal defect (2/3). The boy died at 25 day of life of progressive emphysema and multiple pneumothorax. In the girl, skin abnormalities and developmental delay improved in the course of the disease. Skin histology showed a lack of elastic fibers in 2/3 cases. X-rays, ophthalmologic examinations and blood chromosomes were normal. Autosomal recessive cutis laxa type II could be considered because of the association of cutis laxa, mental retardation and joint laxity but facial dysmorphism is unusual in this syndrome. Emphysema in one patient was also suggestive of autosomal recessive cutis laxa type I, but the other clinical features did not fit with this syndrome. Our patients share clinical features with the spectrum of wrinkly skin syndrome, namely cutis laxa and mental retardation but absence of growth delay and of wrinkled skin over the dorsum of hands and feet of our patients rules out this diagnosis. We propose therefore that this distinctive association represents a novel entity of autosomal recessive inheritance.

**Microcephaly with jejunal atresia, a possible new syndrome.** *D.N. Abuelo<sup>1</sup>, W.D. Brown<sup>1</sup>, A. Kurkchubasche<sup>1</sup>, W.B. Dobyns<sup>2</sup>.* 1) Rhode Island Hosp, Brown University School of Medicine, Providence; 2) Department of Human Genetics, University of Chicago School of Medicine.

Two patients with severe microcephaly associated with similar MRI findings of smooth gyral pattern also had intestinal obstruction at the level of the jejunum. Case 1: Born at 35 weeks gestation with birth weight 2300 gms and head circumference 29 cm. Prenatal ultrasound showed microcephaly, echogenic bowel and hydronephrosis. Amniocentesis revealed a normal male karyotype. Physical examination showed a sloping forehead, poorly reactive pupils, thin, downturned lips, a small phallus and nonpalpable testes. He was found to have a small ASD and a large PDA, which was ligated. There was also right-sided UPJ obstruction and a small left kidney. BAER testing showed profound neurosensory deafness. At operation, he was found to have multiple jejunal atresias with a distal "apple-peel" deformity. All intestinal segments were salvaged with anastomoses over a stent. MRI showed severe microcephaly, relative frontal lobe hypoplasia, reduced number of gyri causing a simplified gyral pattern, and normal cortical thickness. He developed spasticity by 6 months and seizures by 14 months. Case 2: Born at 36 weeks gestation with birth weight 2055 gms and head circumference 24 cm. Prenatal ultrasound showed microcephaly and bowel that was echogenic and distended. The forehead was sloping, but there were no other dysmorphic features. Audiologic testing was abnormal. At laparotomy he was found to have two sequential type I jejunal atresias amenable to tapering jejunoplasty and repair. Cranial imaging studies were similar to case 1. Muscle tone at birth was normal, but spasticity gradually developed. The combination of marked microcephaly together with simplified cerebral gyral patterns (MSG) has been reported (Barkovich et al, 1998). Our two patients fit into this classification and in addition required surgery for jejunal obstructions. One of the reported patients with MSG also had jejunal atresia. We therefore suggest that this combination of anomalies constitutes a unique syndrome.

**Hypoplastic corpus callosum and pachygyria in a patient with distal 2q duplication syndrome.** *J. Ibrahim<sup>1</sup>, B. Levy<sup>1,2</sup>, T. Dunn<sup>1</sup>, J. Willner<sup>1,2</sup>, N. Kardon<sup>1,2</sup>.* 1) Department Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY.

We describe an infant with a distinct set of clinical findings. A 3020g male infant was born at 39 weeks gestation to a 29 year old woman. At birth the infant was vigorous but became floppy and cyanotic at ten minutes of life. He was noted to have multiple dysmorphic features including small anterior fontanelle, short forehead, hypertelorism, down-slanting eyes, "cobblestone" appearance to the brow when furrowed, broad and prominent nasal bridge, anteverted nares, and increased folding of the superior helices. The chest was broad with low, wide-spaced nipples. The fingers were tapered and fifth digit clinodactyly was present bilaterally. The thumbs were proximally placed. The scrotum was hypoplastic and the testes were undescended. MRI of the brain revealed a hypoplastic corpus callosum and pachygyria.

G-banding revealed additional material at the chromosome 2 terminus. The origin of the additional material was determined to be chromosome 2 using FISH with a Whole Chromosome Paint. The revised karyotype was 46,XY inv dup(2)(qterq37.1).ish2(wcp2+). Further delineation of the breakpoints using CGH is anticipated.

Our patient exhibits typical features of the duplication 2q syndrome but this is the first detailed description of abnormal brain morphology. Several cases of duplication 2q exist in the literature but none are limited to the region q37.1@qter. This case further refines a critical region for the duplication 2q syndrome through the use of molecular cytogenetic techniques.

**De novo chromosomal insertion in a child with autism.** *L. Mehta*<sup>1</sup>, *A. Yenamandra*<sup>2</sup>, *R. Perrone*<sup>2</sup>, *P. Koduru*<sup>2</sup>. 1) Div Medical Genetics; 2) Dept. of Laboratories, North Shore University Hospital-N.Y.U School of Medicine, Manhasset, New York.

A 2.5 year old male was evaluated because of autistic features. He was delivered at full term following an uncomplicated pregnancy, to non-consanguineous parents with no family history of relevant problems. Parents were not exposed to radiation or chemicals. Motor development was mildly delayed. There were major communication and language delays with poor social interactions. Hyperactivity, poor eye contact, rocking, humming and repetitive hand movements were present. Criteria for a DSM-IV diagnosis of autism were met. There were no significant dysmorphisms or birth defects. Head circumference was 25-50%. Growth was normal. Cafe-au-lait pigmentation was present in the right axilla. Head CT scan, EEG, ophthalmology exam, plasma amino acids, urine organic acids and fragile X DNA analysis were normal. Peripheral blood chromosome analysis revealed additional material on chromosome 14q and an abnormal chromosome 18q. Fluorescence in situ hybridization with chromosome 14 and 18 painting probes (Vysis, Inc.) revealed an apparently balanced insertion of a chromosome 18 segment into chromosome 14. Therefore the karyotype was 46,XY,add(14)(q24),abn(18q).ish ins(14;18)(q24;q12.2q21.1). Parental chromosomes were normal. Reports of autosomal chromosome abnormalities in autism are infrequent but of potential interest in identifying candidate genes. Regions of interest have included chromosome 15q11-13, 7q21, 10q21.2, 16q23 and 17p11.2. Random unbalanced chromosome rearrangements presenting with autism, birth defects, dysmorphisms and mental retardation are also reported. Our patient presented with typical autistic features without physical abnormalities. No other etiology for his symptoms was found on testing. The apparently balanced karyotype therefore implicates sequences at 14q24, 18q12.2, 18q21.1 as candidate gene regions for autism. Detecting the chromosome abnormality has enabled accurate genetic counseling for this couple. Recurrence risks are lower than the 3-5% quoted for autism of multifactorial etiology. Normal prenatal karyotyping would be reassuring in future pregnancies.

**Microcephaly with pachygyria: a new pedigree with autosomal recessive inheritance.** *G.H. Mochida<sup>1</sup>, L. Flores-Sarnat<sup>2</sup>, A. Del Angel<sup>3</sup>, J.G. Gleeson<sup>4</sup>, C.A. Walsh<sup>1</sup>.* 1) Neurology, Beth Israel Deaconess Medical Center, Boston, MA; 2) Neurology, Children's Hospital, University of Washington, Seattle, WA; 3) Genetics, Universidad Nacional Autónoma de Mexico, Mexico City; 4) Neurosciences, University of California, San Diego, CA.

Microcephaly with pachygyria is a heterogeneous group of brain malformations. We report 3 siblings with pachygyria and one healthy sibling, born to consanguineous Mexican parents. Patient 1 is a 12-year-old girl with severe developmental delay. She cannot walk or talk, has spastic quadriparesis and generalized tonic-clonic epilepsy controlled by valproic acid. Brain MRI showed a diffusely simplified convoluted pattern with broadening of gyri (pachygyria), paucity of posterior cerebral white matter and enlarged lateral ventricles. Patient 2 is a 7-year-old boy with microcephaly noted since birth. He started walking after age 3 years, and currently speaks several words. Patient 3 is a 2-year-old girl born at 32 weeks gestation. She can stand unsupported, but independent walking and speech have not yet developed. Brain MRIs of patients 2 and 3 were nearly identical in showing diffuse pachygyria and no ventricular enlargement. Patients 2 and 3 have not had seizures. All 3 patients had a normal karyotype. Though generally seen as sporadic cases, there are several reports of pachygyria with autosomal recessive (AR) inheritance. This family appears to be distinct from previously reported cases in clinical features, however. Sztriha et al. (1999) reported AR cases of "microcephaly with simplified gyral pattern", arthrogryposis and a poor neurological outcome. Peiffer et al. (1999) described 6 affected children, each with seizures beginning during the first several months of life. The clinical heterogeneity between families supports the hypothesis of multiple AR loci for pachygyria. The identification of genes responsible for this condition will facilitate a better understanding of genetic mechanisms of brain development, and will most likely lead to a revised classification of this entity in accordance with genetic etiologies. GHM is a Howard Hughes Medical Institute Physician Postdoctoral Fellow. Supported by the NINDS.

**Secondary Leber Hereditary Optic Neuropathy (LHON) mitochondrial DNA mutations 4216 and 4917 associated with migraine-like episodes.** *E.C. Lichtenberg<sup>1</sup>, L.E. Walsh<sup>1,2</sup>, J. Biller<sup>2</sup>*. 1) Dept Medical & Molec Genetics, Indiana Univ, Indianapolis, IN; 2) Dept Neurology, Indiana Univ, Indianapolis, IN.

We report the case of a 16-year-old girl with a 5-year history of headaches. Her headaches were accompanied by photopsias and vomiting. She complained also of fatigue, blurred vision, and paresthesias. Past medical and developmental histories were normal otherwise. Family history was notable for her mother's depression, anxiety disorder, and severe headaches; her father's apparent job-related hearing loss; her grandparents' strokes and hearing loss in senescence, and a maternal second cousin with complicated migraine and seizures. Physical examination was normal except for very mild left arm weakness. MRI scans of the brain showed mild cerebral atrophy, and scattered periventricular and subcortical hyperintensities localized mostly to parietal and occipital regions, but also involving the thalami, consistent with ischemic changes. Cerebral angiography was normal. Neuro-ophthalmologic evaluation revealed questionable visual field deficits, but no findings consistent with LHON. Ancillary testing (including CSF examination) for inherited and acquired causes of stroke was negative except for mitochondrial DNA testing. Tests for common MELAS mutations in peripheral blood and muscle were negative. However, analysis of muscle tissue for primary and secondary LHON mutations identified 2 mutations within the mt DNA ND1 and ND2 domains (4216, 4917). Muscle biopsy was normal otherwise and plasma lactate was 1.4 mmol/ml. The patient's clinical presentation suggested MELAS; however, her MRI lesions were atypical for this disorder. Familial hemiplegic migraine and CADASIL were also considered. The 4216 and 4917 mutations have been reported in controls and in optic neuropathy associated with primary LHON mtDNA mutations. The 4216 mutation also has been reported previously to be more frequent in young patients with stroke than in controls. These putative secondary mutations may represent coincidental findings in our patient, may modify her condition, or may be markers for disorders of mtDNA maintenance, suggesting either a nuclear defect or unknown primary mtDNA mutation.

**Fits and pulmonary haemorrhage: Cortical malformation disorder and Ehlers-Danlos syndrome. S.**

*Worthington<sup>1</sup>, T. Underwood<sup>2</sup>, J. Wiley<sup>3</sup>.* 1) Clinical Genetics, Liverpool Hospital, Sydney, Australia; 2) Respiratory Medicine, Nepean Hospital, Sydney, Australia; 3) Haematology Department, Nepean Hospital, Australia.

Ehlers-Danlos syndrome (EDS) is a heterogeneous group of heritable connective tissue disorders, characterized by joint hypermobility, skin extensibility and tissue fragility. Cortical malformation disorders are due to a disturbance in neuronal migration during fetal development. They include lissencephaly (agyria/pachygyria spectrum), polymicrogyria and bilateral periventricular nodular heterotopia (BPNH).

Periventricular heterotopias and polymicrogyria have been described in association with features of EDS in 5 cases. We report the clinical, pathology and radiological findings of a woman who presented with haemoptysis who has both familial BPNH and features of EDS. This case provides further support for the association of a cortical malformation disorder with EDS. We will also consider the pathogenesis of pulmonary haemorrhage in the context of these 2 disorders.

**Expanded phenotype of partial trisomy 11q.** *H. Zhao, A. Rope, R.I. Blough, H.M. Saal, R.J. Hopkin.* Division of Human Genetics, Children Hospital Medical Center, Cincinnati, OH.

Three new patients with partial trisomy 11q are presented. Case 1 presented with seizures, metabolic acidosis, and hypoxia. He was found to have an unbalanced paternally derived trisomy 11 with partial monosomy 5q [46,XY,der(5)t(5;11)(q35.3;q23.3)pat]. He also had a complex congenital heart defect (tetralogy of Fallot with pulmonary atresia). Case 2 had lissencephaly, a malformed epiglottis, congenital heart defect (AV canal), hypoplastic kidneys with renal insufficiency, and cleft palate. Her karyotype was 46,XX,der(9)t(9;11)(p23;q21)mat. Case 3 presented with dysmorphic features, developmental delays, mental retardation, heart defect (atrial septal defect), seizures, and malformed epiglottis. Her karyotype was 46,XX,add(11)(q23).ish11(WCP11+). There were several features common to trisomy 11q identified in the three patients, including developmental disabilities, hypotonia, microcephaly, growth retardation, congenital heart defects, cleft palate, short nose, micrognathia, external ear anomalies, and renal anomalies. Of interest is the new finding of epiglottis malformation in cases 2 and 3. This leads to the speculation that there may be at least one gene located on 11q that plays a role in the development of the epiglottis.

**Familial aggregation of trichotillomania in four living generations.** *H.H. Wright<sup>1</sup>, C.M. Wolpert<sup>2</sup>, S.A. Ravan<sup>1</sup>, R.K. Abramson<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, M.A. Pericak-Vance<sup>2</sup>.* 1) University of South Carolina, Columbia, SC; 2) Duke University Medical Center, Durham, NC.

Trichotillomania (TTM) is defined as an impulse-control disorder characterized by recurrent pulling on one's own hair (DSMIV; American Psychiatric Association, 1994). This classification is controversial as some researchers suggest that the disorder may be a subtype of obsessive compulsive disorder (OCD) or a feature of Tourette syndrome. The genetic basis of TTM is not well defined. Case reports of familial aggregation exist and there are several spontaneous-occurring animal models of compulsive self-grooming that are considered useful parallels for the study of TTM in humans (feather picking in birds, psychogenic alopecia in cats). We have ascertained a family with 7 individuals with TTM in 4 living generations suggesting apparent autosomal dominant transmission. Diagnosis and characterization of the phenotype in this family was performed using the TTM Diagnostic Interview, the National Institute of Mental Health (NIMH) TTM scales, and the Yale-Brown Obsessive-Compulsive Scale Symptoms Checklist (self-report version). All affected family members met the diagnostic criteria for TTM, but not for OCD or Tourette syndrome. These data warrant the further investigation of the underlying genetic basis of TTM as an independent disorder separate from OCD and Tourette syndrome.

**Using the Aberrant Behavior Checklist (ABC) to Refine the Autistic Disorder (AD) Phenotype.** *S.A. Ravan<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, D.D. Wallace<sup>1</sup>, R.K. Abramson<sup>1</sup>, C.M. Wolpert<sup>2</sup>, S.L. Donnelly<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, H.H. Wright<sup>1</sup>.* 1) Neuropsychiatry & Behavior, Univ South Carolina Sch of Med, Columbia, SC; 2) Center for Human Human Genetics, Duke University Medical Center, Durham, NC.

The ABC is a standardized measure of maladaptive behavior in individuals with developmental disorders (Aman & Singh, 1986). This 58-item rating scale yields composite scores in five areas that reflect mood and behavioral states. Recent studies using the ABC have reported specific profiles for developmental disorders such as Angelman syndrome (Clarke & Marston, 2000). Autistic Disorder (AD) is a neurodevelopmental disorder with core impairments in social, communicative, and behavioral functioning. Accurate phenotype description is crucial to genetic studies (Ashley-Koch et al. 1999; Cook et al. 1999; Pericak-Vance et al. 1999). Due to heterogeneity, AD phenotype refinement is ongoing.

As part of a genetic study of AD, caregivers of AD individuals (n=131) completed the ABC to define AD behaviors (Mean ABC factor scores Irritability=12.8, Lethargy=11.6, Stereotypy=6.4, Hyperactivity=17.7, and Inappropriate Speech=3.6). Principal component and factor analyses were run to examine factor structure of the ABC in an AD sample. A four-factor solution (promax rotation) yielded interpretable results. The basic factor structure was similar to that of the original ABC as well as Brown et al (1998). In our analysis the Irritability and Hyperactivity factors formed a single factor, Disruptive Behavior. The other factors (Lethargy, Stereotypy, and Inappropriate Speech) were confirmed. Mean scores for ABC factors were contrasted as a function of language level based on the Autism Diagnostic Interview-Revised (Lord et al 1994). Significant between group differences were found on the Inappropriate Speech factor.

This study is the first to examine the usefulness of the ABC for AD. The ABC may help examine other behavioral features of the AD phenotype in a quantitative fashion. This may prove a useful strategy to stratify individuals with AD in genetic studies.

**Does imprinting influence brain development in X monosomy?** *S.M. Zeng<sup>1</sup>, M. Haberecht<sup>2</sup>, S. Eliez<sup>2</sup>, W.E. Brown<sup>2</sup>, I. Warsofsky<sup>2</sup>, J. Yankowitz<sup>1</sup>, A.L. Reiss<sup>2</sup>.* 1) Univ Iowa College of Med; 2) Stanford Univ School of Med.

Several studies have evaluated whether the phenotype of Turner syndrome (TS) is influenced by imprinting. We used the parental origin of the X chromosome as a surrogate for potential imprinting effects. We evaluated whether parental origin of the retained X affects brain development and structure. Blood was collected from 23 TS (45, X) pts, their parents, and sibs as available. DNA was extracted in standard fashion and genotype analysis used PCR amplification at 9 polymorphic sites on the X chromosome (HAR, HPRT, DXS6799, DXS6089, DXS8378, DXS9895, DXS9898, DXS101 and DXS1120). 3D-SPGR magnetic resonance images (TR=35, TE=6, FA=45, NEX=1, 256x192, FOV=24, 124 1.5 mm slices) were analyzed using BrainImage generating gray, white, and total lobar tissue volumes. Statistical analyses were performed on brain measurements using the Mann-Whitney U test.

Eight of 23 (34.7%) samples had a paternally derived X (Xp) and 15/23 (65.3%) a maternally derived X (Xm). Compared to controls, Xm subjects showed decreased gray matter volume (11%) in the right occipital lobe and white matter loss (12%) in the left and right occipital lobe. Also, increased gray matter volumes (11%) were observed in Xm subjects in the cerebellum bilaterally. Girls with Xp demonstrated decreased gray matter (7%) in the right temporal lobe relative to controls.

Our preliminary data suggest that girls with Xm show decreased lobar tissue volumes in key posterior brain regions compared to controls. This is consistent with previous studies suggesting parietal/occipital abnormalities as well as variable involvement of the cerebellum in TS. We also observed varying patterns of structural brain alterations on the basis of TS parental inheritance subgroup. These findings are interesting in light of reports showing that the Xp group have superior verbal and higher-order executive function skills. Future studies will investigate the differential contributions of X monosomy and parental origin to parieto-occipital structure, spatial cognition and executive function in TS.

**X-linked cerebellar atrophy and mental retardation: a new syndrome.** *P.L. Plotner<sup>1</sup>, S.T. Iannaccone<sup>2</sup>, J.K. Mills<sup>2</sup>, S.H. Blanton<sup>3</sup>, H. Northrup<sup>1</sup>.* 1) The University of Texas Houston Medical School, Houston, TX; 2) Texas Scottish Rite Hospital, Dallas, TX; 3) University of Virginia Health Science Center, Charlottesville, VA.

We report a family with a distinct phenotype of cerebellar atrophy and mental retardation that appears to be inherited in an X-linked recessive fashion. The family contains 13 individuals with 4 affected males in 2 generations: 3 second generation sons and 1 third generation grandson. The second generation is the product of non-consanguineous parents of Hispanic origin. The third generation is the product of a second generation daughter and her non-consanguineous spouse. A simulation study found the maximum obtainable LOD score to be 2.7.

All affected males have had early onset of mental delay leading to an eventual diagnosis of mental retardation (borderline to mild) and significant verbal delay. Cerebellar signs develop by mid-childhood, usually by age 11 years. These signs include: ataxia, tremor, decreased DTRs, and poor saccadic eye movement. No dysmorphic features are present.

Affected adult males display cerebellar atrophy by MRI. In contrast, MRI of one affected male child (age 5) did not reveal cerebellar atrophy. He has speech and intellectual delay but has not yet developed overt cerebellar signs. An affected adult male has slow nerve conduction velocity, a nerve biopsy suggestive of metabolic impairment, and a muscle biopsy demonstrating acute and chronic denervation. The family has been tested for SCA 6 and 7 with negative results. Routine neuropathy testing has been within normal limits. Linkage analysis was performed using 18 dinucleotide markers spaced approximately at 10cM intervals on the X chromosome: 15 markers do not show linkage, the other 3 markers are not informative.

We conclude that this family represents a newly described non-specific X-linked mental retardation syndrome associated with cerebellar atrophy. Additional testing of markers at 5cM intervals will be performed to define a candidate gene region.

**A new variant for Autosomal Recessive Spinal Muscular Atrophy in Childhood.** *L. Viollet<sup>1</sup>, D. Leclair-Richard<sup>2</sup>, P. Burllet<sup>1</sup>, C. Belser<sup>1</sup>, E. Vial<sup>1</sup>, S. Bertrand<sup>1</sup>, S. Lefebvre<sup>1</sup>, A. Munnich<sup>1</sup>.* 1) INSERM U-393, Hopital Necker, Paris, France; 2) Service de Pediatrie et Reeducation Neuro-respiratoire, Hopital Raymond Poincare, 92380 Garches, France.

Spinal muscular atrophy (SMA) is a group of neuromuscular disorders in childhood characterized by progressive anterior horn cell degeneration, leading to early or juvenile onset paralysis, amyotrophy and denervation. The genetic heterogeneity of autosomal recessive SMA in childhood has been demonstrated. Indeed, two disease loci have been hitherto identified on chromosomes 5q13 (proximal SMA) and 11q13-q21 (Distal SMA with Diaphragmatic Palsy), respectively. The most common form is the proximal SMA that results from mutations of the Survival Motor Neuron (SMN) gene. We described here a new variant of autosomal recessive SMA in a consanguineous family of four affected children. The three affected daughters presented with motor weakness at the age of 3 years. Proximal and distal muscle weakness progressively worsened, leading to the lost of walking ability at the age of 7,5 years. Walking disability was due to bilateral foot malposition and pelvic girdle weakness. Severe involvement of scapular muscles was also present, with hand weakness and fasciculations. Early hyperlordosis and scoliosis were noted. No sensory defect was detected and deep tendon reflexes were abolished. Electromyography revealed partial and progressive denervation, with normal motor and sensory nerve conduction velocity. The affected son showed a milder phenotype with similar proximal and distal distribution, that began at the age of 10 years. Linkage analyses in this family showed that two affected sibs were carrying discordant haplotypes at both the 5q13 and the 11q13 loci. These data support the view that this variant form of autosomal recessive SMA maps to a third locus. A genome wide search is under current investigations and should allow the mapping of a novel locus for autosomal recessive SMA.

**Co-occurrence of Autistic Disorder and Chiari type 1 malformation in Five Patients: Further Evidence for Potential Cerebellar Involvement in AD.** *C.M. Wolpert<sup>1</sup>, D.S. Enterline<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, S.L. Donnelly<sup>1</sup>, S.A. Ravan<sup>2</sup>, R.K. Abramson<sup>2</sup>, H.H. Wright<sup>2</sup>, M.C. Speer<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Dept Medicine, Duke Univ Medical Ctr, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Autistic Disorder (AD) is a neurodevelopmental disorder with a well established genetic component; the general population prevalence is 2-10 per 10,000. Chiari type 1 malformation (CM1) is a rare condition defined as  $\geq 5$  mm bilateral herniation of the cerebellar tonsils through the foramen magnum. The general population prevalence of CM1 is estimated to be 1/5000. Through two separate studies, one investigating the genetic basis of AD and one investigating the genetic basis of CM1, we have identified 5 patients in which AD and CM1 co-occur. For these cases, AD was confirmed using the Autism Diagnostic Interview-Revised and CM1 was diagnosed if there were  $\geq 5$  mm of bilateral descent of the cerebellar tonsils. Of 289 AD individuals, only 84 had neuroimaging studies of the brain. Of these 84 patients, three probands (families 7501, 7707, 7939) were found to have CM1. Interestingly, two of these three families also have a history for AD: the proband in family 7501 has a brother with AD; the proband in family 7707 has a half brother with AD. There is no family history of AD in family 7939. No other family members have had MRI studies. From the CM1 study, monozygotic twin males (family 9430) were concordant for CM1 and AD. The parents of these boys underwent MRI studies; the father was also found to have CM1. The mother's MRI was normal. Since AD and CM1 are rare disorders, this co-occurrence, although in a small series, suggests a common underlying mechanism for both disorders in a subset of cases. This finding is especially intriguing in light of research that indicates potential cerebellar involvement in AD. In addition, the presence of CM1 and AD in families suggests the possibility of an objective phenotype for stratifying AD and CM1 families, leading to the identification of genes important in the development of both conditions.

**Late-onset central hypoventilation with hypothalamic dysfunction: a possible neural crest disorder. S.**

*WILKERSON<sup>1</sup>, N. TALIB<sup>1</sup>, J. JACOBSON<sup>1</sup>, M.J. DASOUKI<sup>1</sup>, C. ENG<sup>2</sup>.* 1) PEDIATRICS, CHILDREN'S MERCY HOSPITAL, KANSAS CITY, MO; 2) DEPARTMENT OF MEDICINE. OHIO STATE UNIVERSITY.

Congenital central hypoventilation syndrome (CCHS) is characterized by inadequate ventilation during sleep in the absence of primary neuromuscular, pulmonary or cardiac disease. Usually, it occurs as an isolated phenotype and in 16% of patients in association with Hirschsprung disease (HSCR). Current records indicate that there are 160-180 living children with CCHS and approximately 100 published case reports. Idiopathic central hypoventilation has occasionally been reported in previously healthy children after infancy [11 cases]. The late onset-CHS also features evidence of hypothalamic dysfunction, including hyperphagia, hypersomnolence, thermal dysregulation, emotional lability, and endocrinopathies. Both disorders occur in patients with a histologically normal central nervous system. While CCHS is known to be associated with mutations in at least 3 genes [RET, GDNF (glial cell line derived neurotrophic factor), and EDN3 (endothelin 3)], such associations with the late onset type are not known. Here, we report on a 6-year old hispanic boy with "Late Onset-CHS with endocrinopathies" who was normal until 2 years of age. His symptoms consisted of obesity, recurrent episodes of somnolence/lethargy, temperature instability, psychomotor delay, thoracic paraspinal ganglioneuroma and hypothalamic endocrinopathies. His VER and ERG responses were abnormal. An antibody screen was negative. Medroxyprogesterone did not significantly improve his response to mechanical ventilatory support. Direct mutation analysis of the RET, GDNF and EDN3 genes is in progress. Given the similarities between the congenital and late-onset forms of central hypoventilation syndromes, we propose that the 2 disorders may be etiologically related. Adequate mechanical ventilation in such patients is necessary to prevent sleep apnea, cardiac failure and hypoxic seizures.

**Huntington's disease with childhood onset of mental retardation and possible late onset disease in the father.** *J.G. Pappas, D. Punales-Morejon, V.B. Penchaszadeh.* Div Medical Genetics, Beth Israel Medical Ctr, New York, NY.

Huntington's disease (HD) is an autosomal dominant disorder with usual onset between the 35th and 40th year of life. The clinical manifestations include personality changes of a varied but non-specific kind, followed by choreiform movements and dementia. The inheritance of HD shows anticipation and complete penetrance. The molecular basis of this disease is expansion of the trinucleotide repeats in the Huntington's disease gene. Childhood onset of HD with behavior disorder, mental retardation, seizures and movement disorders has been documented. All reported childhood cases have documented typical HD in their fathers. 90% of the individuals with onset before 30 years of age have 55 or more repeats (normal range 10-35) (Illarioshkin et al., *Ann Neurol* 1994;36:630-635; Lucotte et al., *Hum Genet* 1995;95:231-232). Our case is a 44 year old black male from the Dominican Republic who presented with mental retardation, tremors of the extremities and inability to sit still for long. The onset of the progressive mental retardation was at 7 years of age and was diagnosed at his school. He followed special education for developmentally delayed children. He had no malformations or dysmorphic features and no family history of mental retardation. His mother age 65 years old reported that the tremors of our patient started at age 40 and they are worsening. DNA analysis of the HD gene revealed 49 CAG repeats. His father died by suicide at age 63 and reportedly had occasional extremity tremors and personality changes during the last year of his life; which suggests late onset HD. Our case suggests that HD can be a cause of childhood onset of mental retardation even in the low range of trinucleotide repeats associated with the disease. The prevalence of the disease is much higher in whites than blacks. The phenotype in black individuals of Dominican descent like our case may be associated with early onset of mental retardation.

**Beckwith-Wiedemann syndrome (BWS)-related features and segmental monosomy 18q.** V. Gaston<sup>1</sup>, C. Houdayer<sup>1</sup>, V. Soupre<sup>1</sup>, J. Couturier<sup>2</sup>, R. Couderc<sup>1</sup>, C. Gicquel<sup>1</sup>, A. Munnich<sup>3</sup>, M-P. Vazquez<sup>1</sup>, Y. Le Bouc<sup>1</sup>, M. Bahuaui<sup>1</sup>. 1) Explorations Fonctionnelles (V.G., C.G., Y.LB.), Biochimie (C.H., R.C., M.B.), Chirurgie Maxillofaciale (V.S., M-P.V., M.B.), Hôpital Trousseau, Paris, France; 2) Cytogénétique, Institut Curie, Paris, France; 3) Génétique Médicale, Hôpital Necker Enfants-Malades, Paris, France.

Beckwith-Wiedemann syndrome (BWS, MIM 130650) is a tumor-predisposing condition with cardinal features of exomphalos, macroglossia, and gigantism in the neonate. BWS and BWS-related tumor growth have been linked to genetic imbalance in the 11p15.5 region resulting in overexpression of *IGF2*, with downregulation of *H19*. Further adding to the genetic complexity of this disorder, point mutations of neighboring *p57(KIP2)/CDKN1C* tumor-suppressor may also cause WBS. It is now admitted that several genetic loci, 11p15.5-linked or not, may determine BWS or BWS-related features. In particular, deletion 18q22.1 was shown in an infant with findings of macroglossia, umbilical hernia, and neonatal hypoglycemia. Authors stated that this region of chromosome 18 might contain a transactivator for maintenance of *IGF2* imprinting since RT-PCR analysis showed biallelic expression of *IGF2*, uniparental disomy (UPD) ruled out. We report on a patient, term-born by C-section in a state of apparent death, who had findings of cleft palate, auditory canal stenosis, bilateral inguinal hernia, clubfoot, and pulmonic valve stenosis. Hypotonia was major and contact was poor. There was de novo translocation 46, XY, der(18)t(18;?)(q21;?), leading to segmental monosomy 18q and to trisomy for another chromosome. A small ring chromosome was seen in 2/12 mitoses. His tongue became progressively enlarged, causing major prognathism and hindering feeding. Adenoidomegaly caused airway to obstruct. Molecular analysis for *IGF2* showed absence of UPD in both lymphocyte and tongue (glossectomy-derived) DNAs, and normal, paternal-only, expression from tongue RNA. This observation confirms the existence of a genetic locus for WBS-related features on 18q. However, unlike previous findings, transactivation of *IGF2* through loss of imprinting does not seem to be the underlying mechanism.

**Atypical Radiation-Sensitive Chromosome Breakage: New Syndromic Presentations.** *S.E. Palmer<sup>1</sup>, R.A. Gatti<sup>2</sup>, B. Hirsch<sup>3</sup>, P.J. Concannon<sup>4</sup>, J.E. Anderson<sup>1</sup>*. 1) Univ. Texas Health Sci. Cntr, San Antonio; 2) Univ. of California at Los Angeles; 3) Univ. of Minnesota, Minneapolis; 4) Virginia Mason Research Cntr, Seattle.

Clinical presentations of radiation-sensitive chromosome breakage disorders include Ataxia Telangiectasia and Nijmegen Breakage Syndrome (NBS). NBS displays microcephaly, short stature, and distinct facies that resemble Seckel Syndrome, due to a gene on 8q21. We present 2 families who display radiosensitivity by Colony Survival Assay, but do not fit key features of NBS. **FAMILY 1:** A 6 y.o. girl has cleft palate, ASD, no speech, pseudoobstruction, and distinct dysmorphic facies (broad face, small nose, ptosis, brachycephaly, unusual brow) that do not resemble Seckel Syndrome. Stature and head size are normal. She developed myelodysplasia. Routine chromosomes (blood, skin) were normal at multiple labs, but breakage studies showed increased spontaneous breakage, normal SCE and Mitomycin C studies, but borderline DEB results. She lacks the common Slavic NBS1 mutation; addition studies are pending. **FAMILY 2:** A 45 y.o. male presented with myelodysplasia. He has microcephaly, aged skin, short stature, developmental disability, cryptorchidism, and Seckle-like facies. He tolerated bone marrow transplantation without radiation. His 49 y.o. sister has identical exam, abnormal menses, and mild anemia. Their age is atypical for NBS, as the registry lists none older than 20s likely due to malignancy and immunodeficiency. Routine chromosomes (blood, marrow) were normal at multiple labs, but breakage studies showed mild increase in spontaneous breakage, normal SCE and MMC, and borderline DEB results. NBS1 gene analysis failed to reveal a mutation; Western blotting for nibrin showed normal levels. These findings suggest 1) routine chromosome analysis may be inadequate to detect increased spontaneous breakage; 2) myelodysplasia with any syndromic feature should prompt radiosensitivity studies; 3) adult females with radiosensitive breakage raise debates about mammography in homozygotes at high risk for malignancy; 4) these 2 families may represent new syndromes and loci encoding radiation-sensitive chromosome breakage.

**Retinal Capillary Hemangioma and von Hippel-Lindau Disease: Phenotypic Variability and Progression.** *A.D. Singh<sup>1</sup>, M. Nouri<sup>2</sup>, N. Perez<sup>1</sup>, C.L. Shields<sup>1</sup>, J.A. Shields<sup>1</sup>.* 1) Oncology Service, Wills Eye Hospital, Philadelphia, PA; 2) Department of Ophthalmology, Hahnemann University, Philadelphia, PA.

**Introduction:** von Hippel-Lindau (vHL) disease is a multisystem disorder with a predilection for the central nervous system (CNS) and retina. It is of particular relevance to the ophthalmologist because retinal capillary hemangioma (RCH) is the most frequent and often the earliest manifestation of vHL disease. The inheritance of vHL disease is autosomal dominant with high penetrance. The penetrance of vHL disease is age dependent achieving full penetrance by 65 years of age. The cumulative probability of developing RCH increases progressively with age reaching the maximum of 70% by the age of 30 years. **Purpose:** To study the phenotypic variability and progression of RCH in patients with or without vHL disease. **Methods:** Retrospective case series of 68 patients with RCH (median follow up: 77 months). **Results:** 31 (46%) patients had vHL disease (family history: 19, multiple RCH: 9, systemic features 3). The average age at diagnosis was 24 years. 51 (75%) of patients had unilateral involvement and the 25% were bilaterally affected. Of 170 tumors, location was juxtapapillary in 18%, superotemporal periphery in 44%, and other quadrants in 38%. Only 3 of 50 eyes with solitary RCH developed additional tumors and all three cases had vHL disease. **Conclusions:** RCH can vary in number, location, and size. However, isolated RCH and RCH associated with vHL disease are clinically indistinguishable. Additional tumors do not develop in the majority (94%) of cases presenting with solitary RCH. Whereas solitary RCH can occur sporadically or in association with vHL disease, multiple RCH is highly suggestive of vHL disease.

**Familial recurrence of congenital heart defect in patients with d-transposition of the great arteries.** *M.c. Digilio<sup>1</sup>, B. Marino<sup>1</sup>, A. Toscano<sup>1</sup>, S. Anaclerio<sup>1</sup>, A. Giannotti<sup>1</sup>, V. Colloridi<sup>2</sup>, R. Calabrò<sup>3</sup>, M.G. Russo<sup>3</sup>, M. Marasini<sup>4</sup>, E. Banaudi<sup>5</sup>, B. Dallapiccola<sup>2</sup>.* 1) Medical Genetics and Cardiology, Bambino Gesù Hospital, Rome, Italy; 2) Cardiology and Genetics La Sapienza University, Rome Italy; 3) Cardiology Monaldi Hospital, Napoli Italy; 4) Cardiology G. Gaslini, Genova Italy; 5) Cardiology Regina Margherita Hospital, Torino Italy.

Transposition of the great arteries (TGA) is considered to be rarely associated with genetic syndromes and to have a low risk of recurrence among relatives of affected patients. We investigated the overall occurrence of congenital heart defect (CHD) and the recurrence risk in relatives of 370 patients with d-TGA evaluated from January 1997 to April 2000 in five Italian pediatric institutions. All probands had atrial situs solitus, d-ventricular loop with patent atrioventricular valves and TGA. Family pedigrees were constructed to include first- and second-degree relatives and first cousins. Results: One or more relatives affected by CHD were found in 40/370 (10.8%) families. D-TGA was present in 7 relatives, l-TGA (congenitally corrected) in 5, discordant CHD in 31. The occurrence of CHD in sibs was 8/433 (1.8%), in parents 4/740 (0.5%), in first cousins 15/3284 (0.5%), in uncles/aunts 3/2120 (0.1%), in grandparents 1/1474 (0.06%). In 11 cases CHD was diagnosed in more distant relatives. Conclusions: 1) Our results show that d-TGA is not always a sporadic occurrence in the families; 2) In our series the recurrence risk rate for sibs is 1.8%; 3) In some families with high recurrence of d-TGA and/or l-TGA a Mendelian mechanism of inheritance can be hypothesized; 4) It is noticeable that d-TGA and l-TGA (congenitally corrected) can segregate in the same family due to at present surprising and unknown genetic mechanisms.

**Progressive heart block linked to SCN5A, and long QT syndrome with bradycardia linked to HERG: ion channel disorders with bradycardia in two Scottish families.** *J.C. Dean<sup>1</sup>, J. Watson<sup>1</sup>, K. Jennings<sup>2</sup>, M. Cowie<sup>2</sup>, N. Haites<sup>1</sup>.* 1) Dept Medical Genetics, Medical School, Aberdeen, Scotland, UK; 2) Dept Cardiology, Aberdeen Royal Infirmary, Aberdeen, Scotland, UK.

Long QT syndrome may be associated with mutation in any of six genes encoding components of either potassium or sodium ion channels. Recently, mutations in one of these genes, SCN5A, have also been found in Brugada syndrome (paroxysmal VT without long QT) and in two families with hereditary cardiac conduction defects (Lenegre-Lev disease). In one of these families, the conduction defect was progressive and associated with right bundle branch block, while in the other the atrio-ventricular block was non-progressive. We report a third family with inherited heart block, in which the ECG demonstrates normal QRS complexes, but progressive prolongation of the PR interval from the early twenties, resulting in complete heart block by the forties. While some relatives in earlier generations died suddenly, younger affected individuals have been treated by pacemaker insertion. Molecular studies using markers D3S1298 and D3S1100, flanking the SCN5A gene, are consistent with linkage to this locus, with a maximum LOD score of 1.04 at zero recombination. Neither of the two previously reported mutations have been detected in this family: a search for a new mutation is under way. In another family, who have long QT syndrome, bradycardia following beta-blockade was associated with episodes of ventricular tachycardia. The arrhythmias were abolished by permanent pacemaker insertion. Molecular studies in this family using D7S505, D7S636 and D7S483 suggest linkage to HERG (maximum LOD score 1.81 at zero recombination). This is in keeping with other studies suggesting that HERG associated long QT families require pacing more frequently than other genetic forms of long QT syndrome. These families with symptomatic bradycardia of differing origins contribute to increasing knowledge of genotype-phenotype correlations in the cardiac ion channelopathies.

**Initial clinical manifestations of Arrhythmogenic right ventricular cardiomyopathy (ARVC).** *E. Dicks<sup>1</sup>, K. Hodgkinson<sup>1</sup>, S. Connors<sup>1</sup>, M. Norman<sup>2,3</sup>, L. Thierfelder<sup>2</sup>, M. Longley<sup>2</sup>, W. McKenna<sup>3</sup>, A. Bassett<sup>4</sup>, P. Parfrey<sup>1</sup>.* 1) Faculty of Medicine, Health Sciences Centre, St. John's, NF, Canada; 2) Max-Delbruck Centre, Berlin, Germany; 3) St. George's Hospital, London, UK; 4) University of Toronto, Ontario, Canada.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) is a difficult to diagnose AD disorder with genetic and clinical heterogeneity and variable expressivity. To determine the natural history of ARVC5 (OMIM) we investigated six Newfoundland families linked to 3p23 comprising 235 family members who were either affected clinically, obligate carriers, or at 50% risk of inheriting the gene. Of 174 (74%) subjects born after 1929, 87(50%) were considered affected either by i) a high risk DNA haplotype (n=43) or ii) obligate carrier (n=6), or iii) sudden death or defibrillator or pacemaker or defibrillation before 50 years of age (n=38); 37 (22%) were considered unaffected (low risk DNA haplotype); with the remaining 50 (29%) unknown: (29 (59%) of these have DNA testing in progress). Medical record data on the first cardiac manifestation was available for 124 subjects. Symptoms of arrhythmia (palpitation, syncope and sudden death) were assessed. 50 of 52 affected males had a clinical problem: syncope in 11 (22%) palpitations in 10 (20%) and sudden death in 22 (44%). Clinical presentation differed in 21 of 35 affected females: syncope in 3 (14%) palpitations in 15 (71%) and no sudden deaths. Mean age of onset was 30 years (95% CI 28-33), and 39 years (CI 33-45) for males and females respectively (rr=2.3, p=0.003). In unaffected subjects, a cardiac symptom was recorded in 6 of 16 males (38%) and 9 of 21 females (48%) with mean age of onset 36 years (CI 29-43) and 38 years (CI 28-49) respectively. The positive predictive value (ppv) for syncope or palpitations in diagnosing ARVC in subjects who did not present with sudden cardiac death was 84% in males with 70% sensitivity and 72% ppv in females with 60% sensitivity. We conclude that ARVC5 expresses in early adulthood, frequently with sudden death in males. Expression is later and less malignant in females. Diagnostic utility of symptoms of arrhythmia in females is poor.

**Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) in six Newfoundland families: a sex-limited disease with malignant phenotype in males.** *K. Hodgkinson<sup>1</sup>, E. Dicks<sup>1</sup>, S. Connors<sup>1</sup>, L. Thierfelder<sup>2</sup>, M. Norman<sup>2,3</sup>, W.*

*McKenna<sup>3</sup>, M. Longley<sup>2</sup>, A. Bassett<sup>4</sup>, P. Parfrey<sup>1</sup>.* 1) Faculty of Medicine, Health Science Ctr, St John's, NF., Canada; 2) Max-Delbruck Centre, Berlin, Germany; 3) St. George's Hospital, London, UK; 4) University of Toronto, Ont., Canada.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) is a difficult to diagnose autosomal dominant disorder with variable expressivity. Six large (up to 8 generations) Newfoundland families are linked to chromosome 3p23 (ARVC5: OMIM), suggesting a common founder. Comprehensive clinical and family history information was obtained in 235 subjects (135 males, 100 females); data were less likely to be available for subjects born in earlier generations. Subjects were either affected or at 50% pedigree risk; linkage data were available for a subset. Disease status was defined as: i) affected (high risk DNA haplotype, OR obligate carrier, OR sudden death under 50 years, OR cardiac intervention for ARVC with defibrillator/pacemaker or defibrillation under 50 years) n=118 (50%), ii) unaffected (low risk DNA haplotype), n=37 (15%), or iii) unknown, n=80 (35%). Genotyping results pending on DNA obtained from 34 subjects in the unknown group will raise ascertained disease status to 189 (80%) of the sample. 58 of 74 affected males, have died; 42 sudden deaths (72%). Mean age at death was 41 y (95% CI: 38-44); 22% died by age 30 y, 51% by 40 y, 82% by 50 y, and 92% by 60 y. 10 of 44 affected females have died; 2 sudden deaths (20%). Mean age at death for females was significantly older: 66 y (CI: 60-72); there were no deaths under 40 y, 15% by age 50 y, and 28% by 60 y. Relative risk comparing deaths in males to females was 6.1 (p=0.00001). Results were not significantly different when subjects born after 1929 were analysed separately; mean age at death for affected males was 37y (CI: 34-41). The results indicate a clear sex-limitation for ARVC5 with males having a malignant phenotype expressed in early-mid adulthood.

**Familial occurrence of both left and right heart hypoplasia in two different sibships.** *J. Martinovic<sup>1</sup>, D. Bonnet<sup>2</sup>, A. Benacht<sup>3</sup>, L. Fermont<sup>2</sup>, F. Encha-Razavi<sup>1</sup>, M. Vekemans<sup>1</sup>.* 1) Service d'Histo-Embryologie et de Cytogenetique, Hopital Necker, Paris, France; 2) Service de Cardiologie Pediatrique, Hopital Necker, Paris, France; 3) Service de Gynecologie et Obstetrique, Hopital Necker, Paris, France.

A familial recurrence is very well known in isolated congenital hypoplastic left heart syndrome (HLHS). Familial occurrence of hypoplastic right heart syndrome (HRHS) has also been reported. Here we report on a familial occurrence of left and right heart hypoplasia in one pair of dizygotic twins as well as in two sibs from a second sibship where one sib had a hypoplastic left heart and the other sib had a right heart hypoplasia. In the first family, a 23-week male fetus presented isolated HLHS with a small left ventricular cavity, mitral stenosis and aortic atresia. His twin sister presented a HRHS with a small right ventricular cavity, pulmonary atresia, intact ventricular septum and ostium secundum atrial septal defect. No other anomalies were found in both fetuses. In particular, a single DCDA placenta without anastomoses between both circulations was found. Chromosome analysis was normal and family history was unremarkable. In the second family, a male infant was born with prenatally diagnosed isolated classic HRHS. Family history revealed the presence of HLHS in a first cousin female infant. According to the developmental-mechanistic theory both HLHS and HRHS belong to the group of flow lesions. A high concordant recurrence rate is usually observed in families with classic HLHS, affected members having a left-sided blood-flow lesions. To our knowledge this is the first report on the occurrence of the left and right heart hypoplasia among the sibs of the same family. Therefore, the present observation is puzzling and may be useful in stimulating further studies and shed light on the etiology of these congenital heart diseases.

**Complex cardiac anomalies in deletion 9p22, duplication 5q34 of maternal origin: a case report.** *F. Lacbawan<sup>1</sup>, S. Schonberg<sup>2</sup>, D. Walton<sup>1</sup>, P. Koroulakis<sup>1</sup>, H. Thackray<sup>3</sup>.* 1) Children's National Medical Center, Washington, DC; 2) American Medical Laboratories, Chantilly, VA; 3) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

We report a deletion of 9p22-pter with duplication of 5q34-qter in an infant with multiple congenital anomalies, most notably complex cardiac defects. The infant was born at 36 weeks gestation, and after eight years of infertility and two previously documented spontaneous abortions, to a mother with balanced translocation t(5;9)(q34;p22). There was in utero growth retardation and oligohydramnios. Emergent cesarean delivery was performed for fetal distress. Echocardiogram revealed ASD, VSD, bicuspid aortic valve, abnormal pulmonary arch, coarctation of the aorta, inadequate left ventricular volume, and bidirectional shunting through the ductus arteriosus. Head ultrasound was normal and renal ultrasound revealed echogenic kidneys. She was hypotonic, and microcephalic with bifrontal narrowing. She had a flat sloping forehead, neutral palpebral fissures, small nose with tall and broad nasal bridge and anteverted nares, and posteriorly rotated, low set ears with overfolded helices. There was cleft palate, micrognathia, short broad neck, and widely-spaced nipples in a broad flat chest. She had single palmar creases, broad thumbs, and bulbous digits with hyperconvex, hypoplastic nails. The infant succumbed upon withdrawal of life support in her second week of life.

The clinical findings of the deletion 9p syndrome (9p del) have been well described. The deletion in most cases is de novo and the most common breakpoint is at 9p22, as in our patient. Our patient had similar clinical characteristics of 9p del, however, the typical findings of upslanting palpebral fissures, long philtrum, hypoplastic supraorbital ridges and hernias were not readily observed. In contrast, 9p del is not usually associated with such severe cardiac defects. We believe this patient's manifestations expand the clinical picture associated with deletion 9p and duplication 5q.

**CONGENITAL ANOMALIES ASSOCIATED WITH FETAL CONGENITAL HEART DISEASES. M.**

*HASANHODZIC<sup>1</sup>, E. GARNE<sup>2</sup>, M. CLEMENTI<sup>2</sup>, C. STOLL<sup>1</sup>*. 1) Gntique Mdicale, Hpital de HautePierre, STRASBOURG, FRANCE; 2) EUROSCAN study group.

The objective of the study was to evaluate the major extra cardiac malformations associated with congenital heart defects (CHD) of the fetus. Out of 2,454 fetuses with CHD coming from 709.030 fetuses registered by 20 European registries of congenital anomalies, 761 (31,0%), of them had associated malformations including 375 (49,3%) chromosomal abnormalities, 104 (13,0%) non chromosomal syndromes and 282 (37,0%) multiply malformed fetus with non chromosomal and non other recognized syndromes. Among the chromosomal abnormalities 239 were Down syndromes, 59 trisomies 13 and 14 Turner syndrome. The extra cardiac malformation were central, renal, digestive, musculo-skeletal anomalies and facial clefts. Twenty eight of the 104 recognised non chromosomal syndromes were deletion 22q11, 17 had situs anomaly and 15 VATER association. The major extra cardiac anomalies of non syndromic multiply malformed were renal, digestive including abdominal wall defects, central nervous system and musculo-skeletal. This study shows that it is very important to have a complete investigation of the fetus after the ultrasonographic detection of a fetal CHD as 31% of the fetuses have cardiac malformations. The detection of these associated anomalies will improve the prenatal diagnosis and therefore the care of the patient.

**Tetralogy of Fallot and dysmorphic features associated with partial trisomy 8q/monosomy 1q.** A. Yenamandra<sup>1</sup>, S. Buckwald<sup>2</sup>, R. Schiff<sup>2</sup>, N. Cagungan<sup>1</sup>, L. Trinchitella<sup>1</sup>, P. Koduru<sup>1</sup>, L. Mehta<sup>2</sup>. 1) Dept. of Laboratories; 2) Dept. of Pediatrics, North Shore University Hospital-N.Y.U School of Medicine, Manhasset, New York.

Tetralogy of Fallot (TOF) and conotruncal heart defects are heart defects best known to be associated with chromosome 22q11.2 microdeletion. Few other consistent chromosome abnormalities are reported with this defect. The SLV rec(8) chromosome is highly associated with conotruncal heart defects. We report an infant with partial trisomy 8, monosomy 1q and TOF. A full term male infant was delivered to a 33 year old G2P1 mother. Birth weight was 2685 gm and head circumference was 34.5 cm. There was early onset of seizures, poor respiratory effort and low oxygen saturations. Cardiology evaluation diagnosed tetralogy of Fallot, valvar and infundibular pulmonic stenosis, right aortic arch and patent foramen ovale. Facial dysmorphisms consisted of downslanting palpebrae, broad nasal root, prominent nasal tip, bilateral pre-auricular pits and unfolded ear helices; toes were overlapping with a deep groove between digits 1 and 2. There was a right undescended testis. Renal ultrasound showed mild hydronephrosis. Brain MRI, chemistries and metabolic screen were normal. Chromosome analysis was 46,XY,der(1)t(1;8)(q44;q21.2). Fluorescence in situ hybridization with the diGeorge syndrome critical region probe (Vysis, Inc) was normal. Maternal chromosome analysis was normal. The father carried a balanced reciprocal translocation between chromosomes 1 and 8. The infant inherited his derivative 1 chromosome after adjacent-1 segregation, and was therefore trisomic for segments 8q21.1-ter and monosomic for segments 1q44-ter. He had overlapping features of trisomy 8q and 1q monosomy. Congenital heart defects and seizures are reported in 1q44 monosomy. Ear anomalies and pits, bulbous nose and plantar grooves are reported in partial trisomy 8. Tetralogy of Fallot is highly associated with the SLV rec(8) chromosome [inv(8)p23q22] but is not a feature of 8q duplication, mosaic trisomy 8 or deletion 8q. Hence, this region of chromosome 8 influences cardiac development by unknown mechanisms.

**Does every Neonate with Down syndrome need an Echocardiogram?** *V. Shashi, M.N Berry, W. Covitz.* Pediatrics, Wake Forest Univ Sch Med, Winston-Salem, NC.

Echocardiography is the accepted method of screening for congenital heart defects (CHD) in neonates with Down syndrome, since a large number can be missed on physical examination (PE) and early intervention can minimize consequences such as pulmonary hypertension. Surprisingly, few studies have evaluated the efficacy of an electrocardiogram (ECG) along with PE, in detecting CHD. We performed a retrospective chart review of 287 children with Down syndrome. Exclusion criteria were: prenatal echo; echo performed prior to PE; age over 1 month at exam; insufficient information; PE by individuals other than a geneticist/cardiologist. With these exclusions, 49 medical records were analyzed, from 1991 onwards. The age ranged from 1 day to 1 month. CHD was detected in 33 of 49 neonates (67%). This high percentage is likely to be due to ascertainment bias. Of the 33 with proven CHD, 13 (39%) had a normal cardiac exam and thus would have been missed on PE alone. Of these 13, 10 defects were hemodynamically significant (AV canal, VSD, secundum ASD). Three were not hemodynamically significant (small muscular VSD, small ASD). In the 10 significant CHD cases, the ECG was abnormal and indicative of the underlying abnormality in all the 6 cases in which it was available. No ECG was available in the other 4 significant defects. In all 3 cases with insignificant defects, the ECG was normal. The sensitivity of PE alone was 61%; and the specificity was 90%;. The ECG was highly predictive of CHD, with a specificity of 98%;. In instances where the PE was erroneously normal, the ECG correctly identified cases with a significant CHD (6/6, no ECG available in 4). Although we speculate that the ECG may be predictive in the other 4 cases, for the purpose of this analysis, it is assumed that the ECG in those 4 cases was not abnormal. Thus, the sensitivity of ECG in combination with PE is 78%. Interestingly, in all 3 cases with hemodynamically insignificant CHD, the ECG was normal. Our conclusions are: 1) PE alone is insufficient to detect CHD in neonates with Down syndrome. 2) A combination of PE and ECG will detect the majority of significant CHD. This may be an alternative approach when an echocardiogram is not readily available.

**Trisomy 18 syndrome with unusual karyotype.** *C.M. Cazano, S. Chowdhury, A.F. Grieg, M.J. Macera, S.M. Kleyman, R.S. Verma.* Departments of Pediatrics and Medicine, Wyckoff Heights Medical Center, Brooklyn New York Hospital/Weill Medical College of Cornell University, New York, N.Y.

Trisomy for the entire chromosome 18 and monosomy for a large portion of the long arm [18q-] or short arm [18p-] exhibit typical features resulting in at least three types of clinical syndromes that can be recognized even prior to cytogenetic evaluation. A new born boy delivered after 29 weeks of gestation with birth weight of 875 gm, was referred for cytogenetic evaluation to rule out trisomy 18 syndrome. The mother is a 39 years old G3P2002, and the father is 50 years old. Prenatal care was provided. Maternal triple marker screening was negative. Amniocentesis was offered but she refused. Major clinical features of the proband include: marked hypotonia, muscle waste, skin with poor fat content, triangular face, very small palpebral openings, box forehead, prominent occiput, small sternum, separation of wide nipples, hepatomegaly, small pelvis, clenched hands and rocker-bottom feet. Chest X-ray and EKG showed abnormal right superior axis. Echocardiogram showed dextrocardia, pulmonic valve dysplasia, PDA and severe lung dysfunction with evidence of pulmonary hypertension. He had hematuria at birth. GI studies showed an esophageal pouch. On the fourth day, the child developed sepsis. On the fifth day, he had severe hemolysis, hyperbilirubinemia, anemia, metabolic acidosis, and despite exchange transfusion he expired on the sixth day with severe NEC, shock and respiratory failure. Cytogenetic findings with GTG and FISH-techniques revealed an abnormal 47,XY,t(3;18)(q23;q11.2)mat, +18.ish(wcp3+,wcp18+;wcp3+,wcp18+) karyotype. The mother was a carrier of the balanced translocation i.e. 46,XX,t(3;18)q23;q11.2). The father was cytogenetically normal. The proband inherited the balanced translocation plus a normal chromosome 18, resulting in trisomic condition due to 3:1 segregation at meiosis in the mother that was confirmed by centromeric alphoid heteromorphism. To the best of our knowledge, such cytogenetic findings have not been previously reported.

**Preliminary Analysis of Recurrence Risk and Familial Aggregation in Lipo(myelo)meningocele.** *C. Drake<sup>1</sup>, T. George<sup>1</sup>, E. Melvin<sup>1</sup>, J. Nye<sup>2</sup>, A. Franklin<sup>1</sup>, D. Enterline<sup>1</sup>, S. Guy<sup>2</sup>, M. Speer<sup>1</sup>, NTD Collaborative Group<sup>3</sup>.* 1) Medicine, Duke University Medical Center, Durham, NC; 2) Pediatrics, Northwestern University Medical School Chicago, IL; 3) NTD Collaborative Group.

Neural tube defects (NTDs) are a common, complex birth defect, caused by genetic and environmental factors with two main classifications: open and closed. Open NTDs occur when the brain and/or spinal cord is exposed at birth through a defect in the skull or vertebrae. Closed NTDs have a layer of skin covering the spinal defect. Common examples of closed NTDs are lipo(myelo)meningocele and lipomeningocele, in which fatty elements infiltrate into the meninges and/or spinal cord.

Given the similarities in the bony defects of the open and closed NTDs, the two may result from the same genetic mechanisms. To investigate this hypothesis, we calculated recurrence risk for NTDs when a proband has lipo(myelo)meningocele. We also identified aggregation in extended pedigrees. We ascertained 59 Caucasian families in which the proband had lipo(myelo)meningocele. A standardized three generation pedigree was obtained.

In the 23 younger siblings of the probands, there were no recurrences of NTDs although there were precurrences. Four pedigrees indicated familial aggregation. One family had an affected sibling with anencephaly and another family had an affected maternal half sibling with lipo(myelo)meningocele. Two families each had two additional affected relatives. Family 8642 had a sibling with spina bifida and a paternal half sibling with myelocystocele. Family 8776 had a sibling and a maternal first cousin with spina bifida. The sample is currently being expanded. Familial aggregation maybe the result of environmental factors or pure chance and does not prove genetic involvement. However, these families are consistent with a genetic component in lipo(myelo)meningocele and suggest that lipo(myelo)meningocele may be genetically related to the open forms of NTD.

**Premature Ovarian Failure and Marfanoid Features: A new association?** *O. Goker-Alpan<sup>1</sup>, C. Kozma<sup>2</sup>, L.M.*

*Nelson<sup>3</sup>, C.A. Francomano<sup>4</sup>.* 1) NICHD/HDB, National Institutes of Health, Bethesda, MD; 2) Department of Genetics, Georgetown University Medical Center, Washington DC; 3) NICHD/DEB, National Institutes of Health, Bethesda, MD; 4) NHGRI/MGB, National Institutes of Health, Bethesda, MD.

Premature ovarian failure (POF) is defined as cessation of ovarian function under the age 40 and affects one percent of women of reproductive age in general population. POF is characterized by secondary amenorrhea, hypogonadism and elevated gonadotropin levels. We describe for the first time a group of patients with POF and Marfanoid features. Four patients (ages 28-36) were found to have POF as evidenced by elevated gonadotropins. The age of onset of POF ranged from 26 to 34 years. Karyotyping from peripheral blood lymphocytes and skin fibroblasts failed to show any chromosomal abnormalities. Fragile X premutation carrier state was ruled out by molecular and cytogenetic studies. One patient was evaluated for Marfan syndrome prior to her referral. All patients had a history of myopia, joint laxity, joint pains and one patient suffered from recurrent dislocations as a teenager. Easy bruising and fragility of skin were reported in three patients. There was no history of Marfan syndrome in patients' families. High arched palate, reduced upper to lower segment ratio, increased arm span to height ratio and subjective arachnodactyly were among the significant findings in all four patients. Three had pes planus with medial displacement of medial malleoli and genu recurvata. One patient had scoliosis. None of them had aortic dilatation on echocardiography. Their ophthalmologic evaluation did not show ectopia lentis, and none met the diagnostic criteria for Marfan syndrome. Ovarian dysfunction is not a feature in any of the known connective tissue disorders. These findings may represent an unrecognized connective tissue abnormality associated with POF. The mechanism of our observed association between premature ovarian failure and Marfanoid features remains to be determined.

**Bilateral anterior temporal lobe cystic leukoencephalopathy with microcephaly, minor dysmorphisms, and psychomotor retardation.** *G.M. Bibat<sup>1</sup>, E.R. Melhem<sup>2</sup>, S. Naidu<sup>1</sup>*. 1) Div Neurology & Dev Medicine, Kennedy Krieger Institute/Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Neuroradiology, Johns Hopkins Hospital, Baltimore, MD.

We report 3 unrelated patients (2 boys and 1 girl) aged 20 months to 7 years with cystic leukoencephalopathy, born to healthy non-consanguineous parents. Severe cognitive and motor impairment with spasticity occurred within the first year of life. They were microcephalic with minor dysmorphisms but seizure free and without retinal abnormalities. Cytogenetic and metabolic (including mitochondrial, lysosomal and peroxisomal) screening in all three patients were unremarkable. However, MRI of the brain consistently revealed multiple foci of abnormal white matter, and bilateral cystic changes in anterior temporal lobes. The constellation of clinical and neuroimaging findings form a unique diagnostic entity. There are some MRI similarities to vacuolating leukoencephalopathy described by Van der Knaap, M et al. (*Ann Neurol* 37:324-334, 1995) and Singhal, B et al. (*Ped Neurol* 14:291-296, 1996) mapped to chromosome 22qter (Topcu, M et al. *Am J Hum Genet* 66:733-739, 2000). However, these patients differ from our cases in having megalencephaly, absence of dysmorphisms and a milder cognitive impairment. Also, their degree of white matter abnormality is more severe than in our patients and their survival into adulthood is associated with progressive severe spasticity. Three Turkish cases reported by Olivier, M et al. (*Neuroped* 29:225-228, 1998) may resemble our patients except that all our cases had microcephaly with mild dysmorphic features and were seizure free. Our cases are of European descent suggestive of multiethnic prevalence of this entity. Despite our patients being singletons, its occurrence in Turkish sibs of consanguineous parents suggests an autosomal recessive mode of inheritance.

**Deletion of chromosome 14q32.2 is apparently associated with scoliosis and retrognathia.** A. Jain<sup>1,2</sup>, A. Krauss<sup>1</sup>, L. Lumicao<sup>1</sup>, M.L Alonso<sup>2</sup>, M.J Macera<sup>3</sup>, R.S Verma<sup>2,3</sup>. 1) Pediatrics, Jamaica Hosp. Medical Center, Jamaica, N.Y; 2) The New York Hospital/Weill Medical College of Cornell University New York; 3) Wyckoff Heights Medical, Brooklyn, N.Y.

Based on the clinical findings, a single band deletion of a chromosome has been associated with a specific clinical syndrome. The results of an exhaustive literature search, in which overlapping features associated with deletion of this chromosomal band have been compared, has with a few exceptions, produced no definite conclusion [Brewer et al Am J Hum Genet 63:1153-1159,1998]. We report a case of a new born baby girl who is the product of a 37 weeks gestation delivered by caesarian section. She has minimal dysmorphic features, with a birth weight of 1450 gm. A head sonogram was normal with a circumference of 30 cm. She had an episode of seizures and was placed on phenobarbitol. The most significant findings were scoliosis and retrognathia. To the best of our knowledge, a single band deletion of 14q of this minute nature has never been reported earlier. The initial cytogenetic diagnosis using routine GTG banding was 46,XX,del(14)(q32.2). This was revised to 46,XX,del(14)(q32.2).ish del(14)(q32.1q32.3)(14q Tel Vysion x2) after a 14q telomere probe(Vysis) was applied. Since telomeric signals were observed over both homologous, the deletion of only band q32.2 was concluded. It is tempting to hypothesize that these two abnormalities may be related with band q32.2 on the long arm of chromosome 14. However, scoliosis has been associated with 2p15-13, 6q13, 15q12 in earlier cases. Furthermore, it is our belief that earlier cases need to be reevaluated as they can easily be misidentified as terminal deletions rather than interstitial.

**Sanjad-Sakati Syndrome (MIM 241410) in a West-African family: The search for an ancestral mutation. M.**

*Markowitz<sup>1</sup>, A. Shanske<sup>1</sup>, B. Schofield<sup>2</sup>.* 1) Center for Congenital Disorders and Division of Environmental Medicine, Children's Hospital at Montefiore, Bronx, NY; 2) Terence Cardinal Cooke Health Care Center, New York, NY.

Syndromic hypoparathyroidism is rare and includes such conditions as the Kenny-Caffey Syndrome (KCS) and the Sanjad-Sakati Syndrome (SSS). SSS was first described by Sanjad in 1988 as an autosomal disorder characterized by growth retardation, congenital hypoparathyroidism, dysmorphic facies, seizures and retardation. Patients lack the bony changes seen in KCS. A recessive form of KCS (MIM 244460) was demonstrated in 1997 and has recently been shown to be allelic with SSS. All of the patients reported to date have originated from the Arabian peninsula. We have identified sibs from the West-African nation of Gambia.

Case Report: **Case 1** was the 1680 gm product of a 37 week gestation delivered by SVD to a 26 year old Gambian mother who is the first cousin of the father. At birth, the HC was 28.5 cm and the length was 43 cm. The forehead sloped, the metopic suture was prominent and the eyes and ears were large. He developed hypocalcemic seizures at 7 months of age. The parathyroid hormone level was undetectable and he is profoundly retarded. **Case 2** is the 6 year old sister of the proband. She was the 1765 gm product of a term pregnancy complicated by IUGR and oligohydramnios delivered by section because of a breech presentation. The H.C. at birth was 27.5 cm and the length was 42.5 cm. The anterior fontanelle was closed, the forehead sloped, the eyes and ears prominent and she had bilateral branched simian creases. She developed congestive failure secondary to a fenestrated VSD which resolved spontaneously and she too is profoundly retarded. At 5 years of age her  $Ca^{++}$  was 8.2 (ionized 4.4), and parathyroid hormone 13.

The gene for SSS has been localized to 1q42-q43. SSS and KCS are now felt to not only be allelic but caused by the same ancestral chromosome in all cases studied thus far. Our family suggests the possibility of genetic heterogeneity or the migration of the ancestral chromosome to West Africa and is the first case in an African family.

**Clinical overlap between Trichorhinophalangeal and Floating Harbor Syndromes.** *J.W. Innis<sup>1,2</sup>, J.L. Schuette<sup>1</sup>, D.M. Martin<sup>1</sup>*. 1) Department of Pediatrics, The University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, The University of Michigan, Ann Arbor, MI.

Trichorhinophalangeal (TRP) and Floating Harbor syndromes are multiple congenital anomaly syndromes with involvement of craniofacial and skeletal structures. Trichorhinophalangeal syndrome exists as three autosomal dominant forms (I, II, III) and one autosomal recessive form, with variable clinical features such as short stature, mild facial dysmorphisms, sparse hair, speech delay, and genitourinary abnormalities. Floating Harbor syndrome, also an autosomal dominant condition, was named after the two hospitals where it was originally identified and is characterized by short stature, expressive language delay, characteristic facies, and delayed bone age. TRP I is associated with mutations in TRPS1, a zinc finger transcription factor on 8q24. We report here a child with features that overlap significantly between TRP I and Floating Harbor syndromes. A.W. presented at age 2 months for evaluation of growth delay and multiple congenital anomalies. He was later found to have severe short stature, triangular face, short, light blonde hair, a prominent nose, protruding, low-set ears, a submucous cleft palate, ivory and cone epiphyses of the phalanges, Perthes disease of the left hip, and severely delayed expressive speech with normal speech reception abilities. Peripheral blood karyotype and FISH22q11deletion studies, endocrine evaluation (IGF-I, IGF-BP3) and hearing tests were normal. Family history revealed no similarly affected family members. Our patient's findings are more consistent with Floating Harbor syndrome; however, his features overlap significantly with TRP syndrome, emphasizing the importance of considering both diagnoses during evaluation of short stature, speech delay, and characteristic triangular facies. Molecular testing for TRPS1 mutations is pending.

**Characterization of Asthma, Atopy and Associated Phenotypes in Families Identified Through Child Probands with Physician Diagnosed Asthma.** *P.J Helms<sup>1</sup>, W. Anderson<sup>2</sup>, K. Barnes<sup>1</sup>, A. Berg<sup>1</sup>, S. Brewster<sup>3</sup>, K. Carlsen<sup>1</sup>, J. Gerritsen<sup>1</sup>, C. Haynes<sup>4</sup>, W. Lenney<sup>1</sup>, P. Manasco<sup>2</sup>, A. Roses<sup>2</sup>, M. Pericak-Vance<sup>4</sup>, M. Silverman<sup>1</sup>, P. Sly<sup>1</sup>, M. Speer<sup>4</sup>, J. Sundy<sup>1</sup>, J. Tsanakas<sup>1</sup>, J. Vance<sup>4</sup>, M. Whyte<sup>1</sup>, Genetics of Asthma International Network<sup>1</sup>.* 1) Genetics of Asthma International Network; 2) Glaxo-Wellcome Inc., Research Triangle Park, NC; 3) Glaxo-Wellcome Research and Development, Greenford, UK; 4) Duke University Medical Center, Durham, NC.

Asthma is a common, complex disorder with both genetic and environmental components. To investigate the genetic basis of asthma, we have established an international network of 11 sites, each collecting 100 nuclear families with at least two siblings (age 7-35) with a physician diagnosis of asthma (PDA). **Patients and methods:** In all subjects (including parents) the following measurements were performed: respiratory questionnaire including detailed family history and environmental risk factor assessment; bronchial reactivity (PC20-methacholine); reversibility of airway obstruction; skin-prick tests and serum total IgE. **Results:** To date, 501 families (2089 individuals) have been fully ascertained. Of the affected children, 54% are boys with a median age of 12 and a median age of physician diagnosis of asthma of 4 yrs. Among asthmatic children eligible for methacholine challenge, approximately 52% demonstrated bronchial hyperreactivity (PC20 for FEV1 < 8mg/ml) and 75% had at least one positive skin prick test (> 2 mm greater than negative control). Approximately 7% of asthmatic children had PC20 = 0.12 mg/ml, representing one subset with more severe disease. 35% of the parents had asthma and the majority (74%) were skin prick positive to at least one allergen. In 63% of families, one or both parents reported a history of regular cigarette smoking. Blood samples have been collected for DNA and an approximately 7 cM resolution genomic screen initiated in the first 379 families. **Conclusion:** These data should provide insight into genetic factors and traits involved in asthma and other related phenotypes.

**Molecular Basis of Bernard-Soulier syndrome.** *D. Ng*<sup>1</sup>, *S. Schonberg*<sup>2,3</sup>, *N. Luban*<sup>3</sup>, *S. Kaler*<sup>4</sup>. 1) NICHD, National Institutes of Health, Bethesda, MD; 2) American Medical Laboratory, Chantilly, VA; 3) Children's National Medical Center, Washington, DC; 4) NINDS, National Institutes of Health, Bethesda, MD.

The platelet membrane glycoprotein (GP)Ib-V-IX complex is the receptor for von Willebrand factor and is composed of four membrane-spanning polypeptides: GPIb alpha, GPIb beta, GPIIX, and GPV. A qualitative or quantitative deficiency in this complex causes the human platelet disorder Bernard-Soulier syndrome (BSS). BSS is an autosomal recessive disorder presenting with mild thrombocytopenia, circulating "giant" platelets and a bleeding phenotype. The bleeding in patients with BSS is disproportionately more severe than suggested by the reduced platelet count and is explained by a defect in primary hemostasis owing to the absence of the platelet glycoprotein (GP) Ib-V-IX membrane receptor.

We report on an infant with facial dysmorphism, a congenital heart defect and neonatal thrombocytopenia in whom heterozygous deletion of the chromosome 22q11 critical region consistent with velocardiofacial (VCF) syndrome was demonstrated by FISH analysis. The patient's father, who has a history of mild thrombocytopenia, did not harbor the 22q11 deletion. Maternal testing for platelet antibodies was negative, ruling out neonatal alloimmune thrombocytopenia (NAT).

Platelet surface glycoprotein studies in the infant demonstrated extremely reduced expression of GPIb beta, the gene for which localizes to 22q11. We speculate that this patient harbors a mutation in his paternally inherited GPIb beta allele; molecular studies formally evaluating this hypothesis are in progress in our lab. A literature search (6/00) indicates that mutations in GPIb beta in VCF patients with comparable hematological phenotype have been documented in only two individuals to date.

We wish to bring further attention to this association and suggest that (1) molecular testing for VCF be considered for thrombocytopenic infants when NAT has been excluded, and (2) 22q11 deletion VCF patients with enlarged platelets and bleeding tendencies be screened for alterations in GPIb beta.

**Repetitive behaviors differentiate autism subgroups.** *J.H. Miles, N. Takahashi, J.D. Mudrick.* Univ of Missouri, Columbia, MO.

Repetitive or stereotypic patterns of behavior and activities are one of three diagnostic criteria for Autistic Disorders (AD). We studied repetitive behaviors (RBs) in 153 individuals diagnosed with idiopathic infantile autism to develop a classification system, severity scale and protocol for study of the significance of RBs in our previously defined clinical subgroups. We question whether RBs in autism are a response, possibly palliative, to noxious external stimuli or an indicator of non-specific brain damage. Probandes were ranked, based on parent reports in a semi-structured interview, on four areas of RBs; hand flapping, spinning, humming and "other". The low RB category (46/153 - 30%) included probands with RBs in 0 or 1 of the areas and the high RB category (69/153 - 45%) group in 3 or 4. The high and low categories were compared for hypersensitivity to noise, resistance to change, and other variables. The high RB individuals were more likely to be hypersensitive to noise (59.4% vs 42.1%,  $p < 0.025$ ) and resistant to change (84.0% vs. 57.9%  $p < 0.001$ ). This supports previous findings that RBs in autism are a response to distressing sensations or situations (Hutt, 1968). The high and low RB groups did not differ significantly in physical morphology, head circumference, type of onset or family history of autism or psychiatric disorders. Thus RBs, by this grouping, did not help refine our previously defined autism subgroups (Miles, 1996). However, children with no prominent RBs were consistently different from those with prominent RBs: with a lower sex ratio (0.7:1 vs. 7.3:1,  $p < 0.001$ ), higher IQs ( $> 55 = 42\%$  vs  $66\%$   $p < 0.1$ ), higher SES ( $p < 0.001$ ), less sibling recurrence risk for autism or autistic traits (0% vs 22%  $p < 0.1$ ), and less family history of autism (0% vs 22%  $p < 0.1$ ), affective disorders (17% vs 42%  $p < 0.1$ ) or addictive disorders (17% vs 41%  $p < 0.1$ ). Only the family history of obsessive compulsive disorder was higher in the no RB than the RB group (8% vs 6.7%). This suggests that children with no prominent RBs, though they fit DSM -IV AD criteria on the basis of interests or rituals may comprise a subgroup of AD more closely related to obsessive compulsive disorder.

**Sternal cleft with supraumbilical midline raphe and hemangiomas: An X-linked lethal syndrome?** *S.G. Kaler<sup>1,3</sup>, H. Thackray<sup>2</sup>*. 1) Clinical Neurosciences Program, NINDS/NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 3) Children's National Medical Center, Washington, DC.

The association of sternal cleft (SC) and supraumbilical raphe (SR) is a midline developmental defect considered to occur sporadically. Embryologic formation of the thoracic and vascular structures involved in these defects suggests a critical period at approximately 8 weeks gestation. Review of the available medical literature indicates that this association has an equal sex predilection (42 examples reported). In contrast however, when SC and SR are accompanied by unilateral hemangiomas, a marked female predilection is observed (29 of 31 reported cases, greater than 93%). We report on a female infant with upper sternal cleft, midline abdominal raphe, and capillary and cavernous hemangiomas of the face, chest, left arm and left leg. The sternal cleft was covered with a thin translucent membrane; normal cardiac function and a small atrial septal defect were noted on echocardiogram. The abdominal raphe extended from the lower border of the sternal cleft to the umbilicus, with a small palpable midline muscular defect. Head, chest, and abdominal ultrasound exams excluded internal vascular malformations, and chromosomes were 46,XX. Repair of the sternal defect was performed without complications. During the first 7 months of life, the congenital hemangiomas progressed and then began a slow regression. At 10 months of age, cognitive and motor development were slightly delayed. The family history was notable for one prior miscarriage in the mother, and two female relatives with cutaneous hemangiomas (patient's maternal aunt and the maternal aunt's daughter). To our knowledge, a single gene etiology has not been considered for the constellation of SC with SR and hemangiomas. We speculate that this syndrome may represent an X-linked trait that is lethal in males, explaining the pronounced female predilection. X inactivation studies in our patient's peripheral white blood cells and cultured fibroblasts to assess for skewed inactivation will enable us to formally evaluate this hypothesis.

**Molecular characterization of a 45,X/46,XY/46,X,r(Y) in a newborn male.** *H.O. Shah<sup>1</sup>, M.J. Macera<sup>2</sup>, J. Sherman<sup>1</sup>, B. Feldman<sup>1</sup>, J.H. Lin<sup>1</sup>, M. Pugliese<sup>1</sup>, M. Chester<sup>1</sup>, S.M. Kleyman<sup>2</sup>, R.S. Verma<sup>2</sup>.* 1) Nassau County Medical Center, East Meadow, NY; 2) Wyckoff Heights Medical Center, Brooklyn, NY.

Chromosomal mosaicism with 45,X/46,XY may be found in male patients with gonadal dysgenesis. Patients with such mosaicism can have a cell line with an additional marker chromosome. The incidence of cells with Y chromosome-derived markers must be investigated, because its presence predisposes these individuals toward gonadoblastoma formation. We were recently referred a baby boy who was the product of a full term uncomplicated pregnancy carried by a 23-year-old mother. Upon physical examination, the child had 3° hypospadias with chordee. The phallus length was 4.2 cm with good erectile tissue volume. The right testicle was descended and of normal size and consistency. The left testicle was not palpable and the left hemi-scrotum appeared uninhabited. Ultrasound evaluation revealed structures compatible with the upper 1/3 of a vagina. No testicle was identified on the left. Laboratory evaluations (including progesterone, DHEA, testosterone, LH and FSH) done at 3 days and 30 days of life were reasonably within normal limits for a male child. Initial cytogenetic evaluation with routine GTG-banding revealed a 45,X/46,XY/46,X,r(?) karyotype. QFQ-banding confirmed the presence of a Y chromosome. Molecular characterization with probes specific for the Y satellite III and the SRY gene (cepY, LSI SRY, Vysis) using the FISH technique on metaphase chromosomes confirmed the ring chromosome as a ring Y. The SRY gene and satellite III DNA were present on both the Y and r(Y) chromosomes. The breakpoints of the ring were determined to be r(Y)(p11.2q12). Approximately half of the cells containing the SRY locus were ring chromosomes. Analysis of the interphase cells (cepX, cepY, Vysis) gave the following information: 45,X.nuc ish Xcen(DXZ1x1)Ycen(DYZ1-)[140]/46,XY/46,X,r(Y).nuc ish Ycen(DZY1x1)[60]. It was determined that 70% of the cells were 45,X, 15% were 46,XY and 15% were 46,X,r(Y)(p11.2q12). With 30% of this child's cells containing a Y or r(Y) chromosome, it is imperative to follow his progress closely to prevent the formation of gonadal tumors.

**A syndrome of autosomal dominant progressive renal failure and hypertension is mapped to chromosome 1q21-q22.** *M. Shohat<sup>1</sup>, T. Shohat<sup>1</sup>, M. Yahav<sup>1</sup>, G. Rechavi<sup>2</sup>, T. Ilan<sup>2</sup>, L. King<sup>3</sup>, D. Cohn<sup>3</sup>.* 1) Medical Genetics, Rabin Medical Ctr, Petah Tikva, Sackler School of Medicine, Tel Aviv University, Israel; 2) Pediatric Hematology and Oncology, Sheba Medical Center, Tel Hashomer, Sackler School of Medicine, Tel Aviv University, Israel; 3) Human Genetics and Ahmanson Department of Pediatrics, Cedars-Sinai Research Institute, UCLA, Los Angeles, CA, USA.

Several distinct clinical phenotypes have been described that lead to autosomal dominantly inherited end-stage renal failure. Examples include Alport syndrome and non-Alport nephritis, nephronophthisis/ medullary cystic kidney disease, interstitial nephritis, adult polycystic kidney disease, and various inherited glomerulopathies. Genetic loci for many of these conditions have been defined, and the disease genes have been isolated for several disorders in this group. However, in many of the aforementioned disorders there are additional, non-renal manifestations such as deafness or ocular abnormalities. In forms of nephropathy and hypertension without extrarenal findings (e.g. OMIM #161900), neither a locus nor a specific gene defect has yet been defined. We have ascertained a large Israeli family of Iraqi Jewish origin with an autosomal dominant form of adult onset nephropathy and hypertension. Hypertension was the presenting symptom in all of the patients. There was progressive renal failure and patients eventually required hemodialysis followed by renal transplantation. The aims of this study were to describe the clinical features in the family and determine the chromosomal location of the defective gene by a genome-wide linkage search. By performing a genome-wide linkage search, the disease gene was localized to chromosome 1q21; the highest lod score was obtained for the marker at locus D1S305, which yielded a maximum lod score of 4.71 at a recombination fraction of zero. Recombination mapping defined an interval of about 3 cM, between the markers at loci D1S2696 and D1S2635, which contains the disease gene. Localization of the disease-causing gene in this family represents a necessary step toward isolating the defective gene and providing a deeper understanding of the mechanisms of hypertension and progressive renal failure.

**Severe neonatal hypotonia : high prevalence of Prader-Willi syndrome, myotonic dystrophy and spinal muscular atrophy in a molecular prospective study.** *L. Van Maldergem, P. Hilbert, Y. Gillerot.* Centre de Genetique Humaine, Inst Pathology & Genetics, Loverval, Belgium.

**Background** Severe neonatal hypotonia in the absence of obstetrical complications remains a clinical problem with respect to its aetiology, and particularly to genetic disorders underlying the condition. Among these, Prader-Willi syndrome, the neonatal form of myotonic dystrophy and spinal muscular atrophy have recently become amenable to molecular diagnosis. **Methods** We performed DNA analyses in order to diagnose these three genetic disorders in 80 subsequent blood samples received for severe neonatal hypotonia between 1995 and 2000. **Results** 11 newborns (10 percent) were diagnosed with one of these disorders : six cases with Prader-Willi syndrome, four with Myotonic Dystrophy and one with Spinal Muscular Atrophy. **Conclusion** Prader-Willi, Myotonic Dystrophy and Spinal Muscular Atrophy altogether represent a significant proportion (13.75 %) of severe unexplained hypotonia of the newborn. It proves useful to perform a panel of three DNA tests in this situation in order to diagnose these conditions. It may prevent further invasive diagnostic procedures like muscle biopsy and allows early handling and genetic counselling for these disorders.

**Johnson-McMillin syndrome, a neuroectodermal syndrome with conductive hearing loss and microtia: report of a new case.** *D.N. Schweitzer<sup>1</sup>, S. Yano<sup>2</sup>, D.L. Earl<sup>1</sup>, J.M. Graham, Jr.<sup>1</sup>*. 1) Med Genet Birth Defects Center, Cedars-Sinai Medical Center, UCLA School of Medicine, LA, CA; 2) Childrens Hospital Los Angeles, LA, CA.

In 1983, Johnson et al. described 16 related individuals with alopecia, anosmia or hyposmia, conductive hearing loss, microtia and/or atresia of the external auditory canal, and hypogonadotropic hypogonadism inherited in an autosomal dominant pattern and with variable expressivity. Variable manifestations included mild facial asymmetry, mental retardation, congenital heart defect, and cleft palate. We describe an unrelated female patient with features resembling the family described by Johnson et al.. The propositus was the 1950 gm product of a 38 week gestation born to a 19-year-old G1P0-1 woman and her healthy unrelated 21-year-old partner. Family history is significant for delayed menarche, slightly small auricles, possible hyposmia, and unilateral choanal stenosis in the mother. C-section at 38 weeks was done for oligohydramnios with severe IUGR. She presented with growth deficiency, alopecia, bilateral microtia with canal atresia, tetralogy of Fallot, posterior cleft palate, left choanal stenosis and right thumb polydactyly. Developmental evaluation at chronological age 13 months showed skills at 7 months. At 19 months length and weight were 6 SD below expected mean for age and OFC was 8 SD below mean for age. Total alopecia, brachycephaly, left facial palsy and hypotonia were noted. Phenotypic abnormalities involving neuroectoderm, craniofacial structures, heart and the endocrine system can be explained on the basis of involvement of the ectoderm and neuroectoderm of the first and second brachial arches, Rathkes pouch, and the diencephalum. Microtia with conductive hearing loss differentiates this condition from the other ectodermal dysplasias. Phenotypic expression appears to be quite wide, and the mother of our patient could be a mildly affected female who passed the condition to her daughter in an autosomal dominant fashion.

**Cerebral vasculopathies as the cause of acute neurologic complications in Down Syndrome.**

. R.D.

*Blackston*<sup>1</sup>, *P.C. Davis*<sup>2</sup>, *K.L. Carter*<sup>1</sup>, *K. Coleman*<sup>2</sup>. 1) Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA; 2) Children's Healthcare of Atlanta at Egleston, Atlanta, GA.

There is a growing body of information that cerebrovascular disorders, particularly Moya Moya disease, may produce acute neurologic findings in Down Syndrome. Moya Moya is a chronic occlusive disorder of progressive stenosis of the supraclinoid internal carotid artery with secondary development of enlarged basal collateral vessels. We present an initial case of Down Syndrome with angiographically demonstrated localized internal carotid artery disease bilaterally with occlusion at the internal carotid origin on the right and a string sign beginning at the internal carotid origin on the left with collateral intracranial circulation. These findings are compared to Moya Moya. The patient is 3 y.o., WM, classic Down with trisomy 21, but no history of heart disease. Weakness of left arm was the presenting finding and within three weeks, patient lost movement of right arm and lost the ability to sit, crawl or pull to stand. Speech was unaffected. He was hospitalized two weeks later. MRI of cervical spine was normal; however, MRI of brain showed areas of subacute infarction. The mechanism of increased incidence of cerebrovascular abnormalities in Down Syndrome may be explained in several ways. Superoxide dismutase 1, interferon gamma receptor, and cystathionine synthase are proteins encoded on chromosome 21 which may increase arterial narrowing. The alpha chain of collagen type VI is also on chromosome 21, and previous post mortem studies have shown internal vascular thickening with vascular deposition. Excessive vascular thickening could be related to overexpression of collagen type VI in trisomy 21. An inflammatory or autoimmune mechanism could also be relevant to the pathogenesis. Obviously, further studies are needed. An unexplained propensity to cerebral artery abnormalities likely accounts for both our case and Moya Moya. We recommend consideration of cerebrovascular abnormalities in children with Down Syndrome who present with acute neurologic symptoms as well as appropriate neuroimaging studies.

**Noonan-like/multiple giant cell lesion syndrome: a separate entity from Noonan syndrome?** *D. Bertola<sup>1</sup>, C. Kim<sup>1</sup>, A. Pereira<sup>2</sup>, G. Mota<sup>2</sup>, J. Krieger<sup>2</sup>, I. Vieira<sup>3</sup>, M. Valente<sup>4</sup>, M. Loreto<sup>5</sup>, R. Magalhaes<sup>5</sup>, C. Gonzalez<sup>1</sup>*. 1) Dept. of Pediatrics, Instituto da Crianca - USP, Sao Paulo, Brazil; 2) Laboratory of Genetic and Molecular Cardiology, InCor, Sao Paulo, Brazil; 3) Dept. of Pathology, USP, Sao Paulo, Brazil; 4) Dept. of Radiology, Instituto da Crianca - USP, Sao Paulo, Brazil; 5) Dept. of Head and Neck Surgery, USP, Sao Paulo, Brazil.

Noonan syndrome (NS) is an autosomal dominant condition comprising short stature, craniofacial dysmorphisms, mainly hypertelorism, ptosis and downslanting of the palpebral fissures, webbed neck, congenital heart defects, cryptorchidism in males, skeletal defects and bleeding diathesis. A gene for NS has been mapped to the long arm of chromosome 12 (12q24), but some families affected by this disorder showed no linkage to this region, indicative of genetic heterogeneity. In 1974, Cohen et al. described a female patient presenting short stature, craniofacial dysmorphisms, short webbed neck, pulmonic stenosis, multiple lentiginos and giant cell lesions of both bone and soft tissue. Cohen and Gorlin (1991) proposed that this disorder would represent a separate entity from NS and LEOPARD syndrome, although there was an evident clinical overlap among them. They named it Noonan-like/multiple giant cell lesion syndrome. We report on a family (a mother and two children) that has typical characteristics of NS and multiple giant cell lesions in maxilla and mandible. The linkage analysis performed in them showed that the three affected members studied share an identical 12q haplotype. We discuss the obvious clinical overlap between NS and Noonan-like/multiple giant cell lesion syndrome and we give further clinical and molecular support that these two entities could be allelic conditions.

**A bovine model of a connective tissue disorder.** *E. Felix*<sup>1</sup>, *G. Sherman*<sup>3</sup>, *C. Gwilt*<sup>2</sup>, *J. Winterboer*<sup>2</sup>, *S. Beiraghi*<sup>1,2</sup>, *D.J. Steffen*<sup>3</sup>, *M. Godfrey*<sup>2</sup>. 1) Pediatric Dentistry; 2) Center for Human Molecular Genetics Univ. Nebraska Medical Center, Omaha, NE; 3) Veterinary Diagnostic Center, Univ. Nebraska, Lincoln, NE.

An animal model of a human disease has obvious advantages including the ability to study pathogenesis and novel therapies aimed at human disease. We have recently begun to study a family of Angus cattle with an apparent connective tissue disease. Some of the early pathology seemed to indicate the possibility of a Marfan syndrome like phenotype. The Marfan syndrome is an autosomal dominant heritable disorder of connective tissue with manifestations in the skeletal, ocular, and cardiovascular systems. Marfan syndrome is known to be caused by defects in the *FBN1* gene encoding fibrillin-1. Most people with the Marfan syndrome have abnormal expression of fibrillin-1 in skin. Immunofluorescence studies of skin from affected and unaffected calves using a monoclonal antibody to fibrillin demonstrated normal staining in all animals. A possible Stickler syndrome like phenotype was suggested by their lax joints and unusual gait. Biochemical analysis of cartilage collagens was normal. As the calves aged and attempted to be more mobile, leg fractures became common and continued to point to a connective tissue etiology, possibly osteogenesis imperfecta. Studies to examine type I collagen are now underway. The fact that we have DNA on some 20 affected and unaffected calves, their dams, and their obvious germline mosaic sire makes this an informative pedigree for genetic analyses. While a specific diagnosis for these calves is currently unknown, the pleiotropic phenotype is reminiscent of human heritable connective tissue disorders.

**A syndrome of microtia, cleft palate and Diamond-Blackfan anemia in first cousins.** *K.W. Gripp<sup>1</sup>, D. McDonald-McGinn<sup>1</sup>, D. La Rossa<sup>1</sup>, S.E. McKenzie<sup>2</sup>, J. Lipton<sup>3</sup>, E.H. Zackai<sup>1</sup>*. 1) Human Genetics, CHOP, Philadelphia, PA; 2) duPont Hospital, Wilmington, DE; 3) Schneider Children's Hospital, New Hyde Park, NY.

Diamond-Blackfan anemia (DBA) is a rare form of pure red cell aplasia presenting in infancy. Hematologic findings often include macrocytosis, and elevated hemoglobin F and erythrocyte adenosine deaminase (eADA) levels. Associated physical findings were noted in over 40% of cases; cleft lip or palate occur in 3%.

We report first cousins with microtia, cleft palate and hematologic abnormalities consistent with DBA. Pt 1 had bilateral microtia, micrognathia and a submucous cleft palate. Treacher Collins syndrome was suspected, but no TCOF1 mutation was found. Steroid responsive anemia developed at 16 months; macrocytosis and elevated hemoglobin F were consistent with DBA. Pt 2 had bilateral microtia, micrognathia, cleft palate, and mildly downslanting palpebral fissures. He had macrocytosis, elevated eADA and hemoglobin F, consistent with DBA. Our patients share bilateral microtia, midfacial hypoplasia, cleft palate and hematologic abnormalities of DBA. Except for a female with microtia, micrognathia and cleft palate (Hasan & Inoue, 1993), no cases of microtia and DBA have been reported. While the inheritance pattern in our cases could be X-linked recessive, this is an unlikely explanation for the female. Autosomal dominant inheritance with incomplete penetrance of DBA was confirmed by heterozygous mutations in the ribosomal protein 19 (RPS19) gene. Currently 46 cases with RPS19 mutations have been reported, none had microtia or cleft palate (Willig et al, 1999; Matsson et al., 1999). DBA is heterogeneous, only about 25% have identifiable RPS19 mutations. A second locus maps to 8p, and another locus is inferred. Sequence analysis of the RPS19 coding region did not identify a mutation in our cases, and 2 alleles were present in each. Segregation analysis is being performed. Once additional DBA genes are identified it will become clear if there is a correlation between the microtia-cleft palate phenotype and a specific genotype.

**Two patients with distinct structural anomalies of chromosome 10 determined by advanced molecular cytogenetic techniques.** *K.M. Dent<sup>1</sup>, Z. Chen<sup>2</sup>, B. Issa<sup>2</sup>, A. Meloni-Ehrig<sup>2</sup>, R. Shepard<sup>2</sup>, D. Forsyth<sup>2</sup>, X. Zhu<sup>2</sup>, K. Carroll<sup>3</sup>, X. Guan<sup>4</sup>, A. Brothman<sup>2</sup>, J. Carey<sup>1</sup>.* 1) Medical Genetics/Pediatrics, Univ Utah, Salt Lake City, UT; 2) Cytogenetics Lab/Pediatrics, Univ Utah, Salt Lake City, UT; 3) Orthopedics, Univ Utah, Salt Lake City, UT; 4) National Center for Human Genome Research, Bethesda, MD.

Patient 1 is a 9-month-old female with multiple congenital anomalies and a mosaic female karyotype with an extra ring chromosome consisting of the entire short arm of chromosome 10 (10p). Spectral karyotyping (SKY), chromosome microdissection, and fluorescence in situ hybridization (FISH) clearly identified the mosaic extra ring to be completely of 10p origin. She had characteristics of children reported previously with trisomy 10p including growth retardation, developmental delay, hypotonia, congenital heart defect, and hypertelorism. In addition, she had severe joint laxity and a congenital knee dislocation, features not described previously. While trisomy 10p is a well-delineated chromosome abnormality, complete trisomy 10p has been reported only infrequently. Furthermore, this is the first reported case of isolated, complete trisomy 10p resulting from an extra ring chromosome. Patient 2 is a 4-month old male with a duplication of the proximal part of the long arm of chromosome 10 (10q11.23-10q23.2). This duplication was confirmed to be of chromosome 10 origin using FISH analysis with the chromosome 10 painting probe. The phenotypic findings are similar to those described in the three other published cases with the same karyotype and include growth retardation, prominent philtrum, bowed mouth, micrognathia, thick cupped ear helices, single crease on the fifth finger, and mild developmental delay. He also had a ventriculoseptal defect and atrial septal defect. Congenital heart defects have not previously been reported in patients with the same size duplication. Parental chromosomes were normal in both cases.

Our studies in these two patients further demonstrate the value of advanced molecular cytogenetic techniques in the identification of unknown structural rearrangements.

**Clinical indications for Uniparental Disomy (UPD) testing in growth retarded patients: presentation of own results by searching for UPDs 2, 6, 7, 14 and 20.** *S. Mergenthaler*<sup>1</sup>, *H.A. Wollmann*<sup>2</sup>, *P. Kloos*<sup>1</sup>, *B. Albrecht*<sup>3</sup>, *S. Spranger*<sup>4</sup>, *K. Eggermann*<sup>1</sup>, *K. Zerres*<sup>1</sup>, *T. Eggermann*<sup>1</sup>. 1) Inst Hum Genet, Technical Univ, Aachen, Germany; 2) Childrens Hospital, Univ Tuebingen, Germany; 3) Inst Hum Genet, Univ Essen, Germany; 4) Inst Hum Genet, Univ Bremen, Germany.

The association of UPD and short stature has been established for different chromosomes and in several conditions. Therefore, we investigated a cohort of 21 patients with intrauterine and postnatal growth retardation for UPD of chromosomes 2, 6, 7, 14 and 20. Additionally, a healthy female carrier of two isochromosomes 2p and 2q and a newborn suffering from neonatal diabetes mellitus (NDM) were tested for UPD2 and 6, respectively. Typing of microsatellite markers revealed maternal segmental UPD14 and maternal UPD20 in one case each. The growth retarded newborn with segmental UPD14 showed some additional clinical signs common with the putative "maternal UPD14 syndrome". The maternal UPD20 patient showed minor features. Testing of the isochromosomes carrier revealed paternal UPD2p and maternal UPD2q. The woman was healthy and of normal growth. In the growth retarded neonate with NDM paternal isodisomy 6 was detected. Based on these results and those from the literature, the following guidelines for UPD testing can be delineated: maternal UPD2 and paternal UPD2p do not seem to be correlated with growth retardation. Paternal UPD6 seems to be restricted to growth retarded patients with NDM, maternal UPD7 to Silver-Russell syndrome patients. Testing for UPD14 is useful in growth retarded patients with maternal UPD14 syndrome features (hypotonia, developmental delay, small hands, hyperextensible joints, premature puberty). Whether maternal UPD20 is a frequent finding and associated with characteristic features remains to be elucidated by screening a larger number of growth retarded patients. Nevertheless, the phenotypic transitions in UPD patients might be fluid, therefore making consideration of different UPDs difficult, particularly among newborns with IUGR and unspecific dysmorphisms. This problem is increased by the possible finding of segmental UPD, thereby leading to greater phenotypic variability.

**Co-localization of distichiasis-lymphedema-cleft palate (DLC) with distichiasis-lymphedema syndrome in**

**16q24.3.** *M. Bahuau*<sup>1</sup>, *V. Soupre*<sup>1</sup>, *B. Karcenty*<sup>1</sup>, *Y. Le Bouc*<sup>1</sup>, *R. Couderc*<sup>1</sup>, *A. Munnich*<sup>2</sup>, *M-P. Vazquez*<sup>1</sup>, *C. Houdayer*<sup>1</sup>. 1) Biochimie (M.B., R.C., C.H.), Chirurgie Maxillofaciale (M.B., V.S., B.K., M-P.V.), Explorations Fonctionnelles (Y.LB.), Hôp. Trousseau, Paris, France; 2) Génétique Médicale, Hôp. Necker Enfants-Malades, Paris, France.

In view of identifying pedigrees with monogenic cleft lip and/or cleft palate, we investigated a family showing autosomal dominant segregation of upper- and lower-eyelid distichiasis (double row of eyelashes) in seven affected relatives over three generations, in addition to below-knee lymphedema of pubertal onset (lymphoedema praecox) in three of them. Two children had cleft palate/velum in addition to distichiasis, and without the previously reported association to the Pierre Robin anomalad. Other ophthalmologic anomalies included divergent strabismus and early-onset myopia. This family appeared to feature a discrete Mendelian condition distinct from previously delineated entities such as distichiasis (MIM 126300), type-1 (Nonne-Milroy's; MIM 153100), or type-2 (Meige's; MIM 153200) hereditary lymphedema. The clinical picture presented by this family also seemed to differ from distichiasis-lymphedema syndrome (MIM 153400), a disease entity recently mapped to 16q24.3, in that pterygium colli, congenital heart disease, or facial dysmorphism were not features here. Analysis using fluorescently-labeled microsatellite markers D5S498, D5S1353, D5S1354, D5S408, and D5S2006, excluded linkage to the type-1 hereditary lymphedema locus in 5q35.3. However, analysis using markers D16S511, D16S422, D16S402, D16S3037, D16S520, and D16S3074, mapped in 16q24.3, favored linkage with a maximum two-point LOD score of 2.10 at  $q = 0$  for D16S3074. No recombination was observed between the markers studied. Neither was there evidence for haploinsufficiency that would have possibly indicated a contiguous gene syndrome. These findings are consistent with co-localization of distichiasis-lymphedema-cleft palate (DLC) with distichiasis-lymphedema syndrome in 16q24.3. Therefore, these two entities might be caused by mutations of a single, or of two closely-related gene(s).

**Wolf-Hirschhorn/Pitt-Rogers-Danks phenotype with no detectable deletion.** *F.F.B. Elder<sup>1</sup>, G.N. Colasurdo<sup>2</sup>, V.M. Rose<sup>3</sup>*. 1) Dept Pathology, The Univ TX Southwestern Med Ctr, Dallas, TX; 2) Div Pediatric Pulmonary Medicine, Dept Pediatrics, The Univ TX Houston Medical School, Houston, TX; 3) Div Medical Genetics, Dept Pediatrics, The Univ TX Houston Medical School, Houston, TX.

We present a patient with features consistent with Wolf-Hirschhorn/Pitt-Rogers-Danks (WHS/PRDS) phenotype but without a detectable deletion of 4p16.3 by either chromosome analysis or by fluorescence in situ hybridization (FISH). No deletions were found by FISH using a commercially available probe to the WHS critical region as well as 9 cosmid probes (provided by Dr. Michael R. Altherr, Genomics Group, Life Sciences Division, Los Alamos National Laboratory) spanning the WHS critical region. This 46 month old dysmorphic female from El Salvador presented with recurrent pulmonary infiltrates and failure to thrive. She was a term infant weighing 2.4 kg (5th%). She has short stature, microcephaly, moderate mental retardation with speech and language delay, a high forehead with a broad nasal bridge, telecanthus, slightly upslanting palpebral fissures, proptosis, simple protruding ears, short philtrum, wide mouth with down-turned corners and thin upper lip, micrognathia, and 5th finger clinodactyly bilaterally. She has not had seizures and does not have a cardiac defect.

Patients with PRDS have been demonstrated to have deletions of the 4p16.3 region, and PRDS is thought to be a less severe form of WHS. A few patients with PRDS but without detectable deletions have been reported. It is possible that these patients have a point mutation in the WHS gene. Our patient's phenotype appears to correspond with the milder end of the WHS/PRDS phenotypic spectrum.

Recurrent pulmonary infections and transient IgA deficiency have been described in a patient with WHS. Our patient had recurrent respiratory symptoms and interstitial infiltrates on chest radiographs. A lung biopsy revealed eosinophilic pneumonia which has not previously been associated with WHS. She was treated successfully with steroids.

**Analysis of the p63 Gene in Classic EEC Syndrome, Related Syndromes, and Nonsyndromic Orofacial Clefts.**

*L.L. Barrow*<sup>1</sup>, *S. Daack-Hirsch*<sup>2</sup>, *T. Faaborg*<sup>2</sup>, *H. van Bokhoven*<sup>3</sup>, *J.C. Murray*<sup>2</sup>. 1) Dept Otolaryngology, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA; 3) Dept Human Genetics, Univ Hospital Nijmegen, Nijmegen, The Netherlands.

EEC syndrome is an autosomal dominant disorder with the cardinal signs of ectrodactyly, ectodermal dysplasia, and orofacial clefts. Five families with EEC syndrome were recently linked to chromosome 3q27, and heterozygous p63 mutations were detected in nine unrelated EEC families (Celli et al, 1999). Homozygous p63 null mice exhibit craniofacial abnormalities, limb truncations, and absence of epidermal appendages such as hair follicles and tooth primordia (Mills et al, 1999; Yang et al, 1999). In this study, we screened 39 syndromic patients, including four with EEC syndrome, five with syndromes closely related to EEC syndrome, and 30 with other syndromic orofacial clefts and/or limb anomalies. We identified heterozygous p63 mutations in three unrelated cases of EEC syndrome, two Iowa Caucasian families and one sporadic case in a Filipino boy. One mutation ablates a splice acceptor site, and two mutations produce amino acid substitutions, R280C and R304Q, that alter conserved DNA binding sites. Germline mosaicism was detected in one case. The three cases demonstrate significant interfamilial and intrafamilial variability in expressivity. EEC patients with heterozygous p63 mutations presented with both isolated clefts of the secondary (soft) palate and clefts of the lip and primary (hard) palate. Genetics and embryology suggest that isolated clefts of the secondary palate may be a distinct clinical entity from clefts of the primary palate that involve the lip with or without the palate (Schutte and Murray, 1999), implicating p63 as an early gene in development prior to an important bifurcation in palatogenesis. We also screened p63 in 62 patients with nonsyndromic orofacial clefts, identifying an intronic single nucleotide polymorphism but finding no evidence of mutations that would explain even a subset of nonsyndromic orofacial clefts. This study supports a common role for p63 in classic EEC syndrome, both familial and sporadic, but not in other related or nonsyndromic forms of orofacial clefts.

**Micrognathia, midfacial hypoplasia, hypotonia and severe developmental delay in brothers. A new X-linked or autosomal recessive condition?** *R. Babul-Hirji*<sup>1,3</sup>, *D. Chitayat*<sup>1,2,3</sup>, *A. Toi*<sup>2,3</sup>. 1) The Hospital for Sick Children, Toronto, ON., Canada; 2) The Mount Sinai Hospital, Toronto, ON., Canada; 3) The University of Toronto, Toronto, ON., Canada.

Although micrognathia is associated with numerous syndromes, the occurrence of severe micrognathia, developmental delay and hypotonia has not been previously reported. We report two brothers with the constellation of these findings. The first pregnancy was terminated after micrognathia was detected prenatally and the second pregnancy resulted in a newborn with micrognathia, hypotonia and severe delay. The mother was a 33-year-old primigravida woman and the father was 32 years old. The couple was non-consanguineous, healthy and their family histories were non-contributory. The first pregnancy was complicated with fetal ultrasound finding of severe micrognathia. The couple decided to terminate the pregnancy and this was done at 23 weeks gestation. Fetal autopsy revealed severe micrognathia, short forehead, midfacial hypoplasia and posteriorly rotated ears. The second pregnancy, which we did not follow, resulted in a newborn with severe micrognathia, posteriorly inserted tongue, high arched and intact palate and midfacial hypoplasia. He was hypotonic and later showed severe global delay. The brothers' karyotypes were normal and male, including FISH for 22q11.2 on the living male. Metabolic investigations done on the living brother showed no abnormalities. This is a hitherto new syndrome not reported previously that includes severe micrognathia with intact palate, midfacial hypoplasia and severe global developmental delay with hypotonia. The inheritance may be autosomal recessive or X-linked with prenatal diagnosis being possible.

**Osteoglophonic dysplasia: Radiographic and pathologic features of a neonatal lethal form.** *D.K. Grange, D.S. Brink, A. Luisiri, F. Sadiq, C. Sotelo-Avila.* Saint Louis University School of Medicine, St. Louis, MO.

We report an infant with a lethal form of osteoglophonic dysplasia, an autosomal dominant skeletal dysplasia characterized by craniosynostosis, rhizomelic shortening of limbs, lucent metaphyseal defects, bowing of long bones, and vertebral abnormalities. Lytic bone lesions contain fibrous tissue. The patient was born at 36 weeks gestation to normal parents. She had macrocephaly and a Kleeblattschaedel skull deformity, a tiny thorax and marked rhizomesomelic shortening of the limbs. Facial features were coarse with proptosis, depressed nasal bridge, protruding tongue and severe micrognathia. Respiratory failure lead to death at age 4 days. Radiographs showed craniosynostosis of coronal, sagittal, parieto-mastoid and squamosal sutures. There was extreme hypoplasia of the mandible. The ribs were very short and clavicles were markedly hypoplastic. Bowing of the femurs and tibiae was present, with an apparent fracture of the right femur. There was endosteal thickening of the medial cortex of the long bones. Proximal metaphyses of both humeri had cleft-like lesions. There was brachydactyly with angel-shaped phalanges, seen in only one of the eight previously reported cases of osteoglophonic dysplasia. Lytic lesions of the proximal and distal metaphyses were present in phalanges, metacarpals and metatarsals. On pathological examination, there was abnormal endochondral ossification with poorly formed physes. Fibrous tissue was present within the metaphyses and diaphyses of multiple bones. In the phalanges, the bone trabeculae were dense and the metaphyseal lytic lesions corresponded to replacement of bone by masses of fibrous connective tissue. In the right femur, in the region of the apparent fracture, continuity of bone was interrupted by fibrous connective tissue and osteoid in a fibrous dysplasia-like pattern. The distal epiphysis and metaphysis of the humerus had a large synovial-lined cyst that communicated with the joint space and was surrounded by dense fibrous tissue. This case expands the spectrum of the radiographic and pathologic features of osteoglophonic dysplasia and may contribute to the understanding of the pathogenesis of this rare disorder.

**Ellis van Creveld syndrome (chondroectodermal dysplasia MIM 22550) in three siblings from a non-**

**consanguinous mating.** *E. George*<sup>1</sup>, *E. Lieber*<sup>1,2</sup>. 1) Department of Pediatrics, New York Methodist Hospital, Brooklyn, NY; 2) Department of Medicine(Division of Genetics), New York Methodist Hospital, Brooklyn, NY.

Ellis van Creveld syndrome (EvC), is a rare autosomal recessive condition. Approximately 200 cases have been described in the literature - half of them within a subgroup of the Amish population in Pennsylvania. The syndrome includes features of acromelic and mesomelic shortening of long bones, postaxial polydactyly, nail dysplasia, and dental anomalies. We describe three siblings with EvC from a non-consanguinous mating of Ashkenazi Jewish origin. All the siblings had classic features of EvC. Two of the patients had complications that are seen in EvC. The first daughter died at nineteen days of life with respiratory failure secondary to a narrow rib cage. The second daughter underwent open-heart surgery for repair of atrial septal defect. The third daughter, the proband, was diagnosed prenatally with fetal ultrasonography at 25 weeks of gestation. The sonogram revealed short extremities, a narrow rib cage, and polydactyly. The infant was born by vaginal delivery at 42 weeks of gestation. She is scheduled for surgical removal of bilateral extra digits and extraction of natal teeth. The differential diagnosis of EvC includes Jeune's asphyxiating thoracic dysplasia (JATD), Weyers acrodistal dysostosis, and short rib polydactyly syndrome. The mutant gene in individuals with EvC has recently been identified on chromosome 4p16, proximal to other genes associated with conditions of short stature (classic achondroplasia, Weyers acrodistal dysostosis) and other skeletal disorders. Five different mutations have so far been characterized. It is plausible to assume, that a range of mutations in the critical gene is responsible for the variation of phenotypic expression in EvC.

**A new association comprising distinctive facies, chest deformity and camptodactyly with normal thrive and normal intelligence.** *H. Chaabouni<sup>1,2,3</sup>, M. Chaabouni<sup>2,3</sup>, F. Maazoul<sup>3</sup>, N. Smaoui<sup>2,3</sup>, L. Ben jema<sup>2,3</sup>, R. Mrad<sup>2,3</sup>.* 1) El Menzah 1XA, Tunis, Tunisia; 2) Laboratory of Human Genetics. Medical School Tunis, Tunisia; 3) Department of Hereditary Diseases .Charles Nicolle hospital. Tunis, Tunisia.

We report the clinical findings in a 14 years-old Tunisian boy with distinctive facial dysmorphism, chest deformity ; camptodactyly , with normal stature and normal intelligence. Abnormal facies findings are proptosis, down-slanting palpebral fissures, hyperterolism, broad nasal tip with large nostrils, hypoplastic maxillary with thin upper lip, delayed eruption of teeth , dental malocclusion , high narrow palate and malformed ears. The skull is characterised by flat occiput. The child has severe pectus excavatum and bilateral camptodactyly of second, third and fourth fingers. External genitalia examination is normal. Radiographic studies of hands, feet, skull and chest showed reported deformities without bone or cartilage lesion. The karyotype is normal. The clinical features have been observed in neonate and there is no evolutive variation. His mother has few same features : proptosis ,dental malocclusion, thin upper lip and she has partial conductive deafness. This pattern is concordant with dominant inheritance and variable expression of the syndrome. We suggest that this is a new association that has not been described previously in the literature.

**Symptoms of Schizophrenia in adults with 22q Deletion Syndrome.** *A.S. Bassett<sup>1</sup>, E. Chow<sup>1</sup>, L. Scutt<sup>1</sup>, P. AbdelMalik<sup>1</sup>, K. Hodgkinson<sup>1</sup>, R. Weksberg<sup>2</sup>.* 1) Dept Psychiatry, CAMH, QSD, Univ Toronto, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, HSC, Toronto, ON, Canada.

22q Deletion Syndrome (22qDS), including velocardiofacial and DiGeorge syndromes, is associated with 22q11 deletions, and has an increased prevalence of schizophrenia (SZ). Objective: To determine whether the pattern of schizophrenic symptoms differed in 22qDS from other forms of SZ and whether childhood functioning was associated with outcome in adults with 22qDS. Methods: 17 subjects with 22qDS and SZ were compared with 16 age- and sex-matched subjects from a familial SZ sample. All subjects were assessed for symptoms of schizophrenia using a standard scale (PANSS); 22qDS-SZ subjects were also assessed using the Premorbid Adjustment Scale for social functioning in childhood/adolescence. Results: There were no significant differences between 22qDS-SZ and familial SZ groups in median age at onset of schizophrenia (20 y vs. 22 y), global functioning, or negative (e.g., social withdrawal) or mood (anxiety/depression) symptom scores. The 22qDS-SZ group had higher excitement symptom (e.g., poor impulse control) ( $z=2.5$ ,  $p=0.01$ ) and cognitive (e.g., abstract thinking) ( $z=3.2$ ,  $p=0.001$ ) symptom scores. In the 22qDS-SZ group there was a significant correlation between poor childhood social functioning and negative symptoms in adulthood ( $r=0.67$ ,  $p=0.008$ ). Conclusions: The results suggest that 22qDS-SZ may not be easily distinguishable in SZ populations based on clinical psychiatric symptoms. Poor childhood social functioning may be associated with enduring symptoms in individuals with 22qDS who develop schizophrenia.

**Hypoparathyroidism: The link between femoral-facial syndrome and maternal diabetes.** *B.N. Chodirker<sup>1,2</sup>, A. Chiu<sup>1</sup>, S.M. Menticoglou<sup>3</sup>*. 1) Pediatrics and Child Health, University of Manitoba, Winnipeg, MB., Canada; 2) Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, MB., Canada; 3) Obstetrics and Gynecology, University of Manitoba, Winnipeg, MB., Canada.

A 36 year old Aboriginal Canadian woman was seen at 29 weeks gestation when a prenatal ultrasound examination documented significant fetal femoral bowing. The femurs appeared thin and shortened. No other fetal anomalies were identified at that time. Family history was unremarkable. She was on insulin as she had been diabetic since age 19. Her diabetes control was poor. The initial prenatal blood glucose at 10 weeks gestation was 17 mmol/L. Biochemical testing showed that she had normal serum levels of calcium, phosphate, alkaline phosphatase and 25-hydroxy vitamin D. Her parathyroid hormone (PTH) level was low at 5 ng/L (normal range 12-72). At 36 weeks, she delivered an infant girl with typical features of femoral facial syndrome (FFS). Birth weight was 3480 grams (95 %tile). There was significant micrognathia. There was a cleft of the soft palate. The baby required intubation after birth due to airway obstruction. Skeletal survey confirmed short bowed femurs but did not detect any other significant anomaly. Neonatal problems included hypoglycemia, hypocalcemia and hypophosphatemia. Serum magnesium was low normal at 0.62 mmol/L (normal 0.5- 1.2). A serum PTH level was initially low normal (15 ng/L). The medical literature supports the following: Infants of diabetic mothers (IDM) are at increased risk for various congenital anomalies e.g. caudal regression. These are thought to result from poor glucose control early in pregnancy. FFS is associated with maternal diabetes. PTH levels are lower in diabetic women in pregnancy compared to non-diabetic women. Hypocalcemia in IDM is thought to be due to failure to increase PTH synthesis after birth possibly secondary to hypomagnesemia. Bone mineral density is significantly decreased in infants of diabetic mothers. Fetal parathyroids are needed to maintain increased calcium levels and stimulate fetal osteoblasts and bone mineralization. These findings along with the features of this case support a role for hypoparathyroidism in the pathogenesis of FFS.

**The adult phenotype of Meier-Gorlin syndrome (ear-patella-short stature syndrome) with comparisons to previous cases.** *G.C. Gowans<sup>1</sup>, M. Pelletier<sup>1</sup>, M. Tanzer<sup>2</sup>, F.C. Fraser<sup>1</sup>.* 1) The F. Clarke Fraser Clinical Genetics Unit, Departments of Pediatrics and Human Genetics, Montreal Children's Hospital and McGill University, Montreal, QC, Canada; 2) Department of Orthopaedics, Montreal General Hospital, McGill University, Montreal, QC, Canada.

We report a 39-year-old man of normal intellect with microcephaly, a small triangular-shaped face, bilateral microtia, maxillary and mandibular hypoplasia, unilateral cryptorchidism, and absent patellae among other anomalies. The proportionate short stature, characteristic and distinct craniofacial appearance, small, simple and low-set ears, and absence of patellae correspond to most previous reports of Meier-Gorlin syndrome (MGS) or Ear, Patella, Short stature syndrome (MIM #224690). However, with only approximately a dozen cases of this syndrome in the literature, there has been some question as to what constitute "cardinal" signs or symptoms. Some cases included as representative of MGS do not have the distinctive small and simple ears reported in the original patient of Meier et al. (1959) or in the second patient reported by Gorlin (1975 and 1992). The absence of patellae reported in these original two patients are not obligate findings since hypoplastic and normal patellae have been found in patients considered to have MGS. In addition, the adult phenotype of MGS has rarely been described and therefore the natural history of clinical manifestations is not well known. We compare the clinical manifestations of our patient with those reported in children and adults thought to have this short stature syndrome in order to further delineate MGS. We also describe the knee arthroplasty used to treat our patient.

**Pleiotrophy or coincidence: unusual findings in DiGeorge/velocardiofacial syndrome (DGS/VCFS).** *L.P. Cook<sup>1</sup>, L.E. Walsh<sup>1,2</sup>, J.K. Hartsfield, Jr.<sup>1,3</sup>*. 1) Dept Med & Molec Genetics, Indiana Univ Sch Med, Indpls., IN; 2) Dept Neurology, Indiana Univ Sch Med, Indpls., IN; 3) Dept Oral-Facial Development, Indiana Univ Sch Dentistry, Indpls., IN.

We report two patients with DGS/VCFS who also had findings not usually associated with this disorder. Patient 1 was a 2-week-old boy born after pregnancy complicated by gestational diabetes requiring insulin. Physical findings included downslanting palpebral fissures, prominent nose, micrognathia with intact palate, dysplastic ears, systolic murmur, closed omphalocele with large inguinal hernias, camptodactyly, and bilateral equinovarus deformity. Initial karyotype (46, XY), head CT scan, and renal ultrasound were normal. Echocardiogram showed an abnormal right subclavian artery. Subsequent evaluation of the child's mother revealed history of depression, hypernasal speech, ventriculoseptal defect (VSD), and borderline hypocalcemia. DGS FISH analyses demonstrated 22q11 deletion in both child and mother. Patient 2 was a 6-year-old boy, the product of an unremarkable pregnancy. By age 6 months, he was found to have ASD and VSD. Recurrent infections and hypocalcemia prompted discovery of a hypoplastic thymus and parathyroid glands. His facial features suggested DiGeorge syndrome, but his mother deferred further genetic testing. At age 3 years, he was developmentally delayed, especially in language, borderline microcephalic, and preferentially used his left hand. A brain MRI showed an isolated Dandy-Walker malformation. At age 5 years, he was microcephalic, spoke 6 words, but used sign language well. DGS FISH analysis revealed microdeletion of 22q11. Karyotype was normal (46, XY) otherwise. Omphalocele has not been reported previously in the literature with VCFS; Dandy-Walker malformation has been reported once in DiGeorge syndrome complicated by further findings of CHARGE association. It is possible that our patients' unusual manifestations were caused by their underlying microdeletions. The presence of such dramatic malformations may overshadow more subtle, but more diagnostic abnormalities in DGS/VCFS and should not preclude specific genetic testing for the disorder.

**Are Hypotrichosis Simplex and Monilethrix Allelic Forms?: Description of a Mexican family.** *N. Davalos<sup>1,2,3</sup>, I.P. Davalos<sup>2</sup>, B. Patiño-García<sup>1,2</sup>, A. García-Vargas<sup>3</sup>, V. Tarango-Martínez<sup>3</sup>, M.E. Sánchez-Castellanos<sup>3</sup>, I. Villarreal<sup>3</sup>, D. García-Cruz<sup>1,2</sup>, A. Feria-Velazco<sup>4</sup>, J.M. Cantu<sup>1,2</sup>, L.E. Figueroa<sup>1,2</sup>.* 1) Div. Genética y Medicina Molecular, CIBO-IMSS, Guadalajara, Mexico; 2) Doctorado Genética Humana, CUCS, UdeG, Guadalajara, Mexico; 3) Instituto Dermatológico de Jalisco José Barba Rubio. Guadalajara, Jalisco Mexico; 4) CIATEJ, Guadalajara, Jalisco, Mexico.

We describe a Mexican family with 19 affected individuals through five generations, presenting a hair characterized by defect limited to the scalp. Clinically the 11 year-old proposita was normal at birth. Between 9-10 years of age displayed hypotrichosis. The hairs were sparse, thin, light, and short and were not easily plucked. Dental defects, other nail or sweat gland disorders and mental retardation were excluded. Psychomotor development was normal. Laboratory tests including complete blood count, urine analysis, metabolic screening were all in the normal range. Karyotype analysis gave no evidence of chromosomal abnormalities. Microscopic examination of the hair showed delicate hairs with irregular pigment distribution, structural defects varying reduced shaft diameters. The other 18 affected individuals (ranging from 11 to 60 years of age) were examined, showing similar characteristics, and no other associated features, all of them had on-set of the trait at 8-11 years of age. Hypotrichosis is a common feature of many inheritable disorders, among them are hypotrichosis simplex and monilethrix. They have been differentiated based on the beading of the hair only present in monilethrix. The family here presented has shown an irregular diameter pattern in some of the analyzed hair shafts, but not in others. Given the intermediate clinical features displayed by the affected individuals we propose both entities could be considered alleles having different mutations at the same locus.

**Assessment of variation in clinical outcome and mechanisms underlying mosaic Down Syndrome.** *N. Gursoy<sup>1</sup>, G. Hill<sup>1</sup>, A. Gregory<sup>1,2</sup>, B. Landa<sup>1</sup>, A. Pandya<sup>1</sup>, L. Vanner<sup>1</sup>, C. Jackson-Cook<sup>1</sup>.* 1) Department of Human Genetics, Medical College of Virginia Campus, Richmond, VA; 2) DNA Dynamics, Inc., Del Mar, CA.

Mosaicism for trisomy 21 is seen in only 1%-2% of all individuals with Down syndrome. Factors contributing to variations in phenotype for people with mosaic Down syndrome (MDS) are not well understood. To assess this variability in clinical outcome and mechanism underlying MDS, we performed a multidimensional project. To date, we have studied 44 cases of MDS (along with their parents and sibs), ranging in age from 4 months to 33 years. The information collected for the MDS cases included the: (1) proportion of lymphocytes (cultured and uncultured) and buccal mucosa cells that were trisomic; (2) physical and developmental outcome; and (3) cellular timing of the malsegregation resulting in the observed mosaicism. Using FISH to enumerate the chromosomes 21, no significant difference in the percentage of cells having a trisomic complement was detected between cultured and uncultured lymphocytes. In contrast, the proportion of trisomic cells in the buccal mucosa cells was different from that of lymphocytes ( $p < 0.001$ ), with a trend toward higher levels of trisomic cells being seen in the buccal cells. The proportion of trisomic cells in our cohort ranged from 16%-97%. In general, the highest level of trisomy identified (either in lymphocytes or buccal smears) led to a higher correlation with clinical outcome. A trend toward increased severity was noted in the individuals having higher levels of trisomic cells. In particular, two-thirds (7/11) of all patients having congenital heart anomalies had trisomy levels of >75%. Differences in the chromosomal malsegregation events leading to mosaicism, assessed using SSR DNA markers, were also seen and included cases arising from (1) both a meiotic and mitotic nondisjunctional event; or (2) a single mitotic error. To date, no clear correlation has been detected between clinical outcome and mechanisms of the chromosomal malsegregation. In summary, by studying a large group of individuals with mosaicism we hope to improve our understanding of the observed diversity in people having MDS, as well as the causes of chromosomal malsegregation.

**A new MR syndrome associated with bilateral global colobomas, cleft palate, cerebral, skeletal and genital anomalies in three brothers.** *S. Cappon, M. Khalifa.* Dept Pediatrics and Pathology, Queen's University and Kingston General Hospital, Kingston, Ontario, Canada.

We describe three Native Canadian brothers of a sibship of six with a previously undescribed pattern of malformations, including bilateral colobomas, cleft palate, craniofacial anomalies, skeletal defects, hypospadias with bifid scrotum and severe psychomotor retardation. The proband is currently five years old and has an associated heart defect (VSD and mild right pulmonary venous stenosis). Eye examination revealed bilateral iris and chorioretinal colobomas and right optic disc coloboma. MRI of the head was significant for polygynea, cortical dysplasia and shallow orbits. Hearing test was normal although no speech has developed to date. The chromosomes were normal. The next son was full term and had identical facial, cranial, skeletal and genital anomalies. He also had a diaphragmatic hernia, identified prenatally. His chromosome study was normal as well as FISH for 22 deletion. He died shortly after birth because of pulmonary hypoplasia. The third son is ten months old with the same facial anomalies, colobomas, cleft palate, triangular face, widely separated sutures, skeletal and genital anomalies. A skeletal survey showed brachycephaly, metaphyseal flaring, wormian bones, and 11 sets of ribs. His cytogenetic study was normal. To our knowledge, this constellation of abnormalities has not been described before. The inheritance pattern could be consistent with an X-linked or autosomal recessive disorder.

Program Nr: 614 from the 2000 ASHG Annual Meeting

**von Voss-Cherstvoy syndrome: A second family with affected siblings.** *N.S.N. Gilpin.* Dept Pediatrics, Christie Clinic Assoc, Champaign, IL.

von Voss-Cherstvoy syndrome, sometimes referred to as DK Phocomelia, is a multiple congenital anomaly syndrome of occipital encephalocele, radial ray defects and urogenital anomalies. This report describes an Amish family with 2 consecutive affected children. This is the second family reported with affected siblings, supporting the theory of autosomal recessive inheritance and allowing further delineation of the syndrome. Development appeared arrested at 18 to 20 weeks gestation. Chromosome and platelet studies were normal. von Voss-Cherstvoy syndrome is attributed to a gene controlling early development.

**The association between paternal alcohol exposure and Turner syndrome(TS): Preliminary results of a health and lifestyle survey of parents of children with TS.** *S. Kagan<sup>1</sup>, S. Vohra<sup>1</sup>, G. Koren<sup>1</sup>, P. Selby<sup>1,2</sup>.* 1) Department of Clinical Pharmacology and Toxicology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Center for Addiction and Mental Health, Toronto, Ontario.

TS is a sex chromosome aneuploidy that occurs as a result of a nondisjunctional error in meiosis I or anaphase lag; however, the etiology of this disorder remains unknown. Anecdotal evidence suggests that paternal alcoholism may play a role in the etiology of Turner syndrome (TS). Accordingly, the objectives of this study were: (1) to determine the potential association between paternal alcohol exposure and TS; and (2) to determine the potential association between selected health and lifestyle behaviors of the parents and TS. This descriptive study employed a self-report survey methodology. The questionnaire was designed to solicit information about the parents' health and lifestyle habits occurring one year prior to and throughout the pregnancy of their daughter with TS. The primary outcome measure included in the questionnaire was the Brief Michigan Alcohol Screening Test (BMAST). The remainder of the questionnaire included questions about 5 other health and lifestyle behaviors that were determined by clinical experts to be relevant to the objectives of this study. The study population was solicited from the Turner's Syndrome Society of Canada and included any parent(s) having a child with TS who was of any age. The questionnaires were mailed to 245 families and 212 families completed and returned the survey (86.5% response rate). Six of the fathers (3.6% n=166) and six of the mothers (3.6% n=165) had scores of 5 or more on the BMAST (scores of 5+ are considered to be in the "alcoholic range"). This is considerably lower than the population norm of 9.5%. An interesting finding suggested that 54% of the fathers and 36% of the mothers reported that they had been exposed to two or more environmental hazards. Our study has not indicated that there is a potential association between paternal or maternal alcohol consumption and TS. However, we were surprised to learn that a previously unidentified association between exposure to environmental hazards and TS may exist.

**Unilateral ocular malformations, postaxial polydactyly and delayed intramembranous ossification; a new autosomal dominant condition.** *D.M. Martin<sup>1</sup>, J.L. Gorski<sup>1,2</sup>*. 1) Department of Pediatrics, The University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, The University of Michigan, Ann Arbor, MI.

Molecular genetic analysis has substantially enhanced our understanding of eye embryogenesis. Uniformly, of the genes identified in ocular development, mutations result in bilateral malformations and disease. Here we present a family segregating unilateral ocular malformations in association with postaxial polydactyly and delayed intramembranous ossification. This family was referred for evaluation of multiple congenital anomalies. The father exhibited unilateral microphthalmia, retinal coloboma, scleralized cornea and abnormal iris, nonosseous unilateral postaxial polydactyly, and delayed closure of the anterior fontanelle. His growth and cognition were normal. His first son, age 2 at initial presentation, displayed unilateral postaxial polydactyly, delayed closure of the anterior fontanelle, and unilateral talipes equinovarus requiring surgical correction, with normal growth and development. His second son, age 5 months, presented with unilateral congenital glaucoma, postaxial polydactyly, and a large anterior fontanelle. Skeletal survey revealed delayed intramembranous ossification. No shortened or abnormally formed skeletal elements were identified. His growth and development were normal. Both sons had normal peripheral karyotypes and thyroid function tests. We conclude that this family appears to be segregating a trait that adversely affects ocular development and intramembranous ossification, with male to male transmission suggesting autosomal dominant inheritance.

**New Family Member in Previously Reported Autosomal Dominant Vertebral Hypersegmentation Pedigree Increases Likelihood of Association with Cleft Lip and/or Palate.** *K.B. Nash, A. Sommer, A.C. Lidral.* Ohio State University and Children's Hospital, Columbus, OH.

Autosomal dominant vertebral hypersegmentation has only been described in 1 family (Sommer, 1993). The male proband with 8 cervical and 6 lumbar vertebrae and 14 ribs was ascertained at birth upon chest X-ray for hyaline membrane disease. The family reported that the proband's father and the father's sister also had extra ribs. Subsequent X-ray of the father showed identical hypersegmentation of vertebrae and ribs as the proband. The aunt reports that her extra ribs were confirmed at age 9 y. when she was X-rayed after an accident. Her son also appears to be affected with a disproportionately long torso. An interview with the paternal grandmother revealed that she too had the same hypersegmentation. At that time, a complete work up of the proband revealed no additional abnormalities. The affected relatives reported no other clinical manifestations, except that the father had unilateral left cleft lip and palate (LCL+P). Since cleft lip with or without cleft palate (CL±P) is a common birth defect (1/1000), it was unclear whether this was an incidental finding representing nonsyndromic CL±P.

We now report on the proband's new sister who has the same radiological findings of 14 thoracic vertebrae and ribs, as well as LCL+P. In addition, the affected aunt reports having had a pharyngeal flap put in place at age 21 y. to improve hypernasal speech, which may be a manifestation of the cleft palate spectrum (CP). Nonsyndromic CL±P and CP are distinct genetic entities, occurring at different times during development, and usually not occurring in the same family. To the contrary, several pleiotropic syndromes show CP or CL±P occurring within families.

In summary, we report a family with apparent autosomal dominant hypersegmentation with 2 of the 5 affected members having overt cleft lip and palate and another with symptoms often associated with cleft palate. It is unclear whether these are two independent traits segregating in the family or whether the two traits are etiologically related.

**Partial trisomy 12 and 13 in a newborn.** *J.G Habecker-Green<sup>1</sup>, V.L Ramie<sup>1</sup>, R. Naeem<sup>3</sup>, L. Bayer-Zwirello<sup>2</sup>, G.M Cohn<sup>1</sup>.* 1) Clinical Genetics, Baystate Medical Center, Springfield, MA; 2) Maternal Fetal Medicine, Baystate Medical Center, Springfield, MA; 3) Cytogenetics, Baystate Medical Center, Springfield, MA.

We present a case report of a unique chromosomal syndrome. A 25-year-old, pregnant female of Puerto Rican ethnicity presented to genetics at 28 weeks gestation for the ultrasound finding of fetal tetralogy of Fallot and a vertebral anomaly. History information indicated that she had had three unexplained first trimester pregnancy losses, and had never been evaluated for peripheral karyotype. Amniocentesis was discussed and declined. Karyotypic analysis of the patient was discussed and accepted. The patient's karyotype was 46,XX,t(12;13)(q24.3;q14). This information was discussed with her, along with the possibility that the fetal karyotype could be unbalanced. The patient chose to analyze the fetal karyotype through amniocentesis. Fetal karyotype was 47,XX,+der(13)(12;13)(q24.3;q14). It was discussed with the patient that previous case reports of this chromosomal anomaly could not be located, so prognostic information was limited. However, with large, unbalanced chromosomal segments, we expected a greatly increased risk for neonatal mortality and for mental retardation in survivors. This and her options for neonatal management were discussed with the mother. The mother chose to have her child treated as clinically indicated.

The infant was born at 39.6 weeks gestation, and required resuscitation. She weighed 5 lb 5 oz, and the following features were noted: posteriorly sloping forehead with midline crease, broad nasal root, micrognathia, excess nuchal skin, generalized loose skin, fistled hands, diastasis recti, a prominent clitoris, and a right rocker bottomed foot. Renal, head, and abdominal ultrasounds were normal. Echocardiography confirmed tetralogy of Fallot. Neurology evaluation was significant for hypotonia. Currently the child is 6 months of age and has developmental delays and growth retardation. Other case reports of either patients' karyotype have not been located.

**A new genetic malformation syndrome characterized by microcephaly, jejunal atresia, and XY sex reversal.** *C.E. Keegan, J.W. Innis.* Dept Ped Gen, 1924 Taubman Ctr, Univ Michigan, Ann Arbor, MI.

The patient is a female infant born at 32 weeks gestation to a non-consanguineous couple by spontaneous vaginal delivery. She was evaluated by Genetics secondary to microcephaly, with a birth OFC of 25 cm, and jejunal atresia. No other dysmorphic features were noted on physical examination. Karyotype revealed a 46 X,Y male chromosomal complement. Endocrinologic evaluation revealed testosterone levels in the normal range for a male infant. Androstenedione, cortisol, DHEA, 17-OH pregnenolone, and 17-OH progesterone were normal. Ultrasonography and MRI revealed a primitive gonad on the left and a retrovesicular fluid-filled cyst, most likely a Mullerian remnant. No definitive uterus or ovaries were identified. Jejunal atresia was repaired in the neonatal period by excision of the atretic segment and end-to-end anastomosis. Upon re-evaluation at age 7 months, her head circumference was still less than the 5th centile at 36 cm. Genitourinary exam showed clitoromegaly. Development was normal for corrected gestational age. A high-resolution prometaphase karyotype was normal. SRY mutational testing and 7-dehydrocholesterol are currently pending. Removal of the primitive gonad is planned. The sex reversal phenotype in this patient is most consistent with mixed gonadal dysgenesis although partial androgen insensitivity cannot be excluded. This constellation of findings represents a previously undescribed syndrome associated with sex reversal.

**Facial Dysgenesis: A new facial syndrome with absent eyes and palpebral fissures, presence of proboscis, square stoma and clefting.** *J.E. Hoover<sup>1</sup>, J. Cai<sup>1</sup>, C.B. Cargile<sup>2</sup>, G.H. Thomas<sup>2</sup>, E.W. Jabs<sup>1</sup>, A. Hamosh<sup>1</sup>*. 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

We report a female infant with primary anophthalmia and cryptophthalmos, temporal remnant "eye tags", bilateral cleft lip, unilateral cleft palate, choanal atresia, bilateral external auditory canal atresia, grossly normal brain by MRI and an interstitial deletion of chromosome 7. The pregnancy was complicated by polyhydramnios, breech presentation, and premature rupture of membranes and fetal bradycardia at 33 weeks gestation necessitating C-section. Her birth weight and head circumference were at the 5%tile. She transferred to our institution at 22 days of life with a tracheostomy and poor gain in weight, length and head circumference. Grossly her limbs, trunk and genitalia were normal. Skeletal survey, echocardiogram and abdominal viscera were normal except for a split central sinus of the right kidney. BAER exam indicated she could hear and temporal CT confirmed the presence of cochlea and possible ossicles. She died at six months of age from sepsis/airway obstruction precluding evaluation for craniosynostosis or cognitive impairment. Cytogenetic studies revealed a deletion of chromosome 7, del(7)(p15.1p21.1) at 650-band resolution. By FISH using BAC370M10 (188 kb) as a probe, one allele of the TWIST gene was found to be deleted. No mutations were detected upon sequencing the coding region of the other TWIST allele. Parental karyotypes and phenotypes were normal. There are no other reported patients with bilateral anophthalmia, cryptophthalmos and a grossly normal brain, limbs and genitalia. Furthermore, patients with chromosome 7 deletions that overlap or include that of our patient do not have anophthalmia, cryptophthalmos or external auditory canal atresia. These data suggest that this clinical presentation, which is similar to but distinguishable from Fraser syndrome, may be caused by a bi-allelic mutation in this interval in a single gene other than TWIST.

**Phenotypic characteristics of Warrdenburg syndrome type I and type III in a family.** *D. Lin, S. Lin.* Dept Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan.

Warrdenburg syndrome is an autosomal dominantly inherited disorder with variable penetrance. The major characteristics features are as follows: 1)Dystopia canthorum; 2)synophrys; 3)broad nasal root 4)pigmentation of hair , skin, or both; 5)heterochromic or hypochromic irides; 6)congenital deafness. Genetic heterogeneity has led to classification of affected families as type I (WS-I), with dystopia canthorum, or type II, without dystopia canthorum. Klein-Warrdenburg syndrome (WS-III) is a disorder with many of the same characteristics as WS-I and includes musculoskeletal abnormalities. We report otherwise typical WS-I and WS-III in a family, 3 females with WS-I and 2 males with WS-III. All affected members demonstrated dystopia canthorum, synophrys, and broad nasal root, and both WS-II had clinodactyly and contracture digits. Other characteristics features including: hypoplastic blue irises affected 1 WS-I and both WS-III, a unilateral sensorineural hearing loss in both WS-III and a bilateral sensorineural hearing loss in 1 WS-I, and pigmentary disturbance in 1 WS-III. To our knowledge, both WS-I and Ws-III in a family has not been previously reported in Warrdenburg syndrome.

**Molecular Studies in Patients with Rare Craniosynostosis Syndromes: Pseudoaminopterin, Shprintzen-Goldberg.**

*D.M. McDonald-McGinn<sup>1</sup>, M. Straka<sup>1</sup>, R. Kirschner<sup>2</sup>, L. Whitaker<sup>2</sup>, S. Bartlett<sup>2</sup>, C. Stolle<sup>3</sup>, K. Gripp<sup>1,3</sup>, E.H. Zackai<sup>1,3</sup>.*

1) Division of Human Genetics and Molecular Biology; 2) Plastic and Reconstructive Surgery, The Children's Hospital of Philadelphia (CHOP); 3) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA.

44% of patients with craniosynostosis seen in the Craniofacial Clinic at CHOP were noted to have classical syndromes and have a confirmed molecular etiology. Amongst the remaining patients, after particular attention to limb abnormalities, two rare clinical syndrome diagnoses have emerged. Patient 1, a full term product of an uncomplicated pregnancy had turricephaly with bicoronal synostosis and partial closure of the right lambdoidal suture. Partial soft tissue syndactyly of fingers 2, 3, 4 and a proximally placed thumb were seen bilaterally. There was only a single digit with a single metatarsal bilaterally. The findings were similar to cases of exposure to aminopterin and cases termed aminopterin like syndrome without aminopterin; the latter most likely here. Patient 2 was noted to have hypotonia at birth and turricephaly, wide set eyes, exorbitism, hypoplasia of the maxilla and mandible, one large fontanel in midparietal region, coronal synostosis, partial lambdoidal stenosis and long fingers and toes. On a follow-up exam at 19 months, the loose skin, high myopia, umbilical and inguinal hernia, together with the craniosynostosis suggested the diagnosis of Shprintzen-Goldberg syndrome. Lower extremity bowing and metatarsus adductus, bowing of the ulna, a short radius, dislocation of the radial heads, 13 ribs, and square box like vertebrae were noted, all consistent with this diagnosis. A cardiac evaluation revealed mild dilatation of the aortic root. Since craniosynostosis is a major component of each syndrome and the majority of cases were reported before the advent of molecular diagnostics for craniosynostosis syndromes, we performed molecular analysis including FGFR1, 2, 3, and TWIST in both of our patients, and deletion studies for the TWIST gene in patient 2. All of the studies were normal. Thus, the etiology of these syndromes remains unknown.

**Partial trisomy 2q:two new cases.** *M.E. Mollica<sup>1</sup>, N. Sganzzetta<sup>1</sup>, M. Aguirre<sup>1</sup>, L. Lopez Miranda<sup>1</sup>, S. Acevedo<sup>2</sup>, P. Barbero<sup>1</sup>.* 1) Centro Nacional de Genetica Medica Buenos Aires, Argentina; 2) Academia Nacional de Medicina.Buenos Aires, Argentina.

Partial trisomy of the distal part of the long arm of chromosome 2 is a rare condition with craniofacial anomalies and visceral abnormalities associated with psychomotor retardation and developmental delay. We report on two female infants with multiple dysmorphic features and partial trisomy of 2q. Patient 1:age 11 months. Clinical findings: brachycephaly, prominent forehead, hypertelorism, depressed nasal bridge with anteverted nares, long philtrum, low set ears,tent-shaped mouth, micrognathia, short neck, single bilateral palmar creases, brachydactyly, clinodactyly of the fifth fingers, cardiac and genital abnormalities and intestinal atresia. Her karyotype was 46,XX,der(15)t(2;15)(q35;p12)mat. Patient 2:age 3months. Clinical findings: brachycephaly, prominent forehead, hypertelorism,depressed nasal bridge with anteverted nares, long philtrum, low set ears, big mouth, short neck, brachydactyly, clinodactyly of the fifth fingers, congenital cardiac abnormalities and polycystic kidney. Her karyotype was 46,XX,der(9)t(2;9)(q33;p12)mat.In both of them partial trisomy 2q was confirmed by FISH using whole painting chromosome 2 (WCP 2).Patient 1 presents a pure 2q trisomy, in patient 2 despite of the associated 9p monosomy the clinical features are more concordant with those of trisomy 2q.Although the severity of the clinical manifestations in previous reports appears to be related with trisomy of the proximal region of 2q33, the internal malformation in our cases seem to be related with the duplication of distal loci.

**Clinical manifestations of Marfan syndrome in Hispanic families.** *F.A Laws<sup>1</sup>, D. Guo<sup>1</sup>, S. Kuang<sup>1</sup>, C.A. Morris<sup>2</sup>, D.M. Milewicz<sup>1</sup>.* 1) Internal Medicine, UT-Houston Medical School, Houston, TX; 2) Clinical Genetics, Univ NV Sch Med, Las Vegas, NV.

Marfan syndrome (MFS) is an autosomal dominant condition with pleiotropic manifestations involving the skeletal, ocular, and cardiovascular systems. The diagnosis is primarily a clinical diagnosis based on involvement of these and other systems, referred to as the "Ghent criteria". We have identified 2 Hispanic families with aortic root dilatation and dissection inherited in an autosomal dominant manner. The first family had 12 affected and 10 unaffected members available for assessment. FBN1 sequencing of DNA from affected individuals revealed a frameshift mutation in exon 24 (3074delT). Fibroblasts explanted from an affected member were metabolically labeled to study fibrillin-1 (fib-1). These studies revealed diminished amounts of fib-1 synthesized and <5% fib-1 deposited in the extracellular matrix when compared with control cells. Assessment of the clinical features in 8 affected adults in the 3rd and 4th generation revealed that none of the affected individuals had major skeletal manifestation of MFS. Only 3 of the 8 meet the criteria for involvement of the skeletal system. None of the individuals have involvement of the ocular system. A second Hispanic family with aortic root dilatation and dissection had 7 affected and 9 unaffected members. The cardiovascular phenotype was linked to markers within and near FBN1. Two affected adults were examined and only one had skeletal system involvement. Two adults with the affected haplotype were assessed by local cardiologists and reported to have no skeletal features of the MFS. The family has not been examined for ocular manifestations. Other large Hispanic MFS families have not been identified. The results with these 2 families suggest that Hispanic individuals may not manifest skeletal features of the MFS to the same extent as Caucasians, indicating that the Ghent criteria for diagnosing MFS may need to be revised for this ethnic group.

**A new Weaver-like syndrome with osteochondroma and epiblepharon.** *D. Wattanasirichaigoon<sup>1</sup>, N. Ruangdaraganon<sup>2</sup>*. 1) Genetics/Pediatrics, Ramathibodi Hospital, Bangkok, Thailand; 2) Developmental Pediatrics, Pediatrics, Ramathibodi Hospital, Bangkok, Thailand.

Weaver syndrome is a rare condition of macrosomia, accelerated skeletal maturation, camptodactyly, flared metaphysis, characteristic facial appearance, and mental retardation. We describe an 11 year-old girl who had features of Weaver syndromes, including facial phenotypes, postnatal somatic overgrowth, omphalocele, contracture of interphalangeal joints and thin deep-set nail, but metaphyseal splaying. In addition, the patient possessed congenital epiblepharon and osteochondroma at her both proximal ends of tibias. These clinical findings have not been reported in Weaver syndrome. After comparing Weaver syndrome with and contrasting it to other disorders, we concluded that novel findings in this patient could represent a new Weaver-like disorder.

**A de novo mutation [45,XX,der(5), t(5;14) (pter;q11.2)] and a neuroectodermal disorder, mimicking the MLS phenotype.** R. Zannolli<sup>1</sup>, R. Mostardini<sup>1</sup>, L. Pucci<sup>1</sup>, M. Guarna<sup>2</sup>, T. Hadjistilianou<sup>3</sup>, G. Zerega<sup>4</sup>, M. Pierluigi<sup>4</sup>, B. Franco<sup>5</sup>, G. Morgese<sup>1</sup>. 1) Department of Pediatrics, University of Siena, Siena, Italy; 2) Electronic Microscopy Unit for Genetics, Department of Biomedical Science, University of Siena, Siena, Italy; 3) Department of Ophthalmology and Neurosurgery, Policlinico Le Scotte, University of Siena, Siena, Italy; 4) Human Genetics Laboratory, Galliera Hospital, Genoa, Italy; 5) Telethon Institute of Genetics and Medicine (TIGEM), San Raffaele Biomedical Science Park, Milan, Italy.

We report on a two-year-old girl with a de novo mutation [45,XX,der(5),t(5;14) (pter;q11.2)] and a neuroectodermal disorder, resembling the phenotype of microphthalmia with linear skin lesion (MLS). She had corpus callosum agenesis, multiple cysts (cerebral and cardiac), subtle ocular abnormalities and at least two different skin defects, strongly indicating neuroectodermal involvement: first, a neuromuscular choristoma (hamartoma); second, an eccrine hamartoma. Fluorescent in situ hybridization experiments with different single-locus probes were performed, to determine the extent of chromosome involvement in the translocation [45,XX,der(5),t(5;14) (pter;q11.2)]. The results showed that chromosome 5 has a very small deletion, confined to a region composed of repetitive sequences. By contrast, the q arm of chromosome 14 seems much more important, and is involved in the rearrangement, with partial monosomy spanning from the centromere to the D14S72 and D14S261 loci. The extension of the deletion region of chromosome 14 is approximately 16 cM. To our knowledge, this is the shortest reported deletion involving the chromosome 14q11.2 region to be associated with a developmental disorder resulting in variable eye, skin and brain anomalies (e.g., corpus callosum agenesis), similar to the MLS phenotype. We suggest that a new syndrome, mimicking the MLS phenotype, could be caused by a de novo autosomal mutation on the distal long arm of the chromosome 14q11.2 region.

**Ocular anomalies in 22 Brazilian patients with Williams-Beuren syndrome.** *S. Sugayama<sup>1</sup>, L. S<sup>1,2</sup>, D. Bertola<sup>1</sup>, L. Albano<sup>1</sup>, P. Gerritsen Plaggert<sup>1</sup>, S. Bechara<sup>2</sup>, C. Kim<sup>1</sup>.* 1) Pediatrics, Inst da Crianca, Sao Paulo, Brazil; 2) Ophthalmology, Hospital das Clinicas, Sao Paulo, Brazil.

Williams-Beuren syndrome (WBS) is a rare contiguous gene deletion syndrome with typical facies, cardiovascular anomalies, mental retardation and a friendly and outgoing personality. The syndrome is caused by a submicroscopic deletion in the chromosome region 7q11.23 which is detectable by FISH analysis in 90-95% of the patients. Main ocular anomalies described in WBS patients are stellate anterior iris stromal pattern, strabismus, hypermetropia and retinal vascular tortuosity. We report on ophthalmological evaluation of 22 patients (13M:9F); all sporadic cases. They presented typical elfin facies, neuropsychomotor delay/mental retardation, skeletal and dental anomalies. Deletion of the elastin gene analysed by FISH was found in sixteen patients (73%). An indirect ophthalmoscopy of the ocular fundus was performed in all patients; a slit-lamp microscopy was done in 20 patients. The age of ophthalmological evaluation ranged between 2y and 17y (mean 8,7y). The following ocular anomalies were observed: strabismus (41%), punctate opacities in the lens (33%), stellate iris pattern (28%), retinal vascular tortuosity (29%) and optical nerve hypoplasia (9%). So far, the punctate lens opacities observed by slit-lamp have not been previously described in WBS patients. Half of the patients who presented these punctate opacities have hypercalcyuria and two others have serum calcium in the high normal range. Once hypercalcemia is a known cause of lens opacities, this metabolic disturb could be responsible for this finding in WBS patients. Ocular anomalies in WBS children may have implications in cognitive development. Thus, we recommend a regular ophthalmological examination for all children with WBS.

**A case of multiple congenital anomalies due to an unbalanced intrachromosomal rearrangement of chromosome 7.** *V.M. Rose, P.L. Plotner.* Div. Medical Genetics, Dept. Pediatrics, The University of Texas Medical School, Houston, TX.

Duplication of 7p terminus and deletion of 7q terminus are both rare events with about 20 described patients in the literature. Characteristic features of individuals with 7p terminal duplications include psychomotor retardation, dolichocephaly or microbrachycephaly, large fontanel, hypertelorism, large apparently low-set ears, micrognathia, hyperextensible joints subject to dislocation, joint contractures and a high rate of cardiac septal defects. Analysis of reported breakpoints suggests that the critical region for this phenotype is 7p15<sup>®</sup> pter.

Characteristic features of individuals with 7q terminal deletions include developmental and growth retardation, unusual facies, cleft lip/palate, genital anomalies (males), abnormal EEG, microcephaly and eye defects. Holoprosencephaly has been variably reported. Analysis of reported breakpoints suggests that the critical region for this phenotype is 7q35<sup>®</sup> qter.

We report a case of an infant with multiple congenital anomalies and a 7p terminal duplication and a 7q terminal deletion. The proband is the product of her nonconsanguineous parents' second pregnancy. The course of the pregnancy was unremarkable. At birth, the infant was noted to have multiple congenital anomalies including: small for gestational age, microcephaly, dislocated hips bilaterally, and right club foot. Echocardiogram revealed thickened, dysplastic heart valves. An initial finding of hydronephrosis resolved over a 2 month course. Karyotypic analysis showed an unbalanced intrachromosomal rearrangement of one chromosome 7. This rearrangement resulted in a deletion of band 7q36 to qter and a duplication of band 7p21.3 to pter: 46,XX,der(7)del(7)(q36<sup>®</sup>qter)dup(7)(p21.3<sup>®</sup>pter). Parental chromosome analyses were normal.

The patient displays distinct characteristics of both 7p terminal duplication and 7q terminal deletion syndromes. We propose that the critical regions of each syndrome can be further refined based on the patient's clinical and karyotypic information. Also, further delineation of the clinical course will be obtained by continued observation.

**Autoimmune disorders in velo-cardio-facial syndrome.** . *E.K. Schorry, H.M. Saal, M.H. Passo, H.I. Brunner.*  
Children's Hospital Medical Center, Cincinnati, OH.

Autoimmune disorders are becoming a well-recognized manifestation of deletion 22q11.2 (velo-cardio-facial syndrome, VCFS). We present two patients with VCFS with multiple autoimmune disorders. Case 1 was referred to genetics at age 15 years for evaluation of possible VCFS. She had a history of neonatal seizures due to hypocalcemia, submucous cleft palate, and developmental handicap. She had multiple hospital admissions beginning at age 3 years for thrombocytopenia, hemolytic anemias, and autoimmune neutropenia. At age 13 she presented with erosive polyarticular arthritis. VCFS was diagnosed at age 15.

Case 2, an 8 y.o. white male, had a history of laryngeal web, right sided aortic arch, and speech delay. Autoimmune manifestations included thrombocytopenia and hemolytic anemia. VCFS was diagnosed at age 8 years. Some of the facial features of VCFS were obscured by prednisone therapy in this patient.

We conclude that a wide variety of autoimmune disorders are possible complications of VCFS. The etiology is unknown, but may be related to T-cell dysfunction. Typical facial features of VCFS may be distorted by JRA or steroid treatment. Clinicians should keep a high index of suspicion of VCFS in patients with autoimmune disorders. Likewise, clinicians caring for patients with VCFS should be aware of their increased risk for autoimmune dysfunction.

**Turner Syndrome: A genetic model for Attention-Deficit/Hyperactivity Disorder.** *H.F. Russell<sup>1</sup>, T.J. Power<sup>1</sup>, L.E. Mitchell<sup>1</sup>, P.M. Robins<sup>2</sup>, J.L. Ross<sup>3</sup>, M. Muenke<sup>4</sup>.* 1) The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) duPont Hospital for Children, Wilmington, DE; 3) Thomas Jefferson University, Philadelphia, PA; 4) Medical Genetics Branch, National Human Genome Research Institute, Washington DC.

Girls with Turner Syndrome (TS) have previously been found to exhibit increased levels of hyperactivity and inattention. However, no studies have assessed whether these individuals meet strict (DSM-IV) criteria for Attention-Deficit/Hyperactivity Disorder (ADHD). The present study evaluated 52 girls with TS between the ages of 7 and 16 years in order to determine the prevalence of ADHD in this group. Cognitive ability and academic achievement were assessed, in addition to parent and teacher behavioral rating scales, in order to make the diagnosis of ADHD. Preliminary analysis of the data on the first 45 subjects yields a significantly higher Verbal IQ (101.2 +/- 12.5) than Performance IQ (85.8 +/- 13.0) with a Full Scale IQ of 93.1 +/- 12.8. This split between verbal and non-verbal skills has been previously demonstrated in girls with TS.

The behavioral data demonstrate more than a 15 fold increase ( $p < .01$ ) in the prevalence of ADHD in girls with TS (24%) compared to girls in the general population (1.3%) and a 4.4% increase ( $p < .05$ ) when compared to the prevalence of ADHD in boys and girls in the general population (5%). Of the TS subjects with ADHD, the Predominantly Inattentive Type (n=4) and the Predominantly Hyperactive/Impulsive Type (n=4) were most common, followed by the Combined Type (n=3) suggesting an alteration in the pattern of subtypes present in girls in the general population.

Molecular studies show no evidence of a relationship between parent of origin of the intact X chromosome and ADHD status ( $p=1.0$ ). In addition, these data demonstrate no relationship between karyotype (i.e., XO vs. mosaic) and ADHD status ( $p=1.0$ ). Overall, these data support the notion of a gene(s) on the X chromosome predisposing to ADHD. This gene(s) might be identified using detailed linkage studies.

**Osteoporosis in neurofibromatosis type 1 (NF1).** *M. Poyhonen*<sup>1</sup>, *J. Heikkinen*<sup>2</sup>, *K. Väänänen*<sup>3</sup>, *J. Peltonen*<sup>4,5</sup>. 1) Dept Medical Genetics, Family Federation of Finland, Helsinki, Finland; 2) Osteoporosis Clinic, Oulu Deaconess Institute, Oulu, Finland; 3) Department of Anatomy, University of Turku, Turku, Finland; 4) Department of Anatomy and Cell Biology, University of Oulu, Oulu, Finland; 5) Department of Medical Biochemistry, University of Turku, Turku, Finland.

Skeletal changes are common and well-known in neurofibromatosis type 1 (NF1). The most frequent findings include scoliosis in about 10 % of NF1 patients and congenital bowing and thinning of the long bones with or without pseudarthrosis in about 3 % of the cases. Other skeletal abnormalities consist of erosive defects due to the presence of neurofibromas contiguous to bone, disorders of growth, intra-osseous cystic lesions, and congenital anomalies of the skeleton such as sphenoid bone wing dysplasia. The pathophysiology of these changes in NF1 are still mostly unknown and osteomalacia has been reported only in a few cases. In spite of the actively ongoing research into NF1, there are still only a few reports, mainly case reports, that have investigated the role of osteoporosis in the disease. We report a systematic study on bone density evaluated by LUNAR-DPX (DEXA) scan in 35 NF1 patients. The NF1 diagnosis was confirmed in all cases by the NIH consensus criteria. Of the patients 21 were male and 14 female. The age distribution ranged from 11 to 73 years (mean 37 years). In 26 adults (over 20 years, 14 male and 12 female) the bone density evaluated by scan revealed osteoporosis in 13/26 (50 %). The osteoporosis was mild in 10 cases (T-score -1.0 - -2.4) and moderately severe in 3 cases (T-score -2.5 or under). The bone density varied in different regions being in all cases lowest in the ribs and highest in the head. Also the bone mineral content (BMC) gave different results at different sides of the same region. The total bone calcium in adults varied in males from 799 g to 1416 g and in females from 582 g to 1025 g. The risk of developing osteoporosis may be increased in patients with NF1, especially with young adults this risk needs to be recognized, and bone density should be evaluated in the potentially at-risk patients.

**New evidence for autosomal recessive mode of inheritance in hypomandibular faciocranial dysostosis. C.**

*Robinet<sup>1</sup>, T. Rousseau<sup>2</sup>, C. Durand<sup>3</sup>, N. Laurent<sup>4</sup>, C. Maingueneau<sup>2</sup>, P. Sagot<sup>2</sup>, A. Nivelon-Chevallier<sup>1</sup>, V. Cormier-Daire<sup>5</sup>.* 1) Centre de Genetique Medicale, Hopital d'Enfants, Dijon, France; 2) Clinique gynecologique et obstetrique, Hopital du Bocage, Dijon, France; 3) Service de Radiologie, Hopital d'Enfants, Dijon, France; 4) Laboratoire d'Anatomie-Pathologie, Hopital du Bocage, Dijon, France; 5) Departement de Genetique, Hopital Necker-Enfants Malades, Paris, France.

Hypomandibular faciocranial dysostosis is a rare disorder, presenting with craniosynostosis, prominent eyes, deficient midface and zygomatic arches, short nose with anteverted nares, protruding lower face, major microstomia, persistent buccopharyngeal membrane and severe mandibular hypoplasia. Three cases have been yet reported and the observation of recurrence in two sibs has suggested an autosomal recessive mode of inheritance. Here, we report on the prenatal diagnosis of an affected female infant born from consanguineous parents. At 31 weeks of gestation, prenatal manifestations included severe microretrognathia and microstomia. The diagnosis of hypomandibular faciocranial dysostosis was suggested. The child was born at 33 weeks of gestation. Birth weight was 2,110 g, length 46 cm and head circumference 33 cm. The child died few minutes after birth of respiratory distress. Autopsy features were down slanting palpebral fissures, deficient midface and zygomatic arches, short nose with anteverted nares, low-set ears, protruding lower face, major microstomia, severe hypoglossia, persistent buccopharyngeal membrane, bifid uvula, laryngeal hypoplasia, median cleft palate and severe mandibular hypoplasia. Examination of the brain was normal. Despite the absence of craniosynostosis the clinical manifestations in the child are highly suggestive of hypomandibular faciocranial dysostosis. The parental consanguinity argues in favor of an autosomal recessive mode of inheritance. Other reports will help to better delineate this rare entity.

**Wolf-Hirschhorn Syndrome: developmental outcome and mortality correlate with deletion size.** *N.L Shannon<sup>1</sup>, R. Regan<sup>2</sup>, E.L. Maltby<sup>1</sup>, J. Flint<sup>2</sup>, A.S. Rigby<sup>1</sup>, D.M.B. Hall<sup>3</sup>, O.W.J. Quarrell<sup>1</sup>.* 1) Sheffield Children's Hospital, U.K; 2) Wellcome Trust Centre for Human Genetics, Oxford, U.K; 3) Inst. of General Practice, University of Sheffield, U.K.

Wolf-Hirschhorn Syndrome is a well recognised deletion syndrome. Early research described a high mortality and poor developmental outcome irrespective of deletion size but there has never been a large scale study to prove or refute this. The prognosis may need to be revised as children with smaller deletions are now detected and treatment for congenital anomalies has improved. These observations led us to undertake a clinical and epidemiological study. Details of 156 cases were collected from the UK; of these, 108 (69.2%) were *de novo* deletions. The status (alive or deceased) has been confirmed in 143 of which, 96 are alive, 34 deceased and 13 were detected on prenatal testing. Age at death was ascertained in 31 cases. The overall mortality was 22.5% but the data show a significantly higher mortality (48%) in children with deletions proximal to and including p15.2 compared to those with smaller deletions (10%). The relative risk is 8.4 (95% CI=2.5, 28.7). 77.4% of deaths occurred in the first 2 years of life. 66 individuals were visited at home; developmental progress was measured using the Vineland Adaptive Behaviour Score normalised for age. 46 families consented to blood collection for repeat cytogenetic analysis and in addition, 11 PAC FISH probes were developed along 4p to provide an objective measure of deletion size. There was a trend for lower Vineland scores with increasing deletion size ( $p=0.08$ ) after adjusting for age by analysis of covariance. Mean values for small (p16.3-p16.2), medium (p16.1) and large deletions (p15.3 and larger) were 55.0, 48.6 and 45.7 respectively. A separate analysis of FISH data showed a similar trend; larger FISH deletion scores were associated with lower Vineland scores (mean change= -1.2; 95% CI= -2.6, 0.2). Therefore, the regression analysis confirms our clinical impression that children with smaller deletions make significantly better developmental progress. These findings will have important implications when discussing the prognosis with families.

**Navajo poikiloderma with cyclic neutropenia in Turkish children, clinical description and exclusion of linkage to the Rothmund Thomson RECQL4 gene.** *J.L. Van Hove<sup>1</sup>, S. Grünewald<sup>2</sup>, K. Minner<sup>2</sup>, C. Van Geet<sup>1</sup>, G. Matthijs<sup>2</sup>.* 1) Dept Pediatrics, Catholic University Leuven, Leuven, Belgium; 2) Center for Human Genetics, Catholic University Leuven, Leuven, Belgium.

Navajo poikiloderma is a unique genodermatosis described in 14 Navajo American Indians consisting of poikiloderma, pachyonychia, neutropenia, and chronic lung disease. We describe two siblings, a girl aged 21 months and a boy of 12 years, out of four children born to consanguineous Turkish parents. They developed a papular erythematous rash on the limbs in infancy, which developed into pronounced teleangiectasis predominantly acral and facial, and not limited to sun-exposed areas as would be seen in Rothmund Thomson syndrome (RTS). Both children have hyperkeratosis under the feet, and pachyonychia of the toes. They have mild dyserythropoiesis and persistent neutropenia of 100-400/microL, which responded with increased neutrophils with infections. They both had hypoglycemia and transient thrombocytopenia in the neonatal period. The boy, born at 34 weeks gestational age, had a grade IV intraventricular bleeding with subsequent hydrocephalus, spastic tetraparesis, and mental retardation. The girl has mild developmental delay. They have very frequent purulent upper respiratory tract infections, otitis media, and bronchopneumonia. Patchy areas of hypercalcification are noted on pelvic X-rays. Mutations in the human helicase gene RECQL4 on chromosome 8q24.3 have been found in RTS patients. Using closely linked polymorphic markers spanning this region, we found that both affected children did not share similar parental chromosomes, excluding linkage of this gene to the Navajo poikiloderma in our patients. This report expands the clinical description of this rare genodermatosis, and includes patients outside the Navajo population. The exclusion of the RECQL4 region adds genetic differences to the clinical distinction from RTS.

**A Possible Locus for Setleis Syndrome - A Rare Ectodermal Dysplasia.** *K.J. Swanson, X. Li, J. Bergoffen.* Genetics, Kaiser Permanente, San Jose, CA.

Setleis Syndrome is a rare congenital condition with characteristic ectodermal findings of the face. Typical abnormalities include bitemporal scarring resembling forceps marks, periorbital puffiness, wrinkling of the facial skin, upslanting laterally deficient eyebrows, scalp hair and eyelash abnormalities, bulbous nasal tip and thick protruding lips. Growth and psychomotor development are usually not impaired.

Our patient OA is a 6 yo boy with typical facial features seen in Setleis syndrome. In addition, he has short stature, vocal cord paralysis, laryngomalacia, stridor, h/o sleep apnea, atrioseptal deviation, redundant pulmonic valve, GERD, hydroceles, brachydactyly, unusual finger positioning, and severe developmental and attention problems with autistic features.

Peripheral blood chromosome analysis revealed a male karyotype with a de novo interstitial rearrangement within the short arm of chromosome 1. This rearrangement appears to be an inverted duplication in 1p from subbands 1p36.21 to 1p36.13. Fluorescence in situ hybridization (FISH) using DNA probes TEL1p1q (subtelomeric, Cytocell Ltd.) and D1Z2 (1p36.3, Oncor Inc.) revealed normal hybridization patterns and therefore ruled out an unbalanced translocation involving 1pter and another chromosome. FISH analysis with a partial chromosome paint probe for 1p (AI Technology) confirms the 1p origin of the additional segment.

To our knowledge, this is the first report of an isolated 1p duplication involving this region. Halal et al. (1989) reported a newborn with a duplication of 1p31-pter and a deletion of 2q33-qter who presented with microcephaly, cryptorchidism, facial anomalies, and growth and mental retardation but no features of Setleis Syndrome. We propose that the locus for Setleis syndrome is in the region between 1p36.21-1p36.13. The manifestations of Setleis syndrome in our case are likely due to a disruption of the gene by the inversion or a submicroscopic deletion. The additional findings, which are not typically associated with Setleis syndrome, would then be secondary to the partial duplication of chromosome 1p.

**Duplication 1q32-q42 syndrome in a child with  $\alpha$ -Thalassemia trait.** *K.H. Ramesh<sup>1</sup>, D. Wei<sup>1</sup>, L. Cheng<sup>1</sup>, S. Soni<sup>2</sup>, N. Green<sup>2</sup>, P. Levy<sup>2</sup>, L.A. Cannizzaro<sup>1</sup>.* 1) Dept Pathology, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 2) Dept. Pediatrics, Montefiore Medical Center, Bronx, NY.

Phenotypic/genotypic correlation of the duplication 1q syndrome is not yet clearly established due to wide variations in presenting clinical features. The severity of mental and growth retardation along with other dysmorphic features depend on the extent of the duplicated segment. The larger the duplication, the more severe are the associated malformations. We report a 14 year old female of Cambodian ethnicity with a history of development and speech delay, as well as, persistent anemia. Physical examination revealed short stature, severe developmental delay, mental retardation, with minimal dysmorphic features. These include height, weight and head circumference being lower than the 5th percentile, brachycephaly of the head, epicanthal folds, slightly flattened upturned nares, and slight webbing of the neck. Her heart had a grade II/VI vibratory systolic ejection murmur. Genitalia were normal female, but with delayed puberty. Exam of extremities revealed clinobrachydactyly of the 5th digits of both hands and clinodactyly of the 5th digits of both feet. Cytogenetic analysis detected a 46,XX,dup(1)(q32q42) karyotype in all cells and was confirmed by whole chromosome painting analyses. The mother's and (half) sister's karyotypes were normal. The father was unavailable for cytogenetic testing. The proband was also positive for  $\alpha$ -thalassemia trait. Southern blot analyses confirmed this, showing deletions of two of the  $\alpha$ -globin genes, a condition that is common among Southeast Asians, and its occurrence in this proband with the 1q syndrome may be purely co-incidental. The clinical features present in this proband show some similarities as well as differences when compared with other documented cases of 1q duplication of the q32-q42 segment. This suggests that the various breakpoints involved, may be critical in the manifestation of some of the features in this syndrome. Interestingly, the Coagulation Factor XIII B (F13B) gene has been mapped to the 1q31-q32 region. It would be worthwhile to determine if this gene is duplicated or deleted in this particular patient.

**Triophtalmia and Down syndrome: a previously unreported association.** C. Perandones<sup>1, 2</sup>, M. Segovia<sup>1</sup>, J. Golberg<sup>2</sup>, O.H. Pivetta<sup>1</sup>, R.D. Bennun<sup>2</sup>. 1) centro Nacional de Genetica Medica. Buenos Aires, Arentina; 2) Piel, Cirugia Plastica Infantil, Avellaneda, Argentina.

The first report of triophtalmia was performed in 1995 by Cohen and Stelnicki. The patient presented a duplication of the left globe and left cerebral hemisphere. They termed this rare anomaly triopia. Another case was documented by Tayel in 1998 in a boy with an unusual phenotype including facial clefting. We present the previously unreported association of triophtalmia and Down syndrome (DS). A five year-old girl was referred for consultation due to the presence of unilateral exophtalmia. She has been diagnosed as having Down syndrome soon after birth. Her karyotype was 47,XX, + 21. The pregnancy was uneventful and there was no history of drug intake or exposure to irradiation, infection or teratogens during pregnancy. Preoperative CT scan revealed the presence of a solid retro-ocular mass. The tumor was excised by an extracranial approach using a lateral external orbitotomy. Histological studies confirmed the presence of ocular structures. Taking into account the rate of trisomy 21 (1/ 645) and the fact that triophtalmia was only previously reported twice, the probability of concurrence by chance in the same patient of triopia and DS is very low. Thus, a causal relationship between both conditions must be suspected. Shapiro (1983) has suggested that aneuploidy may lead to magnified responses to disrupting agents. So, trisomy 21 may increase susceptibility in the embryo to develop triophtalmia in the presence of certain environmental factors. However, in our case, this factor did not exist and no other potential teratogenic factors could be identified. Several genes involved in the regulation of eye development have now been identified including the mouse Pax 6 gene, which is believed to play a master role triggering the development of eye components. However, none of these genes has been mapped to chromosome 21. The aim of this report is to describe a previously unreported association and to discuss embriological and molecular mechanisms potentially involved in its origin.

**Post-zygotic origin of a biparental 13;13 Robertsonian translocation in the mother of a fetus with trisomy 13.**

*M.L. Begleiter<sup>1</sup>, G.F. Cox<sup>2</sup>, L.M. Pasztor<sup>1,3</sup>*. 1) Sect Medical Gen/Molec Med, Children's Mercy Hosp & Clinics and the University of Missouri School of Medicine, Kansas City, MO; 2) Division of Genetics, Children's Hospital and Harvard Medical School, Boston, MA; 3) Palo Verde/Sonora Quest Labs, Tempe, AZ.

A 29-year-old primigravida was referred for further evaluation of multiple congenital anomalies identified in her fetus by a screening obstetric ultrasound. A level II ultrasound showed a single vertex intrauterine pregnancy with a mean gestational age of 29.3 weeks; 2.8 weeks behind her established dating by LMP, as well as the following fetal abnormalities: mid-line cleft lip, partial lobar holoprosencephaly absent anterior horns with dilated posterior horns and lateral ventricles, a prominent thalamus, hypotelorism, a flat sacral neural tube defect and abnormal positioning of the toes. Due to the fetal position, the heart could not be evaluated. Amniocentesis revealed a male fetus with trisomy 13 associated with a derivative chromosome 13: 46,XY,der(13;13)+13. Paternal chromosome studies were normal, 46,XY, whereas, the maternal karyotype was 45,XX,der(13;13). Subsequent cytogenetic studies demonstrate that the der(13;13) was dicentric and the revised karyotype was reported as 45,XX,dic(13;13)(p11.1;p11.1). To determine the parental origin of the maternal 13;13 chromosome rearrangement, the mother and her parents were genotyped using a panel of seven microsatellite markers from chromosome 13. Five of the seven markers were fully informative and showed biparental inheritance of the alleles, demonstrating that the maternal 13;13 was a true Robertsonian translocation and not an isochromosome. Several previous studies have addressed the parental origin of de novo 13;13 chromosome rearrangements. Most homologous rearrangements of chromosome 13 studied have been determined to be isochromosomes, whereas only a few were found to be true Robertsonian translocations. Our case of a balanced 13;13 translocation confirms that Robertsonian chromosomes may originate at conception or postzygotically.

**Trisomy of the short arm of chromosome 5 due to a de novo inversion, duplication (5)(p13-p15.3).** *A. Gonzalez-del Angel, M. Cervera, S. Sanchez, B. Molina, M.A. Alcantara, A. Carnevale, V. del Castillo.* Dpto. Genetica Humana, Instituto Nacional de Pediatría, Mexico.

Partial trisomies of the short arm of chromosome 5 are uncommon. It has been shown that patients with duplication distal to 5p13.3 have mild and relatively different phenotypes as compared to patients with complete duplications and proximal duplications that include band 5p13, suggesting that the critical region for 5p trisomy syndrome lies between 5p10 and 5p13.1. We report a 5 year-old Mexican girl who developed severe mental retardation and generalized tonic clonic seizures at one year-aged. She had cranium with tendency to turricephaly, upslanted palpebral fissures, bilateral inner epicanthal folds, deep nasal root, and malformed ears with posterior rotation. The cytogenetic study with G bands in lymphocytes from peripheral blood showed a 46,XX karyotype, in which one of the chromosome 5 had an extra segment on the short arm in all the analyzed cells, this suggested a 5p duplication. We performed FISH technique to confirm the diagnosis. The hybridization with a coatosome 5 total chromosome probe, revealed that the additional segment involved the same chromosome. In addition, with the Cri-du-chat 5p15 unique sequence probe, we observed two fluorescent signals on the short arm of the chromosome. We concluded that our patient had a duplication and an inversion of 5p: 46,XX,inv,dup(5)(p13p15.3 :: p15.3 qter). Both parents had normal karyotypes. As far as we know, only one case has been reported in the literature by Kleczkowska et al. (1987) who also had the same cytogenetic rearrangement as our patient but with a different phenotype. Since they only performed conventional cytogenetics, the differences in the phenotypes between both patients could be explained by the presence of other chromosome regions involved in the rearrangement found in the patient described previously by Kleczkowska et al. This case is a clear example that molecular cytogenetics is a complementary tool of conventional cytogenetic analysis. The combined use of these methods allows a precise diagnosis and an accurate genetic counseling as is illustrated in the present case.

**Partial trisomy 4q and monosomy 18p resulting from a de novo unbalanced translocation.** *P.L. Devers, A. Asamoah, K. Zubrickas, D.L. Van Dyke.* Department of Medical Genetics, Henry Ford Hospital, Detroit, MI.

We present a case of a male infant with a de novo translocation involving chromosomes 4q and 18p and resulting in duplication 4q31-qter and deletion 18p11.2-pter. The pregnancy was complicated by premature rupture of the membranes and delivery by c-section because of heart decelerations. Birth weight was 1473 g and birth length was 42 cm. Chromosome analysis was obtained because of dysmorphic facies and a single umbilical artery. The neonatal course was significant for jaundice, temperature instability, ventricular septal defect and patent foramen ovale. Physical examination at 2 months and 6 months revealed length, weight and head circumference below the 5th percentile, prematurely aged facies, retrognathia, carp mouth, broad alveolar ridge with gingival hyperplasia, excess skin around the base of the penis, and hypertonia. Development at 6 months was delayed. Surgical correction was necessary for malrotation of the bowel. Immunoglobulin levels were normal. The G-banded karyotype from peripheral blood lymphocytes culture was 46,XY, add(18)(p11.2).

FISH analysis using a chromosome 4 painting probe (Oncor, Inc.) identified the additional material to be derived from chromosome 4. The karyotype was interpreted as 46,XY,der(18)t(4;18)(q31;p11.2). Parental karyotypes were normal. Features of trisomy 4q syndrome include growth retardation, mental retardation, microcephaly, congenital heart defects, and dysmorphic facies (epicanthal folds, low set ears, micrognathia, carp mouth). Features of deletion of the short arm of chromosome 18 include low birth weight, short stature, mental retardation, carp mouth, ptosis, and IgA deficiencies. The clinical features of the present case are similar to those reported previously with each of these two chromosome abnormalities. To our knowledge, malrotation of the bowel has not previously been reported in association with either duplication 4q or deletion 18p.

**Ring chromosome 22: Physical and developmental profile in 8 patients.** *G.A. Anadiotis<sup>1</sup>, L. Celle<sup>1</sup>, S. Saitta<sup>1</sup>, I.D. Krantz<sup>1</sup>, E.M. Kaye<sup>1</sup>, N.B. Spinner<sup>1</sup>, B.S. Emanuel<sup>1</sup>, P.P. Wang<sup>2</sup>, E.H. Zackai<sup>1</sup>.* 1) Division of Human Genetics and Molecular Biology; 2) Division of Child Development and Rehabilitation, The Children's Hospital of Philadelphia.

We have analyzed the phenotype of eight patients with a constitutional non-mosaic ring chromosome 22. Five females and three males ranging from 17 months to 6.5 years underwent full physical and developmental evaluations. At birth all eight patients had normal height, weight and head circumference. At the time of evaluation, all had normal physical growth, except for 1 female with head circumference less than the fifth percentile. Two of eight patients had multi-systemic involvement including TAPVR, VUR, umbilical hernia and tracheomalacia (patient 1); multicystic kidney and polycystic ovaries (patient 3). Dysmorphia if present, was minor. Seven patients ranging between 17 months and 36 months of age had gross motor delay, three of which were in the severe category. Language was delayed in all seven and worse than motor skills in four. The eighth child was aged 6.5 years and had an IQ of 71 (Stanford-Binet). This further emphasizes the need for chromosome studies in non-dysmorphic children with developmental delay.

**Natural history of inv dup (8p): Clinical and cytogenetic findings in six cases.** *K. Kurosawa<sup>1</sup>, H. Kawame<sup>2</sup>, Y. Ochiai<sup>2</sup>, M. Matsuo<sup>1</sup>, K. Imaizumi<sup>1</sup>, Y. Kuroki<sup>1</sup>.* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Tokyo Metropolitan Kita Med Rehab Ctr, Tokyo, Japan.

Inverted duplication of short arm of chromosome 8 (inv dup (8p)) is one of the most common unbalanced structural abnormalities and is associated with a well-delineated clinical picture. The duplicated region includes band 8p11.2 to 8p23. We report on the natural history of 6 Japanese cases with inv dup (8p) according to the medical records. Cytogenetic abnormalities of chromosome 8 were noted in all patients, but FISH with whole chromosome painting of chromosome 8 and probe D8S596 (ONCOR) were performed in four. Parental origin of inv dup (8p) was analyzed in 3 families with polymorphic microsatellite markers. Sex ratio (M:F) of 6 cases are 1:5. The ages ranged from 3 years and 6 months to 10 years. The parental ages at birth were no different from those of general population. Seizures and feeding difficulties were the most important problems in early infant period. However, seizure control with anti-convulsant agents provided generally good prognosis on this neurological problem. Agenesis or hypoplasia of corpus callosum was a common feature of central nervous systems. The developmental milestone was severely retarded and the degree of retardation was increasing for age over infant period. Final scores of developmental quotient of the cases were less than 10 except for case 2. Although no patient attained to walking without support and speaking a meaning word, eye contact and simple emotional expression was possible. In childhood, the stable daily life was attained in most cases. Attending on the special school was possible in three. Few life-threatening problems were held in most cases over infant periods. Maternal origin of de novo inv dup (8p) was revealed in one of 3 pedigrees analyzed with microsatellite marker D8S264, which is located at 0.7cM from 8p terminal. These information is of great importance for understanding of the natural history of inv dup (8p) and useful for caring the patients with the disorder.

**Terminal deletion of chromosome 1p36: New insights into clinical features and medical management.** *J.A. Johnson, R.I. Blough, C.H. Jayne, E.K. Schorry, R.J. Hopkin, H.M. Saal.* Division of Human Genetics, Children's Hospital Medical Center, Cincinnati, OH.

A very common but under recognized chromosome deletion syndrome is that of deletion 1p36. In our institution we have identified this deletion in 9 patients over the past 5 years from a total of 4500 cytogenetics samples. All deletions were apparently de novo. Most patients were identified because they presented with developmental delays and congenital malformations. The facial dysmorphism was consistent among most patients with brachycephaly, prominent forehead, micrognathia, small mouth and short palpebral fissures. Other consistent features were seizures seen in 6 patients, hypotonia, developmental disabilities, and severe verbal apraxia. Genital anomalies were frequent in males. One patient had a cleft lip with cleft palate and one patient had Pierre Robin sequence with a cleft palate. A very common problem in infants was failure to thrive despite adequate caloric intake. In our institution this is the second most common chromosome deletion syndrome, after velocardiofacial syndrome. The level of suspicion for this condition should be raised in the presence of the typical dysmorphic features, seizures, severe verbal apraxia, and failure to thrive.

**Two cases of partial trisomy 10q and monosomy 7q with features similar to Cornelia de Lange syndrome, including split hand/split foot deformity.** *S. Randall-Pinto<sup>1</sup>, G. Johnson<sup>1</sup>, V. Lopes<sup>1</sup>, I. Teshima<sup>2</sup>, P. Wyatt<sup>1</sup>.* 1) Dept. of Genetics, North York General Hosp., Toronto, ON, Canada; 2) Hospital for Sick Children, Toronto, ON, Canada.

A 38 year-old woman presented for advanced maternal age counselling. Family history revealed a child that died at 2 days of age of Cornelia de Lange syndrome. Parental chromosomes later ordered for pregnancy losses demonstrated that the father was a balanced translocation carrier; 46,XY,t(7:10)(q32;q24).

The couple elected to have amniocentesis at which time holoprosencephaly was detected. The pregnancy was terminated and chromosome analysis revealed a 46,XY,der(7)t(7:10)(q32;q24) karyotype. Pathology assessment revealed microcephaly, hypotelorism, central proboscis, macrognathia, short neck, pterygia, bilateral absent forearm bones, bilateral claw hands with two digits each, imperforate anus, unilobar right lung, holoprosencephaly, hypoplastic right heart, and pulmonary artery stenosis.

Records were obtained for the earlier neonatal death. Multiple congenital anomalies similar to those previously described were noted including a short webbed neck, arthrogryposis, and absent ulna with a single digit. Although chromosomes were initially reported as normal, a subtle imbalance was detected after reviewing both the father's chromosomes and those from the terminated pregnancy.

To the best of our knowledge, this chromosome abnormality has not previously been reported. Further, the presence of split hand/split foot deformity in each of these cases supports the hypothesis that a gene involved in limb development is localized to chromosome 10q24<sup>1</sup>. We therefore propose the addition of split hand/split foot deformity to the clinical spectrum of abnormalities associated with distal 10q trisomy syndrome and recommend careful investigation of chromosome 10q24 in patients with apparent Cornelia de Lange syndrome including split hand/split foot deformity.

**Cytogenetic(Somatic and Germinative)and Molecular(AZF,CFTR and AR genes)evaluation in Male Infertility.**

*J.M. Pina-Neto*<sup>1</sup>, *R.C. Carrara*<sup>1</sup>, *R. Yamasaki*<sup>2</sup>, *M.A. Llorach-Velludo*<sup>3</sup>, *E.L. Sartorato*<sup>4</sup>, *S. Raskin*<sup>5</sup>. 1) Dept Genetics, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil; 2) Dept Surgery, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil; 3) Dept Pathology, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil; 4) Molecular Biol Center, UNICAMP, Campinas, Brazil; 5) Laboratorio Genetika, Curitiba, Parana, Brazil.

Approximately 10% of phenotypically normal men are infertile, with 30-40% of them classified as idiopathic. The genetic factors involved in human male infertility are chromosomal(classical somatic chromosomal aberrations and germinative meiotic anomalies),mutations of the CFTR and AR genes and, microdeletions of AZFs genes(Yq11 region).In the present study we performed a clinical,cytogenetic(100 metaphases from blood lymphocytes and a meiotic study from testicular biopsy)and molecular(27 primers for AZFa,b and,c by PCR multiplex;24 mutations of the CFTR gene;and,mutation and deletion study of the AR gene)evaluation of a sample of 70 infertile men with the major objective of determining the frequencies of this genetic factors in brazilians patients.The results are:30%(21/70)of the infertile men presented genetic etiologies; 14.3%(10/70)presented environmental etiologies, and 39(55.7%)remain idiopathic after the complete evaluation.Among the genetic etiologies we detected 7.1%(5/70)with classical somatic chromosome aberrations(4 Klinefelter syndrome and one with a 13/14 robertsonian balanced translocation);7.1%(5/70)presented meiotic(asynapsis)anomalies;4.3%(3/70)presented microdeletions of the AZFc gene causing disruption of the DAZ gene; and, 2.8%(2/70)were heterozygotes for mutation of the CFTR gene(all with CAVD).The importance of these results are discussed.

**Deletion of SHOX gene without short stature, Turner skeletal features or Leri-Weill syndrome.** *H. Thiele, C. Baldermann, I. Hansmann.* Institut fuer Humangenetik, Martin-Luther Universitaet, Halle, Germany.

Haploinsufficiency of the SHOX gene has been shown to cause not only short stature but also Turner skeletal features, such as short 4th metacarpals and cubitus valgus as well as Leri Weil syndrome (LWS). We report on a 20-year-old woman with hemizyosity for a Xp22 segment including the SHOX gene in about 75% of her lymphocytes without short stature, Turner skeletal features or LWS. The 20-year-old female was referred for genetic counselling and cytogenetic diagnosis due to primary amenorrhoea. At 5 months of age a muscular torticollis and a talipes calcaneus was observed. At the age of 1 year she presented with a severe progressive idiopathic thoracic scoliosis. Later on a displaced right kidney was observed. At referral to genetic counselling her height was 162 cm with a weight of only 46.1 kg. Hearing and smelling were normal and there were no signs for dental anomalies or ichthyosis. Family history is reported to be normal without any sign of skeletal defects, scoliosis or infertility. Chromosome analysis was performed on G-banded metaphases of cultured lymphocytes at 500 band stage. Due to slightly altered band staining at Xp22 in several but not all metaphases FISH analysis was performed using cosmid 34F5 containing the SHOX gene, kindly provided by G. Rappold (Heidelberg). FISH signals for SHOX were observed at the distal end of the short arm of both X chromosomes in 7/30 metaphases (23%). In 23/30 metaphases (77%) only one X chromosome revealed signals at the distal p-arm. A Y chromosome paint revealed characteristic PAR1 signals in 5/20 metaphases (25%) at the distal end of the short arm of both X chromosomes and on only one Xp-chromosome in 15/20 metaphases (75%) thus confirming the Xp-deletion of SHOX in the majority of cells. The karyotype therefore is: 46,XX/46,X,del(X)(p22). Mapping of the breakpoints within Xp22 is in progress using probes flanking the SHOX gene.

**Are the phenotypic features of a large interstitial deletion 11q14.2-11q23.1 distinct from Jacobsen Syndrome (terminal deletion 11q)?** *C. Theda*<sup>1,2,3</sup>, *E.M. Garcia Soto*<sup>1,2</sup>, *C.B. Cargile*<sup>1,2</sup>, *N. Hendi*<sup>3</sup>, *M.K. Miller*<sup>1,3</sup>. 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Frederick Memorial Hospital, Frederick, MD.

The majority of patients with deletions of chromosome 11q reported in the literature have terminal deletions distal to 11q23. It has been postulated that band 11q24.1 is the critical region for the phenotype - which is also referred to as Jacobsen syndrome. This phenotype includes growth and mental retardation, initial hypotonia with later spasticity, trigonocephaly, eye and midface abnormalities, carp shaped mouth, cleft lip and palate, congenital heart defects, and thrombocytopenia.

Our review of the literature identified only two reports of patients with interstitial deletions of chromosome 11q. Deleted regions were 11q21-11q23 and 11q22.3-11q23.2. The reported features of the patients that appeared to be distinct from Jacobsen syndrome were Pierre Robin sequence and Ebstein anomaly of the heart.

We report here a female patient with a 46,XX,del(11)(q14.2q23.1) karyotype. The proband was born vaginally at 38 wks with a birth weight of 2655 g. The infant appeared floppy. Dysmorphic features including depressed nasal bridge, small nose, anteverted nares and significant micrognathia were noted. The fifth toes were both displaced dorsally and overlapped the fourth toes. Further evaluation revealed high but intact palate, cardiac murmur due to peripheral pulmonary stenosis and patent foramen ovale, no thrombocytopenia. Her postnatal course was dominated by feeding difficulties due to the micrognathia and extremely poor suck-swallow coordination. The initial hypotonia resolved and increasing muscle tone and spasticity developed.

A detailed review of the phenotypic features of our patient with a large and previously not described 11q deletion in comparison with the two reported cases of smaller interstitial deletions and patients with Jacobsen syndrome will be presented.

**Fish and PCR analysis in three patients with 45X/46X,mar(Y) Kariotype: Clinical and pathologic spectrum.** *F. Alvarez, M. Soto, M. Prieto, L. Borjas, A. Rojas-Atencio, J. Cañizalez, Z. Alvarez.* Unidad de Genetica Medica, Universidad del Zulia, Maracaibo, Zulia, Venezuela.

Alterations of sexual differentiation occur as small structurally abnormal sexual chromosome (marker chromosome). We describe the clinical and molecular characterization of three patients with 45X/46X, mar (y) Karyotypes. The patients, two males and one female (ages 2-26 years) had varying degrees of impairment of sexual differentiation, with or without testis formation. One patient (reared as female) had a phenotype far more severely affected than expected in Turner syndrome (mental retardation, growth delayed and an unusual facial appearance) with streak gonad bilaterally. The second patient (12 years old) had ambiguous genitalia with a dysgenetic testis with a contralateral streak gonad. And another patient (26 years old) had bilateral dysgenetic testes (dysgenetic male pseudohermaphroditism). All patients had 45X/46,X,mar(Y). The ratio of the two stemlines was varying between the patients and between different tissues. The marker chromosomes were identified as Y chromosome, using FISH and PCR based analysis to detect Y specific sequence. The marker chromosome was deleted proximal and distal part of the normal Y chromosome, but the SRY gene was present in all patients and all tissues. The extend of male or female differentiation in these patients depends in part on the prevalence, time occurrence, and distribution of the 45,X line and possibly in part on the alteration of other genes (non-SRY) involved in sex differentiation.

**Mother to Daughter Transmission of Silver-Russell Syndrome.** *C.H. Jones, S. Nourbash.* Dept Pediatrics, Section Gen, Loyola Univ, Maywood, IL.60153.

Silver-Russell syndrome is of unknown etiology. Clinical features include intrauterine growth retardation, postnatal growth retardation and characteristic dysmorphic features. These characteristics include triangular face, small pointed chin, asymmetry, delayed closure of the anterior fontanelle and fifth finger clinodactyly. Other features include mental retardation and developmental delay. We are reporting the case of a mother and daughter both affected with Silver-Russell syndrome (SRS). SC was evaluated at 17 months for failure to thrive and developmental delay. She was noted to have delayed growth parameters. Her weight was 7.82kg (<5 percentile), length 74.5cm (<5 percentile) and head circumference of 43.5cm (5 percentile). She had asymmetry of the face and chest with the left being more prominent than the right. The left leg was 3 cm longer than the right. She had fifth finger clinodactyly bilaterally. Chromosomal analysis was normal (46,XX). SC's mother JC was 19 years of age. She was 60cm tall. She has slight facial asymmetry, limb asymmetry and fifth finger clinodactyly. Her chromosome analysis was also normal (46,XX). Both SC and her mother were diagnosed with Silver-Russell syndrome. Uniparental disomy of chromosome 7 has been described as cause of SRS syndrome in approximately 10 percent of cases. There has also been 17 families described with vertical transmission of SRS in the literature. We report another case of mother to daughter transmission of SRS. This report further demonstrates a possible dominant mode of transmission in addition to variable penetrance with the daughter more affected than the mother.

**Clinical, cytogenetical and molecular studies of the Angelman syndrome in 62 Brazilian patients.** *G.A. Molfetta<sup>1</sup>, V.F. Ferraz<sup>1</sup>, W.A. Silva-Jr<sup>2</sup>, J.M. Pina-Neto<sup>1</sup>.* 1) Dept Genetics, Sch Medicine, Ribeirao Preto - USP, Sao Paulo, Brazil; 2) Molecular Biology Unit, Fundacao Hemocentro, Ribeirao Preto - USP, Sao Paulo.

The Angelman syndrome (AS) is clinically characterized by central congenital hypotonia, delayed neurological and psychomotor development, severe mental deficiency, absence of speech. Neurologically, the patients have seizures, ataxia and unusual electroencephalogram. The AS is associated with genetic defects in the 15q11-13 region of the maternal chromosome 15. Different genetic mechanisms lead to the onset of AS: 65-70%; of the cases involve de novo deletions in the maternal 15q11-13 region; 3-5%; are uniparental paternal disomy; 7-9%; are mutations in the imprinting center, 4-6%; are mutations in the UBE3A gene and 10-14%; present biparental inheritance. In order to establish the diagnosis of the AS, clinical, cytogenetical and molecular evaluations were performed in 62 patients, in whom the AS diagnosis was suspected. The clinical evaluation established the most frequent phenotypic characteristics in the affected individuals. The cytogenetic investigation was performed to detect chromosomal rearrangements using the GTG, CBG and Ag-NOR banding techniques. The molecular approach was based in the methylation analysis of the 15q11-13 region and segregation of the (CA)<sub>n</sub> repeats polymorphism analysis using primers in the 15q11-13 region and in 15qter region. The molecular approach was performed to confirm the diagnosis and determine the genetic cause of AS. Genetic counseling was also offered to the families. The cytogenetical analysis detected two cases with chromosomal abnormality, a pericentric inversion 46, XX, inv(15p;15q) in both of them. All the other cases were chromosomally normal (46,XY). The molecular analysis confirmed 9 cases of AS caused by de novo maternal deletion, 2 cases with mutation in the imprinting center, no cases of paternal disomy and 27 cases showed biparental inheritance. In other 22 cases with biparental inheritance, the diagnosis of AS was excluded by clinical criteria. This method of investigation has proved to be efficient for evaluation of patients under suspect of having AS. Financial Support: FAPESP (process No 98/02378-9).

**Update on the clinical features and natural history of Wolf-Hirschhorn syndrome (WHS): Experience with 48 cases.** *A. Battaglia*<sup>1,2</sup>, *J.C. Carey*<sup>2</sup>. 1) Inst Child Neurology & Psych, Stella Maris Inst/Univ Pisa, Pisa, Italy; 2) Dept Peds/Div Med Genet., Univ of Utah Health Sciences Ctr., Salt Lake City, UT.

The knowledge of the natural history of a clinical condition is of the utmost importance for many reasons. To help delineate more accurately the natural history of WHS and to obtain better information to answer parents' questions in a clinical setting, we decided to develop a detailed questionnaire, dealing with the clinical manifestations of the syndrome and with the psychosocial development. The questionnaires were sent to the families of children with WHS, through their national support groups in the Italy and USA. Overall there were data on 48 patients (32 females, 16 males). 35 cases were detected by standard cytogenetics, while the remaining 13 required FISH. 46/48 (95.8%) had a seizure disorder; 21/48 (43.7%) underwent gastrostomy due to feeding difficulties; 24/48 (50%) had heart lesions; 18/48 (37.5%) had oral facial clefts; and 5 (10.4%) of them had sensorineural deafness; 13/48 (27%) had genitourinary tract defects. Of note, only 32/48 (66.6%) had severe/profound developmental retardation; while retardation was moderate in 12/48 (25%), and mild in 4/48 (8.3%). This is different from the literature, where it is conventionally stated that severe mental deficiency is a hallmark of this syndrome. Moreover, 9/48 (18.7%) patients were able to walk with support (between age 2-12 yrs), whereas 13/48 (27.1%) patients were able to walk unassisted (between 2 1/2-7 yrs). Five/48 (10.4%) patients also achieved diurnal sphincter control. Five/48 (10.4%) patients became self-feeders between age 4-12 yrs. The 34/48 (70.1%) patients receiving serial EEG studies showed fairly distinctive abnormalities, usually outlasting seizures. Although difficult to control in early years, seizures tend to disappear with age. A slow, but constant progress in development was observed in all cases, during the follow-up period. In conclusion, our combined cases represent considerable experience, providing new information on several aspects of this important deletion syndrome.

**Pierre Robin sequence and microdeletion 2q32.** *C. Houdayer*<sup>1</sup>, *M-F. Portnoi*<sup>2</sup>, *V. Soupre*<sup>3</sup>, *F. Vialard*<sup>2</sup>, *Y. Le Bouc*<sup>4</sup>, *R. Couderc*<sup>1</sup>, *M-P. Vazquez*<sup>3</sup>, *A. Munnich*<sup>5</sup>, *M. Bahau*<sup>1, 3</sup>. 1) Biochimie Biol. Moléculaire, Hôp. Trousseau, Paris, France; 2) Cytogénétique, Hôp. St-Antoine, Paris, France; 3) Chirurgie Maxillofaciale, Hôp. Trousseau, Paris, France; 4) Explorations Fonctionnelles, Hôp. Trousseau, Paris, France; 5) Génétique Médicale, Hôp. Necker Enfants-Malades, Paris, France.

The Pierre Robin sequence (PRS) consists of the nonrandom association of micrognathism, cleft palate (CP) and glossoptosis. Respiratory and feeding difficulties are common and appear to be not merely mechanical but also neurogenic in causation. PRS may be part of a well delineated syndrome, or present as an isolated nonsyndromic entity. PRS is mainly a sporadic finding though rare familial instances may occur, sometimes including individuals with CP only. On the basis of rare chromosome deletions and translocations, a locus for CP could be defined in 2q32. Here, we report a female patient showing the association of nonsyndromic PRS with microdeletion 2q32. Family history was unremarkable and moderate intrauterine growth retardation was noted. In addition to full-blown PRS, the examination showed axial hypotonia and minor physical anomalies such as small low-set ears. An unbalanced reciprocal translocation 46,XX, t(2;21), del 2(q32.3q33.2) was found in the proband's lymphocytes. Her father's karyotype was normal whereas her mother's showed a complex apparently balanced rearrangement 46, XX, t(2;21)(q33.2;q21.2) ins(4;2)(p14;q32.3q33.2). The chromosomes were analyzed by high-resolution G-banding as well as FISH approaches. Hemizygoty analyses using a set of 25 fluorescently-labeled microsatellite markers mapped the deletion between D2S355, telomeric, and D2S2173, centromeric. This observation suggests that some PRS cases might originate from mutation of (a) gene(s) localized in a region hitherto known for harboring a gene for CP. Whether mutations of a single gene mapped to 2q32 could cause both CP and PRS, a possibility suggested by families with mixed heredity, remains to be determined.

**Aberrant human genome without phenotypic consequences.** *R.S. Verma, M.J. Macera, T. Shklovskaya, S.M. Kleyman.* Division of Molecular Medicine and Genetics. Wyckoff Heights Medical Center, Brooklyn New York Hospital/Weill Medical College of Cornell University, New York, N.Y.

The clinical consequences of an aberrant chromosome have been correlated with as small as a single sub-band. In some cases, duplicated or deleted single bands have resulted in distinct syndromes, while in other situations, the same duplicated and deleted bands have no phenotypic effects. There are a few reports that describe a small inherited duplication of chromosomal regions including 1q21, 1p21-31, 2q11.2-q21.1, 6p23-pter, 6q22-q24, 7p12-p13, 8p23.1, 9p12, 9p22-p24, 9q12, 9q13-21.1, 14q13-q22, 15q11-13, 15q12, 18p11.2-3, and 18q12.1. Similarly, patients have been observed with a variety of deletions for various chromosomal segments including 3p25.3, 3p26, 5p14, 6q23.3-q24.2, 10p14, 11p12, 13q21, 16q21, and Xq26. These findings have created confusion and anxiety in the minds of clinicians and counselors. A 35 year-old normal female was referred because her sister has an unbalanced translocation between chromosomes 4 and 8. Cytogenetic findings with G-banding and FISH-techniques revealed an abnormal karyotype in her peripheral blood: 46,XX, del(3)(p26).ish (TelVysion 3p-). The deleted chromosome was missing the telomere-associated sequences, thus establishing the fact that band p26 was missing on chromosome 3. However, TTAGGG telomere cap was apparently present (Pan telomere probe, Cytocell). In general, ascertainment of such individuals has been through abnormal progenies, and genomic imprinting is the most plausible explanation for abnormal expression. It has been hypothesized that the G-positive bands are rich in repetitive DNA sequences and thus are genetically inert. It is only the G-negative bands which have an apparent adverse effect. Presently, she is expecting with the same chromosome del(3) present in her fetus. These findings have dire consequences for both clinicians and counselors. A concise compendium with detailed clinical manifestations of such cases is being annotated.

**A novel mutation in exon 22 underlies a mild cognitive phenotype and atypical renal features in a patient with oculocerebral renal syndrome (OCRL).** *A.L. Gropman<sup>1</sup>, S.W Levin<sup>2,3</sup>, L. Yao<sup>3</sup>, T. Lin<sup>4</sup>, S. Suchy<sup>4</sup>, S. Sabnis<sup>5</sup>, D. Hadley<sup>1</sup>, R.L. Nussbaum<sup>1,4</sup>.* 1) Neurogenetics Branch, NHGRI/NIH, Bethesda, MD; 2) Heritable Disorders Branch, National Institutes of Child Health and Human Development, NIH, Bethesda, M.D; 3) Department of Pediatrics, Walter Reed Army Medical Center, Washington, D.C; 4) Laboratory of Genetic Disease Research, NIH, Bethesda, M.D; 5) Armed Forces Institutes of Pathology, Washington, D.C.

The oculocerebrorenal syndrome of Lowe, (OCRL), is an X-linked disorder characterized by congenital cataracts, mental retardation and renal tubular dysfunction. The gene encodes a lipid phosphatase, phosphatidylinositol 4,5, bisphosphate [PtdIns(4,5)P<sub>2</sub>]-5-phosphatase, which localizes to the Golgi apparatus and is suspected to play a role in Golgi vesicular transport [Suchy, et al.,1995]. In addition to the ocular and renal manifestations, the majority of boys with OCRL have cognitive problems as well as maladaptive behaviors including tantrums and stereotypies. We report a boy with a history of congenital cataracts and mild developmental delay was also found to have hematuria with proteinuria but minimal signs of renal tubular dysfunction. Subsequent renal biopsy was compatible with a diagnosis of a noncomplement fixating chronic glomerulonephritis. Despite the atypical renal findings, skin fibroblast analysis for PtdIns (4,5P<sub>2</sub> 5-phosphatase was performed and enzyme activity was low, consistent with the diagnosis of OCRL. Mutation analysis using denaturing high performance liquid chromatography (DHPLC) and sequencing revealed an insertion of T between bases 2498 and 2499 in exon 22. The mutation changes a glutamic acid to a stop codon and results in a truncated protein. Western blot analysis from cell lysates showed the *ocrl* protein was decreased in size and amount. Subsequent screening of the proband's mother revealed her to be a carrier, despite a normal ophthalmic examination. The possibility of OCRL should be considered in boys with cataracts and glomerular disease, even in the absence of renal tubular defects and frank mental retardation usually associated with the syndrome.

**Neurofibromatosis in a brazilian reference center : clinical profile and natural history survey.** *M. Geller<sup>1,3</sup>, G. Carakushansky<sup>2</sup>, A. Bonalumi Filho<sup>1</sup>, F. Pereira Nunes<sup>1</sup>, F. C. Franca<sup>1</sup>, D. Rubem Azulay<sup>4</sup>.* 1) Microbiology/Immunology, Teresopolis School of Medicine, Rio de Janeiro, RJ; 2) Department of Pediatrics, UFRJ, Rio de Janeiro, RJ; 3) National Neurofibromatosis Foundation, Inc., USA; 4) Hospital Geral da Santa Casa da Misericórdia do RJ, Rio de Janeiro.

Neurofibromatosis (NF) is a genetic condition with two distinct clinical presentations: NF1 and NF2. The first is one of the most common dominantly-inherited genetic disorders, occurring once in every 3000-4000 people. It is characterized by the occurrence of café au lait spots, neurofibromas, plexiform neurofibromas and axillary or inguinal freckling. Other features include an increased risk for optic glioma, osseous lesions, and learning disability. DNA-based testing of the NF1 gene (chromosomal locus 17q11) is available clinically, but is rarely utilized for diagnosis. Prevalence for NF2 is only 1:37,000 individuals. It is characterized by bilateral vestibular schwannomas with associated hearing loss. Other findings include schwannomas of other cranial and peripheral nerves, meningiomas, and juvenile posterior subcapsular cataract. The authors evaluated 46 consecutive children and adults with NF1 and NF2 between June 1998 and April 2000. This prospective study represents the first brazilian clinical survey of patients with NF fully assessed by the the Natural History International Multicentric Protocol under the coordination of the Clinical Genetics Program of Harvard University. The protocol included evaluation of several variables such as age, sex, socio-economic status, disease severity, family history, and the presence of learning disabilities. Complementary exams of affected systems were routinely performed. Our sample was characterized by interfamilial differences in disease severity and tumour susceptibility. Neoplasms alterations which required surgical treatment occurred in 4 patients (8.69% of the sample) and included meningiomas and schwannomas. The diverse array of clinical manifestations found in our sample was analyzed and compared with those described in the literature. A team approach, coordinating the expertise of multiple specialties is strongly recommended for the evaluation of NF patients.

**DEB test in mexican patients with atypical manifestations of Fanconi anemia.** *C. Esmer, S. Sanchez, L. Gomez, S. Ramos, B. Molina, S. Frias, A. Carnevale.* Department of research in human genetics, National Inst of Pediatrics, Mexico.

Fanconi anemia (FA) is characterized clinically by pancytopenia, hyperpigmentation, skeletal malformations, small stature, diverse congenital abnormalities and predisposition to neoplasia. It has been recognized that the FA phenotype is extremely variable, making diagnosis difficult on the basis of clinical manifestations alone. Hypersensitivity of FA cells to the clastogenic effect of DNA cross-linking agents such as diepoxybutane (DEB) provides an unique marker for the FA genotype and constitutes an useful diagnostic test for FA before anemia develops as well as after the beginning of hematological manifestations. The majority of patients are diagnosed between 3-7 years of age, however the diagnosis of FA is frequently delayed until the pancytopenia appears. In this study we included forty patients with clinical conditions related to the FA phenotype that are not usually screened by the DEB test and we performed the chromosomal breakage test in order to make an earlier diagnosis of the disease. The DEB test was done in a peripheral blood sample by standard procedures in ten patients with aplastic anemia, ten patients with VACTER association, six with radial ray abnormalities, three with tracheoesophageal fistulae, eight with anal atresia and three with myelodysplastic syndrome. Among them we found four DEB-positive patients: Two of them were male patients, twelve and eight years old each, in which their only clinical complaining was aplastic anemia without any other sign of FA. The third patient was a female who has anal atresia, renal hypoplasia, preaxial polydactyly and normal blood cell counts that was diagnosed as VACTER association. The fourth patient was a newborn male showing bilateral radial ray aplasia but lacking other physical or hematological signs. Our results remark the need to amplify the number of abnormalities that indicate when a patient has to be tested for chromosomal instability. Delay in the diagnosis of FA may have serious consequences for the patients and their family.

**Iris coloboma with ptosis, hypertelorism, and mental retardation: report of six Brazilian patients.** *C.A. Kim, S.M.M. Sugayama, L.M. Albano, C.E. Andrade, T.C. Lyra-Netto, P.S. Gerritsen Plaggert, D.R. Bertola.* Dept Pediatrics, Inst da Crianca - USP, Sao Paulo, Brazil.

In 1988, Baraitser and Winter described a new syndrome with iris coloboma, ptosis, hypertelorism, broad nasal and epicanthal folds in two sibs and an unrelated single patient. Similar phenotype was described in two patients with inversion of chromosome 2 inv(2)(p12q14) by Ayme et al(1979) and Pallota(1991). Ramer et al(1995) assembled 9 children with similar phenotype and two of them presented the same pericentric inversion of chromosome 2. We studied six Brazilian patients (4F;2M) with strikingly similar dysmorphic facial features. They presented hypertelorism(6/6), palpebral ptosis (6/6), broad nasal bridge(6/6), trigonocephaly(3/6) and coloboma(2/5). Other associated findings were cardiac defects(4/6), urogenital anomalies(3/6), umbilical hernia(2/6), and criptorchidism(2/2). Hip dislocation, camptodactily, and tapered halux was present in one patient. Mental retardation was present in 4/6(66%). All patients were sporadic cases from non-consanguineous parents. Chromosome analysis were normal except one with pericentric inversion of chromosome 9, also present in his mother. The oldest patient, a 19 year-old girl, had mild to moderate mental retardation and seizures. She maintained the same facial dysmorphisms. There is some phenotypic overlap with patients described by Richieri-Costa et al (1999) and Masuno et al (2000) with frontonasal dysplasia, macroblepharon, eyelid colobomas, ear anomalies, macrostomia, mental retardation and CNS structural anomalies. It is possible that both conditions could represent variable expressivity of the same disorder. Further reports are necessary to clarify the spectrum of this rare condition.

**Hirschsprung's disease associated with high birth-weight and coarse facial features - a new syndrome?** *I.F.M. Lo, F.W.F. Lam, E.W.L. Hau, H.H.N. Woo, S.T.S. Lam.* Clinical Genetic Service, Department of Health, Hong Kong SAR, China.

Two patients with similar features of Hirschsprung's disease, high birth-weight and coarse facial features were described. The concurrence of these features is never reported before and suggests a new syndrome.

Patient 1 is a 7-year-old Chinese boy born to normal, non-consanguineous parents at 41 weeks of gestation, with birth-weight 4.05 kg. He presented with intestinal obstruction and was diagnosed to have Hirschsprung's disease and Meckel's diverticulum at 2 weeks. Coarse facial features were noticed, together with hypertelorism, epicanthi, protruding tongue, and full cheeks. He was otherwise healthy with normal neurodevelopment. However, his head circumference, height and weight were all along above the 97th percentile. Karyotyping showed normal 46,XY. Bone age at the chronological age of 17 months was appropriate.

Patient 2 is a 21-year-old Chinese gentleman. His parents are non-consanguineous. The mother was mentally slow but otherwise normal. He was born full term with birth-weight 3.9 kg. Hirschsprung's disease was diagnosed at age of 3 months. He was hypotonic with delay in gross motor development in childhood. His intelligence was normal. He suffered from bilateral retinal detachment of unknown cause at age 7. Assessment at age 20 revealed coarse facial features with malar hypoplasia, broad nose, long philtrum, and thick lips, and a stocky built with head circumference 57.5 cm (75th percentile), height 174 cm (50-70th percentile), and weight 98 kg (>97th percentile). Karyotyping showed normal 46,XY.

The differential diagnoses include the well-known overgrowth syndromes like Beckwith-Wiedemann syndrome (BWS), Simpson-Golabi-Behmel syndrome (SGBS), Sotos syndrome (SS), Weaver syndrome (WS), and Perlman syndrome (PS). The one syndrome that bears a similar phenotype to that of our patients is SGBS. However, SGBS patients are, unlike in our patients, usually mentally retarded. Furthermore, Hirschsprung's disease was never reported in SGBS patients previously.

Program Nr: 659 from the 2000 ASHG Annual Meeting

**Report of 23 cases of Leber Congenital Amaurosis in Lore Tribe of Sirjan, Kerman, IRAN.** *M.H. Karimi-Nejad<sup>1</sup>, M.R. Meshkar<sup>2</sup>, S. Sohbaty<sup>1</sup>, H. Najmabadi<sup>1</sup>, R. Karimi-Nejad<sup>1</sup>, S. Saryazdi<sup>2</sup>, M. Sarfarazi<sup>3</sup>.* 1) Pathology & Genetics Ctr, Tehran, Iran; 2) Ophthalmology dept. Kerman Medical Science University. Kerman, Iran; 3) University of Connecticut Health Center, Framington, Connecticut USA.

We have been informed that among the Lore tribes of the rural areas of Sirjan city; a kind of congenital blindness is so frequent, that they are named the blind branch (Tayefehe Couran). At first investigation we concluded that the blindness is hereditary; transmitting as an autosomal recessive trait.

We did several field studies, examined the affected individuals, interviewed the Seniors, drew pedigree charts going back 11 generations. We ascertained 23 patients, 8 of whom were dead. We did G Banded chromosomal study, took blood samples of the patients and their first degree relatives, including parents, and sibs, for DNA analysis and Linkage analysis. The materials are under study.

The 12 living patients ranging from 6-63y, mean age 21.5, were fully worked up by our clinician and ophthalmologist. The blindness is recognized in the early neonatal period, without noticeable objective findings (12/12).

Nystagmus (8/12), Keratoconus: 3 bilateral, 2 unilateral; leukoma: 2 bilateral, 1 right; and 2 bilateral and one right eye cataract appearing later on.

On fundus visualization narrowing of retinal vessels (9/12), dispersed pigment deposition (3/12), white spot, and retinal degeneration (1/12) were remarkable. Electro retinogram of 2 cases revealed characteristic pattern.

Blindness is profound, ranging from 2/10 one case, finger count 2/12, hand movement 3/12, light perception 5/12, to complete blindness with NLP in one. Eye tension were normal in cases that could be examined.(4/12)

We think that we are dealing with Lebers Congenital Amaurosis. We are still working on identification of the genes molecular structure and its chromosomal mapping.

This research is being sponsored by the National Iranian Research Organization.

**Violating the law of parsimony: independent segregation of facioscapulohumeral dystrophy, autosomal recessive deafness, and mental retardation in a single sibship.** *L.E. Walsh<sup>1,2</sup>, E.C. Lichtenberg<sup>1</sup>, B.P. Garg<sup>2</sup>*. 1) Dept Medical & Molecular Gen, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept Neurology, Section of Pediatric Neurology, Indiana Univ Sch Medicine.

Facioscapulohumeral dystrophy (FSHD) is an autosomal dominant disorder consisting of muscle wasting and progressive weakness about the face, neck and shoulder girdle; progressive sensorineural hearing loss is seen in 60-70% of patients and cognitive disability has been reported. We report a nuclear family, including 10 siblings, with weakness, deafness, and mental retardation. The mother had progressive shoulder weakness but no hearing loss or history of learning disorders. Her 10 children ranged in age from 7-20 years. Within this sibship, 2 (1 boy, 1 girl) had only shoulder girdle weakness; 2 others (1 boy, 1 girl) were deaf but otherwise normal. Two boys were mentally retarded with onset of hypotonia in infancy; 1 was deaf, but had required extracorporeal membrane oxygenation as a newborn. One girl was mildly learning-disabled, had normal hearing, and questionable shoulder weakness at age 16, while a 13-year-old boy had only weakness by report, but has not yet been examined. One boy had only mild learning disabilities; 1 girl was normal. Family history was otherwise negative for neuromuscular disorders, hearing loss, or mental retardation; consanguinity is denied. The mother's RFLP analysis revealed heterozygosity for chromosome 4q35 deletion, confirming a clinical diagnosis of FSHD. Four siblings, the 2 with isolated deafness and the 2 with mental retardation (1 with deafness), tested negative for the deletion. Testing of the hearing-impaired children for other causes of deafness is pending. This family presented with a rare combination of FSHD and probable autosomal recessive deafness, which are both relatively uncommon. The coexistence of these two conditions in this family emphasizes the utility of subtle phenotypic differences as aids to diagnosis. It also raises genetic counseling issues in the face of possible phenocopies, and emphasizes the medical and psychosocial need for preparatory genetic counseling coupled with definitive genetic testing.

**Orofacial Clefts and Associated Congenital Malformations.** *S. Beiraghi<sup>1</sup>, C.M. Chan<sup>1</sup>, S.A. Jensen<sup>1</sup>, G.B. Schaefer<sup>2</sup>.*  
1) Growth & Development, Univ Nebraska Medical Ctr, Omaha, NE; 2) Clinical Genetics, Univ Nebraska Medical Ctr, Omaha, NE.

The types of associated malformations with orofacial clefts vary widely between studies. The purpose of this investigation was to evaluate the incidence of associated congenital malformations of orofacial cleft patients in a geographically defined population.

Medical records of 1127 orofacial cleft patients at the cleft palate/craniofacial clinic at Boys Town National Research Hospital were reviewed between the years 1990-1999. All patients had a genetic evaluation and a complete laboratory workup. Patients were divided into two categories: 1) cleft palate only, and 2) cleft lip, with or without cleft palate. Patients were further categorized in respect to occurrence and type of congenital malformations occurring in conjunction with the orofacial clefts.

Of the 1127 cleft patients, 47.2% were born with cleft palate only and 52.8% with cleft lip, with or without cleft palate. Thirty two percent of all cleft patients had associated congenital malformations. Associated malformations were more common in patients who had cleft palate only (38.7%) than in patients with cleft lip, with or without cleft palate (26.4%). Malformations in the facial region were the most common followed by malformations in the cardiovascular, central nervous, and skeletal systems. Of the major malformations 63.1% were diagnosed as occurring in conjunction with chromosomal or syndromic etiologies, while 36.9% did not. These results correlate closely with results from other recent orofacial cleft studies.

The recognition that there is a high association of organ malformations and syndromes with orofacial clefts is vitally important for clinicians. The identification of orofacial clefts should lead to a complete genetic examination of an individual and, if indicated, further diagnostic testing and counseling.

**Midline cervical cleft, a rare malformation of branchial arch derivation.** *D.L. Earl, R.E. Falk.* Medical Gen/Birth Defects Ctr, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Congenital midline cervical cleft with associated anterior cervical webbing is a rare developmental defect. This can be associated with other anomalies including median cleft of the chin, lower jaw, lower lip, tongue, and sternum, congenital heart defects and hemangiomas. It results from failure of branchial arch fusion and occurs sporadically. We describe an infant with a congenital midline cervical cleft and mild cervical webbing born to a healthy G3P2-3, 31-year-old woman and her healthy, unrelated 31-year-old partner. Due to an elevated MS-AFP of 2.53 MoM, ultrasound-directed amniocentesis was performed at 17 weeks gestation. No fetal abnormalities were noted. Cytogenetic analysis revealed a normal male karyotype. The AF-AFP result was normal (1.55 MoM). The infant was delivered at term. Birth weight 3550 gm, length 48.25 cm, and head circumference 35.5 cm were 50th-90th percentiles. He was non-dysmorphic with slightly overfolded superior helices, prominent antihelices, mild retrognathia, and a palpable midline notch of the mandible. A midline vertical soft tissue lesion extended from the hyoid process to above the sternal notch, measuring less than 2.0 cm with the head in a neutral position. With the neck extended, a V-shaped pterygium was visualized reaching from the cleft to the mandible. No discharge, other midline defect, abdominal raphe, cardiac murmur or hemangioma was noted. There were no problems of neonatal adaptation and the infant has continued to grow and develop normally. Newborn hearing screen and thyroid function studies were normal and there was no evidence of a thyroglossal duct cyst or remnant on ultrasound of the neck. Fewer than 50 cases of midline cervical cleft have been reported including 12 cases from a 30 year survey of 612 thyroglossal duct and branchial cleft sinus surgical referrals (Gargan TJ, et al, 1985). Cicatricial scarring leads to progressive flexion contracture of the head and secondary mandibular constraint in untreated cases. Thus, it is important to recognize this rare developmental defect and refer for appropriate early surgical management. Detailed clinical findings and literature review will be presented.

**Mapping the gene for Raine syndrome, a rare lethal autosomal recessive condition.** A. Ion<sup>1</sup>, C. Tipper<sup>1</sup>, A. Crosby<sup>1</sup>, K. Marks<sup>1</sup>, R. Taylor<sup>1</sup>, I. Jeffrey<sup>2</sup>, H.M. Kingston<sup>3</sup>, J.M. Pina-Neto<sup>4</sup>, R. Sachdev<sup>5</sup>, M.A. Patton<sup>1</sup>, S. Jeffery<sup>1</sup>, V. Murday<sup>1</sup>. 1) Medical Genetics, St George's Hospital Medical School, London, UK; 2) Histopathology, St George's Hospital Medical School, London, UK; 3) Clinical Genetics, St Mary's Hospital, Manchester, UK; 4) Genetics, Faculdade de Medicina de Ribeirao Preto, Sao Paulo, Brasil; 5) Clinical Genetics, Churchill Hospital, Oxford, UK.

Raine syndrome is a genetic condition characterised by multiple congenital abnormalities including bone dysplasia, microcephaly, characteristic dysmorphic face, hypoplastic lungs, and in some cases, hepatosplenomegaly. Affected children usually die soon after birth from respiratory distress or cardiac arrest. An autosomal recessive mode of inheritance has been suggested for this disorder since consanguinity in the parents has been demonstrated in several of the reported cases. Since 1989 (when first described by Raine et al.), only 9 such patients have been reported, and the aetiology and physiopathology of this condition are completely unknown. We describe a new case of Raine syndrome, from unrelated parents, presenting with a rearrangement of the short arm of the chromosome 7. The karyotype abnormality resulted in uniparental isodisomy and the loss of a very small fragment from both chromosome 7 homologues. The loss was confirmed by both molecular and FISH techniques, and a YAC/cosmid contig was generated for the deleted fragment as well as for the proximal non-deleted region. At present, only two ESTs have been mapped to this area. To further refine this putative locus, homozygosity mapping was performed in three other cases of Raine syndrome (one reported by Kingston et al. in 1991 and two previously undescribed patients). Candidate genes in this region are discussed.

**An infant of agnathia, situs inversus, and no brain malformation.** *T. Tohma*<sup>1,2</sup>, *Y. Asato*<sup>1,2</sup>, *Y. Chinen*<sup>1</sup>, *Y. Izumikawa*<sup>3</sup>, *K. Sakumoto*<sup>2</sup>, *T. Ohta*<sup>1</sup>, *K. Naritomi*<sup>4</sup>. 1) Dept Pediatrics, University of the Ryukyus School of Medicine, Okinawa, Japan; 2) Maternity and perinatal care center, University of the Ryukyus hospital, Okinawa, Japan; 3) Dept Pediatrics, Nago Institute for Severely Handicapped Children, Okinawa, Japan; 4) Dept Medical Genetics, University of the Ryukyus School of Medicine, Okinawa, Japan.

Agnathia is a very rare congenital anomaly considered to be a lethal condition. We report here a 9-month-old Japanese boy, who is the third survival case. At birth, he was noted to have extreme micrognathia, microstomia, low-set ears, and downward-slanting palpebral fissures. There were no spontaneous respirations. After several trials, intubation with bronchofiberscope was successful after 10 minutes. Apgar scores were 3 at 1 minute and 6 at 5 minutes. He had situs inversus and no brain malformation. A tracheostomy and a gastrostomy were performed at 2 weeks and 2 months respectively. At 9 months of age, his mental development appears almost normal. An infant of agnathia and situs inversus who had no significant brain malformation had been reported. But she died at 5 days of age because of severe hyaline membrane disease (Stoler et. al., 1992). To our knowledge, there have been reported only 2 survival cases, who were 5-year-boy and 14-month-old girl (Kamiji et. al., 1991, Walker et. al., 1995, respectively). Both of them had neither brain malformation nor situs inversus. Our patient differs from these cases in that he had situs inversus.

**Congenital anomalies: a review of 279 consecutive autopsies in Ribeirao Preto, Brazil.** A. Piram<sup>1</sup>, L.C. Peres<sup>2</sup>, J.M. Pina-Neto<sup>1</sup>. 1) Dept Genetics, School Medicine of Ribeirao Preto, Sao Paulo University, Ribeirao Preto, SP, Brazil; 2) Dept Pathology, School Medicine of Ribeirao Preto, Sao Paulo University, Ribeirao Preto, SP, Brazil.

We retrospectively analyzed 1127 autopsy of children aged 0 to 14 years, performed in the Pathology Service of the University Hospital of School of Medicine of Ribeirao Preto from January 1995 to December 1998. Congenital anomalies were present in 279 cases (24.8%). Most cases were children aged 0 to 28 days (40.9%), and 1 to 12 months (36.2%). Sample was separate in two groups: evaluated for clinical geneticist in life or autopsy (157 cases) and not evaluated (122 cases). In the group of evaluated cases the diagnosis can be established in 126 (80.3%); 21 (13.4%) were of single anomalies, and 105 (66.8%) of multiple anomalies. In this group the diagnosis was not defined in 31 cases (19.7%), being 13 (8.3%) of supposed single anomalies and 18 (11.5%) of multiple anomalies. In the group of not evaluated cases 62 (50.8%) had the diagnosis defined; 28 (23.0%) were single anomalies, and 34 (27.9%) were multiple ones. Diagnosis cannot be defined in 60 cases (49.2%); 38 (31.1%) were of supposed single anomalies and 22 (18.0%) of multiple anomalies. Considering the cases with established clinical diagnosis (188 cases), 40 (21.3%) were monogenic, 33 (17.6%) chromosomal, 38 (20.2%) multifactorial, 6 (3.2%) environmental, 54 (28.7%) unknown etiology, and in 17 (9.0%) the etiology cannot be determined. The recurrence risk was considered low in 121 cases (64.4%), moderate in 21 (11.2%), high in 28 (14.9%), dependent of handling in 1 (0.5%), unknown in 7 (3.7%) and not defined in 10 (5.3%). The cases without certainty diagnosis (91 cases), had the etiology and the risk considered as undetermined. Failure in reaching goals in most cases, resulted from the not accomplishment a full protocol that includes evaluation for clinical geneticist, photographic and radiological documentation, cytogenetic and molecular studies. The authors demonstrate that collaborative work between Genetics and Pathology Services can succeed for clinical diagnosis, etiology and recurrence risks definition. Financial Support: FAPESP.

**Probable autosomal dominant aqueductal stenosis.** *S. Sastry*<sup>1</sup>, *E. Schneider*<sup>2</sup>, *J. Halperin*<sup>3</sup>, *M.G. Bialer*<sup>1</sup>. 1) Dept. of Pediatrics; 2) Ob/Gyn; 3) Neurology; North Shore Univ. Hospital/NYU School of Medicine, Manhasset, NY.

A 30 yr old Hispanic female presented at 19 wk gestation with sonogram findings of moderate to severely dilated lateral ventricles and mildly dilated 3rd ventricle with no other abnormalities, consistent with a diagnosis of aqueductal stenosis (AS). Amniotic fluid AFP was normal and amniocyte chromosome analysis was 46,XX. The mother's medical history was significant for seizures, but she was not on medications as her last seizure was at 18 yr. A CT scan done at 18 yr showed mild hydrocephalus. She also had an anal anomaly repaired at birth. On physical exam she had a left single transverse palmar crease with thenar hypoplasia, cupped ears and a small right ear. She had no cognitive or physical limitations. An MRI scan performed on her during the pregnancy showed significant obstructive hydrocephalus involving the lateral and 3rd ventricles, compatible with a diagnosis of AS. The corpus callosum was thinned but no other abnormalities were detected. The baby was delivered by planned C-section at 34 wk gestation due to oligohydramnios. Birthweight was 1905g (25%), length 41 cm (<3%) and OFC 32.7 cm (75-90%). Anterior and posterior fontanelles were large with prominence of the forehead. No other abnormalities were detected. MRI scan confirmed AS. A VP shunt was placed. Results of L1CAM testing are pending. At 1 year, the baby is babbling with specific "ma-ma" and "da-da", is able to stand with assistance and cruises in a walker. She is somewhat small for age but growing proportionately. This history is consistent with autosomal dominant AS. Hydrocephalus is seen in approximately 1/1000 pregnancies, of which about 40% are AS. There is an X-linked recessive form caused by mutations in the L1CAM gene and other cases may be multifactorial. We are aware of 2 families with apparently autosomal dominant AS with 5 affected individuals (J Neurolog Sci 1998;158:101). 4/5 individuals are intellectually normal. The 5th is a 2.5 yr old child with developmental delays. Although AS prenatally diagnosed at this gestational age has a poor prognosis, the outcome in this case has been encouraging, and autosomal dominant AS may have a better prognosis than other forms.

**Otopalatodigital TypeII in a female: clinical and laboratory studies.** *S. Guarducci, A. Cecconi, E. Lapi, G. Ricotti, U. Ricci, M. Lapini, L. Ombroni, E. Andreucci, S. Pelagatti, V. Lazzerini, I. Sani, A. Brusaferrri, M.L. Giovannucci Uzielli.* University of Florence, Department of Paediatrics, Azienda Meyer, Genetics and Molecular Medicine Unit, Florence, Italy.

Otopalatodigital Syndrome (OPD), subdivided into type I (MIM 311300) and type II (MIM 304120) is a rare genetic disorder, transmitted as an X-linked recessive trait. OPD II is a potentially lethal skeletal dysplasia, characterized by abnormal features at the facial and extremities level, and by multiple skeletal abnormalities. Thoracic hypoplasia may lead to early death (Nishimura et al. 1997). The phenotypic overlap among OPD type II and Melnick-Needles syndrome, a disorder transmitted as an X-linked dominant trait, and also Larsen syndrome, may justify the expansion of these different entities. We recently encountered a female newborn, with specific and severe clinical manifestations of OPD type II. Cytogenetic and cytogenetic-molecular analyses revealed a normal 46, XX karyotype, whereas molecular study excluded UPD, and X-inactivation analysis failed to demonstrate a skewed inactivation.

**Evaluation of clinical and molecular criteria in 240 patients affected with Hereditary Motor and Sensory Neuropathy (HMSN).** *R.B. Bernard<sup>1</sup>, A. Navarro<sup>1</sup>, J. Pouget<sup>2</sup>, C. Desnuelle<sup>3</sup>, N. Philip<sup>1,4</sup>, N. Levy<sup>1,4</sup>.* 1) Departement de Genetique Medicale, Hopital de la Timone, Marseille; 2) Service des maladies neuromusculaires, Hopital de la Timone, Marseille; 3) Service de reeducation fonctionnelle, Hopital l'Archet, Nice; 4) Inserm U491, Marseille, FRANCE.

We studied 240 patients affected with neurologic features consistent with HMSN. Our study was conducted on the basis of clinical, genealogical, electrophysiological, histologic and molecular criteria. By using several molecular technical approaches and particularly a new CMT1A-REPs PCR approach, CMT1A duplications were identified in 25% of patients. We evidenced that the association of 5 major phenotypic criteria increases the probability to detect the 17p11.2 duplication (increased risk X 8). Interestingly, we demonstrate the age of diagnosis in CMT1A is significantly higher in females than males, suggesting the existence of sex-dependending factors influencing the disease severity. Eventually, we evidenced a positive correlation between age of onset in CMT1A and motor VCN values. Our data confirm the clinical heterogeneity of the disease, essentially within the same family. A 17p11.2 deletion responsible for HNPP was detected in 14% of patients. None of the HNPP clinical criteria was specific for positive diagnosis. Oppositely, increased distal latencies evaluated by electrophysiology are more contributive. Presence of non-neurological features associated to pressure palsies drastically reduces the probability of HNPP deletion. Point mutations in Connexin 32 gene were identified in 12 patients with common clinical phenotype of CMT1. In such cases, electrophysiological findings are usually atypical. A search of point mutations in P0, PMP22 and EGR2 was conducted in patients affected with severe phenotypes. Very rare mutations in these genes were identified. Our results suggest that prospective studies of the genotype-phenotype correlations in CMT1A disease are still necessary to evidence predictive criteria of severity. This approach will allow to identify families in whom modifier genes could segregate. They also evidence that molecular strategies to explore HMSN have to be supported by precise phenotypic informations.

**Clinical and Molecular Studies in a large unique family with Limb-Girdle Muscular Dystrophy and Paget Disease of Bone.** *V.E. Kimonis<sup>1</sup>, M.J. Kovach<sup>1</sup>, S. Leal<sup>4</sup>, B. Waggoner<sup>1</sup>, R. Khardori<sup>2</sup>, D. Gelber<sup>3</sup>.* 1) Dept Ped, Div Gen & Metabolism, Southern Illinois Univ Sch Med, Springfield, IL; 2) Dept of Internal Medicine, Southern Illinois Univ Sch Med, Springfield, IL; 3) Dept of Neurology, Southern Illinois Univ Sch Med, Springfield, IL; 4) Lab of Statistical Genetics, Rockefeller University, NY, NY.

A large Central Illinois family with Limb-Girdle Muscular Dystrophy (LGMD) and Paget disease of bone (PDB) includes 11 affected individuals (8 M, 3 F) ranging in ages from 33 y to 64 y. Onset of PDB is at a mean age of 41 y with pain in the hips, shoulders and back. Onset of the LGMD is at a mean age of 45.6 y. with weakness of the girdle muscles, and absent/reduced tendon reflexes. Affected individuals have elevated alkaline phosphatase (mean 455 (normal 30-130 mg/dl)), and CPK levels (mean 273 (20-222 mg/dl)). High-resolution karyotype is normal. Muscle biopsies in 5 individuals reveals non-specific myopathy with vacuolar changes seen in the oldest male. Individuals die prematurely from progressive muscle weakness, cardiomyopathy and cardiac failure in the forties to sixties. There are three previous reports of PDB and neuromuscular disease. Caughey et al. (1957) described familial dominant dystrophia myotonica, Tucker et al. (1982) identified a family with dominant amyotrophic lateral sclerosis, and McBride et al. (1966) found recessive LGMD in four of six siblings in addition to PDB. Linkage analysis in this family excluded all the 22 candidate loci for LGMDs, myopathy, PDB and cardiomyopathy. A genome wide search (Marshfield) indicated linkage to a unique locus on 9p21-q21 with D9S301 (max LOD=3.64) which includes the locus for recessive vacuolar myopathy, IBM2, however excludes the LGMD2H locus. Identification of the specific gene mutation may permit understanding the pathogenesis and permit development of specific treatment protocols in this unusual disorder.

**High frequency of Klinefelter syndrome among a large population of patients referred for Fragile X syndrome testing due to undiagnosed mental retardation.** *M. Khalifa, J. Struthers.* Dept Pediatrics and Pathology, Queen's University and Kingston General Hospital, Kingston, Ontario, Canada.

Approximately 3% of the general population have mental retardation, with the majority of cases in the mild range. About 40% of cases with mental retardation remain without a specific diagnosis. In this study, we screened 1619 DNA samples from 1217 patients referred for DNA testing for Fragile X syndrome (FRAX), primarily because of mental retardation, hyperactivity, behaviour problems or learning disability. Our molecular approach for X chromosome aneuploidy screening involved dosage comparison following Southern blotting and cohybridization with two non-polymorphic markers, one on the X chromosome and the other on an autosome. Dosage evaluation was carried out both visually and using densitometric measurement. In normal females (46, XX), the intensity of the two bands should be equal, representing two copies of the alleles on both the X and the autosome. In normal males (46, XY), the X chromosome allele will be half the intensity of the autosomal one. Samples deviating from the expected pattern were retested and confirmatory testing was done. Seven pre-pubertal patients who were referred because of FRAX features or MR were found to have Klinefelter syndrome (47, XXY). Among the same age group, a similar number of patients were found to have FRAX. Since approximately 3/4 of the studied population were males, and 3 of the identified FRAX cases were suspected because of a family history of the disease, Klinefelter syndrome could be the most common cause of undiagnosed mental retardation among pre-pubertal males without a family history of mental retardation or FRAX (~2% versus 1.3% for FRAX). Because of the significant medical and psychological benefits of early recognition of Klinefelter syndrome, we recommend cytogenetic study for all cases of mild mental retardation among pre-pubertal males even without dysmorphic features.

**Bartsocas-Papas Syndrome (MIM 263650) in a West African family: Prenatal diagnosis and further delineation.**

*D. Staffenberg<sup>1</sup>, A. Shanske<sup>1</sup>, B. Russell<sup>2</sup>, O. Rosen<sup>1</sup>.* 1) Center for Craniofacial Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 2) Bronx Lebanon Hospital, Bronx, NY.

Bartsocas and Papas (1972) reported 4 sibs in a consanguineous Greek family with a recessive form of the popliteal pterygium syndrome (MIM 119500). The clinical findings include LBW, ankyloblepharon, cleft lip/palate, filiform bands between the jaws, popliteal pterygium, syndactyly, and nonectodermal anomalies including microcephaly and genital abnormalities. Early lethality is a common feature. We report a case of a Gambian infant with this disorder.

**Case Report:** SB was the 2165 gm product of a 36 week gestation complicated by IUGR. An ultrasound at 30 weeks revealed a talipes deformity and a large gap between the 1st and 2nd toes. He was delivered by section because of breech presentation to a 19 year old primigravida from Gambia who is the first cousin of the father. The newborn examination revealed a right-sided cleft lip/palate, symblepharon, and synechia between the upper and lower alveoli. He had bilateral cryptorchidism and a large popliteal pterygium. There was syndactyly of digits 2,3,4 of both hands, hypoplasia of the fingernails of the same digits and a large gap between the 1st and 2nd toes secondary to the pterygium. The ankylosed mandible resulted in a tracheostomy and gastrostomy within the first 2 weeks of life. The oral synechia and ocular filiform adhesions were also lysed. A 3-D CAT scan demonstrated probable fusion between the left coronoid and zygoma as well as the condylar head to the temporomandibular fossa. A high resolution karyotype was normal.

All but one of the reported cases (10 males and 8 females) have been from the Mediterranean region. Syngnathia is a rare anomaly involving soft tissue or bony adhesions between the maxilla and the mandible. Only about 60 cases have been reported mostly in association with the popliteal pterygium syndrome and involving soft tissue only. Our patient is the first from Africa, the only case with bony syngnathia, and the first case indicating the practicality of prenatal diagnosis of this disorder.

**Unusual findings in a case of Marshall-Smith syndrome. Further delineation of the phenotype.** *E. Tron<sup>1</sup>, M. Velinov<sup>1,3</sup>, S. Barrett<sup>1</sup>, E. Moran<sup>2</sup>, R. Wallerstein<sup>2</sup>, G. Kupchik<sup>1</sup>.* 1) Pediatrics, Maimonides Medical Center, Brooklyn, NY; 2) Clinical Genetics, Hospital for Joint Disease, Orthopedic Institute, NY,NY; 3) NYS Institute for Basic Research, Staten Island, NY.

Marshall-Smith syndrome is a rare disorder of accelerated skeletal maturation, failure to thrive and specific dysmorphic features. Respiratory system complications often cause death in early childhood. We report a female patient who was admitted at 3 years and 9 months of age because of high fever and suspected infection. The physical exam showed dolichocephaly with prominent forehead, blue sclerae, anteverted nares, dysplastic teeth, stridor, pectus excavatum with flared ribs, and generalized hypotonia. Since birth, the patient had extensive diagnostic work up that showed consistently advanced bone age, height at or above 95%, weight at or below 50%, laryngomalacia and duplicated left kidney. Chromosomes were normal: 46,XX. Her metabolic work up and head MRI were unremarkable. The X-ray of hands showed advanced bone age and broad proximal phalanges as well as disharmonious maturation between the carpal bones and the distal aspect of hand. This patient also had history of unexplained high fever causing multiple hospital admissions. Her usual baseline temperature was reported to be 102 degrees. Multiple clinical and laboratory evaluations did not reveal any specific infectious cause for the elevated temperature. There was no evidence of serious chronic or acute respiratory complications during these evaluations. The reported patient has the typical dysmorphic characteristics of Marshall-Smith syndrome. The diagnosis is further supported by advanced bone age, low weight for height and absence of laboratory findings indicating diagnostic alternatives. The unusual finding of consistently elevated body temperature without indication of ongoing infection, suggesting a central regulation abnormality, has not been reported in association with Marshall-Smith syndrome to our knowledge. In addition, our patient did not have serious respiratory complications that are typical presentation of the syndrome. These unusual presentations may help better delineate the clinical features associated with the condition.

**Ovarian failure in neutral lipid storage disease (NLSD): report of a case.** *D.J. Aughton.* Wm. Beaumont Hospital, Royal Oak, MI.

A 24-year-old woman of Mediterranean descent presented for evaluation of idiopathic hepatomegaly, ichthyosis, sensorineural hearing loss, and primary ovarian failure. There was no known consanguinity. She had a slender habitus but with plethora of the face, neck, and upper thorax. Her skin was dry and fissured.

I did not recognize this constellation of findings. Chromosome analysis yielded normal results. I learned in reviewing past records that when the woman was 4 years old, a dermatologist had rendered a diagnosis of nonbullous congenital ichthyosiform erythroderma; skin biopsy was interpreted as being consistent with lamellar ichthyosis; liver biopsy had shown fatty metamorphosis and minimal fibrosis; and peripheral blood smear had shown vacuolation of granulocytes even though multiple later automated blood counts had been normal. In further reviewing the literature relevant to the ichthyoses, I recognized that the woman's findings were consistent with NLSD. I ordered hematopathologic review of the peripheral blood smear. This showed neutrophils, monocytes, and basophils with multiple small- to medium-size round cytoplasmic vacuoles. I confirmed a diagnosis of NLSD.

NLSD (McK 275630) is a rare autosomal recessive condition that is characterized by the presence of nonmembrane-bound cytosolic droplets in a wide variety of cells. Manifestations may include ichthyosis, hepatosplenomegaly, and sensorineural hearing loss as well as neuromuscular, ocular, and other abnormalities. Vacuolated neutrophils are present in all patients; however, automated analyzers often do not identify these, and this valuable clue is thus easily overlooked. I know of no previous reports of joint occurrence of ovarian failure and NLSD; however, only 7 of the 26 cases described in a recent review (*J Pediatr Gastroenterol Nutr* 1997;25:541-547) were women of reproductive age. I do not know with certainty that the woman's ovarian failure is a direct consequence of her NLSD, but the multisystem nature of and the ubiquitous occurrence of cytoplasmic vacuolization in NLSD strongly suggest a causal relationship.

**Homozygosity mapping of a locus for a novel form of syndromic ichthyosis to chromosome 3q27-q28.** *L. Baala*<sup>1,2</sup>, *S. Hadj-Rabia*<sup>1,3</sup>, *D. Hamel-Teillac*<sup>3</sup>, *S.M. Leal*<sup>4</sup>, *A. Sefiani*<sup>2</sup>, *Y. de Prost*<sup>3</sup>, *A. Munnich*<sup>1</sup>, *S. Lyonnet*<sup>1</sup>, *P. Vabres*<sup>1,3</sup>. 1) Genetique INSERM U-393, Hopital Necker, Paris, France; 2) Department of Genetics and Molecular Biology, INH Rabat, Morocco; 3) Service de Dermatologie, Hopital Necker, Paris, France; 4) Laboratory of Statistical Genetics, The Rockefeller University, New-York, USA.

Autosomal recessive congenital ichthyoses (ARCI) are a heterogeneous group of disorders characterized by abnormal scaling of the skin. Here, we describe a novel form of syndromic ARCI associated with sclerosing cholangitis, hypotrichosis of the frontal scalp and vacuolated leukocytes and keratinocytes in two boys and a girl born to second cousin parents. Normal biliary ducts on histological examination excluded ichthyosis congenita with biliary atresia. In addition, despite similarities with Dorfman-Chanarin syndrome (DCS), this diagnosis could be also excluded on the basis of: i) absence of muscular or ocular features, ii) hepatic involvement with sclerosing cholangitis as opposed to the fatty infiltration observed in DCS and iii) the presence of small-sized leukocyte and keratinocyte vacuoles that were absent in unaffected relatives. Thus, while this disorder appears clearly distinct from DCS, clinical overlap may reflect a common genetic origin or metabolic pathway. Finally, Refsum disease, another syndrome with ichthyosis and vacuolated keratinocytes, could be excluded as well. A genome wide search for homozygosity revealed that only marker AFM308yf1 at locus D3S1601 was found homozygous in all affected individuals and heterozygous in parents and unaffected sibs. Two-point linkage analyses at this locus gave a  $Z_{max}$  value of 1.93 at  $q = 0\%$  while a maximum multipoint lod score of 3.0 was obtained across the region of homozygosity loci : D3S3596, D3S1580, D3S2747, D3S1601 and D3S3669. It should be noted that the maximum lod score expected for this pedigree was 3.25. Our data thus strongly suggest that the disease locus maps to a 16.3 cM region on chromosome 3q27-q28, between loci D3S3628 and D3S1265, where no obvious candidate gene has been localized.

**Brauer nevus (congenital temporal triangular alopecia) with distichiasis and adjacent facial hyperpigmentation in an African American male.** *K.A. Fjelstad, S.J. Hassed, J.J. Mulvihill.* Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Congenital temporal triangular alopecia (CTTA) may be defined as a persistent focal area of hair loss occurring in the temporal or frontal area. A ten-year-old African American male had focal scalp hair hypoplasia and facial hyperpigmentation since an age of three years, but not before. Prior treatment with antifungals and topical corticosteroids had not altered the scalp hair growth. On examination, the patient had two areas of hair hypoplasia in the left frontotemporal region. The anterior edge of one area was continuous with a large whorled, hyperpigmented facial lesion. Hyperpigmented skin was also present in the right popliteal fossa. The patient had bilateral distichiasis (two distinct rows of eyelashes) with long eyelashes in each row. Family history was negative for hair hypoplasia, but there was a report of hyperpigmentation in a second degree relative. Patients with Brauer nevus typically present in early childhood and have been reported in Caucasian and Asian subjects but not in African Americans. CTTA may be subtle and unrecognized and is distinct from alopecia areata, tinea capitis, traction alopecia, and scarring of the scalp. CTTA may be associated with other changes in hair growth and skin pigmentation. A family history of alopecia areata has been reported in five cases of CTTA, but CTTA does not appear to be immune-mediated. Similar skin and eyelash changes are seen in subjects with CTTA and alopecia areata. Eyelash trichomegaly is seen with alopecia areata in subjects with HIV infection; alopecia areata has also been associated with depigmentation or vitiligo. It is tempting to consider Brauer nevus (CTTA) with distichiasis and hyperpigmentation as a pattern of somatic cell mosaicism, but the distal hyperpigmentation argues against that notion. Further identification and study of persons with CTTA may lead to better understanding of the development of disorders of the hair and skin.

**Extensive, Acquired Hypopigmentation in a Patient with 22q11 Deletion Syndrome.** *J.L. Hand<sup>1,2</sup>, S.D. Calobrisi<sup>3</sup>, N.M. Lindor<sup>1</sup>*. 1) Dept Genetics, Mayo Clinic, Rochester, MN; 2) Department of Dermatology, Mayo Clinic, Rochester, MN; 3) Boca Raton, FL.

22q11 Deletion Syndrome (also known as Shprintzen or Velocardiofacial Syndrome) is a common chromosomal deletion syndrome that may result in a wide range of clinical findings. We describe a seven-year-old girl who presented with generalized, acquired hypopigmentation and premature graying of the hair. Past medical history was significant for hyperopia since age five, elevated thyroid antibodies, submucous cleft palate and recurrent otitis media requiring myringotomy tube placement. Physical exam revealed hypernasal speech, macrocephaly, coarse thick hair and a bifid uvula. Skin exam showed extensive discrete and confluent macular hypopigmentation over approximately 70% of the body surface area. Hair exam showed graying of single hairs throughout the vertex scalp and eyelashes. Skin biopsy showed hypopigmentation with absence of melanin in the epidermis. Consensus evaluation by several dermatologists was that the findings were atypical for vitiligo. Significant family history included Tetralogy of Fallot and premature graying of the hair in the patient's father and truncus arteriosus in a sister. On laboratory evaluation, karyotype was normal, 46, XX, but a hemizygous 22q11.2 deletion was detected by FISH probe. Echocardiogram, calcium, and phosphorus levels were normal. To our knowledge, this is the first reported case of acquired hypopigmentation associated with familial 22q11.2 deletion. Further cases are needed to determine if premature graying of the hair and hypopigmentation of the skin represents an association with 22q11 deletion or a coincidental finding.

**The development of cutaneous neurofibromas is influenced by familial and local factors in patients with Neurofibromatosis 1 (NF1).** *C. Palmer<sup>1</sup>, J. Szudek<sup>1</sup>, H. Joe<sup>2</sup>, V.M. Riccardi<sup>3</sup>, J.M. Friedman<sup>1</sup>*. 1) Dept Medical Genetics and; 2) Dept Statistics, University of British Columbia, Vancouver, Canada; 3) American Medical Consumers, Los Angeles, CA.

NF1 is an autosomal dominant condition affecting 1 in 3000 individuals. Its defining feature is the neurofibroma: a complex benign tumor arising from peripheral nerve sheaths. The number of cutaneous neurofibromas in NF1 patients increases with age and is highly variable; the cause of this variability is unknown. We tested the hypothesis that development of these lesions may be influenced by local and familial factors.

The presence or absence of 1 or more cafe au lait spots, 1 or more cutaneous neurofibromas, and 1 or more diffuse plexiform neurofibromas was recorded for each of ten divisions of the body surface in 768 NF1 patients, including 117 affected individuals in 52 families. We used a random effects model to obtain the maximum likelihood estimate and confidence interval of intrafamilial correlations in the number of body divisions affected with 1 or more cutaneous neurofibromas, while controlling for age. The correlation amongst first-degree relatives was  $r=0.30$  (95% CI=0.078,0.52), in agreement with previous studies.

We used a Mantel-Haenszel test, stratified simultaneously by body division and number of body divisions with 1 or more cutaneous neurofibromas, to examine associations in the presence of diffuse plexiform neurofibromas and cutaneous neurofibromas in individual NF1 patients ( $n=630$ ). Divisions that include a diffuse plexiform neurofibroma are twice as likely to have 1 or more cutaneous neurofibromas as well (summary odds ratio=2.02; 95% CI=1.28, 2.77). Odds ratios were not homogeneous across body divisions. No significant association was observed between the presence of cafe au lait spots and cutaneous neurofibromas in a body division in NF1 patients ( $n=584$ ).

We conclude that the occurrence of cutaneous neurofibromas in NF1 patients is influenced by familial factors as well as by local factors.

**Reactive perforating collagenosis: a study of a five generation Indian family with autosomal dominant inheritance.** *V. Patel*<sup>1</sup>, *T. Mehta*<sup>2</sup>, *J.V Solanki*<sup>3</sup>, *U. Radhakrishna*<sup>2</sup>. 1) RIA Laboratory, Green Cross Voluntary blood bank and pathology laboratory, Ahmedabad, Gujarat, India; 2) "Samarpan", Centre for skin, sexually transmitted diseases and Research Centre, Sarvoday School, Modasa-383315, India; 3) Department of Animal genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

Reactive perforating collagenosis (RPC) is a rare skin disorder characterized by umbilicated papules on the sun-exposed areas of the face, arms, and legs and usually begins in early childhood. We report an Indian family living in the state of Gujarat (India) in which RPC was observed in five generations. The pedigree consists of a total of 139 persons with 29 (14 females and 15 males) affected individuals. Male to male transmission was documented. There was no history of diabetes and/or renal involvement in the family. Histopathological examination of skin lesions showed transepidermal elimination of altered dermal collagen bundles. To the best of our knowledge, the present family is the first and largest in which the disease clearly shows an autosomal dominant mode of inheritance.

**Cerebrotendinous xanthomatosis(CTX). The first mexican family reported.** *I.A. Gamboa<sup>1</sup>, C.F. Salinas<sup>2</sup>, R. Mendivil<sup>3</sup>, J.M. Aparicio<sup>4</sup>, T.A. Carvajal<sup>5</sup>.* 1) Escuela de Medicina, Benemérita Univ. Autónoma. de Puebla, Puebla, Pue, Mexico; 2) Div. Craniofacial Genetics, Medical University of South Carolina, Charleston, SC; 3) Secretaría de Salud del Edo. de Puebla; 4) Hospital del Niño Poblano, Puebla; 5) Laboratorios Zacatecas, Cd. de Mexico, Mexico.

Cerebrotendinous xanthomatosis (CTX) is a rare inherited lipid-storage disease characterized by progressive neurologic dysfunction, premature atherosclerosis and cataracts. Large deposits of cholesterol and cholestanol are found in every tissue particularly the Achilles tendons, brain and lungs. The onset is in the second decade and it is of autosomal recessive mode of inheritance. The enzyme defect resides in sterol 27-hydroxylase, a mitochondrial cytochrome P-450 enzyme. CYP27 is short for CTX gene. Leitersdorf demonstrated that CYP27 gene contains 9 exons and 8 introns and encompasses at least 18.6 kb of DNA. Gene Map locus: 2q33qter. In Almolya, a small community near the city of Puebla, Mexico, we found a consanguineous family with two affected sisters of 28 and 23 years of age. Six other siblings were normal for CTX. The affected women had short stature, and showed xanthomas of the Achilles tendons and mild mental retardation. Both were treated for bilateral cataracts and are under simvastatine treatment to lower their high cholesterol levels with good results. Both have history of chronic diarrhea. The oldest women became pregnant in her twenties and a girl was born with low birth weight. She now shows short stature, peculiar face with telecanthus, low set and prominent ears and mental retardation. This case does not show additional stigmata, however clinical findings of CTX are commonly observed after puberty. The last case raises the question of whether she is a CTX carrier or is an affected individual. This is of importance for clinical delineation as well as for treatment considerations in order to at least arrest the progression of the disease. To our knowledge this is the first familial case reported in Mexico and also in a family with known native Mexican Indian ethnic background.

**Hennekam syndrome. Report of a case diagnosed at birth.** *C. Arioni<sup>1</sup>, C. Bellini<sup>1</sup>, D. Massocco<sup>1</sup>, C. Campisi<sup>2</sup>, G. Taddei<sup>3</sup>, G. Serra<sup>1</sup>.* 1) Dipartimento di Pediatria, Università di Genova, Dipartimento Pediatria (DiPe), Istituto Gaslini Genova, Italia; 2) Dipartimento di Scienze Chirurgiche Anestesiologiche e Trapianti d'Organo (DiSCAT), Università di Genova, Italia; 3) Dipartimento di Medicina Interna (DiMi), Università di Genova, Italia.

**CASE REPORT.** The patient was born prematurely to healthy and unrelated parents. Physical examination revealed a flat face, a depressed and broad nasal bridge, a bulbous nasal tip, mild down-slanting palpebral fissures, epicanthal folds, puffy eye lids, hypertelorism, small mouth and low set ears. The skin appeared marbled and the fingertips were prominent. Generalized lymphedema was especially severe in the periorbital region, on the lower arms and hands, on the lower legs and both feet, and on the penis and scrotum. Hypoproteinemia, hypogammaglobulinemia, and lymphatic count approx 5000 mmc were present. Two subsequent examinations of alpha-1-antitrypsin fecal excretion showed 331 and 3800 gamma / gr of wet feces (normal value 7.7-159 gamma / gr of wet feces), respectively, suggesting intestinal lymphangiectasia. His parents refused to consent to duodenal biopsy. Radionuclide scintigraphy (0.32 mCi of <sup>99m</sup>Tc-Lymphoscint) showed delayed drainage of the contrast liquid was observed, and was especially evident in the right inguinal area. Chromosomes, TORCH titer, and skull films were normal. Ultrasound evaluation was normal, a part from mild ascites. He did not show any symptoms pointing to psychomotor delay. In 1989, Hennekam et al. first reported a new autosomal recessive syndrome (OMIM 235510) characterized by the presence of lymphedema of the limbs, facial anomalies, intestinal lymphangiectasia, and/or varying degrees of mental retardation. It could be hypothesized that during fetal life, maternal support compensates for the possible intestinal effect of lymphatic vessel abnormalities, which later lead to growth retardation. Some differences in the clinical picture that were seen in our patient may be related to the early age at observation. Additional reports of neonatal cases and full follow-up studies would better delineate the clinical course of the syndrome.

**X-Linked syndrome of diarrhea, polyendocrinopathy, and fatal infection in two male monozygotic twins.** *M. Mazzella, I. Bertini, C. Arioni, D. Massocco, P. Mezzano, C. Bellini, G. Serra.* Dipartimento Pediatria, Università di Genova, Istituto Gaslini, Genova, Italia.

**CASE REPORT.** We report on two male monozygotic twins who present neonatal diabetes, intractable diarrhea, immune dysregulation and polyendocrinopathy. They were born after 36-week uncomplicated pregnancy to unrelated healthy parents. Family history was negative. Both patients were admitted because of poor feeding, dehydration, lethargy, metabolic acidosis, severe watery diarrhea and persistent hyperglycemia (up 17 mmol/L; C-peptide absent). High levels of thyroid stimulating hormone, increased serum level of antithyroglobulin and increased antithyroid microsomal antibodies. ICA and GAD-reactive autoantibody were present. Serum enterocytes, anti-parietal cell, and antiendomysium autoantibodies were negative (maternal serum studies failed to demonstrate the presence of autoantibodies). Lymphocytes subpopulations, CD4:CD8 ratio, mitogenic responses did not reveal immunological defects. TORCH serology and IgE concentration were normal. HLA typing did not show type 1 Diabetes related haplotypes in both the patients. Persistent watery diarrhea, failure to thrive, recurrent infections, brittle diabetes characterized the clinical course. Both patients died within the third month of life. Histological evaluation showed marked mononuclear infiltration in the pancreas, gut, and thyroid. Our patients are affected by a very rare X-linked autoimmune enteropathy with polyendocrinopathy. Our cases are interesting because of the presence of neonatal diabetes with histological and immunological findings that are typical of type I diabetes but with the absence of typical HLA antigen pattern of susceptibility. The histological and immunological findings seem to be typical of the autoimmune-type diabetes; the striking finding is that the insulinitis can be clinically evident even shortly after the birth. Neonatal diabetes mellitus is a rare illness. Congenital insulin-dependent diabetes mellitus presenting in the first days of life, is even more rare. Secretory diarrhea unrelated to infections is also very uncommon in infants.

**Cleft sternum and aplasia cutis.** *E. Zullino, F. Campone, D. Massocco, C. Bellini, G. Serra.* Dipartimento Pediatria, Università di Genova, Istituto Gaslini, Genova, Italia.

Case Report. A female twin infant was born at term to healthy non-consanguineous parents. The twin brother was healthy. No maternal abuse of alcohol, smoke or drug were reported. The child suffered asphyxia at birth and she underwent cardiopulmonary resuscitation. Thoracic X-ray examination showed superior sternal cleft (approx two-thirds). An isolated small area (0.8 cm in diameter) of aplasia cutis on the anterior trunk was observed. US evaluation confirmed the lesion. Brain and cardiac US were normal. No other skeletal defect was observed. Cleft sternum is a rare thoracic defect due to an embryonic fusion failure during the sixth week after conception. The sternum originates from the lateral plate mesoderm and forms two laterally located mesenchymal bands at the sixth week after conception. Both bands fuse during the ninth week in the cranio-caudal fashion. At the end of the eighth week a mesenchymal infiltration stabilizes the overlying ectodermal epithelium. Superior clefts are most often isolated, or associated with vascular dysplasias. Inferior or complete sternal clefts are usually associated with various other defects of the same developmental field. Associated skin anomalies include facial angiomatosis, a supraumbilical midline raphe, a skin ulcer, keloid, or skin defect. The cause of sternal cleft is unknown. All observations of sternal clefts and/or supraumbilical raphe have been sporadic. No teratogen has been recognized in the literature. It is unlikely that nutritional factors play a role in the pathogenesis of cleft sternum; in fact, most reported patients were born in well-developed industrial countries. Arguments for or against a specific genetic origin are generally lacking. An autosomal recessive inheritance has been suggested, but not confirmed. A female twin (zygosity unknown) with superior cleft sternum associated with supraumbilical raphe, and hemangioma of the face and of the neck has been reported. Our case is a further report of this rare malformation. The existence of a healthy twin-brother could confirm that the teratogenic origin is unlikely.

**A Family with Cleft Palate - Lateral Synechia Syndrome: Report on Additional Findings and Evidence for Intrafamilial Variability.** *L. Fernandez*<sup>1,2</sup>, *J.C. Prieto*<sup>1,3</sup>, *O.L. Gutierrez*<sup>3</sup>, *R. Romero*<sup>3</sup>. 1) Instituto de Genetica Humana, Universidad Javeriana., Bogota, Cundinamarca, Colombia; 2) Universidad del Rosario, Bogota, Colombia; 3) Hospital la Victoria, Secretaria Distrital de Salud, Bogota, Colombia.

Cleft palate - lateral synechia syndrome (CPLS) is a rare disease characterized by the presence of multiple cordlike adhesions between the free borders of the palate and lateral parts of the tongue and floor of the mouth. It has an autosomal dominant pattern of inheritance. In addition to cleft palate and lateral synechia, other findings such as synechia fused eyelids, blocked or absent nasolacrimal duct, blepharophimosis, convex or beaked profile of nose, full cheeks, trismus, pits of lower lip, prominent or everted lower lip, short philtrum, cleft upper lip, cleft uvula, absent or hypoplastic thumbs, club foot, mental retardation and developmental delay have been associated with this syndrome. Here we report a family with additional phenotypic manifestations mainly in genitalia and limbs. Some of this findings are rectum - vagina fistula, clinodactyly of fifth finger, hypoplasia of midphalanx of fifth finger, short fifth finger, absence of the longitudinal arch of feet and short fingers of the hands. We present this case of CPLS syndrome with three affected family members in which is demonstrated the autosomal dominant inheritance pattern and intrafamilial phenotypic variability. To our knowledge, no other reports have described patients with this syndrome and a rectum - vagina fistula and abnormalities of limbs.

**Spinocerebellar Ataxia, Hypogonadotropic Hypogonadism, High Myopic Retinal Degeneration, and Mental Retardation in a 32-Year-Old Man.** *R.S. Colby, L.H. Seaver.* Greenwood Genetic Ctr, Greenwood, SC.

A 32-year-old Caucasian male with ataxia and mental retardation (MR) was evaluated. Family history was negative. Perinatal histories were unremarkable. Development was considered normal until 1 year of age when he could not walk alone. Thereafter, his development was delayed and IQ testing showed functioning in the moderate to severe range of MR. Examination showed a eunuchoid habitus and a high pitched voice. He had only light blond facial hair, sparse axillary hair, and pubic hair in a female distribution. Neurologic exam showed horizontal nystagmus, head titubation, action tremor, poor finger to nose and heel to shin testing, and 3-4+ reflexes bilaterally in all limbs. Eye exam showed high myopic retinal degeneration. MRI of the brain showed cerebellar, pontine, and brainstem atrophy. Serum LH and FSH were significantly low. EEG, EMG, and motor and sensory nerve conduction studies were normal. Chromosomes, methylation at the Prader-Willie/Angelman locus, serum lactate, serum transferrin isoelectric focusing, and plasma amino acids were normal.

The association of spinocerebellar ataxia (SCA) and hypogonadotropic hypogonadism (HH) has been noted for some time (OMIM \*212840). The added feature of chorioretinal dystrophy is the so-called Boucher-Neuhauser syndrome (BNS)(OMIM \*215470). Patients with BNS typically present in adulthood and do not have MR. Laurence-Moon syndrome features include retinitis pigmentosa, MR, spastic paraplegia, and hypogonadism, and may be considered in the differential diagnosis. This patient has high myopic retinal degeneration, but no chorioretinal dystrophy at this point. He also presented at a younger age than most previously reported patients and has MR. Patients with the association of SCA, HH, and retinal changes have shown evidence of autosomal recessive inheritance. X-linked inheritance cannot be excluded in this patient as there was no consanguinity or other siblings affected. This patient seems to fit into the general category of SCA and HH, with or without MR and retinal changes. The possibility that these disorders represent a spectrum seems plausible.

**A fourth patient with the Kapur-Toriello syndrome: Pancreatic nesidioblastosis, digital hypoplasia and late paternal age as novel findings.** *G.E. Graham<sup>1</sup>, A. Pinto<sup>2</sup>, R.B. Lowry<sup>1</sup>.* 1) Department of Medical Genetics; 2) Department of Pathology, Alberta Children's Hospital and University of Calgary, Calgary, Alberta, Canada.

In 1991 Kapur and Toriello described a brother and sister with severe intellectual handicap, growth retardation, similar facial features (a bulbous nasal tip and long columella), cleft lip, cleft palate, congenital heart defects, intestinal anomalies and minor digital anomalies. Eight years later, a third patient described by Zelante et al. confirmed the existence of this new and presumably rare MCA/MR syndrome. We now report a fourth patient in whom we suspect Kapur-Toriello syndrome (KTS). This male infant was born at term to a 24-year-old non-diabetic primigravida and her unrelated 50-year-old partner. Our patient had microbrachycephaly, a large anterior fontanelle, iris and retinal colobomata, severe unilateral cleft lip, cleft palate, square-shaped helices, a short neck, excess nuchal skin, PDA, single umbilical artery, short 5th fingers with narrow nails, hypoplastic fourth toes and absent 4th and 5th toenails. He had a complicated and protracted medical course that included growth retardation, severe hyperinsulinemic hypoglycemia and sepsis, to which he succumbed at 6 months of life. An autopsy revealed hypertrophy and hyperplasia of the pancreatic islet cells associated with multifocal ductoinsular structures, consistent with pancreatic nesidioblastosis. Metabolic investigations, as well as amniocyte and lymphocyte chromosomes, were normal. Our patient provides further confirmation of the existence of this MCA/MR syndrome and suggests that pancreatic nesidioblastosis can be one of the intestinal manifestations. We recommend that newborns with features of KTS be closely monitored for hypoglycemia. KTS may represent a microdeletion syndrome or a single gene disorder caused by an autosomal recessive or new dominant mutation. It may also be etiologically heterogeneous. Advanced paternal age would support a new dominant mutation in our patient, but other modes of inheritance cannot be ruled out.

**Clinical data and Molecular Analysis in twenty-four Mexican Apert syndrome patients.** *L. Cornejo*<sup>1</sup>, *E. Garca*<sup>2</sup>, *S. Chavira*<sup>3</sup>, *M. Muenke*<sup>4</sup>, *D. Saavedra*<sup>3</sup>. 1) School of Medicine, Sciences Health Institute, Autonomous Hidalgo State University, Pachuca de Soto, Hidalgo Mexico; 2) West Biological Research Center and Mexican Social Security Institute, CIBO-IMSS, Guadalajara, Jalisco Mexico; 3) General Hospital "Dr. Manuel Gea Gonzalez" SSa, Mexico City, Mexico; 4) Clinical Genetics Branch, NHGRI, NHI, Bethesda Ma, USA.

**Introduction.-** Apert syndrome is characterized by craniosinostosis, midface hypoplasia, and symmetric syndactily of the hands and feet, minimally involving digits 2,3, and 4. The syndrome has been observed in white, black, and Asian populations. Its inheritance pattern is Autosomal Dominant (AD). Molecular analysis has reported mutations in *FGFR2* gene as: Ser252Trp, Pro253Arg, Pro253Phe; acceptor splice site and *Alu* insertion in patients with Apert syndrome worldwide. **Material and Methods.-** A clinical re-evaluation in 24 mexican patients (mixture of Asiatic and Iberic genes) out of 79 was done. All of them have been attended at the General Hospital "Dr. Manuel Gea Gonzalez" since fifteen years ago. Also the sequencing of exon 7 in *FGFR2* gene was done. **Results.-** Twenty three patients have a heterozygous allele mutation and only one patient has a homozygous allele mutation. Thirteen patients showed a Serine252Trp (TCG to TCC) mutation (homozygous allele);and eleven patients showed a Pro253Arg (CCT to CGT) mutation. Clinical data were not different from the previously worldwide reported cases, including the patient with a homozygous allele mutation. **Conclusions.-** This is the first Mexican - meztizo population series with Apert syndrome reported with clinical and molecular data. The patients show clinical and molecular similarity, included craniofacial antropological measurements. Homozygous allele mutation is not a more deletereous or lethal than heterozygous condition as in other AD diseases.

**Monozygotic twins with fetal akinesia: The value of clinico-pathological work-up in predicting recurrence risks.**

*V.C. Ho<sup>1</sup>, N.C. Ho<sup>2</sup>*. 1) Department of Oral Pathology, National University of Singapore; 2) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Fetal Akinesia Deformation Sequence (FADS) or Pena-Shokeir Sequence is a heterogeneous group of disorders in which prolonged decrease or absence of fetal movements results in a series of deformational anomalies: multiple contractures, pulmonary hypoplasia, craniofacial anomalies, polyhydramnios, intrauterine growth retardation, and short umbilical cord. Three sets of monozygotic twins, two pairs concordant for FADS and one set discordant, were presented, and the clinical and pathological findings were reviewed. Detailed pathological work-up established that the two pairs of twins concordant for FADS were of myogenic etiology while the set discordant was due to anoxic-ischemic damage. Much insight into FADS can be gained from the pathological findings of two studies on arthrogryposis multiplex congenita (AMC) (Strehl et al., 1985; Quinn et al., 1991). Like FADS, AMC is not in itself a diagnosis but a descriptive term, comprising two or more joint contractures since birth, and is associated with any factors that interferes with fetal movements. In the first series of 22 cases of AMC, 9 cases were determined by Strehl and co-workers to be myopathic in etiology. In the other series of 21 cases analysed by Quinn et al., 11 cases were ascertained to be of myogenic origin. A high rate of recurrences was also noted in the myogenic group. This study on monozygotic twins with fetal akinesia focussed on how the etiological findings resulting in FADS could help in predicting risks of recurrence.

**Bilateral coronal craniosynostosis in a patient with Opitz syndrome.** *J. Hedrick, D. Waggoner.* Dept. of Human Genetics, University of Chicago, Chicago, IL.

Opitz (G/BBB) is a syndrome of multiple congenital anomalies characterized by hypertelorism and hypospadias as well as a number of abnormalities of midline structures, including cleft lip and palate, laryngotracheoesophageal defects, imperforated anus, brain anomalies, congenital heart defects, and renal anomalies. Other common findings in Opitz syndrome include downslanting palpebral fissures, epicanthal folds, micrognathia and developmental delay/mental retardation. Opitz syndrome is a heterogeneous condition with loci at 22q11 and Xp22 resulting in both autosomal dominant and X-linked inheritance. Deletions of the well known DiGeorge and Velocardiofacial syndromes (DGS/VCFS) critical region at 22q11 and various mutations in the MID1 gene at Xp22 have been detected in a number of patients with a clinical diagnosis of Opitz syndrome. There is no apparent phenotypic difference between these two groups of individuals. While cranial asymmetry has been associated with Opitz syndrome, craniosynostosis has only been reported once. We report the second case of craniosynostosis and Opitz syndrome in a 9-year-old male ascertained through our multidisciplinary craniofacial clinic. He has a history of developmental delay, bilateral cleft lip and palate, hypertelorism, downslanting palpebral fissures, micrognathia, bilateral coronal craniosynostosis, hypospadias, and premature narrowing of the airway. Chromosome analysis and FISH with TUPLE1 were both normal. Another disorder, Craniofrontonasal syndrome (CFNS), a rare genetic condition characterized by coronal craniosynostosis and a number of features similar to Opitz syndrome with the exception of hypospadias and laryngotracheoesophageal defects, also localizes to Xp22. Due to low copy repeats distributed throughout this region, it is possible that the X chromosome may be more susceptible to unbalanced rearrangements resulting in a microdeletion causing the overlapping phenotype of Opitz syndrome and CFNS in this patient. Molecular analysis of this region is being pursued.

**Further exploring the relationship between lupus and chondrodysplasia punctata.** *D. Kostiner, J. Derstine.* Dept. Pediatrics/Division of Genetics, University of California, San Francisco, CA.

There are several reports in the literature of babies with chondrodysplasia punctata being born to mothers with systemic lupus erythematosus (SLE). The clinical manifestations are similar to those seen with prenatal exposure to oral anticoagulants. It is suspected that maternal autoantibodies produce the spectrum of clinical features. We present the case of a 25-year-old Chinese woman with facial manifestations suggestive of chondrodysplasia punctata who developed lupus as a teenager. We have little information about her parents, but consanguinity is suspected. It is not known whether the patient's mother had lupus. If she did, we could speculate that maternal lupus during pregnancy caused the craniofacial abnormalities in the patient, and that inheritance of a certain HLA type predisposed the patient to developing SLE herself. The patient was born at term after an uncomplicated pregnancy. Birth weight was 3700 gm (60%), length was 19 in (25%), HC was 33 cm (<3%; 50% for 34 weeks). Significant hypotonia was noted in the newborn period. Developmental milestones were delayed. SLE, primarily discoid lupus, was diagnosed at age 16 years. Left hip replacement was performed at age 16 years for recurrent hip dislocations. Craniofacial surgery was performed at age 20 years to correct a hypoplastic mandible. The patient has myopia and bilateral sensorineural deafness. She has mental retardation, lives with a guardian and attends school. Current exam reveals the following: Ht 152 cm (<3%), Wt 51.3 Kg (25%), HC 52.5 cm (-1.8 SD). Dysmorphic facies. Low hairline. Synophrys. Midface hypoplasia. Large eyes. Proptosis. Hypertelorism. Simple ears. Hypoplastic nasal bridge. Flat nasal tip. Paucity of bone and cartilage in nose. Hypoplastic mandible, status-post surgical repair. Mild hepatomegaly. Short digits. No obvious rhizomelia. Abnormal skin and nails secondary to lupus. Chromosomes, peroxisomal studies, and skeletal survey are currently pending. In summary, documentation of SLE in the patient's mother could account both for features of chondrodysplasia punctata in the patient as well as autosomal dominant predisposition to development of SLE.

**Megalencephaly-Cutis Marmorata Telangiectatica Congenita Syndrome: Association of arrhythmia leading to sudden death?** *S. Yano*<sup>1,2</sup>, *Y. Watanabe*<sup>2,3</sup>. 1) Div Medical Genetics, Childrens Hosp, Los Angeles and University of Southern California, Los Angeles, CA; 2) Medical Genetics, Pediatrics, Kurume University, Kurume Japan; 3) Pediatrics, University of Iowa.

Megalencephaly-cutis marmorata telangiectatica congenita (M-CMTC) constitutes a distinct entity characterized by prenatal overgrowth, macrosomia, hemihypertrophy, macrocephaly, nonobstructive hydrocephaly, frontal bossing, hypotonia, developmental delay, generalized or facial capillary malformation with upper philtral nevus flammeus and cutis marmorata, joint hypermobility, loose skin, toe syndactyly, and postaxial polydactyly. All but one of the cases reported previously had benign clinical courses without showing an increased risk of early infantile death. We describe three additional cases with poor clinical outcomes including severe postnatal growth failure, intractable cardiac arrhythmia in two cases and sudden infant death in two cases. Arrhythmia has not been described previously as one of the symptoms of M-CMTC. Patients with M-CMTC associated with severe postnatal growth failure and arrhythmia may constitute a distinct clinical subtype of M-CMTC with an increased risk of life-threatening episodes or sudden death. Recognizing this clinical subtype of M-CMTC is important in order to prevent these serious potential complications.

**FGFR3 P250R Mutation Associated with Hemifacial Microsomia, Craniosynostosis and Sudden Infant Death.** *K. Siriwardena*<sup>1,2</sup>, *G. Taylor*<sup>3</sup>, *L. Steele*<sup>3</sup>, *P. Ray*<sup>3</sup>, *D. Chitayat*<sup>1,2</sup>. 1) Prenatal Diagnosis Program, Mount Sinai Hospital, University of Toronto, Canada; 2) Division of Clinical Genetics, The Hospital for Sick Children, University of Toronto, Canada; 3) Department of Laboratory Medicine and Pathobiology, The Hospital for Sick Children, Toronto, Canada.

FGFR3 P250R mutation is an autosomal dominant, mostly familial condition associated with coronal craniosynostosis, sensorineural deafness, craniofacial and digital abnormalities. We report a mother and daughter with this mutation. The mother presented with coronal craniosynostosis and hemifacial microsomia and her daughter died unexpectedly of upper airway obstruction following which a genetic investigation revealed that both carry the P250R mutation. The G<sub>1</sub>P<sub>1</sub>L<sub>0</sub> mother was seen after the unexpected death of her 2-day old daughter. At birth the infant required oxygen for tachypnea and noisy breathing was noted without cyanosis or apnea. The day after discharge she was found unresponsive. The post-mortem showed dysmorphic features including down-slanting palpebral fissures, left proptosis, preauricular skin tags, right coronal craniosynostosis and orbital hypoplasia. Examination of mother revealed brachycephaly, ridging of coronal sutures, aplasia of the right external auditory meatus, mild proptosis, malar hypoplasia, and bilateral brachydactyly of 5<sup>th</sup> fingers and 1<sup>st</sup> toes, and syndactyly of 2<sup>nd</sup> and 3<sup>rd</sup> toes. In infancy a diagnosis of Treacher Collins syndrome had been made. In childhood X-rays had shown bicoronal craniosynostosis, bony atresia of the external auditory canal and malar hypoplasia; and osteotomies had been performed for bilateral varus metatarsus deformities.

Molecular testing confirmed the presence of FGFR3 P250R mutation in both mother and deceased infant. Though unavailable for testing the grandfather was reported to have similar facial features to his daughter and deceased granddaughter. These patients add hemifacial microsomia and sudden infant death to the clinical manifestations of the P250R mutation. It again emphasizes the inter- and intra-familial variability of manifestations in this condition and the increased severity in females reported previously.

**Linear Nevus Sebaceus with Empty Sella Turcica and Transsphenoidal Meningocele.** *J.C. Prieto*<sup>1,2</sup>, *A. Motta*<sup>3</sup>, *L. Fernandez*<sup>4</sup>, *R. Romero*<sup>2</sup>, *O.L. Gutierrez*<sup>2</sup>, *P. Garavito*<sup>5</sup>. 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Hospital la Victoria, Secretaria de Salud, Bogota, Colombia; 3) Hospital Simon Bolivar, Secretaria de Salud, Bogota, Colombia; 4) Universidad del Rosario, Bogota, Colombia; 5) Universidad del Norte, Barranquilla, Colombia.

Linear sebaceous nevus syndrome also known as nevus sebaceus of Jadassohn is characterized by the presence at birth or soon after, of alopecia with absent or primitive hair follicles and numerous small hypoplastic sebaceous glands with hyperpigmentation and hyperkeratosis. Lesions are usually on the scalp, in the para - midfacial area, from the forehead down into the nasal area. These tend to be linear in distribution, and may also affect the trunk and limbs. At puberty, the lesions become verrucous with hyperplastic sebaceous glands, and tumors may develop. Other findings can include asymmetric overgrowth, cranial asymmetry, lid lipodermoid, coloboma of eyelids, iris and choroid, coarctation of aorta, horseshoe kidney, kyphoscoliosis, finger and toe abnormalities, hemangioma, mental retardation, seizures, vitamin D resistant rickets basal cell carcinoma, epidermal nevus, hydrocephaly, ventricular septal defect, hypoplastic teeth, renal hamartomata and nephroblastoma. The cases reported have been sporadic, a specific pattern of inheritance has not been described, yet. We report on a 26 years old man with bilateral ptosis, amaurosis of the right eye, ocular hypertelorism, telecanthus, broad nasal bridge, hypoplastic nostrils, kyphoscoliosis, gynecomastia, sexual infantilism, absence of testes, bilateral hallux valgus, clinodactyly of fifth finger, bilateral limitations for elbow extension and linear verrucous nevus on the lower extremities. The hormone studies reported a hypopituitarism. The cytogenetic analysis was normal 46, XY. The brain MRI showed a transsphenoidal meningocele which extends to the nasalpharyngeal tract; traction of the optic nerves and optic chiasm and there is not evidence of the hypophysis. This new case of linear nevus sebaceus contributes with new clinical and radiological findings that have not been reported on previous cases.

**40 years later: The health related quality of life of women affected by Thalidomide.** *I. Nippert.* Institut fuer Humangenetik, Westf. Wilhelms-Universitaet, Muenster, Germany.

Introduction: Almost 40 years ago the sudden rise of births of babies with a range of severe deformities shocked the world. It was caused by a drug: the tranquilizer Thalidomide. Thalidomide was marketed in more than 40 countries worldwide. Pregnant women who took the drug in the first trimester of their pregnancy had children with a wide but distinctive range of malformations. Thalidomide claimed more than 10.000 victims in Australia, the U.S.A., Germany, Japan, Sweden, the U.K., etc. Those who survived are now reaching middle-age. How have they fared in major areas of life such as education, employment, reproduction and how is their health related quality of life? Especially women affected by Thalidomide may be at special disadvantage because of combined discrimination based on gender and disability.

Methods: A questionnaire using the WHO QOL-BREF instrument for measuring the health related quality of life was distributed among 166 females affected by Thalidomide, living in the state of North-Rhine Westphalia, Germany. A randomized control group matched by age and area of residence was asked to fill out a corresponding questionnaire. The response rate was 62%.

Results: Women affected by Thalidomide have a significantly lower overall health related quality of life score (63.01) as compared to their matched controls (70.71). They were found to have a marked lower physical health score (67.87) as compared to the controls (77.82). They are significantly less frequently married, have fewer children, have less household income and are less mobile. They suffer from chronic pain because of a steady progress of deterioration of bones and muscles. They rely heavily on medical treatment and are less satisfied than their controls with the availability of health services that meet their needs. Because of ongoing gradual impairment they face an uncertain future in regard to their mobility and their ability to remain in the workforce.

**Autosomal dominant primary empty sella syndrome, congenital glaucoma, sensorineural hearing loss, and tooth dysgenesis.** *S. Finzi*<sup>1</sup>, *J. Auguste*<sup>1</sup>, *E.A. DelBono*<sup>1</sup>, *J.L. Haines*<sup>2</sup>, *J.L. Wiggs*<sup>1,3</sup>. 1) Ophthalmology, New England Medical Center, Boston, MA; 2) Program in Human Genetics, Vanderbilt School of Medicine, Nashville, TN; 3) Division of Clinical Genetics, New England Medical Center, Boston, MA.

Primary empty sella syndrome results from a defect in the diaphragm of the pituitary sella that causes the subarachnoid space to extend into the sella turcica. Inherited forms of this condition have been previously associated with osteosclerotic dysplasia and cranio-facial deformities. A gene responsible for this condition has not been identified, although two patients with primary empty sella syndrome, mental retardation and skeletal abnormalities have been found to have a tandem duplication of Xq13-q21. We have identified a three generation pedigree with 11 affected individuals demonstrating the novel association of primary empty sella syndrome with ocular defects, sensorineural hearing loss and tooth abnormalities. Several affected individuals also have a flat mid-face and a high-arched palate. The ocular defects include: congenital glaucoma, posterior embryotoxon, and lens coloboma. The hearing loss develops in the second to third decades and is associated with periodic vertigo characteristic of Menieres disease. Tooth abnormalities include: delayed secondary dentition, malformed incisors, and extra teeth. Enlargement of the sella turcica was determined by MRI. There was no indication of hydrocephalus or pituitary dysfunction in any of the family members with sella turcica enlargement. Affected individuals are present in three consecutive generations, and equal numbers of males and females are affected. Male to male transmission supports autosomal dominant inheritance. Cytogenetic analysis did not reveal any deletions, insertions, inversions or translocations. Genetic linkage studies using markers flanking existing loci for congenital glaucoma or Axenfeld-Rieger syndrome indicate that this pedigree is not linked to any of these previously identified regions. A genome screen designed to determine the location of a gene responsible for this interesting syndrome is currently underway.

**Microgastria In The Genetic Clinic.** *B.G. Kousseff.* Division of Medical Genetics, Department of Pediatrics, University of South Florida, Tampa, 33613, (813) 233-2720.

Microgastria is a rare anomaly of the GI tract. It is a solitary malformation or part of multiple anomalies (syndromic microgastria). Prenatally absent/tiny stomach bubble is the sonographic sign. Between January 2, 1982 and April 15, 1999 through the USF Genetic clinics there were ten probands with suspected/confirmed microgastria. They were part of the 35,414 probands/families evaluated. Four were seen through the pediatric genetic clinic. All had microgastria with associated anomalies: JC a Mexican one-year-old had it with extensive partial albinism, mixed bilateral hearing loss, blepharophimosis, abnormal nasolacrimal ducts, ASD, pulmonic stenosis, pectus carinatum, asymmetric brachydactyly, mild mental retardation and 46, XY karyotype. JH was a newborn Caucasian girl with polyhydramnios, IUGR, TE fistula, tetralogy of Fallot, partial situs inversus, second and third toe syndactyly and 46, XX karyotype. CC was a premature newborn Caucasian girl with polyhydramnios, TE fistula, spleen with extraneous lobe, GE reflux, pectus carinatum and left inguinal hernia. DW was a newborn Caucasian boy with left cleft lip and palate, GE reflux, ectrodactyly, failure to thrive, short stature, and 46, XY karyotype. All required small feedings and DW has surgery to create a larger stomach. PS, LM, MM, RC, SS, CS were seen through the prenatal clinic. On targeted sonograms their fetuses did not show a "stomach bubble." The male fetus of PS had trisomy 21 with single umbilical artery and polyhydramnios; a stillbirth took place (PS developed class A1 diabetes mellitus during the gestation). LM had a stillborn girl with anencephaly, sacral spina bifida and cleft lip. Autopsies of the stillborns were declined. The 46, XX fetus of MM showed also single umbilical artery and polyhydramnios. The fetuses of RC, SS and CS did not show other abnormalities but all failed to return to the clinic. Postnatal genetic evaluations are a must whenever microgastria is suspected. Without them "no stomach bubble" may or may not represent microgastria. The "absent bubble" is a sonographic impression which requires confirmation. Otherwise microgastria is over-diagnosed.

**Eye findings in Prader-Willi syndrome.** *R. Fox<sup>1</sup>, R.B. Sinatra<sup>1</sup>, M.A. Mooney<sup>1</sup>, G.S. Yang<sup>1</sup>, I.D. Feurer<sup>1</sup>, T. Thompson<sup>1</sup>, M.G. Butler<sup>2</sup>.* 1) Psychology, Vanderbilt University, Nashville, TN; 2) Children's Mercy Hospital, Kansas City, MO.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, obesity in childhood, small hands and feet, hypogonadism, mental retardation, and a paternally derived 15q11-q13 deletion or maternal disomy 15. We report on ophthalmology and visual capacity studies in 43 PWS subjects (24 with 15q11-q13 deletion and 19 with maternal disomy 15), 22 non-PWS equivalent controls and 14 normal controls. No significant differences were found between the deletion or maternal disomy subgroups for standard ophthalmic measures. Similar eye findings were present in the control group except for myopia [larger refractive errors in the PWS group (mean = -5.56 for PWS and mean = -2.33 for equivalent controls)] and stereopsis (81% of controls had stereopsis by performance tests compared with only 44% of PWS subjects). An effect of genetic subgroup was observed for random element stereopsis with maternal disomy group having a greater degree of impairment. Additionally, discrimination of shape of motion produced by forms generated from random elements displayed on a monitor screen was tested in the four subject groups: PWS chromosome 15q deletion subtype; PWS maternal disomy; non-PWS equivalent controls; and normal controls. The performance of the normal controls exceeded all other groups (78% with correct responses in identifying moving forms generated by random elements displayed on the monitor screen,  $p < .009$ ). The PWS deletion group (66% with correct responses) and the equivalent control group (59% with correct responses) did not differ ( $p = .95$ ). However, the PWS maternal disomy group performed significantly worse (38% with correct responses,  $p < .004$ ) than all other groups. The performance of the PWS deletion subjects and equivalent controls is consistent with other data indicating these populations encounter difficulty meeting the processing demands posed by second order visual stimuli. The inferior performance of the maternal disomy group may be due to two active alleles of a maternally expressed gene influencing neural development. One such candidate is the UBE3A gene which is maternally expressed and localized to the 15q11-q13 region.

**Phenotypic Characteristics of Hereditary Benign Intraepithelial Dyskeratosis (HBID).** *P. Challa<sup>1</sup>, G.K. Klintworth<sup>1</sup>, B. Seo<sup>2</sup>, M. Bembe<sup>2</sup>, E. Rampersaud<sup>2</sup>, T. Parrish<sup>2</sup>, J. Gilbert<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, J.M. Vance<sup>2</sup>, R.R. Allingham<sup>1</sup>.* 1) Department of Ophthalmology, Duke University Medical Center, Durham, NC; 2) Center of Human Genetics, Duke University Medical Center.

Hereditary benign intraepithelial dyskeratosis (HBID) is an autosomal dominant disorder of the ocular and oral mucous membranes first described in 1959 by Von Sallman and Paton. The condition predominantly affects a Native American population in North Carolina. HBID has been recently localized to a small duplicated region at the 4q35 locus (see ASHG, Vance et al). HBID generally presents before age 5 years. Individuals present with bilateral conjunctival mucosal plaques and associated erythema. The ocular injection characteristic of HBID has caused the local population to refer to it as "red eye disease". Individuals often complain of irritation and redness but rarely require surgery. Asymptomatic oral buccal lesions are also seen in individuals with HBID. Lesions apparently do not undergo malignant transformation. Provided here is a comprehensive phenotypic description of HBID based on the individuals examined by the authors. Informed consent was obtained from all available members of two families with HBID. Complete ocular and oral exams were performed on fifty-five individuals. Of the twenty-five individuals who had the duplication at the 4q35 locus, all had bilateral conjunctival involvement with variable plaque formation from a translucent granular appearance to nodular whitish lesions with deep and superficial vascularization. Erythema was variable from mild to severe with most in the moderate range. Visual acuity limitation was rare with few individuals requiring conjunctival or corneal surgery. Onset of disease was reported from birth to two years of age in most cases. A few individuals self-reported progressive lesions. Most had associated buccal lesions; of those nearly one-third had focal lingual leukoplakic lesions. A few members reported a seasonal variation in the severity of the conjunctival lesions, with spring and summer being the worst. Individuals who lacked the duplication on 4q35 did not have any of the clinical findings associated with HBID.

**Physical and psychological development of individuals prenatally diagnosed with 45,X/46,XX.** *S.A. O'Neill<sup>1</sup>, K. Ghelani<sup>2</sup>, J. Rovee<sup>2</sup>, D. Chitayat<sup>1</sup>.* 1) Division of Clinical Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 2) Department of Psychology, The Hospital for Sick Children, Toronto, Canada.

**Introduction:** Although several recent reports have indicated that parents and health care professionals request information about the prognosis for patients with 45,X/46,XX, information on the long-term physical and psychological development of these individuals is limited. In the present study, we report on the physical and psychological development of 7 children who were diagnosed prenatally with 45,X/46,XX.

**Methods:** Each child underwent a physical examination and a comprehensive neuropsychological evaluation using selective subtests from the Stanford-Binet Intelligence Scale-Fourth edition, Neuropsychological Investigation for Children, Wechsler Individual Achievement Test, Wide Range Assessment of Visual Motor Abilities, and a Developmental Test of Visual-Motor Integration. As well, the child's behaviour, temperament and social relationships were assessed by the Child Behaviour Checklist, Temperament questionnaire, and Friendship questionnaire. The physical and psychological development of this series of 7 individuals was compared to other individuals with Turner syndrome reported in the literature.

**Results:** Results from this study show those individuals with mosaicism for Turner syndrome have fewer physical and psychological manifestations than individuals who are non-mosaic. Similarly, individuals diagnosed prenatally with 45,X/46,XX have a milder phenotype than individuals with mosaicism who are postnatally diagnosed.

**Conclusions:** This study supports the view that individuals prenatally diagnosed with mosaicism for Turner syndrome have a milder phenotype both in physical and psychological development than individuals who are postnatally diagnosed or who are non-mosaic. As this study had a small number of participants, further research to examine the development of girls prenatally diagnosed with mosaicism is needed.

**Infantile hypophosphatasia represents compound heterozygosity for a milder autosomal dominant trait.** *M.E.*

*Nunes*<sup>1</sup>, *A. Taillandier*<sup>2</sup>, *E. Mornet*<sup>2</sup>. 1) 81st Medical Group, Air Force Medical Genetics Center, Keesler AFB, MS; 2) Centre d'Etudes de Biologie Prénatale, Université de Versailles, France.

Hypophosphatasia occurs in perinatal, infantile, childhood, and adult forms, the first three displaying autosomal recessive inheritance and the last often displaying autosomal dominant inheritance. We report a family displaying three clinical forms which suggest inheritance of a dominant tissue-nonspecific alkaline phosphatase (TNSALP) gene mutation, haplo-insufficiency explaining the milder phenotype and compound heterozygosity explaining the severe perinatal phenotype. The 15 month-old female proband presented with slow to heal fractures of the radius and metatarsal bones and the diagnosis of osteogenesis imperfecta vs. child abuse. Father of the proband, raised with fluoridated water, has had recurrent dental caries in his 20's. The paternal grandmother lost all her permanent teeth in her 20's. The paternal aunt of the proband died in 1963 at 7 days, according to retrieved autopsy, of "hypophosphatasia with defective ossification of skull and ribs". Serum alkaline phosphatase of the proband was 128 U/l (normal 100-300), of the father 54 U/l (normal 38-126). Complete sequencing of TNSALP (including intron/exon boundaries and untranslated exons) revealed only one mutation, G232V, in both the proband and her father. This specific mutation has previously been reported in conjunction with a second frameshift mutation (compound heterozygote) in a case of perinatal hypophosphatasia, suggesting the recessive mode in the paternal aunt and confirming her clinical diagnosis of 37 years ago. Site-directed mutagenesis and transfection studies are in progress with enzymatic assays of fibroblasts from the proband and her father. This family adds to the growing body of genotype/phenotype correlative evidence suggesting that perinatal and infantile hypophosphatasia arise from compound heterozygosity for severe mutations, and that childhood and adult hypophosphatasia arise from either heterozygosity or compound heterozygosity for severe and/or moderate mutant alleles.

**Adaptive functioning and molecular relationships in individuals with fragile X syndrome.** *S.W. Harris<sup>1</sup>, K.E. Brown<sup>1</sup>, J.L. Hills<sup>1</sup>, F. Tassone<sup>2</sup>, P.J. Hagerman<sup>2</sup>, A.K. Taylor<sup>3</sup>, R.J. Hagerman<sup>1</sup>.* 1) Fragile X Treatment & Research Center, The Children's Hospital, Denver, CO; 2) Department of Biochemistry and Molecular Genetics, University of Colorado Health Sciences Center, Denver, CO; 3) Kimball Genetics, Denver, CO.

Fragile X syndrome (FXS) is a broad spectrum disorder and, consequently, individuals with FXS demonstrate a variety of cognitive and adaptive abilities. It is useful to measure both IQ and adaptive function in individuals who have FXS, as many individuals may show strengths in adaptive functioning which may not be reflected in their IQ score. Therefore, areas of strength in adaptive functioning may correlate with FMRP levels.

The Vineland Adaptive Behavior Scales includes an Adaptive Behavior Composite (ABC) score, as well as individual domain scores for Communication, Daily Living Skills, and Socialization. These variables, along with percentage of FMRP expression, were utilized for statistical correlation.

We analyzed clinical and molecular data for 86 individuals with the full mutation or mosaic status for FXS, with an age range of 1.6 to 45.5 years. We utilized the Spearman correlation coefficient with a two-tailed t-test and found that the correlation between FMRP and several of the Vineland domains was significant: FMRP and ABC ( $p=.002$ ), FMRP and Communication ( $p=.005$ ), FMRP and Daily Living Skills ( $p=.000$ ). Interestingly, there was no correlation between FMRP and the Socialization domain ( $p=.278$ ).

We also separately analyzed the male group ( $n=72$ ), of which 58 individuals had the full mutation and 14 individuals had a mosaic FMR1 gene, with an age range of 1.6 to 45.5 years. We utilized the Spearman correlation coefficient with a two-tailed t-test and found a significant correlation between FMRP and Adaptive Behavior Composite ( $p=.009$ ), FMRP and Communication ( $p=.008$ ), and FMRP and Daily Living Skills ( $p=.004$ ). And again, the Socialization domain did not correlate with FMRP ( $p=.180$ ), which suggests that this domain is significantly influenced by background gene effects.

**A novel mutation in a patient with IGF-I deficiency.** *G. Bonapace, D. Concolino, S. Formicola, P. Strisciuglio.*  
Department of Pediatrics, Faculty of Medicine, University of Catanzaro. ITALY.

Igf-I is considered to be one of the most important growth factor but its role has not yet made completely clear. A Patient has been recently described, with severe prenatal and post natal growth failure, sensorineural deafness, mental retardation, very low levels of IGF-I, both basal and post generation test, associated with IGF-I gene partial deletion (1). We described a new case with IGF-I deficiency due to a point mutation in exon 4a of IGF-I gene never described before. The patient was born at 39 weeks of uneventfull gestation by cesarean section because of poor fetal growth. The birth weight was 1,840 Kg (-4SD), the lenght was 41 cm (-6,5SD) and the head circumference was of 26,5 cm (<5pc). The parents were second cousins and the family history showed several miscarriages. His mother was 141,5cm (-3SD)tall and his father was 145,7 cm (-4,3SD).At the age of 1,6 years he showed a weight of 4,750 Kg (-6,2SD)the head circumference was 40,5 cm (p<5) and a ratio L/P <5 pc. Mild dysmorphic signs were present. Psycomotor development was delayed; audiograms showed bilateral sensorineural deafness. The basal serum concentration of GH was 1,6 ng/ml and the peak serum after administration of arginine was 18 ng/ml.The basal serum concentration of IGF-I was 23ng/ml (between -3SD and 2 SD) and after the IGF-I generation test, IGF-I levels remained very low (25ng/ml) while IGFBP3 levels did not change. The bone age according to Greulich and Pyle was in neonatal range. The molecular studies performed, showed in our patient a novel mutation (transversion T-A) that destroys the normal consensus sequence for polyadenilation site in the 3' untraslated region of exon 4a of IGF-I gene. Our expression analysis experiments by Rt-pcr demonstrated a reduction in the exon 4a size. In conclusion our results first demonstrated that the transversion on the consensus sequence AAATATA of polyadenilation site of IGF-I exon 4a is the cause of deregulated pattern of mRNA maturation, and therefore of IGF-I deficiency. **Morphological characterization of non-syndromic Split Hand-Split Foot malformation.** *S. Sifakis<sup>1</sup>, M. Arici<sup>2</sup>, D. Viljoen<sup>3</sup>, P. Beighton<sup>4</sup>, P. Tsipouras<sup>1</sup>*. 1) Dept of Pediatrics, University of Connecticut Health Center, Farmington,CT; 2) Dept of Radiology, University of Connecticut Health Center, Farmington,CT; 3) Dept of Human Genetics,University of Witwatersrand, Johannesburg, South Africa; 4) Dept of Human Genetics,University of Cape Town, South Africa.

Split Hand-Split Foot malformation (SHFM) describes a developmental defect of the distal extremities characterized by the absence of one or more central rays, and syndactyly. There is considerable phenotypic variability, thus the aim of this study was to identify the presence of common morphological and radiological patterns in cases of non-syndromic SHFM. Clinical information from 16 SHFM cases including 27 radiographs from 39 limbs was retrospectively analyzed. The diagnosis in all cases was unequivocally established to be non-syndromic SHFM. Positive family history was present in 12 of the 16 cases. Six cases were members of the Wadoma tribe residing in the border between Botswana and Zimbabwe. Based on the review of the available radiographs, we were able to distinguish five categories of morphological abnormalities of the hands and feet: 1) Monodactylous limbs associated with aplasia and hypoplasia of a variable number of carpals, metacarpals and phalanges. 2) Lobster-claw anomaly of both hands and feet characterized by deep central clefts and syndactyly. The cleft invariably extended to the base of the metatarsal or tarsal level in the feet, while it did not extend beyond the mid-metacarpal level in the hands. 3) Abnormal articulation of one or more metacarpals or metatarsals to adjacent joints. 4) Abnormal positioning of a transversely oriented long bone between the heads of affected metacarpals and the base of phalanges. 5) Osseous and cutaneous syndactyly. Other findings included triphalangeal thumbs, clinodactyly, and axial polydactyly. In summary, five distinct patterns of skeletal abnormalities were observed in non-syndromic SHFM. The functional effect of the skeletal abnormalities varied from mild to debilitating. This clinical variability represents a phenotypic continuum and possibly reflects the underlying genetic heterogeneity associated with SHFM.

**Phenotypic characterisation of three genetically distinct forms of Bardet-Biedl syndrome.** *E. Heon*<sup>1,2</sup>, *C. Westall*<sup>1</sup>, *R. Carmi*<sup>3</sup>, *K. Elbedour's*<sup>3</sup>, *C. Panton*<sup>1</sup>, *L. Mackeen*<sup>1</sup>, *E. Stone*<sup>4</sup>, *V. Sheffield*<sup>4</sup>. 1) Dept Ophthalmology, The Hospital for Sick Children; 2) The Toronto Hospital, University of Toronto, ON, Canada; 3) The Genetic Institute, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 4) Dept Pediatrics, The University of Iowa Hospitals and Clinics, Iowa City, Iowa.

Bardet-Biedl syndrome is an autosomal-recessive multisystemic condition characterised by usually severe retinitis pigmentosa, hypogenitalism, digit anomaly, renal anomalies, obesity, and a variable degree of mental retardation. The disease is known to be genetically heterogenous for which five different loci have been identified on chromosomes 3, 11, 12, 15, and 16. No gene has been identified. Three genetically distinct large Bedouin families from the Negev, affected with Bardet-Biedl syndrome, were examined to define the distinct ocular phenotypes. In addition obligate carriers were studied electrophysiologically to assess if their carrier status could be detected in a reproducible way. Comprehensive eye examination and ERG testing were performed on affected members and obligate carriers available of families linked to chromosomes 3, 15, and 16.

Retinal dystrophy was severe and early in all cases and the three genotypes carried a poor visual prognosis. The major distinctive feature between the 3 groups was the refractive error as one family was very myopic. Also one individual was observed to have bilateral colobomas in addition to the classic features of Bardet-Biedl. Although this finding may be coincidental it may also suggest that Biemond syndrome is either a variant of Bardet-Biedl syndrome or that this may represent a contiguous gene syndrome. It is difficult to detect the carrier status electrophysiologically or clinically in a reproducible way.

**Myotonia congenita in the dog.** *U. Giger*<sup>1</sup>, *M. Gracis*<sup>1</sup>, *A.L. George Jr.*<sup>2</sup>, *T.H. Rhodes*<sup>2</sup>, *C. Fahlke*<sup>2</sup>, *Y. Rajpurohit*<sup>1</sup>, *D.P. Bhalerao*<sup>1</sup>, *J. Melniczek*<sup>1</sup>, *S.W. Volk*<sup>1</sup>, *D.F. Patterson*<sup>1</sup>, *C.H. Vite*<sup>1</sup>. 1) Clinical Studies, School of Veterinary Medicine, University of PA, Philadelphia, PA; 2) Department of Medicine and Pharmacology, Vanderbilt University School of Medicine, Nashville, TN.

In the Miniature Schnauzer dog, a mutation in the CIC-1 chloride channel is responsible for autosomal recessive myotonia congenita. The mutation results in replacement of a threonine residue in the D5 transmembrane segment with methionine. The purpose of this study was to characterize myotonia congenita in this recently identified canine model. Eight affected dogs were examined. Affected dogs exhibit a delay in skeletal muscle relaxation following stimulation; diffuse skeletal muscle hypertrophy; stridor; an abnormal bark; and a stiff, stilted gait that improves with exercise. Dental abnormalities including distocclusion, delayed dental eruption of both deciduous and permanent dentitions, delayed dental exfoliation of the primary teeth, and unerupted or partially erupted permanent teeth have been documented. In no other animals affected with myotonia congenita have such dental abnormalities been described. Clinical and electrophysiological signs are first apparent at 5 weeks of age. Carrier dogs showed no clinical or electrophysiological signs of disease. Two affected dogs were treated with procainamide from 4 weeks of age onward; treated dogs showed amelioration of muscle stiffness and of dental abnormalities as adults.

A DNA-based test capable of detecting the mutant allele in both carrier and myotonic Miniature Schnauzers was developed. The incidence of the mutation in the East Coast Miniature Schnauzer population was determined; 30% of 134 dogs tested thus far in a biased sample carry the mutation. All affected dogs examined to date are descendents of a common ancestor.

A breeding colony has been established at the University of Pennsylvania. The availability of a well-characterized canine model of myotonia congenita allows for the study of improved treatments for this disease. Supported in part by NIH (RR02512; NS02032; AR44506; T32-GM07628) and a grant from the Muscular Dystrophy Association.

**Heterogeneity in Familial Autosomal Dominant Paget Disease of Bone and Muscular Dystrophy.** *B. Waggoner<sup>1</sup>, V.E. Kimonis<sup>1</sup>, M.J. Kovach<sup>1</sup>, D.A. Gelber<sup>2</sup>, R. Khardori<sup>3</sup>.* 1) Dept. Pediatrics, Division of Genetics and Metabolism, Southern Illinois University, Springfield, IL; 2) Dept. of Neurology, Southern Illinois University, Springfield, IL; 3) Dept. of Internal Medicine, Southern Illinois University, Springfield, IL.

Autosomal dominant muscular dystrophy with the association of early onset Paget disease of bone (PDB) is an unusual disorder. We recently mapped the disorder in a large family from central Illinois with proximal limb girdle muscular dystrophy and PDB to a unique locus on chromosome 9p23.3-q12 (Kovach et al., 2000). We have identified a new 10-member family with dominant PDB and muscular dystrophy. The father, age 70 y., had onset of myopathy at age 41 y. Progression of the disorder began with foot drop in addition to PDB in the L knee. Presently, he has a severe, generalized, distal>proximal weakness and severe PDB causing deformity of his extremities. He is bedridden and requires a tracheostomy and gastrostomy. EMG and muscle biopsy are compatible with a primary dystrophy. His creatine phosphokinase (CPK) levels are currently 40 U/L (normal range 52-336 U/L), however, these levels have been elevated in the past to 776 U/L. Additionally, alkaline phosphatase levels (530 U/L, normal range 98-250) and osteocalcin levels (140 U/L, normal range 2-10) are markedly elevated.

Of his 8 children, a 41 y. old son has a similar muscular dystrophy with onset at age 37 y. His CPK level is 662 U/L. Two daughters, age 43 y. and 40 y., developed PDB at mean age of 39y. with distribution in the pelvis, arms, spine, and tibia. All of the affected children have elevated alkaline phosphatase levels at a mean of 282 U/L.

Haplotype analysis of nine members (4 affected, 4 unaffected, 1 spouse) with a high-density of markers excluded the critical region on chromosome 9p23.3-q12, thus providing evidence for genetic heterogeneity among families with autosomal dominant PDB and muscular dystrophy.

***MECP2* analysis in possible familial Rett syndrome.** H.K. Gill<sup>1</sup>, J.P. Cheadle<sup>1</sup>, J. Maynard<sup>1</sup>, N. Fleming<sup>1</sup>, A. Kerr<sup>2</sup>, H. Leonard<sup>3</sup>, E.M. Thompson<sup>3</sup>, F. Hanefeld<sup>4</sup>, O. Skjeldal<sup>5</sup>, J. Sampson<sup>1</sup>, A. Clarke<sup>1</sup>. 1) Institute of Medical Genetics, UWCM, Cardiff, Wales, United Kingdom; 2) University of Glasgow, Department of Psychological Medicine, Gartnavel Royal Hospital, 1055 Great Western Rd, Glasgow. G12 OXH. UK; 3) TVW Telethon Institute for Child Health Research, West Perth, Australia, WA6872; 4) Abteilung Kinderheilkunde, Scheuerpunkt, Neuropädiatrie, Georg-August-Universität, Göttingen, Germany; 5) Department of Paediatrics, Nordland Central hospital, N-8017 Bodo, Norway.

Mutations in the methyl cytosine binding protein 2 gene (*MECP2*) have recently been identified as causative in Rett syndrome. The majority of cases of Rett syndrome are sporadic. However, a number of cases have been thought to be familial because of the occurrence of two affected individuals in the same pedigree. We have undertaken mutation analysis of *MECP2* in 20 affected individuals from 10 families, in whom the possibility of familial Rett has been raised. We identified pathogenic *MECP2* mutations in 6 individuals from 5 families. In 1 family we detected the same *MECP2* mutation in two affected sisters and their unaffected mother. In 4 families, one affected individual was found to have a *MECP2* mutation, but the relative in whom a diagnosis of Rett was suspected, did not carry this or any other mutation. In the remaining 5 families no *MECP2* mutation was detected in any individual. These results suggest that familial Rett syndrome is rare and may be overdiagnosed.

**Molecular Detection and Prenatal Diagnosis of Spinal Muscular Atrophy in Iran.** *S. Teimourian*<sup>1,2</sup>, *Y. Shafegati*<sup>3</sup>, *R. Karimi-Nejad*<sup>2</sup>, *Gh. Baba-Mohammady*<sup>2</sup>, *N. Almadany*<sup>2</sup>, *M. Azad*<sup>2</sup>, *H. Najmabadi*<sup>2,3</sup>. 1) Biophysics and Biochemistry, Tehran University, Tehran, Ira, Tehran, Tehran, Iran; 2) Karimi-Nejad Pathology and Genetics Center, Tehran, Iran; 3) Welfare and Rehabilitation University, Tehran, Iran.

Spinal Muscular Atrophy (SMA) is an autosomal recessive disorder resulting in the loss of motor neurons in the spinal cord. SMA has an estimated incidence of 1/10,000 with a carrier frequency of 1/60 to 1/40. The survival motor neuron (SMN) transcript is encoded by two genes, SMNT and SMNC. All three forms of SMA that maps to the 5q12 are caused by mutations in the SMNT gene. SMNT exon 7&8 are not detected in ~95% of SMA cases due to either deletion or sequence conversion events. SMNC and SMNT genes are distinguishable only by single base changes in exon 7 and exon 8. We have employed method by (Chang et al., 1997) to compare the telomeric with centromeric portion (T/C ratio) of SMN gene after restriction enzyme digestion followed by acrylamide gel and samples were analysed by silver staining. Out of twelve families we have analysed, nine showed deletions in exon 7 which include 5 affected children with type one phenotype and 2 affected children with type II phenotype. one family with an affected child with SMA showed deletion in exon 8 and only two showed no deletion in exon 7 or 8. Prenatal diagnosis was performed for two out of twelve of these families where trait fetuses were detected.

**Abnormal early infantile development in Rett syndrome: expanding the criteria for *MECP2* testing.** L. Celle<sup>1</sup>, C. Venditti<sup>1</sup>, L. Brown<sup>2</sup>, S. Levy<sup>3</sup>, J. Coplan<sup>3</sup>, E.H. Zackai<sup>1</sup>. 1) Division of Human Genetics and Molecular Biology; 2) Department of Neurology; 3) Division of Child Development and Rehabilitation, The Children's Hospital of Philadelphia, Philadelphia, PA.

Availability of the molecular diagnostic test for Rett syndrome (RS) permits an opportunity to reevaluate current concepts of the natural history of the disorder. Clinical diagnostic criteria developed by the RS Diagnostic Criteria Work Group (Trevathan and Moser, 1988) include presence of normal development in the first 6 to 18 months of life. Several case reports have disputed that finding. Almost half of the surveyed parents reported unusual development and behavior in the first 6 months of life in a study by Leonard & Bower (1998). We report 3 girls with RS confirmed with *MECP2* mutations who initially presented with developmental delay in the first months of life. All were born at full term with normal growth parameters; all showed appropriate social development but had motor delay noted before 6 months. Patient 1 (T158M mutation) first rolled over at 7 mo, sat at 10-11 mo, crawled at 18 mo, and walked at 4 years. Decreased head growth was noted at 16 mo. At 4 years she can no longer crawl, shows dramatic hand apraxia, and gait ataxia. There has been a single seizure episode. Patient 2 (R306C mutation) came to attention at 9 mo due to decreased head growth velocity. She rolled at 5-6 mo, sat at 9 mo. Regression started at 9-12 mo with decreased babbling. Bruxism began at 15 mo, purposeful hand movements were lost at 20 mo and hand wringing was noted at 22 mo. At 24 mo she has no words and has not learned to walk. Patient 3 (1161del6 and 1180del26) first rolled over at 10 mo and walked at 19 mo. Regression was suspected at 9 mo with decreased eye contact and she was diagnosed with an autistic spectrum disorder at 19 mo. Breath holding and gait ataxia begun at 22 mo and hand wringing started at 23 mo. These 3 cases document delayed motor milestones by 6 months of life. We suggest that the diagnosis of RS must be considered in girls with early developmental delay even when they present for evaluations prior to emergence of hand wringing, hyperventilation and regression.

**Duplication of 17p11.2: An entity resulting from the homologous recombination of the Smith-Magenis deletion region.** *M.A. Deardorff<sup>1</sup>, L. Celle<sup>1</sup>, R. Finkel<sup>2</sup>, S. Friedman<sup>3</sup>, N.B. Spinner<sup>1</sup>, E.H. Zackai<sup>1</sup>*. 1) Division of Human Genetics and Molecular Biology; 2) Division of Neurology; 3) Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Duplication of chromosome 17p11.2, the region deleted in the Smith-Magenis syndrome (SMS) has recently been reported as a distinct entity. Findings in 17p11.2 duplication are predominantly limited to mild to moderate mental retardation and sometimes involve short stature, dental abnormalities, seizures, and behavioral problems. Here we report two additional cases with a duplication of the SMS deletion-specific fragment. Case 1 is a 1-year-old male who was noted to have difficulty feeding, failure to thrive, microcephaly, and developmental delays. At 10 months he was not rolling over or sitting. His mental skills were at 5-7 month level, motor skills at 5 month level, and play skills at 6-7 month level. His dysmorphia was limited to epicanthal folds and downslanting palpebral fissures. Case 2 is a 8-month-old boy who presented with failure to thrive and hypotonia. He acquired head control at 6 months and had not rolled over at 8 months. He had a mildly narrowed cranium, two hyperpigmented spots, and marked hypotonia. High resolution karyotype in both cases revealed cytogenetically visible duplication of 17p11.2. FISH analysis indicated duplication of the SMS fragment (FLI<sub>x</sub>3, ZNF<sub>x</sub>3, 86E11<sub>x</sub>3) and no duplication of the CMT1A probe (PMP22<sub>x</sub>2). These two cases provide further evidence of focal duplication limited to 17p11.2 (SMS region) resulting primarily in developmental delay with minimal dysmorphia which is similar to the 2 patients reported by Brown et al (1996) and the 7 patients reported by Potocki et al (2000). 17p11.2 duplication is among an increasing number of entities resulting from homologous recombination due to repetitive flanking sequence clusters. High resolution karyotype should be performed when evaluating a patient with developmental delay/MR and minimal dysmorphia and 17p11.2 duplication should be included in the differential diagnosis.

Program Nr: 710 from the 2000 ASHG Annual Meeting

**Polymastia In The Genetics Clinic.** *J.D. Ranells, B.G. Kousseff.* Division of Medical Genetics, USF, Tampa, FL, 33606.

Polymastia presents a spectrum from normally shaped breast tissue with nipple lacking areola, glandular tissue with areola without nipple, and ectopic breast tissue with neither areola nor nipple.

In our patient database there are 36,665 families evaluated between January 2, 1982 and December 31, 1999 including three patients with polymastia or ectopic nipples.

WS was a 15 year old Caucasian girl with kyphoscoliosis, short stature, SN hearing loss and trainable mental retardation. She was born to a 19 year old 46, XX primigravida. BWT was 2650 g. Microcephaly was present. There was camptodactyly, exotropia, mild pectus excavatum and polythelia along the Hughes lines. By age 16 years, bilateral polymastia developed with glandular tissue, areolas and nipples. The karyotype showed deletion 9q (q31@qter).

LH, a Caucasian 46, XX girl was born with atypical left split hand, absent pectoralis minor and left polythelia in the axilla. There were also left renal agenesis and scoliosis. BWT was 2030 g, length 46 cm, and OFC 32 cm. At age 6 years, LH was nonverbal and nonambulatory. The diagnosis for the limb abnormality was Poland sequence but the overall phenotype extended beyond that of the sequence.

EJ, a 27 month old Caucasian male showed mild pervasive developmental disorder. He was the product of the second pregnancy for the 28 year old para 1-0-0-1 mother who had polymastia with a third breast with glandular tissue, areola and nipple. BWT was 4450 g, length 56 cm and OFC 39.5 cm, megalencephaly; father had that, and bilateral polythelia category 6 according to Kajava's classifications (Duodecim 31:143-170, 1915).

In the USF Genetics Clinics, the experience with polymastia/ectopic polythelia indicated that chromosome abnormalities, syndromic multiple congenital anomalies and atavism are causes of polymastia.

**Holoprosencephaly in a fetus with Smith-Lemli-Opitz syndrome (SLOS).** *S.A. Farrell<sup>1</sup>, W.S. Sirkin<sup>2</sup>, M.J.M. Nowaczyk<sup>3</sup>*. 1) Dept Lab Medicine, The Credit Valley Hosp, Mississauga, ON., Canada; 2) Dept Lab. Medicine, North York General Hosp, North York, ON, Canada; 3) Dept Pathology & Molecular Medicine, McMaster University, Hamilton, ON, Canada.

We report on a fetus with SLOS with a median cleft lip, oral frenulum, polydactyly with 2-3 toe syndactyly and alobar holoprosencephaly. Ultrasound showed a fetus with a median cleft, nuchal thickening (6 mm-upper limit 5mm), a 2-vessel umbilical cord, and significant growth lag. At 19 5/7 weeks, the biparietal diameter (BPD) was 18 1/7 weeks and femur length (FL) was 18 6/7. Amniocentesis showed a normal male karyotype. At 23 weeks, BPD was 18 5/7 weeks and FL was 20 5/7. A single cerebral ventricle, bilateral club feet and a small right cardiac ventricle were seen. The pregnancy was ended at 24 weeks. Weight was 483 gm (50th centile for 22 weeks; head circumference was 18 cm (50th centile 21 weeks). There was microcephaly and hypotelorism. The tongue was wedged into a median cleft palate and cleft lip. There was a right frenulum between the tongue and mouth. Both nipples were absent and the nuchal skin was thick. Shoulders were square. Digits were tapered with bilateral postaxial polydactyly. The feet showed bilateral talipes equinovarus, with proximally placed broad great toes. There were 6 toes on the right and syndactyly of toes 2-3 on the left. At autopsy, alobar holoprosencephaly was confirmed, with a posterior ventricular cyst. There was a double inlet left ventricle with a VSD, hypoplastic right ventricle, pulmonary artery stenosis and atrioventricular septal defect. Lungs were unilobar. The urethra communicated with a vagina-like blind-ended pouch. There was a decreased number of Leydig cells in the testes. Amniotic fluid, refrigerated for 3 weeks, was used to measure 7-dehydrocholesterol(7-DHC). The level was 423 umol/L, confirming the diagnosis of SLOS. The ultrasound aspects of this case are unusual with holoprosencephaly, extreme microcephaly, remarkable IUGR at an early gestation, and median clefting with evidence of no tongue movement. This case also illustrates the stability of 7-DHC in refrigerated amniotic fluid and the diagnostic capacity of such a stored sample.

**Pervasive Developmental Disorder and 47,XYY males.** *K.J. Briggs<sup>1</sup>, J. Varsamis<sup>2</sup>, A. Slusky<sup>2</sup>, A. Dawson<sup>1</sup>, C. Prasad<sup>1</sup>.* 1) Section of Genetics and Metabolism, Health Sciences Centre, Winnipeg; 2) Section of Psychiatry, Health Sciences Centre, Winnipeg.

The association between chromosomal abnormalities and mental retardation is well known. Less well documented is the impact of aneuploidy on childhood Pervasive Developmental Disorder (PDD). XYY syndrome has rarely been associated with Pervasive Developmental Disorder (1 out of 92 children with PDD had XYY syndrome) (Weidmer et al. 1998). XYY syndrome is characterized by accelerated growth and minor dysmorphic features including a prominent glabella (Parker 1969). Full-scale IQ in these patients is usually within normal limits but often lower than siblings, in particular verbal IQ. Language delay is often described in these patients, as is difficulty with social interaction. XYY males tend to be withdrawn and to have difficulty establishing friendships. An association between XYY syndrome and violent behaviour has been postulated but was not supported by prospective longitudinal studies. We report on a fifteen year old boy who was referred for evaluation of developmental delay and behavioural difficulties. He was found to be withdrawn and oppositional, and to have perseveration and concrete thinking. Developmental assessment showed delay in language acquisition. A maternal uncle was withdrawn and dependent, and a second maternal uncle was described as a loner. The patient was in a modified Grade 10 program. He had spent several months in an adolescent treatment centre for behavioural issues, but at the time he was evaluated in Genetics he was living at home. On examination the patient's weight was at the 75th%, height was at the 90th% and he was normocephalic. The patient was non-dysmorphic and physical examination was unremarkable. Performance IQ was in the mildly mentally retarded range. His karyotype was 47,XYY. Psychiatric assessment was of PDD-NOS. It is important to consider aneuploidy in the differential diagnosis of patients presenting with PDD.

**Longitudinal personality changes as measured by the MMPI in presymptomatic HD gene carriers. S.C.**

*Kirkwood<sup>1</sup>, E. Siemers<sup>2</sup>, R. Viken<sup>3</sup>, M.E. Hodes<sup>1</sup>, P.M. Conneally<sup>1</sup>, J.C. Christian<sup>1</sup>, T. Foroud<sup>1</sup>.* 1) Dept Med & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Eli Lilly and Company, Indianapolis, IN; 3) Department of Psychology, Indiana University, Bloomington, IN.

A sample of individuals at-risk for Huntington Disease (HD) and reporting themselves as asymptomatic participated in a longitudinal case-control double blind study to determine whether longitudinal changes in personality as measured by the MMPI can be detected among clinically presymptomatic individuals carrying the expanded Huntington disease (HD) allele. The participants, examined an average of 3.7 years apart, were categorized into one of two groups: (1) presymptomatic gene carriers (PSGC) (n=12), defined as those individuals with an expanded HD gene (<sup>3</sup> 38 CAG repeats) but who did not have sufficient neurologic symptoms to warrant a clinical diagnosis of manifest HD; and (2) nongene carriers (NGC) (n=31), defined as those individuals with 2 unexpanded HD alleles (< 32 CAG repeats). In addition to molecular testing to determine the number of CAG repeats in the HD gene, the clinical assessment included a quantified neurological examination and an abbreviated Minnesota Multiphasic Personality Inventory (MMPI). The abbreviated MMPI included the Hypochondriasis, Depression, Psychasthenia, neuroticism, hostility-cynicism, and irritability scales and the Harris Subscales of Depression: Subjective Depression, Brooding, and Psychomotor Retardation. The results on the MMPI were evaluated for differences between NGC and PSGC using a one-factor between subjects ANOVA. For the PSGC, a greater increase in abnormality over time was observed for the MMPI scales, hostility-cynicism (p=0.04) and irritability (p=0.005), when compared with the NGC. Among both the PSGC and NGC, no significant correlation was found between the number of CAG repeats and the change in MMPI score from the original to the return visit. This study provides significant evidence for increasing irritability and hostility-cynicism in presymptomatic gene carriers prior to the onset of overt clinical symptoms.

**Trisomy 14q detected by telomere FISH: Unraveling parent-specific effects of 14q dosage.** *V.R. Sutton, S. Lalani, C.D. Kashork, L.G. Shaffer.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

We present the first case report and molecular cytogenetic studies of trisomy 14q detected by telomere FISH. Our patient is a 2 year old girl with growth and developmental delay, myelomeningocele, partial agenesis of the corpus callosum, hypertelorism, tented mouth, simple ears, small mandible and congenital heart disease (atrial and ventricular septal defects with subaortic conus). G-banded chromosome analysis was normal. A set of FISH-based, telomere region-specific probes revealed trisomy for 14q: ish der(22)t(14;22)(qter;p11.2)(14qtel+). Parental FISH studies established that the mother is a balanced carrier for this translocation: ish t(14;22)(qter;p11.2)(14qtel-;14qtel+). Chromosome 14 is known to have regions of imprinting and distal 14q has been suggested to contain imprinted genes. Because our patients features are not similar to maternal or paternal uniparental disomy (UPD) case reports, we suggest that either the area defined by the telomere probe does not contain imprinted genes, or that the phenotype found in UPD 14 is produced by deficiency of a particular parental allele(s), rather than a double dose of a particular parental allele. This case of trisomy 14q illustrates the great utility of telomere-specific FISH probes in finding cryptic rearrangements and aids in uncovering the effects of parent-specific expression for regions of 14q.

**Clinical features of male with short stature, dextrocardia and retinal retraction syndrome with XY translocation suggest possible existence of a new Xpter gene locus involved in situs determination.** *P. Bitoun*<sup>1</sup>, *B. Benzacken*<sup>2</sup>, *J. Gaudelus*<sup>3</sup>. 1) Dept Gen Med, CHU Paris-Nord, Hosp Jean Verdier, Bondy, Cedex, France; 2) Dept Embryo-Cytogenetics; 3) Dept Pediatrics.

We report on an 9 year old male seen for genetic counseling of a malformation syndrome with short stature , dextrocardia and right retinal retraction syndrome. Short stature was diagnosed at age 4 and treated by age 7 for borderline GH deficiency. Brain MRI scan showed normal pituitary gland as well as brain structures and maturation. Dextrocardia discovered at age 1 seems isolated with normal situs of liver and lungs on chest X and lung x rays. Right sided low vision was diagnosed at age 3 and angiography showed an epiretinal membrane. Progressive traction syndrome of retina developed causing visual loss requiring multiple surgeries. This young boy has normal intelligence and development. He has minimal dysmorphism with a short upturned nose and low-set ears, no missing incisors or cleft and normal smell sensation. His peripheral blood high resolution karyotype initially showed a 45 X karyotype with a mosaic with 1 or 2 minute ring chromosomes. Using FISH the SRY probe showed a Y translocated on the Xpter region. Centromeric X probes confirmed the minute ring chromosomes were X chromosomes. Karyotype showed a mosaic variegated aneuploidy with 58% cells with 45 tY;X (p?,pter); 38% cells with 45 tY;X (p?,pter), + X mar; 4% cells with 45 tY;X (p?,pter), + X mar, + X mar. The short stature possibly results from SHOX gene haplo-insufficiency (located at Xp22.32) but it is still unclear which genes might explain the dextrocardia (the only known gene on the X involving right-left pattern determination is ZIC3 at Xq26) or the retinal retraction syndrome. Mother has normal karyotype, Paternal karyotyping and Investigation of the breakpoints on the X and the Y may help explain the pathology observed in this patient. The patient's features suggest there may be another gene involved in situs determination in the Xpter region.

**Genetic Etiology of Blindness. A prospective study at a tertiary Pediatric Hospital.** *A.D. Iglesias<sup>1</sup>, M. Torrado<sup>2</sup>, C. Barreiro<sup>2</sup>*. 1) Pediatrics, Jacobi Medical Center, New York, NY; 2) Hospital de Pediatria, Juan P. Garrahan, Buenos Aires, Argentina.

During one-year, 30 patients with blindness of presumptive genetic etiology were studied at the Department of Genetics. Patients were screened at Ophthalmology. Inclusion criteria included the WHO definition of blindness. Exclusion criteria included environmental causes of blindness, retinoblastoma, and ambliopia. Initial diagnosis included cataracts, leucocoria, microphthalmia, glaucoma, anophthalmia, lens subluxation, aniridia, nystagmus, myopia, and strabismus. Ages range from 19 days to 13 years. Males represented 2/3 of the cases. After genetic evaluation, 10 cases (33%) showed mental retardation (MR) including Down, Lowe, and Lenz syndromes, and COFS disease. Eighteen (60%) cases presented one or more associated defects including MR (8), facial dysmorphic features (7), microcephaly (2), hand anomalies (2), failure to thrive, axial hypotonia, marfanoid habitus, short stature, and phenotype of Down's. Definitive diagnosis of a genetic entity was made in 9 cases including Down, Lenz, COFS, Goldenhar, Rieger, Lowe, Stickler, and Weil-Marchesani syndrome (2) and COATS disease. In 22 cases (73.4%) a defined genetic disorder was found. Seventeen cases were mendelian including 5 autosomal dominant (AD), 5 autosomal recessive (AR), and 2 X-linked recessive (XLR). One case was chromosomal, and 5 cases were multifactorial. Single ophthalmologic entities with genetic inheritance were also identified. Seven were cataracts (1 AD, 3 AR, 3 XLR), 2 glaucoma (1 AD, 1 XLR), 2 XLR coloboma, 1 AD anophthalmia, 6 cases of anophthalmia (2 AD, 2 AR, 2 XLR), and 2 cases of retinitis pigmentosa (1 AD, 1 AR). Overall, 70% of the cases had a definitive diagnosis. Hereditary patterns of inheritance as well as the natural history, prognosis, therapy and genetic counseling for the patients and their families were discussed. The opportune, accurate and timely referral of patients with blindness of presumptive genetic etiology were the clues for a definitive diagnosis. Future delineation of complex entities, as well as single defects of genetic etiology, will help to understand the genetic basis of childhood blindness.

**Are specific eye findings a useful predictor of the presence of associated major anomalies in anophthalmia/microphthalmia?** *A.S. Schneider, T.M. Bardakjian, A.L. Aronson, M.A. Dwyer.* Dept Pediatrics, Albert Einstein Medical Ctr, Philadelphia, PA.

The Anophthalmia/Microphthalmia(A/M)registry was established in 1993 to assemble a national database of individuals with A/M, to determine the local and national incidence of A/M and to undertake a descriptive analysis of the registry population. Analyzing our collection of clinical data on 131 cases of unilateral and bilateral anophthalmia or microphthalmia, we have tried to determine whether specific eye findings can be used to predict the likelihood of other anomalies in the individual. The total number of cases reviewed is 131; 68 males and 63 females. Of the females, 28 have unilateral anophthalmia or microphthalmia (15 left, 13 right) and 35 have bilateral A/M. 3/13 (23%) of females with left microphthalmia had other significant findings with brain and cardiac anomalies. The 2 females with left anophthalmia had no other anomalies. One of the 4 females with right sided anophthalmia had hemifacial microsomia. 3/9 (33%) of females with right microphthalmia had associated brain abnormalities. The total number of males with unilateral microphthalmia is 24 (13 left, 11 right). Only 1 male with left unilateral microphthalmia had associated anomalies. 4/11(36.6%) males with right microphthalmia had other anomalies. There are only 2 males with unilateral anophthalmia (8% of our sample), both have anomalies with syndromal diagnoses. Males and females with bilateral A/M present with a wide range of findings. 51% of males and 63% of females have significant associated findings including cardiac, renal and brain anomalies Our analysis has demonstrated that bilateral A/M in both males and females as well as unilateral A/M in females are associated with a significant number of anomalies of other systems. We therefore recommend that all individuals with A/M be evaluated by a Clinical Geneticist and advocate a full work up for most of these patients. However, males with unilateral A/M in this sample, even with coloboma or PHPV, have a low rate of associated anomalies and the workup may be limited based on clinical assessment of the examining Geneticist.

**PAX2 mutations and Renal-Coloboma syndrome.** L.A. Schimmenti<sup>1</sup>, A.C. Gelb<sup>1</sup>, S. Militar<sup>1</sup>, P.A. Sieving<sup>2</sup>, J.A. Kemp<sup>2</sup>, G.W. Chung<sup>3</sup>, A.O. Edwards<sup>3</sup>, Y.H. Zhang<sup>1</sup>, G.S. Manligas<sup>1</sup>. 1) Departments of Human Genetics and Pediatrics, UCLA, Los Angeles, CA; 2) Ophthalmology & Visual Science, University of Michigan, MI; 3) Department of Ophthalmology, UT Southwestern Medical Center, TX.

We report two new mutations identified in the coding region of *PAX2*. Renal-Coloboma Syndrome, an autosomal dominant disorder associated with mutations in *PAX2*, is characterized by colobomatous eye defects, renal hypoplasia, vesicoureteral reflux, high frequency hearing loss and rarely central nervous system abnormalities. In our search to define phenotypes associated with *PAX2* mutations, we identified a three-generation family and an unrelated isolated proband with Renal-Coloboma Syndrome. In the three-generation family, the proband was an 8 month old boy with nystagmus and bilateral optic nerve dysplasia. His acuity at age 6 is 20/80 OD; 20/600 OS, and he currently has normal renal function. His mother and maternal grandmother also have bilateral optic nerve dysplasia and high tone hearing deficiency; both had renal disease leading to renal transplants. SSCP analysis of the *PAX2* coding region, followed by direct sequencing of exon 3, revealed a novel nonsense mutation, Arg114X (C886>T), in one allele of all three. The unrelated isolated proband is a 9 year old girl with congenital renal hypoplasia who developed endstage renal disease and was transplanted at age 7. She enjoys normal vision (20/20 OU). Optic nerve colobomas were discovered incidentally when the patient was treated for CMV retinitis. Mutation analysis revealed a single base pair deletion in exon 2, delT602 with a resultant frameshift and stopcodon (UGA) 8 codons downstream. As in the majority of patients with *PAX2* mutations, these patients have mutations in the exons encoding the paired domain. Of importance, systemic involvement in both probands was identified surreptitiously and suggests that a history of renal disease should be sought in individuals with colobomas and that examination for colobomas should be entertained in individuals with congenital renal hypoplasia. Identification of mutations in *PAX2* in such individuals will have genetic counseling implications.

**Clinical Features of Four Males and an Obligate Carrier in a Family with Lenz Syndrome.** *N.M. Reynolds<sup>1</sup>, S. Forrester<sup>1</sup>, M.J. Kovach<sup>1</sup>, R. Urban<sup>2</sup>, V.E. Kimonis<sup>1</sup>.* 1) Dept of Pediatrics, Southern Illinois University School of Medicine, Springfield, IL; 2) Dept of Ophthalmology, Tampa General Hospital, Tampa, FL.

Lenz syndrome is a rare X-linked recessive syndrome first described by Lenz in 1955. Clinical features include anophthalmia, microcephaly, mental retardation, cardiac, skeletal, urogenital, external ear, and digital, anomalies. We present three brothers (ages 15 years, 9 years, and 18 months) and a maternal uncle (age 27 years) with congenital anophthalmia, hypotonia and moderate to severe mental retardation. Dysmorphic features include dysplastic ears, high arched palate, pectus excavatum, finger and toe syndactyly, clinodactyly and fetal pads. Other features include scoliosis, cardiac and renal abnormalities. Obligate carriers have a history of recurrent spontaneous losses. One carrier has dysplastic ears and syndactyly of the 2-3rd toes bilaterally; features which may be helpful in identification. Fourteen previously reported cases were additionally reviewed. Mental retardation was present in 100%, 93% had growth retardation, 69% had microcephaly, 88% had ear anomalies, 76% had dental anomalies, 12% had a congenital heart defect, 50% had a urogenital anomaly, 47% had a spinal deformity and 69% had anomalies of the fingers or toes.

Linkage and haplotype analysis in this family indicates that the gene is located in a 17.65 cM region on chromosome Xq27-Xq28 flanked by microsatellite markers DXS1232 and DXS8043. This region overlaps the anophthalmos locus ANOP1, but excludes the OCRL locus for Lowe oculocerebrorenal syndrome. Candidate genes involved in neuronal development that map to this critical interval include CXORF1 and KIAA0006. This is the first report of linkage analysis in Lenz microphthalmia a unique disorder associated with mental retardation and multiple anomalies.

**X-linked omphalocele with obstructive uropathy.** *R.M. Ruzicka, E.R. Wassman, J. Siegel-Bartelt.* Perinatal Alliance Medical Group, Pasadena, CA.

A 23-year old G3 P2 TAB1 Hispanic female patient presented for preconceptional genetic counseling with a striking family history of X-linked omphalocele. Our patient had three male pregnancies, two of which died in the newborn period with omphalocele in Mexico and one of which was terminated at 15 weeks gestation due to the detection of omphalocele by ultrasound. Our patients first son was also noted to have hypertelorism, a congenital heart defect, low-set ears, and posterior urethral valves. The second son was noted to have omphalocele, obstructive uropathy leading to oligohydramnios, and a two-vessel umbilical cord. Amniocentesis performed during the second pregnancy yielded a normal male karyotype. The family history was also significant for two brothers, one nephew, one maternal uncle, and one maternal male cousin of our patient who died in the newborn period with omphalocele. Detailed information on other possible anomalies of the other affected family members is not available. The pedigree is highly suggestive of an X-linked recessive omphalocele condition, similar to that reported previously by Havalad et al (1979). The specific combination of obstructive uropathy with omphalocele in the family we report is uncommon. The differential diagnosis of X-linked syndromes with omphalocele includes Melnick-Needles syndrome, otopalatodigital syndrome type II, thoracoabdominal syndrome, focal dermal hypoplasia, and Opitz/BBB syndrome. However, none of these conditions fits the spectrum of anomalies described in this family particularly well. The patient was counseled that unless a particular mutation or diagnosis can be identified in this family, the options for prenatal diagnosis in a future pregnancy are limited to ultrasound and sex determination through amniocentesis, CVS, or preimplantation genetic diagnosis. The anomalies seen in this family may represent a new X-linked omphalocele syndrome or a new variation of a previously described syndrome.

Program Nr: 721 from the 2000 ASHG Annual Meeting

**Familial prader willi syndrome with unusual findings.** *L.A. Bastaki, S.A. AL-AWADI, S.J. ABULHASAN, F.M. MOHAMMED, S.A. GOUDA, K.K. NAGUIB.* Maternity Hosp, Kuwait Medical Genetic Ctr, Khaldiya, kuwait, Kuwait.

Herein we are reporting 6 sibs with Prader Willi(PWS)(5males and one female).All of them show the cardinal features of PWS except one who does not fulfil the required criteria.chromosomal study confirmed normal karyotype but FISH technique using specific DNA probes revealed del(15)(q11&12) trasmitted from the mother. chromosomal study and FISH technique of the father were normal.Three unusual findings were reported;the multiplicity of the affected sibs;the unusual clinical findings in one of the sibs and the maternal origin of the deleted chromosome 15.The possible explanations are discussed.

**Results of clinical and molecular evaluation of 14 hereditary ataxia families: Mysteries Remain.** *M.E. Ahearn<sup>1</sup>, N. Potter<sup>2</sup>, H. Zoghbi<sup>3</sup>, J. Mater<sup>1</sup>, W. Bradley<sup>1</sup>, L. Baumbach<sup>1</sup>.* 1) Univ Miami School of Medicine, Miami, FL; 2) Univ Tennessee Med Ctr, Knoxville, TN; 3) Baylor College of Medicine, Houston, TX.

The hereditary cerebellar ataxias represent a clinically and genetically heterogeneous collection of progressive neurological disorders. A number of causative genes have been identified but new genes causing specific forms of ataxia are constantly being discovered. Here we report our clinical and molecular investigations of 14 families with a pure or mixed cerebellar ataxia. Of these families, three with significant family history remain undiagnosed as to their genetic etiology. Trinucleotide repeat expansions were found as follows: 1 *SCA1*, 2 *SCA2*, 2 *SCA3* and 1 *SCA6* (with two samples pending completion). Five individuals (three with significant family history) have tested normal for all the known ataxia genes including the recently described *SCA8*. The three families with significant history are the subject of further investigation. Family 1 is a large family with seven affected members spanning three generations. This family exhibits a late onset cerebellar ataxia with dysarthria, lower extremity and truncal ataxia. Family 2 has four affected individuals spanning three generations. Clinical symptoms present in the family include balance and gait difficulties, dysarthria, nystagmus and peripheral sensory nerve problems and also shows anticipation with regard to age of onset. Family 3 who represent an autosomal recessive pattern of inheritance, has four affected sisters, with clinical symptoms very similar to Friedreich's ataxia.

In summary, this study indicates that although the genetic basis for many ataxia patients can be determined in families with strong histories, additional genes that cause ataxia remain to be found.

**Thalassaemia intermedia in Iran: Molecular determinants.** *M.T. Akbari<sup>1</sup>, E. Dudman<sup>2</sup>, M. Izadyar<sup>3</sup>, M. Kleanthous<sup>4</sup>, M. Petrow<sup>5</sup>.* 1) Dept Genetics, Sch Medicine, Tehran Univ Medical Sci, Tehran, Iran; 2) Perinatal Centre, Dept. of Obstetrics and Gynecologist, University college of London, London UK; 3) Dept. Pediatrics, School of Medicine, Tehran University of Medical Sciences, Tehran Iran; 4) CING, Nicosia, Cyprus; 5) Perinatal Centre, Dept. Obstetrics & Gynecology, University College London, London UK.

We report the result of investigation on the molecular foundation of thalassaemia intermedia in 100 Iranian patients. These patients were clinically heterogeneous. The age at diagnosis varied considerably amongst them with mean age of over 7 years. They developed very few symptoms and just a few number of them needed occasional blood transfusion. Other therapeutic interventions were splenectomy in a third of them and administration of folic acid and hydroxy urea in some patients. Hb concentration in the majority of the patients was between 7-10 g/dL and in a quarter of them it was between 10-12 g/dL. Over 90% had high HbF levels. This indicates a substantial elevation of expression of the gamma globin genes. All patients were examined for the -158 C-->T substitution in the G-gamma promoter locus, recognized by cutting with the restriction enzyme Xmn1, and over three quarters of the cases had the mutation in either homozygous or heterozygous form. The patients were also scanned for beta-globin gene mutations. Over 60% of the patients had the IVSII-1 mutation ( the most common in Iranian populations) in either homozygous or heterozygous combinations. Almost all the patients with IVSII-1 mutation had the Xmn1 marker concurrently. Examining the patients for both molecular determinants, it was established that there is physical linkage between the Xmn1 marker and the IVSII-1 allele in the cases who carried the two mutations. It is a known fact that the coexistence of the Xmn1 marker and IVSII-1 allele in cis situation under the condition of hematopoietic stress usually contributes to the overproduction of HbF causing HPFH. It seems this phenomenon endows mild features of intermedia in a big number of the Iranian thalassaemia intermedia patients.

**Siblings with cutis laxa type II(Debre type).** *M.T. Greally<sup>1</sup>, W. Agab<sup>2</sup>, A.H. Ebrahim<sup>3</sup>, K. Ardati<sup>4</sup>, P.H. Byers<sup>5</sup>.* 1) Col Medicine & Med Sci, Arabian Gulf Univ, Manama, Bahrain; 2) Pediatric Dept, BDF Hospital, Bahrain; 3) Pediatric Dept, Salmaniya Medical Complex, Manama, Bahrain; 4) Pediatric Clinic, Toobli, Bahrain; 5) Dept Pathology, Univ Washington, Health Sci Bldg, RM E511, Seattle WA, USA.

Cutis laxa type II (Debre type), an autosomal recessive form of cutis laxa, is a disorder of elastic fibers characterized by joint laxity, large fontanelle and developmental delay. Additional features include distinctive facial dysmorphism, an Ehlers-Danlos-like healing defect, hair abnormalities and central nervous system abnormalities. We present siblings, a brother and sister of consanguinous Arab parents, with features of this syndrome. The boy is more severely affected than his sister with the additional clinical findings of abdominal herniae, bilateral renal stones and multiple episodes of severe joint hematomata following minor trauma. Investigations included type I and type III collagen synthesis and secretion, both of which were normal. Skin electromicroscopy (EM) studies showed apparently normal collagen fibrils while the elastic fibers were small and had a 'motheaten' appearance. These findings were not as striking as those seen in other cases of cutis laxa type II where extreme rarefaction of elastic fibers has been described. The variety of clinical findings in this disorder and the reported differences in skin EM studies of elastic fibers, raise the question of genetic heterogeneity in this form of cutis laxa. E-mail address: mgreally@agu.edu.bh.

**Facial Clefting Syndrome: A new autosomal recessive entity in Mexican population.** *D. Saavedra*<sup>1</sup>, *L. Cornejo*<sup>2</sup>, *B. de la Fuente*<sup>3</sup>, *F. Ortiz-Monasterio*<sup>2</sup>, *M. Muenke*<sup>4</sup>. 1) Craniofacial Genetics Research, Hospital "Dr. Manuel Gea Glz.", Mexico City, Mexico; 2) Medicine School, Health Sciences Institute, Autonomous Hidalgo State University, Pachuca de Soto Hidalgo, Mexico; 3) Medicine Faculty, Autonomous Nuevo Leon University, Monterrey Nuevo Leon, Mexico; 4) Medical Genetics Branch, NHGRI, NIH, Bethesda MD, USA.

**Introduction.**- Any disruption of the anatomic continuity of the craniofacial structures is considered as a cleft. According to Tessier, the rare craniofacial clefts are numbered from 0 through 14 and they follow constant lines across different structures. Gollop described in 1981 the Fronto-Facio-Nasal Dysplasia (FFND), but regarding the description and the clinical pictures, this patient resemble fissured patients as described by Tessier. **Material and Methods.**- A field study was carried out in South Baja California Mexico, in order to determine the existence of a common factor between two affected siblings with facial clefts born from the same couple. **Results.**- Thirteen patients with the same phenotype consisting on 1, 2, 3, 4, 10, 11, 12, 13, and, 0-14 craniofacial clefts were found consisting by: widened frontal with hair lines leading toward the clefts, hypertelorism, bilateral coloboma of eyebrows, eyelashes and eyelids, hypoplastic alae nasi and cleft lip/palate. All patients are descendents of consanguineous couples, related among them by a common ancestor. This pedigree was demonstrative of an autosomal recessive inheritance pattern (AR). **Conclusion.**- We report a new syndrome consisting on craniofacial clefts inherited as an AR trait and therefore we consider that the patients diagnosed with FFND have this new syndrome.

**A common mutation in the methylenetetrahydrofolate reductase gene is not a risk factor for Down syndrome in a population-based study.** *M.B. Petersen<sup>1</sup>, M. Grigoriadou<sup>1</sup>, M. Mikkelsen<sup>2</sup>*. 1) Dept Genet, Inst Child Health, Athens, Greece; 2) Dept Med Genet, JF Kennedy Inst, Glostrup, Denmark.

Trisomy 21 is the most common chromosome abnormality in liveborns and is usually the result of nondisjunction of chromosome 21 in meiosis in either oogenesis or spermatogenesis. Advanced maternal age is the only well documented risk factor for maternal meiotic nondisjunction, but there is still a surprising lack of understanding of the cellular and molecular mechanisms underlying meiotic nondisjunction. It would be of big medical importance to identify younger mothers at increased risk for Down syndrome (DS). A recent study demonstrated increased plasma homocysteine concentration in the mothers of children with DS, partly explained by a higher frequency of the 677C>T mutation in the methylenetetrahydrofolate reductase (MTHFR) gene than in control mothers (Am J Clin Nutr 1999;70:495-501). The risk of having a child with DS was 2.6-fold higher in mothers with the 677C>T substitution in one or both alleles than in mothers without the substitution. The study was based on a small number of mothers (n=57), was not population-based, and the parental origin of the extra chromosome was not determined. We therefore analysed the MTHFR 677C>T mutation in a population-based study of DS in Denmark, where the origin of nondisjunction was determined by DNA microsatellite analysis. The material consisted of 177 mothers of children with DS (non-mosaic free trisomy 21) with origin of nondisjunction in maternal meiosis I or II. The frequency of the mutant allele (677T), which in the homozygous state is associated with mild hyperhomocysteinemia, in the DS mothers was 27.7%, not significantly different from the frequency in the fathers (29.8%) and not significantly different from the frequency in Danish controls (29.0%, n=1,084). Furthermore, there was no difference in the frequency of the 677T allele between mothers with meiosis I errors (27.5%, n=122) and mothers with meiosis II errors (28.2%, n=55). We conclude that the common MTHFR 677C>T mutation is not likely to be a maternal risk factor for DS and that the previously published preliminary findings were probably due to the small sample size.

**Patient with Autistic Disorder and 46, XY, dup (7) (p14.1p11.2).** *S.L. Donnelly<sup>1</sup>, C.M. Wolpert<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, C.W. Poole<sup>1</sup>, H.H. Wright<sup>2</sup>, J.R. Gilbert<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

We identified a 25-year-old male with Autistic Disorder (AD) and a history of a chromosome 7 anomaly. The patient has several dysmorphic features including a high forehead, shallow orbits, a large bulbous nose, macrognathia, brachydactyly, mild scoliosis, and feet that measure at the third percentile. Previous metabolic screens and neurological exams were within normal limits. The Autism Diagnostic Interview Revised (ADI-R) was conducted to further characterize the patient. He has stereotyped speech, odd use of gaze, circumscribed interests and repetitive and ritualistic behaviors. High-resolution chromosome analysis was performed for the patient to confirm the report of a chromosome anomaly. It was revealed that this patient has the following chromosome complement, 46,XY,?dup(7)(p14.1p11.2). An extra segment was observed on the proximal short arm of chromosome 7. The G-band pattern suggested an inverted duplication of 7p11.2-p14.1. In order to confirm the chromosomal origin of this extra segment, chromosome painting was performed. Fluorescence in situ hybridization (FISH) using a whole chromosome 7 DNA probe (Cytocell, Inc.) confirmed that the extra chromosomal material is derived from chromosome 7. Therefore, this patient is partially trisomic for chromosome 7. This type of chromosome anomaly is rare, with about 30 cases having been reported, and is usually associated with a familial balanced translocation. Therefore, high-resolution chromosome analysis of cultured blood lymphocytes was done for both parents of this patient. A normal chromosome complement was found for both parents. It is unclear whether the patient's AD phenotype is causally related to the 7p duplication. However, Rodier et al. (1997) reported that polymorphisms of the HOXA1 gene located on 7p15-p14.2 are over represented in patients with AD. These data suggest that this region of 7p needs to be investigated further as playing an etiologic role in the genetics of AD.

**Molecular characterization of a balanced translocation t(X;21)(p11;q22) associated with non-specific mental retardation.** *F. Laugier-Anfossi<sup>1</sup>, D. Depetris<sup>1</sup>, M.G. Mattéi<sup>1</sup>, B. Delobel<sup>2</sup>, M.F. Croquette<sup>2</sup>, M. Fontès<sup>1</sup>, L. Villard<sup>1</sup>.* 1) Inserm U491, Faculté de Médecine La Timone, Marseille, FRANCE; 2) Centre de Génétique Chromosomique, Hôpital Saint-Antoine, Lille, France.

Non-specific X-linked mental retardation (MRX) phenotypes have been described in a large number of families. Linkage analysis performed in these families has allowed to map the disease loci on the human X chromosome. However, only a small number of such families (0.5-1%) have mutations in the six MRX-causing genes that were identified so far. It is thus obvious that numerous as yet unidentified genes reside on the X chromosome and cause an MRX phenotype when mutated. One powerful way to isolate such genes is to take advantage of balanced translocations involving the X chromosome in female patients presenting a non-specific mental retardation phenotype. We have studied such a patient presenting a de novo balanced translocation t(X;21)(p11;q22). She has moderate MR and very slight dysmorphic features. In order to localize the translocation breakpoint on the X chromosome, several YAC clones were used in FISH experiments and one YAC was shown to cross the breakpoint. We subsequently used PAC clones to further narrow the breakpoint region and we have shown that the breakpoint is containing within a 170 kilobases PAC clone in Xp11.2. Fortunately, the PAC clone sequence was available at the Sanger Center and we used this genomic sequence to 1- design subclones in order to further narrow the breakpoint region and 2- use exon prediction programs to identify potentially transcribed regions. Several exons are located inside this PAC clone and experiments are currently underway to determine if a gene is interrupted by the X chromosome breakpoint in the patient.

**Agyria/pachygyria is associated with 7q31-qter duplication.** *N. Morichon-Delvallez<sup>1</sup>, H. Elghezal<sup>1</sup>, S. Fontaine<sup>1</sup>, C. Esculpavit<sup>1</sup>, Y. Martinovic<sup>1</sup>, M.C. Aubry<sup>2</sup>, P. Sonigo<sup>2</sup>, A. Benachi<sup>2</sup>, S. Romana<sup>1</sup>, M. Vekemans<sup>1</sup>, F. Encha-Razavi<sup>1</sup>.* 1) Dept Genetics, Hosp Necker-Enfants Malades, Paris, France; 2) Prenatal Diagnosis Center, Hosp Necker-Enfants Malades, Paris, France.

Agyria/pachygyria characterized by absence and/or rarefaction of brain convolutions is a common human brain malformation as shown by CT scan and MR Imaging. So far at least two genes, LIS1 on chromosome 17 and DC on chromosome X have been causally related to this genetically heterogeneous condition. Here we report on a novel association of agyria/pachygyria with a duplication of the long arm of chromosome 7. A 28 years old woman was referred at 34 weeks of pregnancy for counselling because ultrasound examination revealed bilateral ventriculomegaly. MR Imaging detected abnormal gyration and vermis hypoplasia. Cytogenetic study including spectral karyotyping and FISH analysis showed a 7q31-qter duplication due to a de novo (Y;7) translocation. After genetic counselling the parents decided to interrupt the pregnancy. Fetopathological examination was carried out : the fetus, a euthrophic boy presented slight facial dysmorphic features with arachnodactyly. No macroscopic and microscopic abnormalities were found at autopsy. X-Ray evaluation was normal. Neuropathological examination detected a pachygyric brain (weight : 310 g ; NI : 340 g) and a cerebellar vermis hypoplasia (weight : 13 g ; NI : 20 g). Microscopical study of brain sections showed a six layered cortical plate, with sub-ependymal and interstitial heterotopias. Vermian folia had a focal dysplastic pattern with purkinje cells rarefaction. Basal ganglia as well as the commissural and cortico-spinal tracts were well developed. The postnatal phenotype of 7qter duplication is usually associated with slight facial dysmorphism and mental retardation but to our knowledge, its association with agyria/pachygyria has not been described so far. Further studies are needed to confirm the association of 7q31-qter duplication and agyria /pachygyria, and to establish a causal relationship.

**Hypoplastic left heart in a female infant with partial trisomy 4q due to de novo 4;21 translocation.** *M. Velinov<sup>1,5</sup>, H. Gu<sup>1</sup>, K. Yeboa<sup>3</sup>, D. Warburton<sup>2</sup>, T. Tubo<sup>2</sup>, S. Dhuper<sup>4</sup>, S. Lanter<sup>4</sup>, D. Delprino<sup>4</sup>, G. Kupchik<sup>5</sup>, E.C. Jenkins<sup>1,4</sup>.* 1) NYS Institute for Basic Research, Staten Island, NY; 2) Department of Genetics and Development, Columbia University, NY, NY; 3) Department of Clinical Genetics, Columbia University, NY, NY; 4) Brookdale University Hospital Medical Center, Brooklyn, NY; 5) Maimonides Medical Center, Brookyn, NY.

We present a female infant, who was born at full term, with birth weight 7lbs, 13oz and presented with mild dysmorphic features: sloping forehead, hypertelorism, short and mildly webbed neck, and was subsequently identified to have congenital heart defects: hypoplastic left heart with aortic atresia and hypoplastic aortic arch, VSD and a nonrestrictive atrial communication. The chromosome study showed an unbalanced chromosomal translocation with additional material from 4q translocated onto 21q. This resulted in partial trisomy 4 and minimal monosomy 21. The derivative chromosome was characterized using M-FISH and whole chromosome painting. The karyotype was finally determined as 46,XX,der(21)t(4;21)(q25;q22.3).ish(wcp4+;wcp21+). The parental karyotypes were normal with the exception of mosaicism for a marker chromosome 2 in the father. This paternal marker was considered not to be related to the de novo translocation in the child. Additional analysis with FISH probes specific for 21q11.2, 21q21.2, 21q22.1 and 21q22.3 as well as typing with two microsatellite markers mapping on 21q21 ruled out a possible duplication of 21q on the derived chromosome. The patient underwent stage 1 Norwood procedure to manage her heart defect. Poor feeding and failure to thrive complicated the postsurgical period. At 4.5 months of age the child presented with significant growth delay. Hypoplastic left heart syndrome is a severe congenital defect accounting for at least 10% of the neonatal death due to structural heart defects. This heart abnormality is seen with increased frequency in relatively common chromosomal aberrations, such as monosomy X, trisomies 21, 18, 13. Our report provides for the first time evidence for the possible role of genes located on chromosome 4q, distal to band 4q25 or on the terminal 21q fragment in the pathogenesis of this heterogeneous condition.

**Chromosomal capping or interstitial deletion in a case of Wolf-Hirschhorn syndrome.** *M.J. Macera, and R.S. Verma.* Division of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn-New York Hospital/Weill Medical College of Cornell University, New York, NY.

The Wolf-Hirschhorn syndrome (WHS), regarded as a contiguous gene syndrome, is characterized by mental and growth retardation, maxillary hypoplasia, midline defects, skeletal abnormalities and a high nasal bridge with large protruding eyes, giving a "Greek Helmet" appearance. This syndrome results from the deletion of the short arm of chromosome 4 with the 165 kb critical region localized to 4p16.3. Varying degrees of expression have been associated with different degrees of deletions. We were referred a boy showing the severest symptoms of WHS. GTG banding of the proband identified a 46,XY,del(4)(p16.1) karyotype in his peripheral blood. Both of his parents were cytogenetically normal. FISH analysis with a probe specific for the Wolf-Hirschhorn region (Vysis) plus the 4 centromere (cep4) probe documented the deletion of the WHS region on his del(4) chromosome. Signals were present on both pairs of his parents' chromosome 4. The 4p telomere probe (4TelVysion Vysis) specific for the unique telomere sequence, gave a positive signal only on the normal chromosome 4 in the proband. No signal was detected over the del(4). We then applied a probe specific for the TTAGGG repeat sequence (Cytocell) that caps the distal ends of each chromosome. Signal was detected over the distal p del(4) chromosome, identifying the presence of the (TTAGGG)<sub>n</sub> cap. His karyotype is 46,XY,del(4)(p16.1).ish (LSI WHS-, TelVysion4-, PanTelomere+). These results suggest two possible pathways that describe the deletion: 1) an interstitial deletion with the distal break point located proximal to the (TTAGGG)<sub>n</sub> capping sequence and distal to the unique telomere sequence or, 2) more likely, a terminal deletion containing all the material from 4p16.1 to pter including the entire telomere complex, later capped through the action of telomerase, which stabilized or "healed" the chromosome by adding a new (TTAGGG)<sub>n</sub> cap to its end. These findings suggest that all terminal deletions should be evaluated by molecular techniques.

**Meiotic pairing resulting in an unusual recombinant chromosome involving heterochromatin in a fetus derived from a paternal translocation [t(1;9)(p13;q32)].** V.R. Pulijaal<sup>1</sup>, S. Gogineni<sup>1</sup>, A. Mohammed<sup>1</sup>, H.M.N. Nitowsky<sup>1</sup>, S. Gross<sup>1</sup>, H. Mootabar<sup>2</sup>, M. Rigs<sup>2</sup>, M.J. Macera<sup>3</sup>, R.S. Verma<sup>3</sup>. 1) Dept OB/GYN, Montefiore Medical Center-Albert Einstein College of Medicine, Bronx, N.Y.; 2) Columbia Prenatal Associates of Westchester, Yonkers, N.Y; 3) and Wyckoff Heights Medical Center, Brooklyn New York Hospital/Weill Medical College of Cornell University, New York, N.Y.

Human chromosome 9 is one of the most morphologically deviant chromosomes due to the highly variable heterochromatin of the secondary constriction region [qh]. Morphological variation of the h region in a homologue chromosome 9 do not have aberrant consequences during meiotic pairing and these variants have been inherited by the progenies without clinical consequences. A 35 year old women [G1P0] was referred for genetic amniocentesis. Cytogenetic findings with the GTG-technique revealed an abnormal 46,XY,t(1;9)(p13;q33),rec(9)dup(q11q13)phqh karyotype from her amniocytes. Parental chromosomes revealed that the mother was apparently normal while the father has a balanced translocation between chromosomes 1 and 9 in addition, the other chromosome 9 has a complete pericentric inversion involving the qh region i.e. 46,XY,t(1;9)(p13;q33),9ph. Although, the translocation in the fetus and the father superficially appeared to be identical, the derivative chromosome 9 in the fetus is a recombinant. Most likely, the recombinant chromosome 9 resulted due to crossing over in the inversion loop during the pachytene state. The recombinant chromosome 9 has heterochromatin in both the long and short arms. This finding indicates that that fetus is trisomic for the 9q12-13 region. This pericentric inversion is involved in a rearrangement with breakpoints in the heterochromatic region and presumably has no clinical consequences. We are in the process of characterizing the heterochromatic block by the FISH-technique using alpha, beta and satellite III DNA probes. Reshuffling of various DNA sequences in the qh region have occurred, possibly contradicting the earlier belief that crossing over does not take place in heterochromatin.

**Report of a case with manifestations of DiGeorge/Velocardiofacial syndrome (VCFS) and microdeletion 22q11.2 mosaicism.** *A. Anguiano<sup>1</sup>, L. Hudgins<sup>2</sup>, M.B. Dinulos<sup>3</sup>, L. Mak<sup>1</sup>, A. Tayag<sup>1</sup>, B.S. Emanuel<sup>4</sup>.* 1) Cytogenetics Department, Quest Diagnostics Nichols Inst, San Juan Capistrano, CA; 2) Stanford University School of Medicine, Stanford, CA; 3) University of Washington School of Medicine Children's Hospital & Regional Medical Center, Seattle, WA; 4) The Children's Hospital of Philadelphia, Philadelphia, PA.

A peripheral blood sample from a 12 year-old male was referred for evaluation of DiGeorge/VCFS by FISH. Clinical indications were developmental delay, short stature, mixed hearing loss, probable bipolar disorder, and attention deficit hyperactivity disorder (ADHD). Congenital clubfoot deformity was noted in the patient and several otherwise normal family members. On exam, hypernasal speech, short palpebral fissures, small ears with thickened superior helices and short terminal phalanges were noted. FISH with TUPLE 1 (Vysis) revealed a 22q11.2 deletion in 52 of 107 metaphases (49 %), indicating mosaicism; a deletion was later also demonstrated in 71 of 100 metaphases from skin fibroblasts. FISH studies of 200 metaphases of both parents were normal, indicating post-zygotic, de novo origin of the child's deletion. To determine origin of the deletion, DNA microsatellite analysis of peripheral blood from the patient and parents was done utilizing several markers from within the deletion (D22S941; 102STS). This revealed that the deletion arose on the paternally derived chromosome 22. To further assess the extent of the deletion, FISH studies of G<sub>0</sub> arrested interphase nuclei were undertaken. This revealed mosaicism for a 1.5 Mb deletion. Based on the map of the region, the deletion was determined to involve the proximal portion of the region typically deleted in DiGeorge/VCFS. This report documents a case of 22q11.2 microdeletion mosaicism in a child with predominantly developmental/psychiatric manifestations of DiGeorge/VCFS. This case suggests that mitotic, as well as meiotic recombination events can give rise to the 22q11.2 deletion. It is likely that the duplications (LCRs) on chromosome 22, in particular LCR-A and LCR-B, mediate intrachromosomal somatic recombination events within the modules shared between them.

**Tetrasomy 12p Masquerading As Trisomy 21.** *L. Dong, R.E. Falk, J. Williams III, M. Kohan, R.R. Schreck.* Medical Genetics-Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA.

CVS was performed on a healthy 38 year old woman at 11 weeks of gestation. Cytogenetic analysis of the direct preparation revealed 5 of 11 cells to have an extra G-group sized chromosome that by G-banding looked like chromosome 21. The direct result was reported as mos 47,XY,+21[5]/46,XY[6]. All 30 cells from two CVS cultures were found to be 46,XY. To clarify the discrepancy between CVS direct preparation and cultures, an amniocentesis was performed at 16 weeks gestation. Ultrasound evaluation was interpreted as normal. However, the amniocentesis result was abnormal with mosaicism for an additional structurally abnormal chromosome. Instead of trisomy 21, an extra small, metacentric chromosome was observed in 12 out of 20 cells. This supernumerary chromosome looked like an isochromosome for either chromosome 21, or for the short arm of chromosome 12. FISH employing a whole chromosome paint for chromosome 12 confirmed the origin of this marker from chromosome 12. To investigate the relationship of this finding to the apparent trisomy 21 cell line in the CVS direct preparation, interphase nuclei from the CVS direct slides were evaluated by FISH using an a satellite probe for chromosome 12. Nine of twenty cells showed three signals. Thus, the extra chromosome seen in the spontaneously dividing cells was derived from chromosome 12, not 21, and could have resulted from breakage of an isochromosome 12p. After termination, a confirmation study revealed 9 of 10 cells from two tissues to have a 47,XY,+i(12)(p10) karyotype. Tetrasomy 12p differs clinically from mosaic trisomy 21, which was suspected based on CVS direct preparation. Tetrasomy 12p is associated with Killian/Teschler-Nicola syndrome which presents with profound mental deficiency, seizures, hypotonia, deafness, coarse facies, and other dysmorphism. While major malformations have been described in prenatally detected cases, ultrasound evaluation of these fetuses is often normal. FISH has proven very useful in defining chromosome material in confusing situations. This case demonstrates the value of molecular cytogenetic tools to clarify and elucidate cytogenetic discrepancies in prenatal diagnosis.

**Low level mosaic r(13) resulting in a large deletion of chromosome 13 in a newborn female with multiple congenital anomalies.** *C.P. Lorentz<sup>1</sup>, D. Babovic-Vuksanovic<sup>2</sup>, D.T. Link<sup>3</sup>, W. Wyatt<sup>1</sup>, S.M. Jalal<sup>1</sup>.* 1) Department of Laboratory Medicine and Pathology; 2) Department of Medical Genetics; 3) Department of Otorhinolaryngology, Mayo Clinic, Rochester, MN.

A newborn female had multiple congenital dysmorphic features including: digital anomalies of both hands and feet with severe thumb hypoplasia, facial dysmorphism, agenesis of corpus collosum, bilateral small kidneys, segmental vertebral anomalies, extranumerary rib, heart defect, bilateral hip dislocation, growth retardation and subglottic narrowing. Newborn aneusomy detection based on interphase FISH (NAD) for chromosomes 13,18, 21, X and Y indicated monosomy 13 in 9% of the cells (normal cut off 8.5% at 95% CI). The follow up banded metaphase based analysis indicated the presence of a small ring and monosomy 13 with normal 46,XX cells at a level of 0/20 and 1/50 cells respectively. The ring was wcp13 positive, RB1 negative and was detected in 2/50 cells by metaphase FISH. FISH analysis of buccal cells, based on the level of monosomy 13 where 21 served as a control, indicated the ring to be present in 23% of cells (normal cut off 10%). The low level (< 4%) mosaicism of ring 13 would most likely have been missed if only 20 banded metaphases were analyzed from the whole blood cultures. Fortunately, in this case NAD results alerted us to the loss of chromosome 13 in some cells. Consequently, the analysis of a larger number of cells and the evaluation of multiple tissues established a low level of mosaicism for ring 13 resulting in deletion of most of the 13q arm. The proportion of the ring may be higher in other tissues than observed in the blood. Clinical findings in our patient were consistent with other reported cases of 13q deletions. In addition, our patient had a subglottic narrowing not previously described in patients with 13q deletion.

**Identification of an 18q- syndrome patient who is mosaic for two different deletions of 18q.** *X.T. Reves<sup>1</sup>, J.D. Cody<sup>2</sup>, N.M. Thompson<sup>3</sup>, R.J. Leach<sup>1,2</sup>.* 1) Cellular & Structural Biology, Univ. Texas Health Sci. Center, San Antonio, TX; 2) Pediatrics, Univ. Texas Health Sci Center, San Antonio, TX; 3) Psychiatry and Behavioral Health Sciences, University of Washington, Seattle, WA.

Structural chromosome abnormalities occurring after fertilization result in mosaicism. This results in different populations of cells with the chromosomal abnormality in various tissues. Individuals who are mosaic for chromosomal abnormalities, such as 18q- syndrome, typically have less severe clinical features compared to individuals with a constitutive chromosomal abnormality. We report a child referred to us with a diagnosis of mosaicism for a deletion of the long arm of chromosome 18: 46,XX/46,XX,del(18)(q21.33). However, this child had a more severe phenotype than would be predicted by her breakpoint, irrespective of mosaicism. In order to further define the extent of the mosaicism, samples were obtained from all three cell lineages: leukocytes for mesoderm, urinary tract cells for endoderm, and a buccal smear for ectoderm. A PCR-based marker for the myelin basic protein (MBP) gene was used to analyze the samples and all three cell lineages were hemizygous for the MBP gene (18q23). We were unable to detect any normal cells, which was confirmed by fluorescence in situ hybridization (FISH) in leukocytes. Further molecular analysis was conducted using PCR-based markers D18S51 (18q21.33) and D18S483 (18q21.32). Mosaicism was observed for these markers, which was also confirmed by FISH analysis. Therefore, we determined that the patient has an 18q deletion in all cells, but the deletions have different breakpoints and the child was indeed mosaic. The patient's phenotype was consistent with other individuals with the larger deletion (18q21.32).

**Inverted 6p21.3p25p25 duplication in a child with bilateral hearing loss.** *D.B. Flannery<sup>1</sup>, C.M. Lovell<sup>1</sup>, S.M. Jalal<sup>2</sup>, A.S. Kulharya<sup>1</sup>*. 1) Department of Pediatrics Medical College of Georgia, Augusta GA; 2) Mayo Clinic Rochester, MN.

Thirty-six cases of partial duplication of short arm of chromosome 6 have been described, however only four have pure duplication of 6p. The remaining cases involve additional deletions from another chromosome, as a result of segregation from balanced reciprocal translocation carriers. We present a rare case of inverted duplication involving 6p21.3-p25. A four-week old infant was evaluated for dysmorphic features. The pregnancy was complicated by oligohydramnios and breech presentation. The birth wt. was 1.32 Kg. Large patent ductus arteriosus and hydrocele were present. Renal sonogram was normal. Thrombocytopenia was present with 20 petechiae. At two weeks all growth parameters were <5th centile. Other features included dolichocephaly, posteriorly rotated ears, prominent forehead, sparse hair, short palpebral fissures, undescended testes, and bilateral hearing loss. Chromosome analysis demonstrated an inverted duplication of 6p21.3p25. FISH with WCP6 confirmed that the duplication was derived from chromosome 6. Analysis of 6p and q-telomere specific FISH probes indicated the presence of the short arm telomere between the terminal end and the duplicated material confirming the inverted duplication. Parental karyotypes were normal. Our patient confirms the phenotype of patients with pure duplication of 6p. The size of duplication does not necessarily seem to correlate to the severity of dysmorphism. The differences in phenotype can be attributed to point mutations, position effect, or parent of origin influence in addition to the size of duplication. The deafness in our patient is a new feature, not previously described. No gene for deafness has been currently mapped in the breakpoints involved in this duplication. Pure duplications involving 6p continue to be very rare, although unequal crossing over involving moderately repetitive sequences are relatively common.

**FISH reveals partial trisomy 16p in a fetus with absent thumbs: Implications for genetic counseling and gene discovery.** *L.M. Call<sup>1,2</sup>, J. Baker<sup>1</sup>, X. Qian<sup>1,2</sup>, E. Lemyre<sup>1,2</sup>*. 1) Brigham and Women's Hospital; 2) Harvard Medical School, Boston, MA.

The study of rare phenotypes may provide important clues about genomic regions containing genes controlling critical aspects of development. Our patient, a 21-year-old female, presented at 13 weeks gestation with abnormal ultrasound findings indicating fetal demise. At autopsy a macerated fetus was noted to have absent thumbs. Due to a family history of SABs, the patient was referred for cytogenetic analysis. Her karyotype revealed a rare balanced 3-way translocation: 46, XX, t(2;16;21)(q13;p13.1;q22.3). Of 20 possible gametes that can result from the 3:3 segregation of this translocation, three will have partial trisomy for 16p13.1-pter with other chromosomal abnormalities. We used targeted FISH on paraffin-embedded tissue of the fetus because routine metaphase analysis was not possible. Cosmids mapping to 16p13.3 were used as probes for FISH; three signals were observed in 47/53 cells analyzed indicating trisomy for 16p13.3. Hybridization of an a-satellite 16 probe detected two signals, demonstrating that fetal demise was not due to full trisomy 16. Hybridization of a cosmid to 21q22.2 also detected two signals. FISH with additional probes for chromosomes 2, 16 and 21 will delineate further the genetic complement of this fetus. Many syndromes feature absent thumbs as a characteristic phenotype, including Fanconi anemia, 13q-, VATER, Baller-Gerold, Holt-Oram, and partial trisomy 16p syndrome. In addition to absent thumbs, individuals with partial trisomy 16p syndrome have developmental delay and a characteristic facies. More than 18 cases of trisomy 16p syndrome have been reported in the literature; at least 6 of these presented with absent or abnormal thumbs. No other imbalance that could result from this 3-way translocation has a known association with absent thumbs. Our findings help explain the etiology of the fetal demise and also have implications in future counseling. In addition, they help to delineate further possible candidate regions for genes involved in limb development.

**Clinical and Cytogenetical Features of Partial Trisomy 13q Due to Maternal Pericentric Inversion.** *J. D. Falcon, E. Lieberman, M. Cervera, C. Salas, V. Del Castillo.* Dept Human Genetics, Inst Nacional de Pediatra, Mexico, DF, Mexico.

We report the case of a newborn male who clinically presented large fontanelles, short palpebral fissures with bilateral anophthalmia, bushy eyebrows, long eyelashes, prominent nose, low malformed ears, holosystolic murmur, hepatosplenomegaly, fingers and toes with hypoplastic nails and postaxial polydactily of the left foot. He was surgically treated for gastroesophageal reflux and an intestinal volvulus and died at age 2 months due to cardiac and respiratory failure. He was the fifth product of elder parents, had three healthy siblings and one who died in the neonatal period due to unknown causes. Karyotype analysis with G-banding of prometaphase spreads demonstrated a 13p+ chromosome with absent satellites. FISH analysis with painting for chromosome 13 allowed us to determine that the segment was a partial duplication 13 (46, XY dup 13q34q22). The fathers karyotype was normal. The mothers revealed a pericentric inversion involving one of the chromosomes 13 (46, XX inv 13p11.2q22). We could infer that the duplicated segment was due to meiotic recombination of the rearrangement in the mother. Phenotypical characteristics of partial duplications of euchromatic regions on chromosomes can be detected by high resolution and molecular cytogenetic techniques. Karyotype-phenotype correlation can be done for accurate diagnosis and genetic counseling in parents. Partial trisomies of chromosome 13 have been described and characteristic phenotypes have been recognized for proximal and distal segments. Some of these partial duplications arise from chromosomal rearrangements, of which, maternal inversions have been commonly reported. Our patient presented many malformations including anophthalmia, not previously reported, and died at an early age, in contrast to previous reports, which refer to less severe malformations and a longer life span. Though variability of the phenotype exists, this could be explained by the influence of regulatory mechanisms of other genes, inconsistency in the karyotype at the submicroscopic level or a position effect of the segment involved.

**A double balanced chromosomal translocation, with development delay and Primary Ciliary Dyskinesia (PCD), suggests candidate genomic regions for PCD loci.** *S. Dahoun<sup>1</sup>, M.S. Williams<sup>2</sup>, C. Vieux<sup>1</sup>, K.D. Josephson<sup>2</sup>, S.E. Antonarakis<sup>1</sup>, L. Bartoloni<sup>1</sup>.* 1) Division of Medical Genetics, University of Geneva Medical School, Switzerland; 2) Dept. of Pediatrics Gundersen Lutheran Medical Center, La Crosse, WI, USA.

A six year old child was evaluated for development delay and minor dysmorphic features. Additional phenotypic features included rhythmical movement disorder of sleep and speech delay. There was also chronic nasal congestion and recurrent sinus and ear infections. Sweat chloride and immune system evaluation were normal. Electron microscopy of the respiratory cilia revealed absence of both outer and inner dynein arms, absence of radial spokes and fused or single central microtubules, suggesting the diagnosis of Primary Ciliary Dyskinesia (PCD). PCD is characterized by immotile cilia, bronchiectasis and recurrent upper respiratory tract infections. Situs inversus, seen in about 50% of PCD patients, was not present in this patient. Because of the developmental delay, a cytogenetic analysis was performed. A double balanced chromosomal translocation 46,XY,t(7;14)(q32.2;q22.3),t(12;20)(q23.2;p13) was found. Chromosomes of both parents were normal and no familial history of respiratory problems was reported. One of the hypotheses for the PCD phenotype in this patient is that at least one of the breakpoints disrupts a gene coding for an axonemal dynein, and the other allele harbors a deleterious mutation. Mutations in dynein genes (one for an intermediate chain and one for a heavy chain) have been previously shown to cause PCD. Two heavy chain dynein genes map to chromosomal regions 7q32 and 14q. The position of these genes with respect to the translocation breakpoints seen in this patient is now under study. [sophie.dahoun@medecine.unige.ch](mailto:sophie.dahoun@medecine.unige.ch)

**Trisomy 20 mosaicism-abnormality or normal variant?** *M.G. Bialer<sup>1</sup>, E. Cox<sup>2</sup>, J.K. Lundberg<sup>1</sup>, C. McKenna<sup>1</sup>, L. Mehta<sup>1</sup>*. 1) Dept Pediatrics, North Shore Univ Hosp/NYU School of Med, Manhasset, NY; 2) Sarah Lawrence College, Bronxville, NY.

A 37 yr old woman had amniocentesis for maternal age. The study revealed trisomy 20 mosaicism (T20mos) with 31 of 33 cells trisomic (47,XX,+20[31]/46,XX[2]). A follow-up ultrasound at 22.9 wk gestation showed the fetus to be 2 wk behind in growth. Fetal echocardiogram revealed tetralogy of Fallot. The couple elected to terminate the pregnancy by D&E. A chromosome study done on kidney from products of conception confirmed T20mos (47,XX,+20[2]/46,XX[5]). T20mos was seen in 6 cases of 13,186 amniocenteses performed at North Shore Univ. Hosp. from 1984-1993, for an incidence of 1 in 2,199. This is, of course, a selected population. We have provided counseling for 13 pregnancies with T20mos and 2 pregnancies with isochromosome 20q mosaicism (i20qmos) since 1984. One pregnancy with both T20mos and T9mos was not included in this study. To our knowledge, all cases resulted in the birth of a normal (nl) baby. We were able to contact all but 2 of the mothers. Nl growth and development were reported in 10 of 11 children with T20mos at the following ages in years: 0.2, 1.6, 1.8, 1.9, 2.3, 3.9, 5.2, 5.7, 5.9, 6.5. Nl growth and development were reported in both children with i20qmos at 1 wk and 3.4 yr respectively. One child with T20mos had nl development until 3 yr when he was noted to have fine motor problems and lost some speech abilities. He was diagnosed with pervasive developmental disorder (PDD). At 9.5 yr his problems include self-stimulatory behaviors, echolalia, hyperacusis, processing problems, short attention span and difficulty relating to others. His growth is nl and he is not dysmorphic. Prenatally diagnosed T20mos has been reported to be compatible with a nl outcome in >90% of cases. The only recurrent anomalies have been congenital heart disease and renal anomalies. There has been little long-term follow-up of children with this diagnosis. Our experience confirms the nl outcome of most cases and the increased risk for congenital heart disease. PDD has not been previously reported with T20mos, and it is possible that this is a chance occurrence, but longer follow-up of children with this diagnosis may be indicated.

**Cryptic duplication of 21q in an individual with a clinical diagnosis of Down syndrome and review of the literature.** *C.J. Forster-Gibson<sup>1</sup>, J. Davies<sup>1</sup>, J.J. MacKenzie<sup>2</sup>, K. Harrison<sup>3</sup>.* 1) Departments of Family Medicine; 2) Pediatrics; 3) Pathology, Queen's University, Kingston, ON.

The clinical features of Down syndrome (DS) have been well described and are identifiable in infancy. We describe an adult male initially diagnosed with Down syndrome at 18 months of age, who had repeatedly normal lymphocyte and fibroblast karyotypes. He had several features characteristic of DS, including mental retardation, 5th finger clinodactyly, open mouth, oblique eye fissures and hypotonia. He did not have Brushfield spots, transverse palmar creases, or congenital heart defect, but did have some dysmorphic features not characteristic of DS. Karyotyping was repeated when he was 33 years old. Analysis of G-banded metaphase chromosomes at the 600 band resolution showed that one chromosome 21 had a possible duplication of 21q22.13 to 21q22.3. Investigational FISH studies were done with a whole chromosome paint probe (wcp21, Oncor Coatasome 21) and a chromosome 21 locus specific cosmid contig probe (LSI-21 (Vysis)) localized within bands 21q22.13-21q22.2. The wcp21 probe hybridized to the entire length of both chromosome 21 homologues. The LSI-21 probe presented as 2 discrete signals on one chromosome 21 homologue and one signal on the other. CGH analysis identified a ratio of 1.5 for part of chromosome 21 involving band 21q22, indicating a gain of part or all of the terminal band of chromosome 21. This was consistent with the conventional cytogenetic and FISH findings. The karyotype was defined as 46,XY,?dup(21)(q22.13q22.2).ish dup(21) (LSI-21++,wcp21+). Review of our case and 12 previously reported cases of pure partial chromosome 21 trisomy indicated that characteristics common to this group included mental retardation (92%), 5th finger clinodactyly (89%), open mouth (88%) and oblique eye fissures (85%). Presence of these features did not appear to depend on the specific portion of chromosome 21 that was trisomic. Features seen frequently in DS (>40%), that were infrequent in this group included a transverse palmar crease (18%) and congenital heart defect (9%). Review of 18 additional DS clinical features showed no consistent phenotype-genotype correlations.

**Large Pericentric Inversion of the Y Chromosome in a Severe Oligospermic IVF donor.** *L. Bao<sup>1</sup>, M. Cedars<sup>2</sup>, D.A. Kelk<sup>2</sup>, T. Gilfillan<sup>1</sup>, S.M. Bundrant<sup>1</sup>, L. McGavran<sup>1</sup>.* 1) Colorado Genetics Laboratory, Depts of Pathology and Pediatrics, University of Colorado Health Sciences Centers; 2) Dept of Obstetrics & Gynecology, University of Colorado Health Sciences Center.

We report a rare pericentric inversion of the Y chromosome in a 43-year-old infertile man with severe oligospermia referred for study prior to using his sperm for in vitro fertilization (IVF). The couple had two previous children by donor insemination prior to the diagnosis of premature ovarian failure in the wife. IVF was planned using donor eggs. The sperm count as assayed in pelleted semen revealed 3 motile and one non-motile sperm. Of 11 mature donor eggs, only 3 were fertilized and 2 embryos were transferred. At 4 weeks post-conception, a singleton fetus with a detectable heartbeat was observed by ultrasonography. The husband's peripheral blood G-banded cytogenetic studies at 650 bands revealed a rearrangement of short arm of the Y chromosome at band Yp11.3. Fluorescence in situ hybridization showed that this arrangement is a pericentric inversion with a large inverted segment and small segments distal to the inversion breakpoints:  $inv(Y)(p11.31q12)$ . The Yp subtelomeric sequences and the SRY gene (Yp11.3) are inverted to the Yq, and the Yq subtelomeric sequences to the Yp. Such a large pericentric inversion of chromosome Y has not been reported previously, possibly because it is difficult to recognize from chromosomal banding patterns alone. Cases with rearrangements of Yp11.3 have been reported in males with an otherwise normal phenotype and azoospermia. We speculate that this inversion is associated with this man's infertility by altering or interfering with meiotic chromosome pairing and therefore inhibiting spermatogenesis. It is also possible that the inversion may increase the likelihood of unequal recombination between the pseudoautosomal regions of the Xp and Yp, which could result in an XX SRY-positive or an XY SRY-negative karyotype in the offspring. The successful IVF demonstrates that gametes from this man are capable of conceiving a viable embryo. This case illustrates the importance of cytogenetic studies of men with oligospermia prior to utilization of their sperm for IVF.

**Clinical studies on subtle chromosomal rearrangements: experiences in the UK.** *B.B.A. de Vries*<sup>1,2</sup>, *S.M. White*<sup>3</sup>, *S.J.L. Knight*<sup>4</sup>, *T. Homfray*<sup>5</sup>, *I. Young*<sup>5</sup>, *B. Kerr*<sup>5</sup>, *C. McKeown*<sup>5</sup>, *M. Splitt*<sup>5</sup>, *O.W.J. Quarrell*<sup>5</sup>, *A.H. Trainer*<sup>5</sup>, *M.F. Niermeijer*<sup>1</sup>, *S. Malcolm*<sup>2</sup>, *J. Flint*<sup>4</sup>, *J. Hurst*<sup>3</sup>, *R.M. Winter*<sup>2</sup>. 1) Clinical Genetics, Erasmus Univ, Rotterdam, The Netherlands; 2) Clinical and Molecular Genetics Unit, Inst of Child Health London; 3) Dept of Clinical Genetics, Oxford Radcliffe Hospital Trust, Oxford; 4) Inst of Molecular Medicine, John Radcliffe Hospital, Oxford; 5) Departments of Clinical Genetics, St George's London, Nottingham, Manchester, Birmingham, Newcastle, Sheffield, Glasgow.

Subtle telomeric defects have been found in 7.4% of children with moderate to severe mental retardation and in 0.5% with mild retardation. To ascertain selection criteria for testing, we studied 29 patients with a known subtelomeric defect and assessed 30 clinical variables concerning birth history, facial dysmorphism, congenital malformations and family history. Controls were 110 undiagnosed mentally retarded children with normal G-banded karyotype and without submicroscopic subtelomeric abnormalities. 41% of the telomere cases had microcephaly compared to 35% of the controls ( $p=0.53$ ), 52% had short stature compared to 32% of the controls ( $p=0.07$ ) and prenatal onset of growth retardation was found in 37% compared to 9% in the controls ( $p<0.001$ ). Other common features in telomere patients were hypertelorism (31%), nasal and ear anomalies (48% resp. 41%), hand anomalies (38%) and cryptorchidism (33%). Two or more facial dysmorphic features were observed in 83% of the patients which was not significantly different from the controls (67%,  $p=0.10$ ). A higher percentage of positive family history for mental retardation was reported in the study group than the controls (50% versus 21%,  $p=0.002$ ). However, miscarriage(s) seems to be less frequent among mothers of telomeric cases than controls (8% versus 30%,  $p=0.028$ ).

Our results suggest that strong indicators for telomeric defects are prenatal onset growth retardation and a positive family history for mental retardation. Using these clinical criteria in addition to features suggestive of a chromosomal phenotype will improve the diagnostic pick up rate of subtelomeric defects among mentally retarded individuals.

**Proximal deletion breakpoints in 15q11-q13 are sites of high homologous recombination.** *J.L. Gair<sup>1</sup>, B.D. Kuchinka<sup>1</sup>, M. Lalande<sup>2</sup>, R.J. Ritchie<sup>3</sup>, W.P. Robinson<sup>1</sup>.* 1) Dept. Medical Genetics, Univ. British Columbia, Vancouver, BC, Canada; 2) Dept. Genetics and Dev. Biol., Univ. Connecticut Health Ctr, Farmington, CT, USA; 3) Research and Productivity Council, Fredericton, NB, Canada.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are caused by loss of imprinted genes within either maternal or paternal chromosome 15q11-q13, respectively. The most common etiology for PWS and AS is a ~4 Mb *de novo* interstitial deletion of this region. There are two common proximal deletion breakpoints (BP1 and BP2) with similar frequencies of each in both maternally and paternally derived deletions, and one common distal breakpoint. Estimates of meiotic recombination around the proximal deletion breakpoints could not previously be analyzed due to lack of a centromeric marker. Using a new marker (738CA), which lies in a duplicated region proximal to BP1, 370 informative meioses from CEPH pedigrees have now been identified in this region. The genetic distance for males and females from 738CA to D15S541 (BP1) and from D15S541 to D15S11 (BP2) is estimated as 7.8 and 2.2 cM in females and 2.3 and 2.0 cM in males, respectively. Although the exact physical distance is unknown, this data suggests that the proximal deletion breakpoints show a relatively high rate of meiotic recombination, particularly in females. In addition, 14 new microsatellite markers plus additional informative meioses have been used to further characterize the sex-specific regions of recombination previously described in 15q11-q13. The new data supports the presence of excess female recombination extending from D15S122 to D15S97 (including the 5' end of the UBE3A gene) with estimates of 5.0 cM in females vs. 2.7 cM in males, as well as excess male recombination from GABRB3 to D15S156. However, the recombination events do not seem to cluster to a specific site within these regions. Overall the genetic distance from 738CA to D15S165, which spans the ~4Mb deletion region, is estimated as 22.4 cM in females and 20.1 cM in males. This high rate of genetic to physical distance could suggest it is a region either particularly prone to double strand breaks or efficient at pairing during meiosis.

**A Unique Finding of Numerical and Structural Three Cell Line Mosaicism Involving Chromosome 18 in a 3 1/2 year old Child.** *D.P. Dumont<sup>1</sup>, O.T. Mueller<sup>1,2</sup>, J.R. Ranells<sup>2</sup>, J.A. McFarland<sup>1</sup>, F. Mawani<sup>1</sup>, D. Conforto<sup>1</sup>, M.J. Sutcliffe<sup>1,2</sup>.* 1) Clinical Genetics Laboratories, All Children's Hospital, St Petersburg, FL; 2) Department of Pediatrics, University of South Florida, Tampa, FL.

A term normal birthweight female born to a 47 year old para 1-0-0-1 mother was diagnosed with supraaortic pulmonary stenosis. Chromosome analysis at a different facility revealed a 47,XX,+del(18)(q22)[18]/47,XX,+18[2] karyotype. Additional clinical presentation included an MRI finding of hypoplastic brain stem with large cisterna magna, apnea, seizures, mild dysmorphic features and a few scattered nevi flammei. Following excellent family care and intensive stimulation, current clinical evaluation demonstrates both psychomotor and physical progress despite growth delay, microcephaly and hypotonia. Due to tissue specific mosaicism, a skin biopsy was performed at 3 1/2 years. A centromeric Fluorescence In-Situ Hybridization (FISH) probe, CEP18, revealed a normal hybridization pattern in 7/100 cells. Fibroblast GTG banding confirmed 46,XX[4] normal cell line with 47,XX,+del(18)(q22)[32]/47,XX,+18[14]. Repeat peripheral blood analyzed by CEP18 FISH showed 39/200 cells with a normal hybridization signal. Further FISH analysis using dual color subtelomeric probes for 18p and 18q showed 8/100 cells with a normal hybridization pattern, 6/100 with +18 and 73/100 with the del(18). Karyotype showed 46,XX[1]/47,XX,+del(18)(q22)[99]. DNA microsatellite analysis using centromerically oriented loci established the maternal origin of the additional chromosome 18, and suggested a meiosis I nondisjunction event. Further, using loci distal to the q22 breakpoint established that the deleted chromosome was the remaining paternal 18. This case illustrates the importance of taking counts above 20 cells in known or suspected mosaicism, since missing the normal cell line has prognostic implications. In addition, this case demonstrates both numerical and structural abnormalities and the limitations of the initial trisomy 18 analysis using a FISH centromeric probe for 18.

**Full term pregnancy after diagnosis of non-mosaic trisomy 10 by amniotic fluid: ultrasound, cytogenetic and morphologic findings.** *S.A. Ebrahim<sup>1</sup>, A.N. Mohamed<sup>1</sup>, H. Lee<sup>2</sup>, F. Qureshi<sup>1</sup>, A. Johnson<sup>2</sup>, M.I. Evans<sup>1,2</sup>.* 1) Department of Pathology; 2) Department of Obstetrics/Gynecology, Hutzel Hospital/Wayne State University, Detroit, MI.

Non-mosaic trisomy 10 is a lethal condition seen in about 1.8 per cent of spontaneous miscarriages. We report the ultrasound, cytogenetic and morphologic findings of a fetus with non-mosaic trisomy 10 detected at 18 weeks of gestation that continued to full-term.

A 40-year-old gravida 5, para 3, VIP 1, female was referred for genetic counseling and amniocentesis due to anomalies detected on a routine ultrasound scan and advanced maternal age. Ultrasound revealed a growth-retarded fetus (16 weeks by ultrasound and 18.5 weeks by LMP date). Multiple anomalies were noted, including absent lower cerebellar vermis, dilated frontal horns of the cerebral ventricles, enlarged thalamus, pericardial effusion, bilateral pleural effusion, clenched hands with flexed wrists, decreased amniotic fluid volume, and a non-septated cystic hygroma. FISH on uncultured amniocytes showed no evidence of numerical abnormality for chromosome 13, 18, 21 X, and Y. Cultured amniocytes showed a 47,XX,+10[20]. The couple was counseled regarding these findings, and opted to continue the pregnancy. At 42 weeks, a stillborn female fetus was delivered. At birth, the fetus weighed 1480 gm and was found to have multiple dysmorphic features and congenital anomalies, including hypertelorism, bilateral microphthalmia, right cleft lip and palate and left cleft palate, posteriorly rotated ears, thymic hypoplasia, multicystic dysplastic kidneys, streak maldeveloped ovaries and splenomegaly. Examination of the cardiovascular system revealed interrupted aortic arch, absent ductus arteriosus and subaortic ventricular septal defect. To our knowledge, this is the first reported case of non-mosaic trisomy 10 detected by amniocentesis early in gestation which survived to full term.

**Interpreting Comparative Genomic Hybridization Data in Clinical Cytogenetics.** *T.M. Dunn, N.B Kardon, K. Hirschhorn, B. Levy.* Depts Human Genetics and Pediatrics, Mount Sinai Medical Ctr, New York, NY.

Comparative genomic hybridization (CGH) is an alternative molecular cytogenetic technique that can characterize unbalanced G-banded material in a one-step global screening procedure. The advantage of CGH over conventional FISH with whole chromosome paints (wcp) and multicolor FISH is its ability to identify not only the chromosome from which the additional unknown material was derived but also to map the region involved to specific bands on the source chromosome. Defining the origin of additional cytogenetic material by FISH with various probes is expensive and laborious as numerous wcp may be required until the source chromosome is identified. To date, more than 430 articles have been published on CGH with ~80% reporting the utility of CGH for analysis of cancer specimens. Technical aspects comprise the majority of the remaining papers and only a limited number have described the application of CGH in a clinical cytogenetics setting. CGH software is now available as an option on many FISH imaging systems without the need for additional equipment. With many laboratories acquiring image analysis equipment for routine cytogenetic and FISH analysis, the utilization of CGH as a tool in clinical cytogenetics is likely to increase. Since 1996, we have performed CGH analysis on 45 postnatal and 6 prenatal clinical samples received from our institution and from thirteen other medical centers. In all of these cases, traditional cytogenetic analyses revealed aberrant chromosomal material of unresolved origin. These samples have included markers, unbalanced translocations, duplications, deletions and inversions. More than 50% of these cases were subjected to multiple wcp and locus specific probes by the referring institutions before being sent to our laboratory for CGH analysis. The results obtained by CGH analysis proved effective in revising the karyotype in all cases. CGH was performed on aberrations which varied extensively in size and thus provided a realistic idea of the minimal size of duplication/deletion detectable by CGH. In this report, we review our experience, detailing the benefits and limitations of CGH in a clinical cytogenetic setting.

**Partial duplication of chromosome 6 associated with obesity and hypogonadism.** *I.K. Gadi<sup>1</sup>, L. Kirsh<sup>2</sup>, P.N. Mowrey<sup>1</sup>, P.R. Papenhausen<sup>1</sup>, J.H. Tepperberg<sup>1</sup>, K. Phillips<sup>1</sup>, R. Johnsonbaugh<sup>2</sup>.* 1) Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Arizona Pediatric Endocrinology, Phoenix, AZ.

A 16 year old Hispanic boy with normal perinatal and neonatal periods (birth weight 3500 gm, length 53 cm and normal discharge from the hospital), mild intellectual delay, emotional impairments, obesity (>95%tile), normal height (75 %tile), absent midline cranial defects, gynecomastia, hypogonadism (testicular volume 4 mL bilaterally, pubic hair Tanner early stage II, mild amount of axillary hair, breasts Tanner stage 4 with a bone age of 16 years) of central origin (testosterone 81 ng/dL, LH<1uIU/ml and FSH<1IU/ml) with normal ability to smell was referred for chromosome analysis. High-resolution chromosome analysis revealed an apparent partial duplication of the long arm of chromosome 6. Fluorescence in situ hybridization (FISH), using a whole chromosome 6 paint probe confirmed chromosome 6 derivation. The G-band pattern suggests a duplication of the q23-q24 region. Previously reported paternal duplications of long arm chromosome 6 or uniparental disomy of paternal chromosome 6 have been associated with transient neonatal diabetes mellitus. Our patient with unremarkable perinatal and neonatal periods is unique. Microsatellite molecular analysis of proband and parental DNA will be pursued to determine the parent of origin of the duplication and the extent of duplication.

**Recombination in the pseudoautosomal region in a 47, XYY male.** *R.H. Martin*<sup>1,2</sup>, *Q. Shi*<sup>1,2</sup>. 1) Medical Genetics Clinic, Alberta Children's Hosp, Calgary, AB., Canada; 2) Department of Medical Genetics, University of Calgary, AB, Canada.

Recombination between the X and Y chromosomes primarily occurs in the pseudoautosomal region and is thought to be necessary for proper segregation of the sex chromosomes during spermatogenesis. Failure of the sex chromosomes to disjoin properly during meiosis can result in individuals with a sex chromosomal aneuploidy. Males with a 47, XYY karyotype generally have chromosomally normal children, despite the high theoretical risk of aneuploidy. Also, studies of sperm karyotypes or FISH analysis of sperm have demonstrated that the majority of sperm are chromosomally normal in 47, XYY men. Our results on FISH studies in two 47, XYY males indicated a frequency of gonosomal abnormalities of approximately 1%. There have been a number of meiotic studies of XYY males attempting to determine if the extra Y chromosome is eliminated during spermatogenesis, with conflicting results regarding the pairing of the sex chromosomes and the presence of an extra Y. We have analyzed recombination in the pseudoautosomal region of the XY bivalent to determine if this is perturbed in a 47, XYY male. A recombination frequency similar to normal 46,XY men would indicate normal pairing between the XY bivalent, whereas a significantly altered frequency would suggest other types of pairing such as a YY bivalent or XYY trivalent. Two DNA markers STS/STS pseudogene and DXYS15 were typed in sperm from a heterozygous 47, XYY male. Individual sperm (23, X or Y) were isolated using a FACStar<sup>Plus</sup> flow cytometer into PCR tubes. Hemi-nested PCR analysis of the two DNA markers was performed to determine the frequency of recombination. A total of 108 sperm were typed. The frequency of recombination between the two DNA markers was 38%. This is very similar to the frequency of 38.3% that we have observed in 329 sperm from a normal 46, XY male. Thus, our results suggest that XY pairing and recombination occur normally in this 47, XYY male. This could occur by the production of an XY bivalent and Y univalent (which is then lost in most cells) or by loss of the extra Y chromosome in some primitive germ cells or spermatogonia and a proliferative advantage of the normal XY cells.

**Partial trisomy 4p and partial monosomy 13q in a patient with pan-lymphopenia.** *L.H. Lockhart, G.V.N. Velagaleti, F.C. Schmalstieg, A.S. Goldman.* Dept. Pediatrics, University of Texas Medical Branch, Galveston, TX.

A six-year old male presented with dysmorphic features, mental retardation, developmental delay and an increased frequency of respiratory infections. He also had a persistent lymphopenia (1000-1200/mm<sup>3</sup>). Chromosome analysis showed an unbalanced translocation involving chromosomes 4 and 13 [46,XY,+der(4)t(4;13)(q12;q12),-13], resulting in partial trisomy 4pter-q12 and partial monosomy 13pter-q12. FISH studies with alpha satellite probes D4Z1 and D13Z1/D21Z1 showed that the unbalanced karyotype resulted from an "adjacent-2" segregation of a maternal balanced translocation. The translocation is known to be segregating for three generations in the family. As shown by flow cytometry, the major blood lymphocyte populations were reduced in number, where as other hemapoietic lineages were normal. Blood T-cells were principally CD45RA+, CD62L+ and deficient in the Fas receptor. Serum concentrations of IgG (632 mg/dl), IgA (106 mg/dl), and IgM (41 mg/dl) were all normal. The serum titers of IgG, IgA antibodies to tetanus and diphtheria toxoids rose significantly after immunization, but only IgM antibodies appeared in response to the first immunization with penumococcal polysaccharides. Serum IgG and IgA antibodies to these polysaccharides appeared, however, after second immunization.

The pan-lymphopenia may be due to an overdose of a gene or genes located in the region of chromosome 4 or a partial deficiency of a gene or genes in the region of chromosome 13 that regulate the development of the lymphocyte lineage. Since the mother contributed two copies of chromosomal region 4pter-q12 and no copy of 13pter-q12, the pan-lymphopenia in our patient could be the result of either uniparental disomy or imprinting.

**A rec(4) dup 4p inherited from a mat inv(4)(p15q35). Case report and review.** *J.A. Martin<sup>1</sup>, W. Chiu<sup>2</sup>, M.F. Garcia<sup>2</sup>, J. Garcia-Heras<sup>2</sup>.* 1) Prescott, AZ; 2) Genetic Testing Center, TDH, Denton, TX.

Rec(4) dup 4p is a rare rearrangement that is usually the product of a parental pericentric inversion of chromosome 4 that results in a duplication of 4p and a deletion of 4q distal to the inversion breakpoints. We present a new case and review 7 previous reports.

A 4-year-old girl received genetic evaluation due to developmental delay, lack of speech, severe behavioral problems and malformations. A physical exam showed microcephaly, short neck, broad chest with widely spaced nipples, hypertonia and craniofacial dysmorphism. Her height was 92.5 cm. (5%), weight 6.3 kg (50%) and OFC was 48 cm. (5th%). A cardiac exam revealed a ductus arteriosus and pulmonary hypertension. A cytogenetic study in lymphocytes demonstrated a 46,XX, rec(4) dup 4p that was inherited from a maternal inv(4)(p15q35). The father was normal and two other healthy sibs carried the same pericentric inversion detected in the mother.

The manifestations of this child resemble trisomy 4p like 3 other patients (craniofacial and chest anomalies in both sexes and abnormal genitalia in males). In the other 4 cases the spectrum of malformations is more variable. In either group the phenotype is not specific, and a diagnosis is not feasible without cytogenetic studies. This lack of a clinically recognizable phenotype could reflect the effects of the variable size of the deletion of 4q, molecular differences in breakpoints and/or the known variable expression of trisomy 4p. Most rec(4) dup 4p derived from familial pericentric inversions with breakpoints at 4p13p15 and 4q35 and are paternal in origin (5/8 cases). A carrier of this inversion could have with equal frequency offspring with the 2 alternate duplication/ deletion recombinants due to the size of the inverted segment. But the rec(4) dup 4p is more frequent (7/9 cases) so either the rec(4) dup 4q is less viable or in these inversion carriers, mostly males, meiotic recombination favors the generation of rec(4) dup 4p. The latter hypothesis could be tested in male carriers with the sperm penetration hamster assay.

**Phenotype-genotype correlation in 7 patients with 5p/autosome translocations. Risk for carriers of translocations involving 5p.** *P.C. Mainardi<sup>1</sup>, A. Cali<sup>1,2</sup>, G. Guala<sup>1</sup>, C. Perfumo<sup>2</sup>, M.E. Liverani<sup>1</sup>, G. Pastore<sup>1</sup>, J. Overhauser<sup>3</sup>, F. Zara<sup>2</sup>, M. Pierluigi<sup>2</sup>, F. Dagna Bricarelli<sup>2</sup>.* 1) Divisione di Pediatria, Servizio di Genetica, Ospedale S Andrea, Vercelli, Italy; 2) Laboratorio di Genetica Umana, E.O. Ospedali Galliera, Genova, Italy; 3) Department of Biochemistry and Molecular Biology, Thomas Jefferson Medical College, Philadelphia, PA, U.S.A.

Seven patients with 5p/autosome translocations were identified during a study of 80 CdC patients in the Italian CdCS Register (198 subjects). Four (5%) presented a de novo translocation while three (3,75%) had a familial translocation. All the patients lacked both the critical regions for cat like cry in 5p15.3, as well as that for dismorfisms and mental retardation in 5p15.2. In two patients with de novo translocation the trisomic portion had no phenotypic effect. The study of the correlation in the other 5 patients showed a prevalence of CdCS phenotype with severity associated with deletion size. Where the chromosome involved was 3p or 9p, the phenotype was hybrid because of the effect of the trisomic segment. The analysis of these patients supports the hypotesis that duplications of 9p22.24 and 3p25.26 are critical, respectively for the trisomy 9p and 3p syndromes. This study confirms that the patients with translocations had more severe phenotypes for malformations, morbidity, and psychomotor development delay than those with terminal deletions. The reproductive risk for carriers of translocations involving 5p were defined by the evaluation of personal and reviewed data from 54 pedigrees. The risk of unbalanced offspring according to pachytene configuration and 5p breakpoint localisation ranges from 10.5% for translocation predisposed to 3:1 disjunction to 18.9% for translocation with breakpoint in 5p15 predisposed to adjacent-1 2:2 disjunction. In families referred for multiple abortions, unbalanced offspring were never observed, suggesting that all unbalanced segregations were lethal. With the exception of translocations predisposed to 3:1 disjunction, risks for males and females are similar. Work funded by Telethon-Italy and the Italian Cri du Chat Childrens Association.

**An unusual mosaic karyotype derived from a familial t(11;22) in a male with developmental delay.** *A.S. Kulharya, C.M. Lovell, D.B. Flannery.* Dept Pediatrics, Medical Col Georgia, Augusta, GA.

Constitutional t(11;22) is the most common recurrent translocation in humans. It is not confined to one particular race or geographic region. The majority of offspring of carriers of the familial translocation inherit either a balanced translocation or an unbalanced karyotype. The abnormal karyotype has 47 chromosomes with der(22) in addition to the normal 46 chromosomes resulting from a 3:1 segregation. We present a developmentally delayed male with an unusual mosaic karyotype derived from t(11;22). He has two sisters who are known carriers of this translocation. The patient is a 26 year old male with developmental delay. The prenatal history revealed considerably diminished fetal movements prior to his birth. He was born with a Pierre Robin sequence and a second curled toe. He is non-communicative and has temper tantrums.

Chromosome analysis of lymphocytes showed a normal male karyotype in all 200 metaphases examined. However, chromosome analysis of fibroblast cells showed a mosaic karyotype: 46,XY[144]/46,XY,der(22)t(11;22)(q23;q11.2)[6]. The der(22) syndrome with a characteristic phenotype is the most common unbalanced consequence from a familial t(11;22). Recently, there have been reports that suggest other forms of unusual segregation for this translocation. In some of these cases the abnormal segregation is a result of either meiosis II or postzygotic nondisjunction of the der(22) chromosome. Our patient provides evidence of yet another form of segregation for t(11;22) that is most likely not viable if present in a non-mosaic form. This form of adjacent-I segregation results in partial monosomy for a significant segment of chromosome 22 and partial trisomy for the distal segment of chromosome 11. The mosaic karyotype in our patient could be a result of a series of postzygotic rescue efforts of a zygote carrying the der(22) chromosome. It is also possible that the patient is a chimera resulting from early fusion of two zygotes; one normal and the other abnormal carrying 46 chromosomes with only the der(22).

**A chromosomal rearrangement causing velopharyngeal insufficiency and developmental delay.** *W.S. Kerstjens-Frederikse, B. Leegte, J.C. Oosterwijk, E. Vogel, A.J. van Essen.* Dept Med Genetics, Univ Groningen, Groningen, Netherlands.

A 4 year old girl was seen at the Genetics Department because of VPI and developmental delay. The parents were healthy and non-consanguineous. Family history was non-contributory. Motor development was slightly delayed, speech was delayed and hypernasal. Height, weight and skull circumference were normal. The face was not characteristic for velocardiofacial syndrome. The face was triangular and showed telecanthus (ICD 3.3 cm, OCD 8.5 cm). The eyebrows showed lateral flaring and the eyelashes were long and curly. The mouth was small. She had persistent fetal fingerpads. She had a clinodactyly of the 4th finger left. Her movements were jerky with normal reflexes and she showed slightly ataxic gait. She had no signs of a cardiac or renal defect. VPI is seen in approximately 30 % of children with microdeletion 22q11.2 (velocardiofacial syndrome), but this girl did not show other characteristic features of VCF, besides the developmental delay. Chromosomal analysis showed 45,XX,der(13)inv(13)(p10q22)t(13;14)(q22;q11~12). No microdeletion 22q11.2 was found with FISH. A pericentric inversion and balanced translocation was found in the mother: 46,XX,inv(13)(p10q22)t(13;14)(q22;q11~12). The grandparents showed normal karyotypes, so the balanced translocation and inversion was de novo in the mother.

**Detailed FISH analyses of Silver- Russell Syndrome (SRS) patients with cytogenetic disruptions of chromosome 7p11.2-p13 define a candidate region for SRS.** *D.N. Monk<sup>1</sup>, M. Hitchins<sup>1</sup>, M. Wassal<sup>2</sup>, K. Temple<sup>3</sup>, A. Sharp<sup>4</sup>, M. Preece<sup>5</sup>, P. Stanier<sup>1</sup>, G. Moore<sup>1</sup>.* 1) Fetal and Maternal Medicine, Imperial College School of Medicine, Queen Charlottes and Chelsea Hospital, London, England; 2) Clinical Genetics, National Research Centre, Cairo, Egypt; 3) Wessex Clinical Genetics Services, Southampton University Hospital NHS Trust, Princess Anne Hospital, Southampton, England; 4) Wessex Regional Genetics Laboratory, Salisbury Health Care Trust, Odstock, England; 5) Institute of Child Health, University College London, London, England.

SRS is a congenital disorder primarily involving lateral asymmetry and both intrauterine and post-natal growth restriction. This disorder is genetically heterogeneous, but maternal uniparental disomy for chromosome 7 (mUPD7) has been demonstrated in approximately 7% of cases. Consistent heterodisomy for the full length of chromosome 7 in five mUPD7 subjects indicates that at least one gene on this chromosome is imprinted and involved in the pathogenesis of SRS. We have previously reported a de novo duplication of 7p11.2-p13 on the maternal homologue in a patient with classical SRS features. This duplication was shown to include the GRB10, IGFBP1 and IGFBP3 genes, but not EGFR. A similar case of a maternally inherited duplication of 7p11.2-p13 has also been described by another group. These two cases suggest that SRS may result from over-expression of a maternally expressed gene involved in growth suppression. Mice with maternal disomy for proximal chromosome 11, the orthologous region to human 7p11.2-p13, demonstrate prenatal growth failure, further implicating this region in SRS. We have performed more detailed fluorescent in situ hybridisation analysis on the two patients with duplications to locate the breakpoints more precisely. In addition, we describe a group of SRS patients with other cytogenetic abnormalities involving 7p11.2-p13. The breakpoint mapping data presented here define a candidate region for genes which may contribute to the SRS phenotype in patients with a genetic aetiology involving chromosome 7.

**Tightly clustered 11q23 and 22q11 breakpoints permit PCR based detection of the recurrent constitutional t(11;22).** *H. Kurahashi, T.H. Shaikh, E.H. Zackai, L. Celle, D.A. Driscoll, M.L. Budarf, B.S. Emanuel.* Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

The constitutional t(11;22)(q23;q11) is the most frequently occurring non-Robertsonian translocation. The breakpoint of the t(11;22) has been identified within palindromic AT rich repeats (PATRRs) on chromosomes 11q23 and 22q11. These PATRRs are predicted to induce genomic instability which mediates the translocation. To examine the role of the PATRRs in the recurrent rearrangement, a PCR-based translocation detection system for the t(11;22) has been developed. PCR primers were designed in regions flanking the PATRRs of both chromosomes. Forty unrelated t(11;22) balanced carriers plus two additional, independent cases with the supernumerary-der(22) syndrome were analyzed to compare their translocation breakpoints. Similar translocation specific junction fragments were obtained from both derivative chromosomes in all 40 t(11;22) balanced carriers, and from the der(22) only in both of the unbalanced supernumerary-der(22) syndrome offspring. This indicates that the breakpoints of all cases localize within these PATRRs, suggesting that the translocation is generated by a similar mechanism in all cases examined. In spite of the fact that five of the balanced carriers, including two de novo cases, have an abnormal phenotype, their breakpoints also localize within the same PATRRs. Previously, t(11;22) carriers have been reported to be at increased risk for breast cancer. In one family, a balanced carrier with breast cancer was studied. Her breakpoint is also located within the same PATRRs. Since we have previously shown that no genes on 11 or 22 are disrupted by the translocation, neither the abnormal phenotype nor the breast cancer in some t(11;22) carriers appears to be directly related to the translocation itself. It is likely that the palindromic ATRRs produce unstable DNA structures in 22q11 and 11q23 that are responsible for the recurrent t(11;22) translocation. This PCR strategy provides a convenient technique for rapid diagnosis of the translocation, indicating its utility for prenatal and preimplantation diagnosis in families with balanced carriers.

**Analysis of genomic instability in Rothmund-Thomson Syndrome.** *J.A. Lane<sup>1</sup>, L. Wang<sup>2</sup>, S.E. Plon<sup>2</sup>, S.L. Wenger<sup>1</sup>.*  
1) West Virginia University, Morgantown, WV; 2) Baylor College of Medicine, Houston, TX.

Rothmund-Thomson Syndrome (RTS) is a rare, autosomal recessive disorder characterized by poikiloderma, skeletal abnormalities and an increased cancer risk. Low level trisomy 8 mosaicism, clonal abnormalities and evidence of genomic instability has been reported in some RTS patient, however these findings have been inconsistent. The defect in the helicase gene (RecQL4) at 8q24.3 has recently been identified in some but not all RTS cases. Lymphoblast cell lines established from 2 RTS patients and one control were karyotyped. One patient was from a family discordant for an intragenic SNP at RecQL4 and the other family was concordant. The RTS cell from the discordant family had a karyotype of 46,XY, t(13;14)(q22;q32)[27]/46,XY,del(6)(q25)[5]/46,XY[68]. The other two cell lines had normal karyotypes. To identify low levels of trisomy 8 mosaicism an alpha-satellite FISH probe for chromosome 8 (D8Z2) was used to score 1000 interphase cells for each of the cell lines. 1% or fewer of the cells from all cultures had three chromosome 8 signals, ruling out low level mosaicism. No increase in spontaneous breakage was seen among 100 solid stained metaphase cells for the three cell lines. Although further studies are necessary, our results suggest that genomic instability may not be characteristic of cells from patients with RTS.

**Mapping phenotypes associated with 20p deletions.** *A. Laufer-Cahana, J.J. Dowhanick-Morrisette, L.D. Bason, E.H. Zackai, N.B. Spinner, I.D. Krantz.* Division of Human Genetics, Children's Hospital of Philadelphia, PA.

The correlation of chromosomal deletions with clinical abnormalities allows for the genomic localization of genes responsible for clinical traits. Patients with deletions of 20p have a number of characteristic features, including Alagille syndrome (AGS), developmental delay (DD), hearing loss, cleft lip and palate, neural tube defects, hypoglycemia and bowel anomalies. We have identified 13 patients with variable deletions of the short arm of chromosome 20. Eight are cytogenetically visible and 5 are submicroscopic. Eleven patients have deletions that include the JAG1 gene and have some features of AGS. Additional phenotypic findings include hearing loss (4/13), cranial nerve palsies (3/13), palatal clefts (2/13) and DD (8/13). One patient has Hirschsprung disease and another has spina bifida occulta. The two patients with the most proximal deletions have unusual developmental features, "savant characteristics" in one and autism in the other. Parental origin could be studied in 9 patients, and the deletions are familial in 3 and de novo in 6 patients. The clinically normal parent of one child with a 20p12 deletion was found to be mosaic, with 9/20 cells from peripheral blood demonstrating the deletion. Review of the literature revealed an additional 18 patients with 20p deletions. Review of phenotypic features in the 31 patients (13 in this study and 18 from the literature) reveals that 29/31 have features of AGS, 26/31 have DD, 9/31 have hearing loss, 5/31 have cleft lip/palate, 4/31 have hypoglycemia and 3/31 have spina bifida. Overall, the frequency of deletions of JAG1 in AGS is relatively low (approximately 3-5%). However, the presence of any of these additional features in an individual with clinical manifestations of AGS (Alagille plus), suggests that cytogenetic analysis should be a first line diagnostic approach. Using a panel of YACs and microsatellite markers the boundaries of the deletions in our 13 study patients are being mapped. We hypothesize that these studies will lead to the identification of critical regions within which genes important in the etiology of hearing loss and cleft lip and palate can be isolated.

**Non-invasive cytogenetic analysis in children: Micronuclei in exfoliated buccal and urothelial cells.** *N.T. Holland<sup>1</sup>, L. Schumacher<sup>2</sup>, L. Gunn<sup>1</sup>, A. Hubbard<sup>1</sup>, B. Nguyen<sup>1</sup>, D. Golden<sup>1</sup>, P. Duramad<sup>1</sup>, M.T. Smith<sup>1</sup>.* 1) Division of Environmental Health Sciences, School of Public Health, University of California, Berkeley, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA.

Children may be more susceptible to the effects of environmental pollution than adults. While all children are sensitive to environmental hazards, minority children and children of lower socioeconomic status are particularly at risk because they tend to live in less healthy environments where they may be affected by both pollution and inadequate diet. However, few studies have examined biomarkers of genetic damage in children. For community-based population studies involving children, it is essential to develop non-invasive methods of collecting samples. Exfoliated epithelial cells from the mouth and bladder can be easily collected and subjected to cytogenetic analysis as well as analysis of DNA-polymorphisms. The objective of this study was to collect data on the background levels and variability of a spectrum of molecular and cytogenetic biomarkers of exposure, effect, and susceptibility. Our first step was the validation of cytogenetic markers in children using micronucleus assay. Micronucleus frequency is a sensitive measure of genetic damage in vitro and in vivo which reflects chromosome breakage and aneuploidy. In collaboration with the Children's Hospital Oakland, CA, buccal and urothelial cells have been collected from 81 healthy African-American children, ages 5-12, and 49 parents/guardians from the inner city East Oakland, CA. Here, data are presented on cytogenetic biomarkers, particularly micronuclei in two types of exfoliated cells. Children had slightly lower levels of micronuclei than adults in both buccal and urothelial cells ( $P < 0.01$ ). Moreover, an age-dependent change in micronuclei in urothelial cells of children was observed ( $P < 0.001$ ). The frequency of micronucleated cells was slightly higher in urothelial cells of children than buccal cells ( $P < 0.001$ ); but the same was not true for adults. Further studies of the effects of various genetic, dietary and environmental factors on the level of cytogenetic damage in exfoliated cells of inner city children are underway.

**Repeat karyotypic analysis may be periodically indicated.** *R. Naeem, G.M Cohn, D.J Carneiro, J.G Habecker-Green.* Baystate Medical Ctr, Springfield, MA.

We present 3 case reports of patients whose clinical diagnosis was confirmed on the basis of repeat karyotype analysis.

Patient 1 presented at age 2 years 10 months for a suspected dwarfing syndrome. She was noted to be dysmorphic, and had developmental delay, VSD, and partial cutaneous syndactyly of all digits. Chromosomes previously done at another laboratory in 1992 were reported as normal. Features were not clearly consistent with any known genetic condition. The patient was seen again at age 8 years 4 months for an endocrinology evaluation; that service ordered chromosome analysis. The revised karyotype was 46,XX,del(11)(q23) ish del(11)(tel 11q-). The patient was seen again, and findings are consistent with Jacobsen syndrome. To make this diagnosis repeat karyotype and FISH analysis were instrumental.

Patient 2 presented at age 15 years 8 months for developmental delay. He had a history of surgery for metopic craniosynostosis, glaucoma, inguinal hernia, and umbilical hernia. Family history was remarkable for 2 anomalous maternal uncles who had died. The child had mental retardation, dysmorphic features, and broad thumbs with spoon shaped nails. Chromosomal analysis prenatally had been reported normal at another laboratory. Repeat chromosomal analysis was notable for an unbalanced translocation 46,XY,der(9)t(8;9)(q24;p22) mat. ish der (9)t(8;9) (wcp8+,wcp9+).

Patient 3 presented at age 4 years with a history of congenital microcephaly, growth retardation, and developmental delay. Routine chromosomes were reported normal. She was not found to have features consistent with any genetic syndrome. The patient returned to genetics at 8 years 5 months of age. Based on clinical findings a diagnosis of trisomy 9 mosaicism was suspected. Repeat chromosomal analysis with mosaicism studies were ordered, and revealed low level trisomy 9 mosaicism.

These patients suggest that periodic repeat kaaryotype may be indicated if a clinical diagnosis remains undetermined or chromosomal anomaly is suspected.

**Case report and literature review: Male with apparent unique chromosome 5 double deletion at 5q10q11.2 and 5q14.2q14.3.** *H.L. Hansen, W.S. Surka, J.L Zackowski, V.K. Proud.* Dept. of Ped., Div. of Med. Gen., Children's Hospital of The King's Daughters, Eastern Virginia Medical School, Norfolk, VA.

After extensive literature review we report the first case with an apparent chromosome 5q double deletion, 46XY,der(5)del(5)(q10q11.2) del(5)(q14.2q14.3). Case Report: JR was a 25 year old white male with short stature, coarse facial features, deep set eyes, epicanthal folds, strabismus, long eyelashes, ptosis, down-slanting palpebral fissures, hypoplastic maxilla, beaked nose, high arched palate, and low set, malformed auricles. Skeletal findings included marked cervical kyphosis, thoracolumbar scoliosis, asymmetric chest, broad thumbs, and overlapping toes. He had moderate mental retardation. His medical history included recurrent respiratory infections, dysphagia, gastroesophageal reflux, congenital right hydronephrosis with tortuous ureter, nephrectomy for dysplastic kidney, and hernia repair. Laboratory Studies: because the phenotype was similar to Rubinstein-Taybi syndrome additional FISH studies on chromosome 16 were performed but were negative. In hundreds of reported cases with 5q rearrangements, only 16 with interstitial deletions of 5q were cited by Kobayashi et al. [1991]. We were unable to identify any case with a breakpoint at 5q10. At least 6 shared a common breakpoint at 5q11.2 and at least 6 had deletions that include the region 5q14.2-q14.3. Detailed analysis of physical and cytogenetic findings in these 12 cases revealed that the 6 cases with rearrangements, inversions, duplications, and deletions involving the common breakpoint 5q11.2 had renal anomalies, mental retardation, prominent forehead, and malformed ears like JR. The 6 cases with deletions of 5q13q15 had low-set, malformed ears, mental retardation, short neck, short stature, and down-slanting palpebral fissures like JR. Tissue samples of this unique double deletion in 5q are available for molecular studies and genotype/phenotype correlation.

**Delineation of trisomy 16q resulting from de novo X:16 translocation by cytogenetic, FISH and late replication studies in a child with mild dysmorphic features - A case report.** *F.M. Mohammed<sup>1</sup>, J. Tolmie<sup>2</sup>, J.M. Connor<sup>2</sup>, L. Bastaki<sup>1</sup>, D.S. Krishna Murthy<sup>1</sup>.* 1) Cytogenetics Laboratory, Kuwait Medical Genetics Center, SULAIBIKAT P.O., KUWAIT, KUWAIT; 2) Duncan Guthrie Institute of Medical Genetics, Glasgow, UK.

We report an 18-month-old female child with dysmorphic features, heart defect, and developmental delay. Routine chromosome analysis using G-banding technique showed an abnormal X chromosome (Xp+). Karyotype of the parents was normal. Application FISH technique using whole chromosome paint and centromeric probes, chromosome arm specific probes (CAP) and chromosome library probes for all autosomes and sex chromosomes (DXZ-1 Oncor; WCP-Cambio; CAP- Biomedical Research Corporation; Cytocell Multiprobe Kit) confirmed an unbalanced between the short arm of X chromosome (Xp22.3) and long arm of chromosome 16 resulting in trisomy 16q (q24). The karyotype is interpreted as: 46,X, -X,+der(X), t(X;16)(p22.3;q24). Late replication studies showed pale staining of the abnormal der X chromosome with the dark band region of the 16q segment in most of the cells, confirming late replication of the abnormal X with an active segment of 16q. The occurrence of balanced/unbalanced structural anomalies involving X autosome translocations is very rare. They are associated with normal to severe pathogenesis, depending on the chromosomes involved and the extent of monosomy/trisomy of the segments involved. Inactivation and spreading effect may also contribute to the severity of the phenotype and pathogenesis. Application of FISH using multiprobe kit enabled in delineating this cryptic de novo X-autosome translocation precisely.

**Study of aneuploidy rate of sperm in a man heterozygous for a t ( 1,10 ) ( p25 ; q32 ) reciprocal translocation by FISH.** *N. Miharū, M. Yoshimoto, Y. Ohashi, H. Honda, K. Ohama.* Dept OB/GYN, Hiroshima Univ Sch Medicine, Hiroshima, Japan.

In order to quantify the relative proportion of sperm with unbalanced chromosomes resulting from the meiotic segregation, molecular cytogenetic analysis was done in sperm from a man heterozygous for a t ( 1,10 ) ( p25 ; q32 ) reciprocal translocation (RT) using fluorescence in situ hybridization (FISH). Semen samples were obtained from a RT carrier and chromosomally normal men. Two color FISH using two DNA probes ( CEP1, CEP10 ) and three color FISH using three DNA probes ( CEP1, CEP10 and Tel 1q) was performed to analyze segregation patterns of chromosomes involved in the translocation. A total of 4664 sperm from a RT carrier and 3161 sperm from the normal men were scored. In two color FISH analysis, the frequency of sperm with alternate segregation or adjacent 1 segregation, adjacent 2 segregation and 3:1 segregation was 95.4%, 0.2%, 3.5% respectively in a RT carrier, while 99.5%, 0.1% and 0.3% respectively in the control men. In three color FISH analysis, the frequency of sperm with alternate segregation or adjacent 1 segregation, adjacent 2 segregation and 3:1 segregation was 88.4%, 1.0% and 5.8% respectively in a RT carrier, while 97.5%, 0.2% and 2.0% respectively in the control men. In the sperm of alternate segregation or adjacent 1 segregation in a RT carrier, 46.3% of them were balanced in the chromosomes involved in the translocation, while 42.1% of them were imbalanced. Overall, 48.9% of the sperm were chromosomally imbalanced in a RT carrier. These data indicate that at least about 50% sperm are produced by unbalanced segregation.

**The parental origin of X chromosomes in 15 Mexican Turner patients with different karyotypes.** *M. Lopez*<sup>1,2</sup>, *N. Monroy*<sup>1</sup>, *A. Cervantes*<sup>1</sup>, *R. Guevara Yanez*<sup>1</sup>, *D. Garcia-Cruz*<sup>3</sup>, *V. Mesa*<sup>3</sup>, *S. Canun*<sup>4</sup>, *G. Zafra*<sup>5</sup>, *J.C. Zenteno*<sup>1</sup>, *S. Kofman*<sup>1</sup>. 1) Genetica Hospital General Mexico, F Medicina UNAM, Mexico DF; 2) S Biologicos UAM-X, Mexico DF; 3) Genetica, CIBO IMSS, Guadalajara, Jal. Mexico; 4) Genetica Hospital Gea Gonzalez, Mexico DF; 5) Genetica Hospital Espanol, Mexico DF.

Several studies have shown that 40-60% of patients with Turner syndrome (TS) are monosomic for the X chromosome, the remaining cases have a structurally abnormal X or Y or are mosaics with a second cell line with a normal or abnormal sex chromosome. Experimental evidence has demonstrated that 70-80% of 45,X patients retain the maternal X chromosome, while X isochromosomes can be either paternally or maternally derived. We studied 15 TS patients, 10 were 45,X and the rest had a second cell line with abnormal X chromosomes: one pseudodicentric, one isochromosome, one large and one small ring, and one with a long arm deletion. In all cases exclusion of Y mosaicism was carried out by PCR amplification of five Y-specific sequences, including the centromeric region. Parental origin of X chromosomes was determined in genomic DNA by PCR using ten (CA/GT)<sub>n</sub> X chromosome microsatellites (p22.3-q28) from panel 28 ABI-PRISM Linkage Mapping Set Ver 2.0 PE. PCR products were analyzed with ABI PRISM 310 genetic analyzer running GENESCAN 2.1 software. We were able to determine that the parental origin of the single X chromosome was maternal in 90% of the 45,X cases. The results were also used to corroborate breakpoints in the abnormal X chromosomes, particularly confirming the presence of the X inactivation center in the tiny ring chromosome [45,X/46,X,r(X)(p21q13)]. Of the structurally abnormal X chromosomes 3 were maternal [45,X/46,X,pseudodic(X)(p11.2); 45,X/46,Xr(X)(p22.3q28) and 45,X/46,X,del(X)(q23)], while the other two [45,X/46,X,i(Xq) and 45,X/46,X,r(X)(p21q13)] were paternal. These data are in agreement with previous reports. We discuss the timing and mechanism of error(s) leading to the formation of abnormal X chromosomes from maternal origin.

**De novo interstitial deletion of 5p14 region in prenatal diagnosis.** *Y.M. Kim<sup>1</sup>, M.H. Lee<sup>1</sup>, E.H. Cho<sup>1</sup>, M.Y. Kim<sup>2</sup>, J.Y. Han<sup>2</sup>, H.M. Ryu<sup>2</sup>.* 1) Laboratory of Medical Genetics, Samsung Cheil Hosp, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Samsung Cheil Hospital & Women's Healthcare Center, School of Medicine, Sungkyunkwan University, Seoul, Korea.

There have been some G-band positive interstitial deletion cases without phenotypic effect such as 5p14, 11p12, 13q21 and 16q21. We report a de novo interstitial deletion of 5p14 region. A 34 year-old-woman with MCDA twin pregnancy was referred for amniocentesis due to high risk of Down syndrome at 17.3 wks of gestation. This pregnancy was done by ICSI after TESE. Karyotype of both fetuses revealed 46,XY,del(5p)(14) by conventional GTG-banding. In the parental study, they showed normal karyotypes. High resolution G-banding and reverse banding using amniocytes showed the interstitial deletion around 5p14. FISH showed positive signal at the 5p15.2 region and CGH (comparative genomic hybridization) confirmed the deletion of 5p14 region. However we couldn't find the exact breakpoint with all these results. The level II sonography (high resolution ultrasound) at 20 wks didn't show any special fetal physical abnormality. The parents declined further study with cordocentesis and wanted to keep their pregnancy. Further study is expected after birth.

**Paracentric inversion of chromosome 12 [46,XX, inv (12)(q12;q24)] in a woman with recurrent fetal anomalies - Coincidental or causal?** *D.S. Krishna Murthy, M.A. Redha, S.A. Gouda, L. Bastaki, S.A. Al-Awadi.* Cytogenetics Laboratory, Medical Genetics Center, Maternity Hospital, Sulaibikat, KUWAIT.

A normal healthy couple with history of multiple congenital anomalies and neonatal death in the offspring were investigated to exclude balanced chromosomal rearrangement. Routine chromosome analysis using G-banding technique confirmed paracentric inversion of chromosome 12 in the mother (46,XX, inv (12)(q12;q24)). Paracentric inversions (PAI) are relatively rare as compared to pericentric inversions (PEI), considered to be heteromorphic variants in the general population. There are very few reports of PAI involving chromosome 12. While PAI involving short segments are likely to be harmless, most of the abnormal zygotes resulting from unbalanced gametes produced by carriers of long PAI are likely to be so grossly abnormal that they would be lost very early, even before implantation. The majority of PAI carriers are apparently normal without any serious deleterious effect. PAI inversions are mostly ascertained among individuals with history of infertility couples with history of recurrent abortions and/or fetal anomalies, or parents of abnormal children. The risk of abnormal structural rearrangement in offspring of PAI carriers has been reported to be relatively small, as most of the affected zygotes from the unbalanced gametes are lethal or lost even before implantation. Couples with increased risk should be offered prenatal diagnosis. PAI of 12 has also been reported in human malignancies. A brief review of PAI involving chromosome 12 will be presented.

**Three cases of unique duplication of the long arm of chromosome 2.** *C.M. Lovell, A.S. Kulharya, W.H. Hoffman, D.B. Flannery.* Dept Pediatric Genetics, Medical Col Georgia, Augusta, GA.

Isolated duplication of the long arm of chromosome 2, particularly the proximal region is extremely rare. A distinctive phenotype has emerged for the distal partial trisomies for 2q. However, there is no consensus on the phenotype for proximal and middle segment duplications of 2q as very few cases of partial trisomy for these segments are reported. We present three patients with overlapping duplications of the proximal and middle segments of 2q.

The first patient is a 19 year old intellectually impaired male with indistinct speech, awkward gait, and hypotonia. He has hypogonadotropic hypogonadism. Karyotype is 46,XY,dup(2)(q23q33). The second patient is a 10 month old female with microcephaly, trigonocephaly, upslanting palpebral fissures, 2 posterior whorls, Brushfield spots, gross developmental delay, and hypertonia in lower extremities. Karyotype is 46,XX,dup(2)(q11.2q21.3). The third patient was a newborn with multiple congenital anomalies. The physical findings included overlapping fingers, cleft palate, horseshoe kidney, dextrocardia with right side aortic arch, seizures, and hypotonia. She died at 5 days of age from severe unremitting lactic acidosis which raised concerns about Finnish lethal neonatal metabolic syndrome [OMIM 603358], which has been mapped to the 2q32-37 region. Her karyotype was 46,XX,dup(2)(q14.2q31). Parental karyotype in all three cases were normal. The identity of the additional material was confirmed with FISH using WCP2.

Although several cases of duplication 2q have been reported earlier, the breakpoints seen in our patient have been not described previously. It appears that the larger partial trisomies for 2q are not tolerated as shown by the short life span of our third patient and also by the lack of reports of abnormal segregant products of reciprocal translocations with more proximal breakpoints in 2q. Our patients share some features described earlier for dup(2) patients such as urogenital anomalies. These patients further define the genotype phenotype correlation for the proximal half of the long arm of chromosome 2.

**Prenatal detection and FISH characterization of a de novo unbalanced translocation between chromosomes Y and 12.** X. Li, K. Wcislo, L. Bros, K. Hartley, C. Tse, J. Bergoffen. Genetics Department, Kaiser Permanente Northern California, San Jose, CA.

De novo unbalanced translocations are rare. We report a prenatal case with a de novo unbalanced translocation between the Yq and 12p. Patient was a 39 year-old G3P1SAB1 woman, and had amniocentesis for advanced maternal age. Conventional cytogenetic analysis showed a male karyotype with a derivative Y involving the Yq heterochromatin region, either a product of an unbalanced translocation of unknown origin or a benign variant. Clinical significance was uncertain. Genetic counseling was further complicated by a normal male karyotype from a previous pregnancy with the same partner two years ago and normal karyotypes from both parents. The Y chromosome from the father appeared to be the same as in the first fetus. Non-paternity was strongly denied. No growth anomalies were seen by ultrasound at 18 weeks. Fluorescence in situ hybridization (FISH) using DNA probes specific for the XpYp and XqYq telomeric (pseudoautosomal) regions (from Cytocell, Ltd) revealed normal hybridization patterns for the XpYp and Xq but a deletion for the Yq (DXS7059-). A small portion of the terminal material on the Yq was negative for a whole chromosome Y paint probe (wcpY-) but positive for a 12p telomeric probe (Tel12p+) when screened with an all telomeric probe panel (Cytocell, Ltd.). There was no evidence that other chromosomes were involved in this rearrangement. Therefore, the derivative Y most likely results from a de novo unbalanced translocation between the Yq and 12p. This results in partial monosomy for Yq12 and partial trisomy for 12p13. Individuals with partial trisomy 12p are reported to have mental retardation, hypotonia, and minor dysmorphic features but no major malformations. Follow-up cytogenetic studies on a repeat amniocentesis sample as requested by the patient demonstrated the same abnormality and therefore ruled out a lab error. The pregnancy was terminated after the results were presented to the patient. We demonstrate here that the FISH technology allows us to distinguish a pathological chromosomal rearrangement from a possible benign Yq variant.

**Screening for subtle structural anomalies by use of subtelomere specific FISH probe set.** *S.M. Jalal<sup>1</sup>, A. Harwood<sup>1</sup>, M. Anderson<sup>1</sup>, C. Lorentz<sup>1</sup>, M. Law<sup>1</sup>, N. Lindor<sup>1</sup>, P. Karnes<sup>1</sup>, A. Kulharya<sup>2</sup>, G. Sekhon<sup>3</sup>, V. Michels<sup>1</sup>.* 1) Mayo Clinic, Rochester, MN; 2) Medical School, Augusta, GA; 3) University of Wisconsin, Madison, WI.

A complete set of human telomere specific probes were developed in 1996 and are now commercially available. Due to a high concentration of genes in telomeric regions, these probes are being used with intense interest to investigate individuals with nonspecific mental retardation (MR), couples with multiple miscarriages (MM) and children with nonspecific mild dysmorphic features. We present our findings involving such individuals and children with mild to severe dysmorphic features that were karyotypically normal. The study included 22 individuals with MM and 27 individuals with a range of dysmorphism and MR. The probe set (43 probes) included all telomeres except the p-arms of acrocentric chromosomes. We were careful in the interpretation as some of the probes produce weak signals on certain chromosomes due to cross hybridizations. Whenever an anomaly or a polymorphic variant was discovered it was confirmed by arm specific probes from another company. We discovered two terminal deletions involving 22q and 10q in two children with moderate to severe dysmorphism, and a complex rearrangement involving 3pter and 3qter in two cases. A euchromatic subtle deletion (that includes D2S2986) variant of 2q was observed in four individuals including a child with severe dysmorphism and a phenotypically normal father. The 2q probe from one source was deleted in all four while the probe of the other company was not deleted in any, leading to the discovery of the normal variant. In addition, these subtelomeric probes were invaluable as markers in cases of r dup(14), r(21), inv dup(6) and mosaic balanced t(3;12). We conclude that with significantly improved quality, the commercially available subtelomeric probes are now effective in the detection of subtle anomalies in a wide range of situations.

**Chromosomal Abnormalities in Cell Cultures from the Baltimore Longitudinal Study: Correlations with Donor Age.** *J.C. Leonard, A. MacMillan, M.A. Wineburg, P.E. Fuller, R.T. Johnson.* Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ.

The Baltimore Longitudinal Study is a continuing survey of the health of volunteers ranging in age from 20s to 90s conducted by the Gerontological Research Center. As part of this study, skin fibroblast cultures have been banked in the NIA Aging Cell Repository and cytogenetic analysis is part of the standard characterization of all cultures in the NIA Repository. Studies of chromosomal aberrations that occur spontaneously in cell cultures have suggested that genomic damage is a factor in the aging process. A review of the 279 routine quality control assays of GRC cultures performed since 1995 considers a larger number of analyses than all of the previous studies combined. Our results confirm that both structural and numerical chromosome abnormalities are commonly observed in low passage fibroblast cultures from adult donors and high levels of these coincide with poor growth and the onset of in vitro senescence. Furthermore, a trend toward increased loss of chromosomes is seen among cultures from donors older than 80, although no age association was seen for other aberration types. As would be expected from previous data, loss of sex chromosomes is the most common cause of mosaic aneuploidy. The nonrandom distribution of structural aberrations suggests some loci are hotspots for chromosomal exchanges. Some but not all of these hotspots are in chromosome bands that are recognized as common fragile sites. Expression of these hotspots is not related to donor age, but more data is needed to determine if they predominate among the aberrations seen with the onset of in vitro senescence.

**Sexual ambiguity in a child with a karyotype 46,XY,del(2)(q32.1-q35) and phenotype resembling the Smith-Lemli-Opitz syndrome.** *J. Lavoie<sup>1</sup>, F. Gros-Louis<sup>1</sup>, M. Bronsard<sup>1</sup>, R. Laframboise<sup>2</sup>, B. Fouquette<sup>3</sup>, R. Drouin<sup>1</sup>.* 1) Unite Recherche Genetique Humaine et moleculaire, Universite Laval, CHUQ, Hopital St-Francois d'Assise, Quebec, PQ., Canada; 2) Pediatrics Department, Medical Genetics, CHUL, CHUQ; 3) Division of pathology, Hopital St-Francois d'Assise, CHUQ.

We report a 3-year-old boy with a clinical phenotype that was at birth compatible with a Smith-Lemli-Opitz syndrome (SLOS). Clinical findings of the new born included craniofacial, genitourinary and intestinal malformations, and later on developmental delay. Despite normal G-banded karyotype on amniocytes, high-resolution banded chromosome study that was carried out on peripheral blood sample permitted the identification of a de novo interstitial deletion of the long arm of the chromosome 2. Molecular analysis using microsatellite markers indicated that the deletion originated from the maternal chromosome and was located between bands 2q32.1 and 2q35. This case is one of the rare cases of deletion 2q presenting abnormal external genital organs. The sexual ambiguity seen in this patient suggest a gene involved in sex determination in this chromosomal region. Moreover, one locus for cleft palate has been recently located to band 2q32. Since our patient does not present this malformation, it therefore contributes to define more precisely the locus to band 2q32.1. Finally, this case denotes the importance of high-resolution chromosome analysis during the course of prenatal and postnatal cytogenetic investigations, in order to ensure an adequate genetic counseling.

**Variable outcomes in 5 cases of mosaic trisomy 16.** *P.M. Hohler<sup>1</sup>, K. Neiswanger<sup>2</sup>, L. Thomas<sup>1</sup>, P. Mowery-Rushton<sup>1</sup>, E. McPherson<sup>1,2</sup>, A. Hogge<sup>1,2</sup>, U. Surti<sup>1,2</sup>.* 1) Dept of Genetics, Magee Womens Hospital, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA.

We report 5 cases of mosaic trisomy 16. 1) A 41yo, with 100% 47,XY,+16 by CVS and 100% 46,XY by AF, delivered an IUGR, but otherwise normal male infant at 33wks. At birth, a normal karyotype was seen in blood and cord samples, while the placenta was mosaic for trisomy 16. The disomic cells were biparental. The trisomy showed CPM, and was maternal and meiotic in origin. 2) A 25yo presented with IUGR by US and 12% 47,XY,+16 by AF. At 36wks, she delivered a male infant with IUGR, plagiocephaly, and VSD. The blood karyotype was normal. DNA analysis revealed a maternal, meiotic non-disjunction, with UPD. 3) A 31yo with elevated hCG, 7.66 MoM, a two-vessel cord by US, and level II mosaicism for 47,XY,+16 by AF, delivered at 37wks an IUGR male infant with multiple skeletal anomalies and dextrocardia. The cord blood karyotype was normal, while the cord tissue was 32% trisomy 16. 4) A 41yo showed 47,XX,+16 by CVS, an elevated hCG, 3.2 MoM, and 60% trisomy 16 by AF. US revealed normal growth with a heart defect. At termination, 46,XX karyotypes were seen in brain, tongue, spleen, and skin, with mosaic trisomy 16 in liver (80%), cord (75%), lung (40%), and muscle (20%), using cytogenetics and FISH. 5) A 33yo presented with elevated hCG, 16.5 MoM. AF revealed level II mosaicism for 47,XY,+16. At 32wks she delivered a male infant with heart defects, who died on day 2. No autopsy was performed. The cord blood karyotype was normal, while trisomy 16 was seen in multiple placental and cord samples by FISH and cytogenetics. The complications in these 5 pregnancies included preeclampsia, IUGR, fetal anomalies and death, with no predictable pattern. In case 4, trisomy 16 showed a variable distribution among tissues. Cases 3 and 5 had level II mosaicism for trisomy 16 by AF. The majority of level II mosaicisms are considered to be pseudomosaicism. However, in both of these cases the trisomic cell line was confirmed upon further study. Our understanding of mosaic trisomy 16 will be greatly enhanced by the use of FISH, in conjunction with other newly evolving cytogenetic and molecular techniques.

**Clinical and cytogenetic findings in an infant with rec(8)dup(8p) and mosaic trisomy 8.** *B.N. Hay<sup>1</sup>, S.A.*

*Schonberg<sup>2</sup>, F. Lachawan<sup>3</sup>.* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Cytogenetics, American Medical Laboratories, Inc., Chantilly, VA; 3) Department of Medical Genetics, Children's National Medical Center, Washington, DC.

We describe a patient who presented at 6 weeks of age with macrocephaly, large anterior fontanelle, hypertelorism, large ears, and broad digits. Karyotype analysis revealed the mosaicism 46,XY,add(8)(q24.3)[15]/47,XY,+8,add(8)(q24.3)[5]. The add(8) banding pattern was most consistent with the interpretation rec(8)dup(8p). This was confirmed by parental chromosome analysis, which revealed a maternal balanced pericentric inversion of chromosome 8 (p21.1q24.3) and defined the probands karyotype as rec(8)dup(8p)inv(8)(p21.1q24.3). In combination with the mosaic trisomy 8, 8p is duplicated in 75% of cells and triplicated in 25% of cells. While both distal duplication 8p and mosaic trisomy 8 have a well-defined phenotype, neither this combination of findings, nor the chromosomal dose abnormality have been previously described. Subsequent to diagnosis, a brain MRI revealed a hypoplastic corpus callosum with absent rostrum plus a diminutive optic chiasm and optic tracts. In return visits, the infant has demonstrated hypotonia, developmental delay, and a decrease in growth rate. We discuss mechanisms leading from the maternal inv(8) to both rec(8) and a presumed chromosome 8 meiotic non-disjunction and compare clinical findings with prior reports of both dup(8p) and trisomy 8 mosaicism.

**Neocentromere in a ring-shaped chromosome 1.** *R.R. Higgins<sup>1</sup>, E. Wright<sup>2</sup>, S. Baldinger<sup>3</sup>, E. Tschider<sup>1</sup>, J. Ahmad<sup>1</sup>, S. Schwartz<sup>4</sup>, C.A. Curtis<sup>1</sup>.* 1) Allina Cytogenetics Lab, Abbott Northwestern Hosp, Minneapolis, MN; 2) Haislet, Wavrin, Wright, Lehrman & Associates, Edina, MN; 3) Minnesota Perinatal Physicians, Abbott Northwestern Hosp, Minneapolis, MN; 4) Case Western Reserve University, Cleveland, OH.

We describe a neocentromere in a ring-shaped chromosome involving the long arm of chromosome 1. A G<sub>5</sub>P<sub>2</sub>AB<sub>2</sub> 39-year-old woman was referred for amniocentesis at 15 weeks of pregnancy for advanced maternal age. Cytogenetic analysis of 20 colonies from 5 coverslips showed a male karyotype with an interstitial deletion in the long arm of a chromosome 1 involving the G-band breakpoints q23 and q32, plus a ring-shaped marker chromosome derived from chromosome 1 involving the G-band region 1q23-q32 [47,XY,del(1)(q23q32),+r(1)(q23q32)]. The abnormalities appeared to be de novo since chromosomal analyses of the patient and her spouse were normal. The ring-shaped chromosome was diagnosed as chromosome 1 chromatin by fluorescence in situ hybridization (FISH) using a "painting" molecular probe specific for chromosome 1. The ring chromosome showed no evidence of a centromere by CBL-staining nor when studied by FISH using a pan alpha-satellite probe and a chromosome 1 alpha-satellite probe. Three of the twenty metaphases studied were missing the ring chromosome, however no colonies having all cells missing the ring chromosome were found. The three metaphases missing the ring chromosome may have been cultural artifacts and not representing true mosaicism. In eleven of the rings studied, eight were approximately the size of the short arm of a chromosome 20 with the 1q23-q32 banding, two rings were half that size with less banding, and one ring was as large as an entire chromosome 20 with additional banding. Thus, the ring chromosome was demonstrating "dynamic mosaicism". An ultrasound analysis at 18 weeks was normal, but the pregnancy was terminated due to the risk of a ring syndrome. The ring chromosome appears to have a neocentromere without alpha-satellite DNA. The ring chromosome is being studied for the presence of CENP-B, -C, and -E.

**Paternally transmitted recurrent true-hermaphroditism associated with SRY mosaicism.** C. Oddoux<sup>1</sup>, H. Yee<sup>1</sup>, V. Clarke<sup>1</sup>, C.M. Clayton<sup>1</sup>, K. McElreavey<sup>2</sup>, M. MacGillivray<sup>3</sup>, H. Ostrer<sup>1</sup>. 1) Div Human Genetics, New York Univ Schl Med, New York, NY; 2) Institute Pasteur, Paris, France; 3) Div Ped Endo, Buffalo Children's Hosp, Buffalo, NY.

In 1987 some of us described a family with coexisting XX chromosomal maleness and true hermaphroditism with 4 affected individuals spanning two generations and displaying a paternal inheritance pattern. Karyotyping of 3 affecteds and their parents revealed normal chromosomes (all affecteds 46,XX). We used DNA probes flanking the testis determining region in Southern analyses of peripheral leukocyte DNA of 2 of the XX males, their normal sister and their father to rule out a Y-to-X or a Y-autosomal translocation of this portion of the Y chromosome. Similarly probes to the pseudoautosomal region were used to rule out the presence of a Y chromosomal inversion polymorphism which could lead to recurrent translocation. PCR analysis with primers to the SRY gene failed to demonstrate its presence. After attaining puberty, gynecomastia was noted in each of these individuals and gonadectomies were performed. Pathological examination of the gonadal tissue indicated that the individuals were in fact true hermaphrodites. Here, we present molecular analyses performed directly on the paraffin-embedded gonadal tissue. Immunohistochemistry using a specific anti-SRY antibody revealed high levels of SRY expression in testicular tubules, some expression in oocytes, and no expression in connective tissue or blood vessels. PCR analysis of gonadal DNA confirmed the presence of the SRY gene but at levels lower than observed in normal males, consistent with the histochemical mosaicism. Individuals mosaic for cells with and without Y chromosomes or Y-chromosomal fragments containing the SRY gene have previously been reported in *sporadic* cases of true hermaphroditism. Suggested mechanisms have included embryonic correction of Klinefelter syndrome or triploid fetuses, or chimerism resulting from the fusion of an independently fertilized oocyte and polar body. These mechanisms are not consistent with recurrent paternal transmission of SRY gene mosaicism and this family provides evidence for existence of a novel mechanism.

**Wolf-Hirschhorn syndrome: Correlation between cytogenetics, FISH, and severity of disease.** *A.M. Meloni<sup>1</sup>, R.R. Shepard<sup>1</sup>, A. Battaglia<sup>2,4</sup>, T.J. Wright<sup>3</sup>, J.C. Carey<sup>4</sup>.* 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) Stella Maris Scientific Research Institute, University of Pisa, Calambrone, Pisa, Italy; 3) Department of Human Genetics, University of Utah, Salt Lake City, UT; 4) Division of Medical Genetics, Department of Pediatrics, University of Utah, Salt Lake City, UT.

Wolf-Hirschhorn syndrome (WHS) is a multiple malformation syndrome characterized by the deletion of the distal short arm of one chromosome 4. Clinical features include a prominent forehead with widely spaced eyes, microcephaly, distinct mouth, as well as mental and growth retardation. Nineteen patients were included in the study (10 cases from the USA and nine cases from Italy). The study was designed to characterize the size of the deletion by cytogenetic and FISH methods and to correlate the results with the severity of the disease. Standard cytogenetics was performed following established methods. FISH studies were carried out using either a commercially available probe (four cases) or a panel of 8 markers known to map within and in proximity to the WHS critical region. Fifteen of the 19 patients analyzed by standard cytogenetics had a cytogenetically visible deletion of the short arm of chromosome 4: eight cases had a small deletion with the breakpoint at 4p16, whereas a larger deletion with the breakpoint at 4p15.3 was observed in seven cases. Four patients had an apparently normal karyotype. FISH was performed in 13 of the 19 cases included in the study. Three of the four cases with an apparently normal karyotype were found to be deleted by FISH. The study definitely showed that the four cases with an apparently normal karyotype had clinical features varying from mild to very severe. In addition, severe clinical features were observed in patients with small deletions, and mild clinical features were seen in patients with large deletions. The results of this study suggest that the size of the deletion on chromosome 4 is not solely responsible for the severity of the clinical features. Therefore, in addition to the deletion of the WHS critical region, a modifying factor may be contributing to the clinical presentation of the disease.

**Full trisomy 8p identified as inv dup (8p) without deletion of subtelomere.** *P.N. Mowrey<sup>1</sup>, J.H. Tepperberg<sup>1</sup>, I.K. Gadi<sup>1</sup>, K.K. Phillips<sup>1</sup>, L. Wisniewski<sup>1</sup>, P.R. Papenhausen<sup>1</sup>, K. Paulyson-Nunez<sup>2</sup>.* 1) Diagnostic Genetics, Laboratory Corporation of Am., Research Triangle Pk, NC; 2) Dept. OB/GYN, Duke U Med Cnt, Durham, NC.

We report a 21 y.o. Hispanic female, G1P0, referred for ultrasound dating. Findings include a 20 week gestation with a 2 vessel cord, and a prominent stomach. A repeat scan at 24 weeks further revealed asymmetric echogenicity of kidneys, colpocephaly, and possible agenesis of the corpus callosum. A heart defect was suspected. The family history was unremarkable. MSAFP was normal. Amniocentesis was performed and chromosome analysis showed a GTW banding pattern consistent with an apparent atypical short arm inverted duplication of chromosome 8 in all colonies. The dup (8) appeared to contain 2 copies of the 8p11.2 to 8p23.2 bands with the telomere region 8p23.3 in between. FISH analysis, using a whole chromosome 8 "painting" probe, revealed complete DNA hybridization with the entire chromosome 8, confirming that the extra material was of chromosome 8 origin and supporting the banding observation. Additional FISH testing, using an 8p subtelomere probe, supported the presence of a telomeric region just proximal to the dup 8p material. Alphoid FISH studies showed a single pericentromeric hybridization signal. These results support an inverted duplication of chromosome 8 short arm including the entire 8p23 region, which is generally deleted in inv dup (8p) cases. This case also demonstrated an unusual banding pattern beyond the distal end of the duplicated segment that is apparently 8 paint positive but negative for the telomere and centromere probes. Additional molecular testing with BACs will be performed to further define this region. Parental chromosome analyses are pending. This case of whole short arm duplication will be contrasted with cases in the literature that show loss of the telomere.

**Prenatal diagnosis of "7q syndrome".** *G.S. Kupchik<sup>1</sup>, M. Velinov<sup>1,3</sup>, D. Rosa<sup>1</sup>, M. Silverman<sup>2</sup>, T. Shklovkaya<sup>2</sup>, S.M. Kleyman<sup>2</sup>, M.J. Macera<sup>2</sup>, R.S. Verma<sup>2</sup>.* 1) Division of Genetics, Maimonides Medical Ctr, Brooklyn, NY; 2) Wyckoff Heights Medical Center, Brooklyn, NY-Weil Medical College of Cornell University, NY,NY; 3) NYS Institute for Basic Research, Staten Island, NY.

A 25 year-old Caucasian woman of Jewish ancestry was referred for amniocentesis at 32 weeks of gestation due to significant IUGR of the fetus. Cytogenetic findings for the fetus with G-banding revealed an abnormal karyotype, 46,XY,del(7)(q32). The pregnancy was continued and the child was born at 34 weeks gestation after otherwise unremarkable pregnancy. The birth weight was 920g demonstrating severe IUGR. The newborn presented with single umbilical artery, micrognathia, low set ears, and prominent nose. In addition, he had hypoplastic nipples, mild hand contractures, hypospadias, undescended testes, and enlarged distance between first and second toes. The echocardiogram and renal sonogram were unremarkable. A family history was obtained following birth and was significant for the couple's 4.5 year old son with developmental delay and chronic lung disease, and 3 year old son with macrocephaly and hypotonia. The cytogenetic analysis of the newborn's blood confirmed the initial diagnosis. FISH analysis with whole chromosome painting probe and telomere probe for chromosome 7 (Vysis) were applied. telomeric signals were only detected over the normal chromosome 7. The karyotype was thus reported as 46.XY,del(7)(q32).ish(wcp7+,Telyvision7-). The parents declined the recommendation that they undergo chromosome analysis to evaluate the possibility of a familial translocation. Since 1968, over 60 cases with various 7q deletions have been reported. Chromosomal breaks have been reported at 7q32, 7q33, 7q34 and 7q35. Nevertheless, the most frequent breakpoints were at 7q32, resulting in growth and mental retardation, cleft lip/palate, as well as lack of significant neurological findings. In conclusion, the severity of the clinical manifestation in this case does not appear to be proportionately related to the size of the missing chromosomal segment. In our view this patient presented with phenotype on the milder end of the previously reported cases of 7q deletion with comparable size.

Program Nr: 780 from the 2000 ASHG Annual Meeting

**Double Trisomy.** *S. Li, S. Hased, J.J. Mulvihill, A.K. Nair.* Department of Pediatrics, The University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Double trisomies are extremely rare, and most of them involve the sex chromosomes (XXX, XXY or XYY) combined with either trisomy 13, 18 or 21. We present a case of a baby girl with non-mosaic double trisomy 48,XXX,+18, detected after birth. Fluorescence in situ hybridization (FISH) analysis with DNA probes specific for the X and 18 chromosomes was utilized to confirm routine cytogenetic studies in both metaphase and interphase cells. We have also reviewed the literature on previously reported cases of double trisomy and discussed implications of double trisomy.

**Cytogenetic and molecular studies of a de novo mosaic trisomy 12p.** *K. Krabchi<sup>1</sup>, J. Lavoie<sup>1</sup>, R. Laframboise<sup>2</sup>, M. Bronsard<sup>1</sup>, R. Drouin<sup>1</sup>.* 1) Dept Medical Biol, Laval Univ, Quebec City, Quebec, Canada; 2) Pediatrics Dept, Medical Genetics, CHUL, CHUQ, Quebec City, Quebec, Canada.

The peripheral blood sample of a 12-year old boy presenting a phenotype resembling to a Fragile X syndrome has been addressed for both cytogenetic and molecular studies. Based upon GTG banding, the constitutional karyotype of the proband revealed the presence of two cellular clones:  $mos46,XY,22p+[25]/46,XY[75]$ . Successive FISH analyses using different coatomers allowed us to identify the translocated fragment on the chromosome 22 as being from chromosome 12. The subtelomeric probe specific for chromosome 12p was hybridized to identify the material translocated to chromosome 22p. This one has precisely defined its origin. The breakpoints have been mapped using high-resolution GTG and RBG banding. Ag-NOR technique, specific for the argentaaffin region bearing the nucleolar organizer regions, showed the integrity of this region on the derivative chromosome. This chromosome is, therefore, constituted of the intact long arm of chromosome 22, the active centromere, the achromic Giemsa zone and the NOR, all directly associated to the short arm segment of chromosome 12. In this rare event, the breakpoints occurred within the band 22p13. In order to continue our investigation, and considering the data from the literature concerning the Pallister-Killian syndrome (PKS), we performed a cytogenetic analysis of fibroblasts obtained from a skin biopsy. Usually, PKS patients have a tissue-specific tetrasomy 12p, mostly mosaic in the lymphocytes, but always homogenous in the fibroblasts. In our case, the translocation 12;22 is found in almost 100% of the fibroblasts. This unusual case, by its similarity with PKS and the presence of active NORs on the rearranged chromosome 22 requires more investigations, particularly determine the parental origin of the proband's chromosome abnormality.

**Prenatal Diagnosis of a De novo Ring Chromosome 11.** *A.N. Mohamed<sup>1</sup>, S.A. Ebrahim<sup>1</sup>, R. Aatre<sup>2</sup>, M.I. Evans<sup>2</sup>.* 1) Dept of Pathology/Cytogenetics,; 2) Dept of Obstetrics and Gynecology/Division of Reproductive Genetics, Wayne State university, Detroit, MI.

Ring chromosomes are uncommon findings in prenatal diagnosis. Growth retardation is the most significant manifestation in particular among patients with ring of larger chromosomes. A 30-year-old gravida 1, para 0 white woman was referred for genetic counseling because of maternal anxiety. An amniocentesis was performed at 18 week 6 day of pregnancy. Cytogenetic analysis revealed an abnormal mosaic female chromosome complement;46,XX,r(11)(p15q25)[14]/ 45,XX,-11[7]. The ring 11 showed no detectable loss of chromosomal material at 450-band level. Chromosomal analysis of both parents' blood showed normal karyotypes. A targeted ultrasound evaluation at time of consultation revealed no significant abnormality. The parents were counseled regarding the possible developmental abnormalities of the fetus based on the available information in the literature. Subsequently, the parents decided to terminate the pregnancy. Chromosome analysis of the fetal skin biopsy confirmed the same abnormality seen in the amniotic fluid culture. The autopsy revealed an immature female fetus with dysmorphic craniofacial features including brachycephaly, low-set ears, and hypertelorism, bicornuate uterus, and calcifications in renal tubules. The abnormal phenotypes could be a consequence of the ring instability, submicroscopic deletion and/or alteration at the site of fusion.

**Hypomethylation, heterochromatin decondensation, and rearrangements targeted to the pericentromeric regions of chromosomes 1 and 16 in cell lines from ICF syndrome patients and in chorionic villus cultures from normal fetuses.**

*F. Tsien<sup>1</sup>, P. Laski<sup>1</sup>, M. Park<sup>1</sup>, C. Tuck-Miller<sup>2</sup>, M. Ehrlich<sup>1</sup>*. 1) Human Genetics Program, Tulane Univ. Medical Sch., New Orleans, LA; 2) Dept. of Med. Genetics, Univ. S. Alabama, Mobile, AL.

The ICF syndrome (immunodeficiency, centromeric region instability, facial anomalies) is a unique DNA methyltransferase deficiency disease with anomalies in the juxtacentromeric regions (qh) of chromosomes 1 and 16 (Chr1 and Chr16) in mitogen-stimulated lymphocytes. These aberrations are qh decondensation and multiradial chromosomes with up to 12 arms, isochromosomes, translocations, and whole-arm deletions. Our previous studies of ICF LCLs and 1qh and 16qh hypomethylation in cancer suggest that multiradials may give rise to more stable pericentromeric rearrangements. We report that high levels of spontaneous pericentromeric abnormalities were targeted to Chr1 and Chr16 in late-passage chorionic villus (CV) cells from randomly chosen fetal samples as well as in three ICF lymphoblastoid cell lines (LCLs) but not in normal LCLs and fibroblast cell strains. Decondensation of 1qh and 16qh was more frequent than pericentromeric rearrangements. The three ICF LCLs had different frequencies of these anomalies. The more of this decondensation that was seen in 1qh and 16qh in a given ICF LCL, the higher the level of 1qh and 16qh rearrangements in that LCL. A similar relationship suggesting that heterochromatin decondensation predisposed to rearrangements in cis was observed for late-passage CV cells. However, more pericentromeric chromatin breaks and chromosome breaks and fewer multiradials were seen in Chr1 and Chr16 in CV cells than in the ICF LCLs. Like ICF cells, these CV cell samples were hypomethylated in the main satellite DNA in this region (satellite 2). Also, treatment of a normal pro-B human cell line induced high frequencies of decondensation of 1qh and 16qh and high levels of demethylation in this heterochromatin. Our results are consistent with the hypothesis that DNA hypomethylation predisposes to heterochromatin decondensation which, in turn, can lead to rearrangements in cis. (Supported by PHS Grant CA81506.).

**Cigarette smoking and aneuploidy in human sperm.** *Q. Shi*<sup>1,2</sup>, *E. Ko*<sup>2</sup>, *L. Barclay*<sup>2</sup>, *T. Hoang*<sup>1</sup>, *A. Rademaker*<sup>3</sup>, *R. Martin*<sup>1,2</sup>. 1) Department of Medical Genetics, The University of Calgary, Calgary, Canada; 2) Genetics Department, Alberta Children's Hospital, Calgary, Alberta, Canada; 3) Cancer Center Biometry Section, Northwestern University, Chicago, IL.

There have been concerns that smoking may increase the aneuploidy frequency in human sperm, because cigarette smoke contains chemicals which are capable of inducing aneuploidy in experimental systems and these chemicals have been shown to reach the male reproductive system. Recently, one study found no increased disomic sperm in smokers and three others examined several categories of disomy and suggested an association between smoking and only a single category of disomy. In these three studies, however, the authors could not rule out combined lifestyle factors as contributory as smokers also consumed more alcohol and/or caffeine than nonsmokers. In our study, semen samples were collected from 31 men with similar demographic characteristics and lifestyle factors except for cigarette smoking. None of the men drank alcohol. These men were divided into three groups: nonsmokers (10 men), light smokers (<20 cigarettes/day, 11 men) and heavy smokers (<sup>3</sup> 20 cigarettes/day, 10 men). There were no significant differences in semen parameters or age across groups. Two multicolor fluorescence in situ hybridizations (FISH) were performed: two-color FISH for chromosomes 13 and 21, and three-color FISH for the sex chromosomes using chromosome 1 as an internal autosomal control for diploidy and lack of hybridization. Approximately 10,000 sperm/chromosome probe/donor were analyzed. The mean hybridization efficiency was 99.8%. The frequencies of X-bearing and Y-bearing sperm were not significantly different from the expected 50% for each of the three groups. The frequencies of disomy 13 were significantly higher in light and heavy smokers than in nonsmokers. A significant decrease was found in diploidy in X/Y/1 hybridization in both light and heavy smokers, and in XY disomy in light smokers. Thus there were no consistent increases in smokers compared to controls. Based on this study and literature, we can conclude that cigarette smoking may increase the risk of aneuploidy only for certain chromosomes.

**Clinical and Cytogenetic Findings from Saudi Arabia: A Report of 6 Abnormal Cases.** *S.A. Tashkandi, B. Al Muzaini, R.K. Graham, H. Al Nafae, I. Abdulkarym.* Riyadh Armed Forces Hospital, Riyadh, Saudi Arabia.

This is a presentation of six abnormal cases from the cytogenetics lab at RAFH with the aim of correlating the clinical and cytogenetic findings with the published literature. The first case is a family study of 8 members. Chromosomal analysis for the father revealed: 46,XY,t(2;18)(p25.3;p11.2). The maternal karyotype is normal. They have 6 children with the following karyotypes: normal female, carrier female, two females with the karyotype 46,XX,der(18)t(2;18)(p25.3;q11.2)pat and a male and a female with the karyotype 46,XY,der(2)t(2;18)(p25.3;q11.2)pat and 46,XX,der(2)t(2;18)(p25.3;q11.2)pat. The second case is a family study of 6 members. Chromosomal analysis on the mother revealed: 46,XX,t(12;18)(p13.1;q21.3). The paternal karyotype is normal. Out of 4 children, one is normal and three died in early infancy with a phenotype suggestive of trisomy 18. All three contained the following karyotype: 46,XX,der(18)t(12;18)(p13.1;q21.3)mat or 46,XY,der(18)t(12;18)(p13.1;q21.3)mat. The third case, a 20 year old female, presented with primary amenorrhea. Cytogenetic analysis disclosed a male karyotype with a balanced reciprocal translocation: 46,XY,t(6;7)(q21;q32). The fourth case, a 1 year old female, presented with dysmorphic features including cleft palate. Chromosomal analysis revealed two different cell lines resulting in a mosaic trisomy 13 state in 16% of the cells: 45,XX,rob(13;14)[84%]/46,XX,rob(13;14),+13[16%]. The last two cases revealed a similar cytogenetic finding however with different phenotype. One case is of a 1 year old male with a phenotype suggestive of Prader-Willi Syndrome. Chromosomal analysis revealed a duplication of band q11q13 on chromosome 15: 46,XY,dup(15)(q11q13). FISH analysis using the ONCOR Prader-Willi microdeletion probe SNRPN confirmed this abnormality. Conversely, a 36 year old male with a normal phenotype was referred for parental karyotyping after amniocentesis performed on his wife (in another hospital) showed a variant chromosome 15. The maternal karyotype was normal. The paternal karyotype was: 46,XY,dup(15)(q12q13).

**Sperm Aneuploidy in Pesticide Appliers.** *J.L. Smith*<sup>1</sup>, *V.F. Garry*<sup>2</sup>, *A.W. Rademaker*<sup>3</sup>, *R.H. Martin*<sup>1,4</sup>. 1) Dept. of Medical Genetics, Faculty of Medicine, University of Calgary, Calgary, AB, Canada; 2) University of Minnesota Laboratory of Environmental Medicine and Pathology, Minneapolis, MN; 3) Cancer Center Biometry Section, Northwestern University, Chicago, IL; 4) Dept. of Genetics, Alberta Children's Hospital, Calgary, AB, Canada.

Male pesticide appliers in the Minnesota Red River Valley have significant decreases in fertility and their offspring have significant increases in birth defects when compared to the general population of the same region. Agricultural chemicals such as insecticides and fungicides utilized in this area include known aneugens. As aneuploid sperm can contribute to decreased fertility and an increased frequency of birth anomalies, this study is investigating the association between male pesticide exposure and aneuploidy in human sperm. Of 40 men, half were actively working as pesticide applicators. These 20 men had the highest exposure of 90 pesticide appliers studied. The 20 controls (matched for age and smoking) have had either low or no exposures previously, but had not been exposed to the chemicals in the past 3 years. Chromosomes 13, 21, X and Y were analyzed using multi-colour FISH (Fluorescence in situ Hybridization). A minimum of 20,000 sperm was scored for each donor - 10,000 for the 13, 21 chromosome pair and 10,000 for the XY pair. An autosome labelled with a third fluorescent colour was used with the sex chromosome pair to distinguish between XY diploidy and disomy. Analysis was performed "blindly" on coded slides. Aneuploidy frequencies in pesticide appliers vs. controls were: 0.44% vs. 0.36% for disomy 13; 0.44% vs. 0.52% for disomy 21; 0.05% vs. 0.05% for XX; 0.05% vs. 0.05% for XY; and 0.5% vs. 0.05% for YY. Diploidy in appliers vs. controls was 1.15% vs. 0.75% for chromosomes 13 and 21, and 0.23% vs. 0.05% for XY. Results thus far (with 75% of the data collected) demonstrated no significant increase in sperm aneuploidy, diploidy, or sex ratio with general pesticide exposure. However, after completion, further analysis will be carried out to compare men exposed to specific types of pesticides and also include data on lifestyle factors in combination with pesticide exposure.

**Fusion of 9 beta satellite and telomere (TTAGGG)<sub>n</sub> sequences results in a jumping translocation.** *K.S. Reddy<sup>1</sup>, T. Murphy<sup>2</sup>*. 1) Dept Cytogenetics, Quest Diagnostics, Inc, San Juan Capistrano, CA; 2) Memorial Hospital of Burlington County, Mount Holly, NJ 08060.

A newborn was found to have an isochromosome for the short arm of chromosome 9, i(9p) and a jumping translocation of the whole long arm. In 94.4% metaphases, 9q was fused to the telomere of chromosome 19p and, in 5.6% of metaphases, 9q was fused to the telomere of chromosome 8p. The net result was trisomy for the short arm of chromosome 9. With the pan telomere probe, FISH investigations found an interstitial telomere on the der(19) and der(8). The 9 beta and classical satellite probes gave a signal only on the long arm of chromosome 9 involved in the jumping translocation. The 9 alpha satellite probe hybridized to i(9p) and not to the other derivative chromosomes. A combination of chromosome 9 (red) and chromosome 19 (green) paint probes used to rapidly screen metaphases for the jumping translocation found 88 metaphases had a der(19)t(9;19) and 4 metaphases had a der(8)t(8;9). For the first time, the junction of a jumping translocation has been shown to involve the telomere sequence (TTAGGG)<sub>n</sub> and beta satellite sequences by FISH. An intriguing model for jumping translocation will be proposed.

**No significant role for a placental diploid cell line in ongoing trisomy 13 or 18 pregnancies.** *G.H. Schuring-Blom<sup>1</sup>, K. Boer<sup>2</sup>, N.J. Leschot<sup>1</sup>*. 1) Dept. of Clinical Genetics, Academic Medical Center, Amsterdam, The Netherlands; 2) Dept. of Obstetrics and Gynecology, Academic Medical Center, Amsterdam, The Netherlands.

In cytogenetic surveys of spontaneous abortions, trisomies for almost every chromosome have been described. A striking difference is observed in intrauterine survival: most trisomies are lethal, whereas a number of them lead to liveborn deliveries. For trisomy 21 20-35% survive to term, while less than 5% of the trisomy 18 cases and 2.5% of trisomy 13 cases are liveborn. To explain these differences it has been suggested that possibly only cases of trisomy 13 or 18, supported by a diploid cell line in the cytotrophoblast, might survive prenatally (trisomic zygote rescue). So far a limited number of trisomy 13 or 18 placentas (pregnancies between 14-40 weeks) has been investigated, partly using conventional cytogenetic methods, partly using fluorescence *in situ* hybridization (FISH). Only one or few sites were analysed, most of them showing mosaicism, some with high levels of diploidy, supporting the concept of trisomic zygote rescue. We set up a study to determine whether a diploid cell line is always present in the placenta. We investigated viable cases of trisomy 13 (n=8) or 18 (n=6) of live newborns (n=5) and terminated pregnancies (n=9). Gestational ages were between 15-37 weeks, comparable with earlier studies, mean maternal age was 34.7 years. Five random biopsies were taken from each placenta and FISH on cytotrophoblast cells (n=100) was performed with chromosome 13 or 18-specific probes. In neither the trisomy 13 nor the trisomy 18 placentas fully diploid sites were observed. In one trisomy 13 placenta low levels of diploid cells (13-20%) were seen at all sites. In two cases of trisomy 18 somewhat higher levels were observed (respectively 17-33% and 12-45%). In all other cases full trisomy was seen at all sites. We have found that the presence of a diploid cell line in the outer layer of the placenta (cytotrophoblast cells) is not a determining factor for survival in these 14 cases of trisomy 13 or 18, conflicting with earlier studies. Although trisomic zygote rescue may exist, other, as yet unknown factors may play a role in morphogenesis and thus affect survival.

**Analphoid marker chromosomes: Report of two cases.** *G.R. Velagaleti<sup>1</sup>, S.M. Jalal<sup>2</sup>, T. Hughes<sup>3</sup>, L.H. Lockhart<sup>1</sup>, J.R. Nichols<sup>1</sup>, V.S. Tonk<sup>4</sup>.* 1) Dept Pediatrics, Univ Texas Medical Branch, Galveston, TX; 2) Dept. Lab Medicine, Mayo Clinic, Rochester, MN; 3) Brackenridge Children's Hospital, Austin, TX; 4) Dept Pediatrics, Texas Tech Univ, Lubbock, TX.

In spite of recent advances in molecular cytogenetics, marker chromosomes continue to be a diagnostic dilemma. The conventional approaches of special banding techniques and FISH using alpha satellite probes have been the principal methods of their identification. However, at times these methods can be inadequate and may lead to erroneous interpretation. We present two cases in which the unusual marker chromosomes were identified by M-FISH

Case 1 involves a 21-month-old Caucasian male. He presented with dysmorphic facies and a cataract in the left eye. Peripheral blood chromosome analysis showed a mosaic karyotype with 48,XY,+marx2[14]/46,XY[40]. The marker chromosomes were identical in morphology and were nearly the size of a G-group chromosome. Case 2 involved a 5-year-old Caucasian male with hyperactivity and developmental delay. He had minor facial dysmorphism and sub mucous cleft. He also showed a mosaic karyotype 47,XY,+mar[17]/46,XY[7]. The marker chromosome appeared smaller than G-group. The marker chromosomes were C- and AgNOR band negative. FISH analyses with several alpha satellite probes including D13Z1/D21Z1 were negative in both cases. M-FISH analysis, however, in both cases showed that the marker chromosomes are derived from a chromosome 13. Subsequent FISH with wcp13 confirmed these findings.

Since both markers were non-satellited, c-band negative and did not hybridize with alpha satellite probes for chromosomes 13 and 21, it is concluded that these marker chromosomes are analphoid in nature and have a neocentromere. Further studies to localize the neocentromere are in progress. In light of these findings caution is warranted in identification of such marker chromosomes using conventional techniques.

**Suspected gonadal mosaicism for isochromosomes 18p and 18q unsubstantiated by FISH analysis of sperm.** *M.S. Williams<sup>1</sup>, K.D. Josephson<sup>1</sup>, N. Gursoy<sup>2</sup>, C. Jackson-Cook<sup>2</sup>*. 1) Dept. of Pediatrics, Gunderson Lutheran Medical Ctr, La Crosse, WI; 2) Dept. of Human Genetics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA.

A father had two children (with two different mothers) who had chromosome 18 abnormalities. The first was diagnosed prenatally as having isochromosome (i) of 18q when holoprosencephaly was seen by ultrasound. The second was diagnosed, following an amniocentesis done for advanced maternal age, as having i 18p. A lymphocyte chromosome analysis of the father showed no evidence of i 18p or i 18q mosaicism. However, given the rarity of these two conditions the father was counseled that he might have gonadal mosaicism for i of 18p and 18q which could confer a high recurrence risk for one or the other of these chromosomal abnormalities. To assess this possibility, dual color FISH was performed on sperm collected from a semen sample provided by this man using probes specific for the subtelomeric regions of 18p and 18q. None of the 1000 sperm scored had a FISH pattern consistent with an isochromosome. Furthermore, the sperm aneuploidy frequency for chromosome 18 (0.3% disomy) was not significantly different from that seen in control males (0.5% + 0.05%). Thus, the sperm population present at the time of semen sampling from this male provided no evidence of mosaicism. This finding suggests that the recurrence risk for this male is low and illustrates the importance of utilizing laboratory confirmation of clinical hypotheses whenever possible.

**Duplication of the proximal portion of chromosome 5p.** *D.L. Persons, H.H. Ardinger, T.M. Arthur, B.D. Davoren, L.D. Hankins, J.E. Ragona.* University of Kansas Medical Center, Kansas City, KS.

Several reports have described duplications of the entire short arm of chromosome 5 or the distal portion of 5p. Partial trisomy restricted to the proximal region of 5p has been reported in only two cases, one resulting from an insertion and one from a marker chromosome. We report the first de novo direct duplication of the short arm of chromosome 5 involving 5p11-p13.1. The 3 year-old female patient presented with a history of significant developmental delay, macrocephaly, hyperopia, abnormal EEG (without seizures) and feeding problems in infancy. She required oxygen in the first year of life for an undefined lung problem. Height and weight were normal. She had scaphocephaly, sparse slow-growing straight scalp hair, mild scoliosis, joint laxity, eleven pairs of ribs, normal bone age, inverted nipples, tiny umbilical hernia and very soft skin that was thin over the dorsa of the hands. Facial features were reminiscent of Noonan syndrome, CFC syndrome, and Costello syndrome, but the other clinical findings did not support any of these diagnoses. Initial routine chromosome analysis was reported as normal. A follow-up high resolution chromosome analysis (800 band level) revealed a small direct duplication of the proximal portion of 5p with breakpoints at p11 and p13.1. A portion of C-band positive material was also duplicated. Fluorescence in situ hybridization using a whole chromosome paint for chromosome 5 confirmed that the duplication consisted of only chromosome 5 material. Parental chromosomes were normal. Direct duplication of the proximal region of 5p has not, to the best of our knowledge, been previously described. The patient's characteristics were consistent with those that have been reported for whole arm 5p duplications and distal 5p duplications involving the 5p13 band. Generally, duplications involving 5p that are distal to the p13 band have milder phenotypic effects. These findings support the importance of the 5p13 band in causing the severe phenotype observed in many whole arm and partial duplications of 5p.

**CGH as a routine procedure in a clinical cytogenetic laboratory : a one-year assessment.** *C. Turleau, J.M. Lapiere, G. Joly, M. Prieur, O. Raoul, M.C. de Blois, N. Morichon-Delvallez, P. Gosset, S. Romana, M. Vekemans.* Laboratoire de Cytogenetique, Hopital Necker Enfants Malades, Paris, France.

Comparative Genomic Hybridization (CGH) is able to detect the origin of extra or missing chromosome material in cases of chromosome imbalances. To assess its usefulness as a routine procedure in a clinical cytogenetic laboratory we performed CGH on a total of 55 cases analyzed previously using high resolution R and G banding (HRB). First, we validated the technique on 9 cases with well-defined deletion or duplications. All imbalances were confirmed using CGH. In 16 cases, further characterization of a chromosome rearrangement detected using HRB was necessary: identification of extra or missing chromosome material (5 cases), confirmation of the unbalanced nature of a rearrangement (9 cases) or accurate definition of the breakpoints (2 cases). CGH was useful in all cases. For example, in one case of add(8p), CGH shows an enhancement and diminution of chromosome 8 material confirming a small inv dup(8p); in another case CGH identified an insertion of a 7p segment into the short arm of chromosome 8. In 24 cases, HRB analysis was normal. Among these, 16 cases also had a normal CGH profile. In 8 cases however CGH detected a chromosome imbalance. They comprise 6 patients (4 families) with an unbalanced familial translocation and 2 other unbalanced translocations (1 de novo and 1 of undetermined origin). Finally 6 prenatal cases with a suspected chromosome rearrangement were studied. All had a normal CGH profile. All abnormal results were always confirmed using whole chromosome painting and/or FISH with subtelomeric probes. Interestingly, in our experience all subtle telomeric imbalances were detected using CGH. In conclusion, we believe that CGH could be used as a routine procedure in a clinical cytogenetic laboratory as an alternative to FISH screening using all telomeric probes. Also this technique is able to analyze interstitial chromosome imbalances.

**Trisomy 8 mosaicism: cell cycle kinetics and distribution of trisomy 8 and normal cells in embryonic and extra-embryonic tissues.** *B.J. Pettit, M. Hummel, L.L. Cook, B.K. Boyd, S.L. Wenger.* West Virginia University, Morgantown, WV.

Amniocentesis performed at 17 weeks gestation due to abnormal maternal serum triple screen identified a fetus with trisomy 8 in one third of metaphase cells while the remaining cells were normal. Trisomy 8 mosaicism is associated with variable clinical manifestations such as mental retardation, deformed skull, prominent forehead, high-arched palate, low-set and/or dysplastic ears, deep palmar and plantar furrows, and reduced joint mobility. The purpose of this study was to determine the level of trisomy 8 mosaicism found within embryonic and extra-embryonic tissues, rates of cell division for the two cell lines, and effect of mosaicism on the phenotype. Tissue samples collected from the baby at birth included cord blood, cord tissue, peripheral blood, and separated placental tissues (chorion, amnion, and villi). The level of trisomy 8 cells in cord blood and peripheral blood was 54%, umbilical cord was 57%, amnion was 43%, and chorion was 8%. Cell cycle kinetics was measured using incorporation of bromodeoxyuridine during 48 hours to determine the number of cell divisions in metaphase cells. Cell cycle kinetics of the cord blood for trisomy 8 cells had 18% 1st division, 25% 2nd divisions, and 57% 3rd divisions; and normal cells had 10% 1st division, 36% 2nd divisions, and 54% 3rd divisions. There was no significant difference in growth rates between the trisomy 8 and normal cells using Chi-squared goodness of fit test. Cell cycle kinetics for other tissues is pending. The infant had bitemporal narrowing, large fleshy ears, hypoplastic nails, deep furrows on palms and soles, first-degree hypospadias, severe cardiac enlargement secondary to pulmonary hypertension, and feeding difficulties. The child expired at 8 weeks due to pulmonary hypertension. Low level of trisomy 8 cells in placental tissue may have allowed the fetus to go to term, while the higher level in patient tissues is probably related to poor outcome.

**Is there a mosaic trisomy 12p phenotype?** *R. Smith, J.M. Cowan, D.W. Bianchi.* Division of Genetics, Department of Pediatrics, New England Medical Center, Boston, MA.

Constitutional trisomy 12p is rarely observed. It most frequently presents with monosomy for another region as a result of meiotic missegregation of a parental balanced translocation. Delineation of the associated phenotype has been complicated by the concomitant monosomy in most cases; however, de novo cases and those involving monosomy for the short arm of acrocentric chromosomes have permitted the delineation of a "trisomy 12p syndrome" phenotype. Some of the features described include normal to large birth weight, severe motor retardation, hypotonia, prominent forehead with flat facies, hypertelorism, bilateral epicanthus, low nasal root, short upturned nose with anteverted nares, large mouth, prominent protruding lower lip, micrognathia and a short neck. The phenotype of mosaic trisomy 12p has not been clearly defined given that there have been only 3 previously reported cases, all with an overall high level of mosaicism.

We present a fourth case of trisomy 12p mosaicism. Our patient was the 10lb. 4oz. product of a term gestation born to a 37 year old G2P1 mother. Generalized hypotonia with developmental delays was evident by 3 to 4 months of age. At 5 months she was evaluated by genetics and her exam was significant for her large size (all growth parameters greater than the 95th percentile). Her forehead was prominent and bossed. Her palpebral fissures were upslanting. She had a low nasal root with a short upturned nose. Her philtrum was long with a thin upper lip and a protuberant lower lip. Her mouth was wide. She had marked hypotonia. Peripheral blood karyotype analysis revealed 47,XX,+del(12)(q11)[13]/46,XX[7]. At 8 months she was able to sit with support for short periods and did not yet have full head control. An EEG showed no seizure activity.

Comparison of our patient's phenotype with those previously reported suggests that the phenotype of mosaic trisomy 12p is similar to the phenotype of full trisomy 12p. More reports will be necessary to determine whether or not a lower percentage of mosaicism has an effect on this phenotype.

**Jumping translocations of 9q onto 14p, 13q and 7q, and pseudo isochromosome 9p results in 9p trisomy syndrome.** *K. Wakui<sup>1</sup>, E. Hidaka<sup>2</sup>, M. Ishikawa<sup>2</sup>, M. Ichikawa<sup>3</sup>, T. Katsuyama<sup>2</sup>, Y. Fukushima<sup>1</sup>.* 1) Dept Hygiene & Med Genetics, Shinshu Univ Sch Medicine, Matsumoto, Nagano, Japan; 2) Dept Laboratory Medicine, Shinshu Univ Sch of Med, Matsumoto, Nagano, Japan; 3) Dept Pediatrics, Shinshu Univ Sch of Med, Matsumoto, Nagano, Japan.

We report a 9p-trisomy-syndrome patient with jumping translocations (JTs) of 9q and pseudo iso chromosome 9p. The patient, a 12-year-old girl, was referred to our clinic because of mental retardation and short stature. She was born at 38 weeks' with a birth weight of 2472 g and length of 47 cm. Developmental milestones were slightly delayed; she rolled over at six months, stood alone at 19 months. Her characteristic features were: short stature (132.4 cm, -3.0 SD), microcephaly (47.8 cm, -3.0 SD), long face, high nasal bridge, long nose, short philtrum, prominent ears, short 5th fingers, brachymesophalangea, and kyphosis. Cytogenetic analysis on both lymphocytes and fibroblasts showed complicated mosaic rearrangements. All cell lines had pseudo isochromosome 9p confirmed by FISH analyses using wcp 9 and 9p telomeric probes. Added to this, JTs of 9q onto 14p (60% of cells), 13q (25%), 7q and other chromosomes were observed. The parents had a normal karyotype. The patient did not suffer from hematologic malignancy. JTs is defined as mosaic chromosomal rearrangements characterized by the relocalization of the same donor chromosome segment to several recipient chromosomes. JTs is commonly observed as an acquired form of chromosomal rearrangement in neoplastic cells from cancer patients, but constitutional forms of JTs are very rare. To our knowledge, this is the first case of JTs of 9q results in 9p trisomy syndrome. The breakpoints of the recipient chromosomes in JTs including our case occur in areas rich in repetitive DNA (telomeric, centromeric, and nucleous organizing regions). It may point to resolving the mechanism of constitutional forms of JTs.

**Abnormal sex development and autism in a 46,XX female with 9p24.1-pter chromosomal rearrangement. L.**

*Telvi*<sup>1</sup>, *A. Ion*<sup>2</sup>, *C. Sevin*<sup>3</sup>, *R. Lallou*<sup>3</sup>, *M. Roger*<sup>3</sup>, *M.A. Patton*<sup>2</sup>, *J.L. Chaussain*<sup>3</sup>. 1) Genetique Constitutionnelle et Moleculaire, St Vincent de Paul Hospital, Paris, France; 2) Medical Genetics, St George's Hospital Medical School, London, UK; 3) Endocrinologie Pediatrique, St Vincent de Paul Hospital, Paris, France.

We describe a female patient harbouring an unbalanced de novo 46,XX,t(9;18) chromosome complement and multiple congenital abnormalities. The child presented with profound mental retardation, autistic features, dysmorphic face and severe developmental delay (-4SD). Puberty delay was also present: stage 2 at 15.5 years of age and absence of the first periods. Ultrasounds investigation showed the presence of an infantile uterus, and two small apparently normal ovaries with immature primordial follicles. Further endocrinological investigations showed the presence of an auto-immune Hashimoto thyroiditis with raised plasma levels of antimicrosomal antibodies. The patient presented with behavioural anomalies including autistic features, automutilations and stereotypic gesticulation. Karyotype analysis showed a homogenous de novo 46,XX,9p+ chromosome complement. The extra material present at the tip of the short arm of the chromosome 9 could be identified as a chromosome 18 fragment after MULTIFISH analysis. The chromosomal abnormality resulted the loss of the terminal 9p region (p24.1-pter). Deletions of this region in 46,XY patients have been intensively investigated, and a gene responsible for sex determination has been mapped at this level. However, little is known about this type of chromosomal abnormality in 46,XX individuals. Two other female 46,XX patients with chromosomal rearrangement involving 9p24.1 were described, both presenting with abnormal gender identity, gender dysphoria and autistic features (unpublished data). It is conceivable that a common gene involved in sex determination might have been disrupted by the chromosomal rearrangements seen in these patients and the different male and female abnormal phenotypes might be determined by a variable expression in XY and XX individuals of this putative gene. The presence at the same locus of a gene responsible for autism is also discussed.

**Three siblings have three different imbalances following 3:1 malsegregation of a maternal translocation.** *R.C. Weaver, C. Jackson-Cook, J. Bodurtha.* Human Genetics, Virginia Commonwealth Univ., Richmond, VA.

The majority of reciprocal translocations malsegregate to produce only one type of viable imbalance in humans. We report a very rare family in whom three different chromosomal imbalances were noted in three siblings. The mother (G4A1P3) of this family carried a balanced translocation between chromosomes 12 and 21 [t(12;21)(p13;q21)]. She was ascertained following the birth of her first child (currently 15 yo), who had Down syndrome due to an interchange trisomy following 3:1 malsegregation of the maternal translocation. Her second (currently 8 yo) and third (currently 6 yo) children (both of whom were diagnosed prenatally) had imbalances resulting from the complementary 3:1 tertiary interchange products leading to partial monosomy [der(12)t(12;21)] and trisomy [47,XX,+der(21)t(12;21)], respectively. Thus, the imbalances in her children include trisomy 21 (child 1); partial monosomy for distal 12p and proximal 21q (child 2); and partial trisomy for proximal 21q and distal 12p (child 3). As expected from the different imbalances, the phenotypes of the children vary. The oldest sibling has findings typical of those noted in children with Down syndrome. The second child (partial monosomies) has developmental delay, severe growth retardation, micrognathia, mild hearing loss, broad tipped nose, broad pectus, heart murmur, and an undescended testicle (which has been repaired surgically). The youngest sibling is mildly affected, having a prominent widow's peak, a narrow vermilion border of the upper lip, and no apparent developmental delay. This translocation is unique in that multiple imbalances resulting from the predicted 3:1 malsegregation are compatible with life. Moreover, this family has presented a unique genetic counseling dilemma in identifying an appropriate support group(s) and calculating recurrence risk.

**Clinical Manifestations associated with Del(2)(q32.1q33.1).** *K.A. Smyth, R. Babul-Hirji, D. Chitayat.* Division of Clinical Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

Over 20 cases of interstitial deletion chromosome 2q have been reported, the most common being del(2)(q31q33). Common manifestations among these children include low birth weight, developmental delay/mental retardation, microcephaly, cleft palate and dysmorphic facial features. Renal hypoplasia, agenesis of the corpus callosum, acetabular hypoplasia, absent ribs, seizures, equinovarus deformities of the feet and iris coloboma have also been reported.

We report on a 14 year old girl with a de novo del(2)(q32.1-33.1) and global developmental delay. The patient was born at 32 weeks with a birth weight of 2kg(50%ile). The pregnancy and neonatal course were uncomplicated. She had valgus deformity of both feet, corrected with bracing. At 14, her height was 135cm(<3%ile), weight 37kg(<3%ile), and head circumference 55.5cm(50-98%ile). Dysmorphic features included brachycephaly, high forehead, frontal bossing, narrow bitemporal diameter, prominent supraorbital ridges, deep set eyes, hypoplastic malar areas, prominent maxilla with malocclusion and wide spaced teeth, and narrow vermilion borders. She had lumbosacral scoliosis of 17-20°, 12 ribs and 4 non-rib bearing lumbar type vertebral bodies, and spina bifida occulta at L5. Her visual acuity was 20/20 with significant myopia and astigmatism bilaterally. Her upper limbs showed dislocation of the radial head, hyperextensibility, and arachnodactyly with wrinkling over the palms. Her lower limbs revealed a "saddle" gap and hyperextensible knees. A brain CT scan revealed mild to moderate ventriculomegaly and the anterior horns of the ventricles were split apart. Comparison of our patient with the literature confirms the association of this deletion with developmental delay and characteristic facies. This report lends support to the association of this deletion with skeletal abnormalities, and is the first report of ventriculomegaly associated with this condition. The genes likely to be important within this region include the distal-less homeobox genes DLX1 and DLX2 (2q32), and the gamma crystallin genes (2q32-35). Further investigation is being done to determine if these genes are deleted.

**Genetics of Klippel-Trénaunay Syndrome (KTS), a vascular disease.** A. Sadeghpour<sup>1</sup>, M. McCane<sup>2</sup>, G. Hoeltge<sup>2</sup>, D. Driscoll<sup>3</sup>, Q. Wang<sup>1</sup>. 1) Center for Molecular Genetics, Cleveland Clinic Foundation, Cleveland, OH; 2) Department of Clinical Pathology, Cleveland Clinic Foundation, Cleveland, OH; 3) Section of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Klippel-Trénaunay Syndrome (KTS) is a congenital vascular disease which is defined as a combination of capillary, venous and lymphatic malformation associated with hypertrophy of affected tissues. The majority of KTS cases are sporadic. However, a few familial cases have been reported and also several studies have shown that frequency of hemangiomas or varicose veins are higher in the first degree relatives. Moreover, two cytogenetic changes in KTS patients: t(5;11) (q13.3;p15.1) and t(8;14) (q22.3;q13) have been identified. Therefore, these findings suggest that genetic factors contribute to pathogenesis of KTS. Our research goal is to identify more cytogenetic abnormalities in KTS patients since this strategy is very powerful in finding the disease-causing gene(s). Identifying and characterizing the KTS gene(s) will help us to understand the molecular mechanisms underlying the vascular morphogenesis. Blood samples have been received from KTS patients and their family members. Family studies have shown that more than 50% of KTS patients have other family members affected with various vascular disorders. Karyotyping (50 patients) and fluorescence *in situ* hybridization (FISH) have been used to identify and localize cytogenetic changes. Several cytogenetic abnormalities with chromosomal mosaicisms have been found: Mos 46, XX/47, XXX; Mos 46, XX/45, X; and 46, XY/47, XY,+r. All the findings point out to a hereditary pattern and possibility of genetic factor(s) for KTS.

**Characterization of a familial acentric marker chromosome identified at amniocentesis.** *J. Winters*<sup>1</sup>, *M. Lipson*<sup>2</sup>, *M. Dolliver*<sup>2</sup>, *S. Owen*<sup>1</sup>, *S. Schwartz*<sup>3</sup>. 1) Genetics Dept, Kaiser Permanente Northern California, San Jose, CA; 2) Sacramento, CA; 3) Ctr for Human Genetics and Dept of Genetics, Case Western Reserve Univ and Univ Hospitals of Cleveland, OH.

Acentric marker chromosomes (generally defined as lacking identifiable a-satellite sequences) have been reported in a number of cases. These markers have been found to originate from several chromosomes and are almost always de novo in origin. We have identified and studied a familial case of a prenatally ascertained acentric marker chromosome. A 38-year-old, G3P1SAB1 woman had an amniocentesis for advanced maternal age. The fetal karyotype was found to be 47,XY,+mar in all 15 colonies examined. Fluorescence in situ hybridization (FISH) studies were performed, and the marker chromosome was found to be negative for the following probes: DXZ1, DYZ3, D15Z1, SNRPN, PML, and a pancentromeric probe (thereby characterizing this marker as an acentric chromosome). Studies of parental blood were performed, and the mother was found to have an apparently identical non-mosaic marker chromosome (47,XX,+mar). She is phenotypically normal (with a negative family history for mental retardation and birth defects), indicating that there are non-centromeric portions of the genome which are not detrimental when present in three copies. Besides probing for a-satellite sequences, CENP (centromere-associated proteins) antibody studies are also used to characterize neocentromeres (non-a-satellite sequences which have centromeric activity). Neocentromeres generally bind CENP-B (which is present at inactive and active centromeres) as well as CENP-C and -E (which are present only at active centromeres). Studies to determine the chromosomal origin and CENP status of this marker are currently underway, as are family studies to identify other carriers. This case demonstrates that (1) detectable a-satellite sequences are not necessary for faithful mitotic or meiotic replication and segregation and (2) partial aneusomy for some non-centromeric regions of the genome is not necessarily associated with phenotypic abnormalities. To our knowledge, this is the first reported case of a supernumerary familial acentric marker chromosome.

**An insertional translocation in an infant with two common fragile sites in the mother.** *U. Tantravahi<sup>1</sup>, D. Abuelo<sup>2</sup>.*  
1) Cytogenetics/Molec Gen/Pathol, Women/Infants Hosp-Brown Univ, Providence, RI; 2) Genetic counseling center/Rhode Island Hospital/Brown Univ, Providence,RI.

Autosomal fragile sites have been implicated in possible predisposition to chromosome breakage and rearrangements in meiosis. We describe a patient with an insertional translocation involving chromosomes 3 and 16 whose mother had fragile sites at both of the break points. Case Report: Amniocentesis done in another country because the fetus had hydrops, pleural effusions and polyhydramnios identified a deletion in chromosome 3p13-p14. The infant was born in Providence, RI at 36 weeks and had dysmorphic features consisting of asymmetric, downslanting palpebral fissures, wide nasal bridge and unusual pinnae. She also had moderate hypotonia and an atrial septal defect was detected. At 8 months of age, psychomotor development was delayed. G-banded karyotype analysis of the patient revealed an insertional translocation with break points in chromosome 3 at p14 and p21. This segment from chromosome 3 was inserted at the q22 region of chromosome 16. These results were confirmed by FISH analysis using whole chromosome paint probes for 3 and 16. The break points at 3p14 and 16q22 are associated with common fragile sites. Although both parental chromosomes were normal, the maternal karyotype revealed a fragile site at chromosome 3p14 without induction in 32% of the cells. Induction with Aphidicolin and Distamycin showed increased expression of fragile sites at 3p14 and 16q22 in the mother compared to the normal background levels. These results suggest that the fragile sites on these two chromosomes in the mother may have contributed to the chromosome rearrangement seen in the child. The clinical symptoms may be due to loss of genetic material that may have occurred in the process of chromosome rearrangement, position effect of genes involved in the rearrangement or breaks in the critical genes.

**Miscarriages: Cytogenetic studies and recurrence risks.** *P.N. Rao*<sup>1</sup>, *P.M. Tsuribe*<sup>2</sup>, *E.O. Rodini*<sup>3</sup>, *L.V. Rodrigues*<sup>4</sup>. 1) Pathology/Lab Med, Univ California, Los Angeles, Los Angeles, CA; 2) ALAG/UNESP, Bauru, SP, Brazil; 3) ALAG/UNESP, Bauru, SP, Brazil; 4) CEPS/USC, Bauru, SP, Brazil.

The global rate of spontaneous abortions is between 33 and 67%. The chromosomal abnormalities constitute the commonest causes. About 50% of fetal deaths, in first trimester of clinically recognized pregnancy, are chromosomal abnormalities. Spontaneous abortions behave like a process of "natural selection", eliminating abnormal conceptuses. In the absence of this mechanism, the percentage of newborn with malformations would rise of 3 to 12%. We studied a sample of 752 Brazilian women during reproductive age (18 to 40 years) to verify the incidence, recurrence risks and etiology of spontaneous fetal loss. 148 of them presented with at least one miscarriage. The incidence of miscarriage was 19,68%. Recurrence risks were estimated as following: 23.6% for a second miscarriage (0.1680-0.3050), and 40% for the third miscarriage (0.2377-0.5623). We performed cytogenetic studies (C,G, and Nor banding) on the products of conceptions (POC), using two methods. The first involved culture of stroma of CVS and the second cytotrophoblast cells to obtain direct chromosomal preparations. The results showed: 47,XY,+13(8.7%); 47,XY,+20; 47,XX,+22, 47,XX,+18; 47,XY,+10; 47,XX,+6; 45,XY,-22; 45,XX,-13; 46,XX/47,XX,+9 (4.3% each one), and 69,XXX(13%). Parental karyotypes showed polymorphism in 3 cases (16qh+), and inversion inv(9)(p11q12) in 2 cases. Miscarriages occurred most frequently in the 8th week of gestation. Average maternal age at miscarriage was 28.5 years. About 27.5% were above 35 years old. In women younger than 35 years old, chromosomal anomalies were observed in 51.7%, while in women 35 years or older 63.6% of the POC's had chromosomal abnormalities. These results show the relevance of the genetic counseling and prenatal diagnoses in mothers 35 years or older, and show the increase in the recurrence risks after the first miscarriage.

**Biparental Familial Inheritance of Two Unrelated Structural Abnormalities Involving Chromosome 11 and 22 in a Two Generation DiGeorge Syndrome Family.** *M.J. Sutcliffe<sup>1,2</sup>, O.T. Mueller<sup>1,2</sup>, J. Ranells<sup>2</sup>, D. Dumont<sup>1</sup>, D. Conforto<sup>1</sup>, J.A. McFarland<sup>1</sup>, F. Mawani<sup>1</sup>, G. Jervis<sup>2</sup>, A. Mahmoud<sup>2</sup>.* 1) Clinical Genetics Laboratories, All Children's Hospital, St Petersburg, FL; 2) Department of Pediatrics, University of South Florida, Tampa, FL.

A six month old Caucasian female with a history of Tetralogy of Fallot diagnosed at 2 months, hypotonia, delayed motor development and mild facial asymmetry was found to have a microdeletion in the DiGeorge/Velo-Cardio-Facial Syndrome (DIG/VCFS) region of chromosome 22q11.2 by Fluorescence In-Situ Hybridization (FISH) analysis. GTG banding revealed, in addition, a paracentric inversion of chromosome 11. Since translocation (11;22) is well documented in familial DIG/VCFS, parental chromosome analysis was recommended. Pedigree analysis revealed a paternal history of coarctation of the aorta and learning disability. FISH analysis confirmed the DIG/VCFS microdeletion in the father, however, no rearrangement of chromosome 11 was noted. DNA microsatellite analysis identified that the deletion was denovo in the father of the proband and originated on the grandpaternal chromosome 22. Inversion (11)(q13.3q25), the same as observed in the infant, was identified in the maternal karyotype. Paternal grandparents have normal karyotypes and an investigation of maternal grandparents is currently underway. DIG/VCFS microdeletion has been described in combination with Turner, Down and Fragile X Syndromes. To our knowledge this is the first case of familial DIG/VCFS with a second independent structural abnormality. Familial DIG/VCFS has been shown to have significant inter and intra familial clinical variability consistent with the hypothesis of contiguous gene syndromes. In view of the apparent increased clinical severity between father and daughter in this family, delineation of the size of the deletion at the molecular DNA level will be presented and may indicate a genetic basis for this observation and provide important patient management information.

**Genomic sequencing and transcript identification over a 700kb region in human 6p24 containing three translocation breakpoints associated with orofacial clefting.** *J. Ragoussis<sup>1</sup>, S. Knaggs<sup>1</sup>, G. Mirza<sup>1</sup>, I. Macris<sup>1</sup>, R. Stephens<sup>1</sup>, A. Mungall<sup>2</sup>.* 1) Div Medical & Molecular Gen, Kings College, Guy's Hosp, London, England; 2) The Sanger Centre, Wellcome Trust Genome Campus, Hinxton, England.

We have previously presented three patients exhibiting the phenotype of orofacial clefting (OFC) associated with balanced translocations involving the 6p24 region (Davies et al 1995 & 1998), suggesting that a gene present in this region, may if disrupted result in OFC. In order to identify such a gene, we first completely cloned the region containing the three breakpoints in YAC, PAC, BAC and cosmid clones, by using YAC fragmentation and genomic clone contigging techniques. The three breakpoints have been located within a 500kb long segment by a combination of fluorescent in situ hybridisation techniques including fibre FISH. At present, sequencing of a 700kb region including the 500kb breakpoint cluster is close to completion. The systematic use of a comprehensive set of sequence analysis tools and RACE techniques lead to the isolation of a single novel transcript expressed in the human fetus which maps to a critical region between two of the breakpoints. Full characterisation of the gene is in progress and this will hopefully lead to an understanding of the molecular basis of the associated developmental defects. Furthermore it will possibly lead to an improved understanding of molecular events during craniofacial development and serve as a candidate gene for cleft lip and palate. **Molecular cytogenetic characterization of partial duplication 21q.** *G.D. Wenger<sup>1</sup>, E. Hamelberg<sup>1</sup>, T. Depinet<sup>1</sup>, J. Labanowska<sup>1</sup>, J.R. Korenberg<sup>2</sup>, J.M. Gastier<sup>1</sup>.* 1) Dept. of Laboratory Medicine, Children's Hospital, Columbus, OH; 2) Molecular Genetics Laboratory, Cedars-Sinai Medical Center, Los Angeles, CA.

We report a patient with some features of Down Syndrome (DS) and partial duplication of chromosome 21q. GTG-banded analysis of peripheral blood chromosomes revealed a subtle abnormality: one chromosome #21 with additional material added to the stalk/satellite region. At the time of initial analysis, no information regarding indication for study accompanied the sample. To discriminate between a polymorphic variant and significant cytogenetic abnormality, NOR-staining and FISH using the b acrocentric probe and WCP21 were performed. NOR staining was positive; the additional material did not hybridize with the b acrocentric probe but did hybridize with WCP 21, indicating duplication of chromosome 21 sequences. When clinical information was obtained, the patient, a 22-year-old female, was reported to have facial and physical appearance suggestive of DS, no known cardiac anomaly, and normal intelligence. FISH with commercially available probes indicated the duplicated region to be distal to D21S65 and to include the loci D21S55, D21S259/S341/S342, and unique subtelomeric sequences (D21S1219/S1220). Additional FISH studies using the P1 probes 82F5, 140K16, and 850B12 failed to indicate the inclusion of any of these sequences in the duplicated region. The duplicated region therefore apparently extends from just centromeric of D21S55 through the telomere. The physical map of chromosome 21 allows molecular definition of loci included in such rare cases of partial trisomy; study of such patients contributes to our understanding of the loci responsible for the distinct features of DS and their pathophysiology.

**Cytogenetic and molecular characterization of unbalanced chromosomal rearrangements in two patients with Wolf-Hirschhorn syndrome.** *C. Sreekantaiah, D. Kronn.* New York Medical College, Valhalla, NY.

Wolf-Hirschhorn syndrome (WHS), a multiple malformation syndrome characterised by developmental and mental defects, results from a hemizygous deletion of the distal short arm of chromosome 4 (4p16.3). The deletion occurs either as an isolated deletion or as a result of segregation of a reciprocal translocation. The deletions can range from one-half of the short arm to cytogenetically undetectable. WHS is considered to be a contiguous gene syndrome with an undefined number of genes contributing to the phenotype because of the complex and variable expression of the disorder. We present the cytogenetic and molecular cytogenetic findings in two cases of Wolf-Hirschhorn syndrome. Cytogenetic and fluorescence in-situ hybridization (FISH) analyses of the patients were performed prenatally on amniotic fluid specimens obtained from amniocentesis performed in the third trimester for intrauterine growth retardation and on peripheral blood obtained postnatally. Karyotypic analyses of the parents' were carried out on peripheral blood cultures. In both patients cytogenetic analyses revealed additional material of unidentifiable origin on 4p. High resolution banding analyses and FISH analyses helped to characterize the rearrangements. Analysis of patient KB and her parents revealed that the patient had inherited an unbalanced segregation product [der(4)t(4;5)(p15.2;q33.1)] from a constitutional balanced translocation in her mother [t(4;5)(p15.2;q33.1)]. The rearrangement in patient AB involved a de novo deletion and inverted duplication of 4p; der(4)del(4)(p16.2)dup(4)(p15.33p14). His parents were karyotypically normal. Shared clinical features in both patients included growth retardation, both were small for gestational age, microcephaly, multiple dysmorphic features and significant developmental delay. Certain unique clinical features were also present. Although different mechanisms can contribute to the origin of WHS, the clinical manifestations of WHS depend on the extent of the deleted segment.

**Cryptic translocations with acrocentric short arms identified by FISH.** *J.H. Tepperberg<sup>1</sup>, I.K. Gadi<sup>1</sup>, P.N. Mowrey<sup>1</sup>, K. Phillips<sup>1</sup>, J. Barnum<sup>1</sup>, C. Costanzo<sup>1</sup>, T. Creeden<sup>2</sup>, M. Hummel<sup>3</sup>, P.R. Papenhausen<sup>1</sup>.* 1) Cytogenetics, LabCorp, RTP, NC; 2) Div Clin Genet, Saint Peter's Univ Hosp, New Brunswick, NJ; 3) Ped/Genet, West Virginia Univ, Morgantown, WV.

Translocations of small, distal chromosome regions to the p-arms of acrocentric chromosomes are often difficult to detect by routine cytogenetics. Failure to identify the rearrangement can lead to a misdiagnosis. We report two cases, showing cryptic rearrangements with the short arm of acrocentric chromosomes. The first case involved a healthy 35yo female, G4P1, referred for amniocentesis because of AMA. Family history was negative. The fetal karyotype analysis showed an apparent deletion of distal chromosome 17p13. Fetal U/S and parental chromosome analyses were normal. Preliminary discussions with the parents, prior to the completion of the FISH study, centered around Miller-Dieker syndrome. A LIS1 DNA probe specific for chromosome 17p13 surprisingly showed probe hybridization with the distal chromosome 21p suggesting an apparently balanced rearrangement. NOR staining of the derivative chromosome 17 was positive. The second case involved a newborn full term female, born to a 23yo G1P1 with MR. Birth wt was 9 lbs 15oz, length 19 in., and HC 37cm. Apgars were 4 at 1 min and 8 at 5 min. Anomalies included horseshoe kidneys, Dandy Walker malformation, ASD and PDA. The infant was mildly dysmorphic with upturned nose, tented mouth, long narrow feet and decreased tone. Chromosome studies showed a G-dark crescent band on the stalk region of chromosome 15p. FISH and karyotype analyses suggested distal 3p origin. This derivative chromosome 15 was correctly identified albeit it could have possibly been interpreted as a normal variant 15p. Furthermore, this case represented pure partial trisomy 3p syndrome. The first case demonstrates the absolute necessity of follow-up by molecular cytogenetic analysis in prenatal cases with apparent terminal deletions. The second case illustrated the importance of investigating the origin of satellite associated G-dark bands, in those cases referred with an abnormal phenotype and/or positive family history.

**Jacobsen syndrome : four Korean children with thrombocytopenia or neutropenia.** *E.J. Seo, S.M. Ahn, J.Y. Lee, H.W. Yoo.* Medical Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea.

Jacobsen syndrome is caused by terminal deletion of the long arm of chromosome 11. Patients with this syndrome have breakpoints in 11q23.3-11q24.2 and typical features including psychomotor and growth retardation, trigonocephaly, dysmorphic faces, ocular anomalies, cardiac defects, digit anomalies, and thrombocytopenia or pancytopenia. We have evaluated four Korean children with terminal deletion of 11q. Two patients had a breakpoint in 11q23.3 which may be related to the FRA11B fragile site. Remaining two patients showed a terminal deletion to distal 11q24. These patients had cardiac defects and dysmorphic facial features such as trigonocephaly, high-arched palates, and low-set ears. Strabismus, foot deformities, imperforated anus, and cryptorchidism were also found. Severe to moderate thrombocytopenia was observed in three patients. Neutropenia was detected in two patients. All patients revealed mild anemia. There are two candidate genes known to map to 11q24-25 that are likely to play some role in hematopoiesis: Ets-1 and nuclear-factor-related-kB (NFRKB) gene. Deletion of these genes appears to cause insufficiency for normal hematopoietic differentiation or development and result in thrombocytopenia or pancytopenia.

**De novo chromosomal abnormalities in prenatal diagnosis.** *S.Y. Park<sup>1</sup>, Y.M. Kim<sup>1</sup>, J.M. Kim<sup>1</sup>, J.W. Kim<sup>1</sup>, B.Y. Lee<sup>1</sup>, M.Y. Kim<sup>2</sup>, J.Y. Han<sup>2</sup>, H.M. Ryu<sup>2</sup>.* 1) Lab Medical Genetics, Samsung Cheil Hosp, Seoul, Republic of Korea; 2) Department of Obstetrics and Gynecology, Samsung Cheil Hospital & Women's Healthcare Center, School of Medicine, Sungkyunkwan University, Seoul, Korea.

We report 17 cases of de novo chromosomal abnormalities detected in 4709 cases of prenatal cytogenetic analysis which had been performed in Samsung Cheil Hospital from 1995 and 1999. Of the 17 cases, 5 were balanced reciprocal translocations and 12 were unbalanced translocations characterized as deletion, addition or marker. The indications for karyotyping of present cases were based on ultrasound abnormal findings (8), high risk of Down syndrome at prenatal screening test (4), and advanced maternal age (5). As a result, we observed unbalanced translocation such as partial chromosomal deletion or addition in 7 cases of ultrasound abnormal findings. Also, one case of translocated Down syndrome and two cases of mosaicism with marker detected in suspected cases for Down syndrome on prenatal screening test. Additionally, in cases indicated by advanced maternal age, 3 were balanced translocations and 2 were unbalanced translocation of chromosome 18 located in short arm and long arm, respectively. Although de novo chromosomal translocation is balanced, it could result in phenotypic abnormalities due to cryptic deletion and duplication or malfunction of gene near the region of breakpoint. We found 2 cases of balanced translocation in ultrasound abnormalities. Taken all together, it became important that the precise diagnosis and adequate genetic counselling is necessary for de novo chromosome abnormalities in cytogenetic analyses prenatally. Thus, we aim to elucidate more accurate characteristic of de novo chromosomal abnormalities using FISH, CGH, and high-resolution banding / reverse banding.

**Microscopic and submicroscopic deletion 22q13.3 found in patients referred for Angelman syndrome.** *P. Van Tuinen<sup>1</sup>, M. Lubinsky<sup>1,2</sup>, C. Brooks<sup>1</sup>, M. Emery<sup>1</sup>, J. Grignon<sup>1</sup>, P. Miller<sup>1</sup>, P. Schalk<sup>1</sup>, H. Radtke<sup>2</sup>.* 1) Pathology, Clinical Cytogen Lab, Medical Col Wisconsin, Milwaukee, WI; 2) Children's Hospital of Wisconsin, Milwaukee, WI.

Features observed in Angelman syndrome (AS) (lack of expressive speech, developmental delay) are commonly found in patients with deletion 22q13. There appears to be significant overlap in the major features of these syndromes, with the apparent result being frequent requests for diagnostic studies for the more widely known AS. Precht et al. (*J. Med. Genet.* 35: 939; 1998) serendipitously found a 22q13 deletion in a patient whose AS studies were negative. Using FISH, this deletion was evident by the absence of a signal for distal 22q13 normally generated by a control probe for velocardiofacial/diGeorge syndrome (VCF/DGS). The authors suggested that 22q13 deletion be considered in patients exhibiting these features, and that a subset of patients suspected of having AS may have deletion 22q13. Following our finding of a visible deletion 22q13 in a patient referred for AS, we began performing simultaneous FISH using an artificial mixture of AS probe (D15S10 and control probe PML) and VCF/DGS probe (TUPLE1 and control probe ARSA). In the last 9 months of operation, 13 patients have been referred to our lab for AS testing. Of these, two had deletion 15q12 with D15S10; the rest were negative by further methylation testing. One patient had a visible deletion 22q13.31, while another with normal high resolution cytogenetic as well as D15S10 studies was deleted for ARSA. A third patient referred only for suspicion of "chromosome abnormality" had add(22)(q13.3). While parental specimens were not forthcoming, loss of material from 22q13 was presumed based on translocation of unknown foreign material to this region. The small sample size notwithstanding, our experience in detecting microscopic and submicroscopic deletion 22q13.3 in patients referred for Angelman syndrome affirms the study of Precht et al., and argues for a multiplex FISH approach in working up patients referred for AS.

**Sperm aneuploidy and semen quality in a non-clinical cohort of healthy non-smoking men.** *E. Slotter*<sup>1,2</sup>, *B. Eskenazi*<sup>3</sup>, *X. Lowe*<sup>1</sup>, *K. Kim*<sup>1</sup>, *F. Hill*<sup>1</sup>, *S. Kidd*<sup>3</sup>, *J. Nath*<sup>2</sup>, *D. Moore, II*<sup>4</sup>, *A.J. Wyrobek*<sup>1</sup>. 1) Bio Biotech Res Prog, Lawrence Livermore National Laboratory, Livermore, CA; 2) Genet Dev Biol Prog, West Virginia Univ, Morgantown, WV; 3) School Public Health Univ California, Berkeley, CA; 4) Pacific Medical Center, San Francisco, CA.

Although previous studies have shown associations between sperm aneuploidy and semen quality among infertile men, there is little information for men with no reproductive health problems. The objective of this research was to investigate the relationship between semen quality and sperm aneuploidy in a large non-clinical cohort of healthy men: 90 non-smokers, aged 20-80y, with no history of infertility or reproductive problems. Semen quality was evaluated using double-blinded analyses of semen volume, sperm concentration, % motility, % progressive sperm averaging 2.9mL (range: 0.3-7.5),  $147 \times 10^6$  sperm/mL (range: 13-575), 40% (range: 6-83), 22% (range: 0-68), respectively. The frequencies of aneuploid sperm were determined using multicolor FISH with probes for chromosomes X, Y and 21 (a total of 961,097 sperm were evaluated). The mean frequency of total disomic sperm (i.e., sum of X-Y, Y-Y, X-X, and 21-21) was 31.0 per  $10^4$  (range: 7-106), and the frequency of diploid sperm was 13.1 per  $10^4$  (range: 1-85). Frequencies of total disomic and diploid sperm were correlated among specimens ( $r=0.44$ ,  $p<0.0001$ ). However, there was little overall evidence for any associations between sperm aneuploidy and the parameters of semen quality measured in this study. Specifically, there were no significant correlations between semen volume or sperm concentrations versus total disomic or diploid sperm. However, we observed a positive association between disomy 21 and sperm motility ( $r=0.29$ ,  $p<0.005$ ). Thus, this study, the largest to date, has found no evidence for an association between poor semen quality and increased frequencies of genetic damage in sperm in a non-clinical population. [Work performed under the auspices of the US DOE by LLNL, contract W-7405-ENG-48, and funding from NIEHS Superfund P4ZES04705 and WVU].

**Spectral karyotyping (SKY™) for identification of supernumerary marker chromosomes in constitutional prenatal and postnatal studies.** *B.J. White, V. Sulcova, A. Anguiano, K. Hoang, S. Wang, K.S. Reddy.* Dept Cytogenetics, Quest Diagnostics, Inc, S J Capistrano, CA.

In many cases with supernumerary marker chromosomes, it is impractical to apply FISH probes specific for each individual chromosome to determine marker origin. The application of multicolor spectral karyotyping (SKY) permits identification of markers found in prenatal and postnatal studies. SKY paint probes (Applied Spectral Imaging, Carlsbad CA) were used in conjunction with the SKY Vision Cytogenetic Workstation for analysis of a minimum of 5 metaphases from 20 such cases. All markers identified by SKY were confirmed by traditional FISH methods such as chromosome painting and centromeric probing. Of the 20 completed studies, 9 were prenatal and 11 postnatal. The postnatal cases ranged in age from newborn to 58 years. Markers originating from acrocentric chromosomes are underrepresented in this series because satellited markers were generally identified by conventional FISH studies. Identification of those included in this study was accomplished in 16 of 20 cases (80%), and in 4 cases origin could not be determined. Marker derivation included chromosomes 4, 9, 15, 17, 19 (1 case each), 1, 2, 8, 22 (2 cases each) and 18 (3 cases). In a previous communication, we suggested that the practical resolution limit of SKY is approximately one band visible at 500 bands per haploid karyotype. It is likely that the small markers which could not be characterized by SKY had one band or less, or no euchromatin material. It is possible that centromeric material adjacent to a minimum amount of euchromatin may yield equivocal signals precluding positive identification. Identification of markers by SKY will build useful information for clinical correlations. Further documentation of findings associated with the various markers will improve genetic counseling in these clinical situations.

**Identification of an unusual i(Y)q chromosome with no detectable DYZ3 centromeric sequence.** *J.G. Assumpcao<sup>1</sup>, N.L.V. Campos<sup>2</sup>, M.I. Melaragno<sup>3</sup>, A.T. Maciel-Guerra<sup>2</sup>, M.P. De Mello<sup>1</sup>.* 1) CBMEG, Univ. Estadual de Campinas, Campinas, São Paulo, Brasil; 2) Dept. Genética Médica, FCM, Univ. Estadual de Campinas, Campinas, São Paulo, Brasil; 3) Disciplina de Genética, Dept. de Morfologia, UNIFESP/EPM, São Paulo, Brasil.

An 18 year old female was ascertained because of primary amenorrhea and hypogonadism. Chromosome analysis from peripheral blood lymphocytes revealed a non-mosaic 46,X,+mar constitution. G and Q banding patterns indicated that the marker could be an i(Yq), however there was no detectable primary constriction. C banding revealed bright bands on both extremities, which could be due to the presence of the distal heterochromatic portion normally present in Yq. Molecular studies proved the Y-origin of the marker. Deletion mapping analysis with Y-specific STS showed that the marker lacked Yp and centromeric (DYZ3) sequences, whereas all STS tested for Yq presented positive PCR amplification. FISH experiments with X and Y centromeric probes showed no hybridization signals. The marker i(Yq) chromosome is found in 100% of the cells, therefore it is mitotically stable despite the absence of both DYZ3 centromeric sequence and a visible primary constriction. The type of chromosome we report here seems to have adopted a new centromere and it raises the question of what DNA sequences act as a functional centromere in the absence of alpha-satellite DNA.

**Response to growth hormone therapy in a patient with a 15q deletion and normal levels of endogenous growth hormone: a challenge to conventional wisdom.** *T. Marini, J. Sullivan, R. Naeem, E. Reiter.* Departments of Pathology and Pediatrics, Baystate Medical Ctr, Springfield, MA.

We report on an 11 year old girl originally referred for short stature at age 3 years. She presented as an extremely small child (-5.0 SDS) in whom no obvious endocrinologic diagnosis was made. Previous cytogenetic studies identified a de novo 15q deletion, 46,XX,?15qter. Parental karyotypes were reportedly normal. Subsequent cytogenetics and fluorescent in situ hybridization (FISH) studies confirmed the previously identified deletion at locus D15S396 on one chromosome 15q. Further FISH studies using a +15 coatasome (total chromosome paint) revealed no evidence of any cryptic translocation. A revised karyotype of 46,XX,del (15) (q26.2) .ish del (15) (q26.2) (D15S396-),wcp15+ was reported. Previous cases of ring chromosome 15 and 15q terminal deletions, presenting with growth failure, have suggested that the growth failure is related to loss of one insulin-like growth factor I receptor (IGF1R) gene located at band 15q26. The mechanism for this relationship, however, is unclear, as these patients reportedly produce adequate amounts of growth hormone and presumably still have one intact and functioning IGF1R gene. Previously, growth hormone therapy has not been a consideration for these patients given their normal levels of endogenous growth hormone. Despite normal endogenous levels of growth hormone, our patient was treated with growth hormone therapy for the past 7.5 years because of her extreme short stature. Against the expectations of conventional wisdom, she has shown a good response to exogenous growth hormone rising in height to about -2.5 SDS. The reason for this response is puzzling and may be the result of some epigenetic effect on the IGF1R gene or perhaps some synergistic effects involving other non-IGF genes related to growth. Regardless, our results suggest that similar cases of 15q anomalies, as well as patients with idiopathic growth failure, may benefit from treatment regimens previously reserved only for patients demonstrating low levels of endogenous growth hormone.

**Centromeric heterochromatin packaging and centromeric protein binding.** *Y.C. Li<sup>1</sup>, C. Lee<sup>2</sup>, S.Y. Li<sup>1</sup>, C.C. Lin<sup>1,3</sup>.*  
1) Dept Life Sci, Chung Shan Medical/Dental Col, Taichung, Taiwan; 2) Dept. Obstetrics and Gynecology, Brigham and Womens Hospital, Harvard Medical School, Boston; 3) Dept. Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada.

The ubiquitous presence and specific chromosomal localization of satellite DNA in diverse mammalian genomes imply that satellite DNA may play a role in centromere structure and function. Although in rare occasions, certain mitotically stable marker chromosomes which appeared to be lacking of satellite DNA still retain centromeric function through some type of epigenetic effect. It is postulated that such an epigenetic effect has indeed achieved some degree of proper chromatin packaging and higher order structure which are needed for kinetochore reassembling during mitosis.

The water deer (*Hydropotes inermis*) has two types of centromeric heterochromatin which can be resolved by FISH analysis using cervid satellite I and satellite II DNAs as probes on either chromosome or resting nuclear preparations. The large cluster of hybridization signal in the centromeric and pericentromeric region produced by satellite I DNA probe appeared as a group of fluorescent sparks. This unique hybridization signal pattern also observed in resting nuclei. These findings suggested that the satellite I DNA chromatin is loosely packed with chromatin fiber extended out over a large area. Whereas, the hybridization signal with satellite II DNA appeared as pairs of distinct fluorescent spots located at the primary constrictions. These pairs of satellite DNA II signals also colocalized with the immunofluorescent signals produced by the human CREST anti-sera. These observations suggested that satellite II chromatin is more densely packed in an orderly manner. Such a way of chromatin packing may be a prerequisite for CENP binding, kinetochore reassembling, and the function of mammalian centromeres.

**Nuclear Matrix Attachment Sequence is not Sufficient for in vivo Chromatin Loop Formation.** *H.H. Heng, S. Bremer, G. Liu, W. Lu, J. Ye, S. Krawetz.* Center for Molecular Medicine & Genetics, Wayne State University, Detroit, MI.

Eukaryotic chromatin is thought to be organized as independent loops that can be visualized as a DNA halo. To form a loop domain, a certain proportion of chromatin must function as an anchor. Sequences associated with the nuclear matrix attachment region (MAR or SAR) have been proposed as providing this anchor function. To test this hypothesis, we established an experimental system of creating the in vivo condition of loop formation with defined MAR (SAR) sequences. By introducing known MAR fragments into mouse and human genomes by utilizing transgenic mice and cell transfection essays, we examined the inserted MAR sequence to determine if it is acting as an "anchor" sequence and if it is responsible for novel loop formation for both meiotic and mitotic loops. Our results of in situ loop digestion with DNase I as well as FISH detection on meiotic loops and mitotic halo clearly document that a percentage of integrated defined MAR sequences are tightly associated with the nuclear matrix of the host cell, serving as anchors for newly formed loops. This demonstrates the necessity of MAR for loop formation. However a large portion of these integrated MAR are detected as not associating with the nuclear matrix and therefore not serving as anchors. This demonstrates that not all MAR are used for anchoring loops, therefore MAR is not sufficient for in vivo chromatin loop formation. Clearly there is a regulation system of loop formation within cells to decide which MAR will be used as an anchor. Interestingly, we detected loop movement along the nuclear matrix. For the sequences tested, the attachment sites on the nuclear matrix were not fixed. This observation is not consistent with the model of fixed anchor sequences suggesting that anchor sites may switch between themselves. Further, if a new anchor is formed with non-MAR sequences, it is possible that other types of sequences can serve as anchors for loop formation as well. This dynamic anchor feature that we have discovered may be related to a novel regulatory transcription mechanism. In this paper, the detailed methodology and the novel features of chromatin loop domain are discussed.

**A novel method for cloning and mapping of unusual sequences located in the human centromeric regions.** *R. Sasi.*  
Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

Most eukaryotic centromeres are composed of a strikingly complex array of varying types of tandemly repeating DNA elements. Normal human centromeres are enriched with alpha satellite DNAs, but the recently discovered human neocentromeres revealed that alphoid DNA is not a prerequisite for the centromeric activity. Sequencing of DNA from the Arabidopsis centromeres and human chromosome 21 centromeric regions indicated surprisingly the presence of varying classes of DNA elements that included expressed genes, pseudogenes and transposon like DNA sequences. Thus identifying those regions of human genome enriched with alpha satellites may not alone pinpoint regions that impart centromeric function. The traditional cloning and mapping strategies often failed to isolate all centromeric DNA sequences. In this report, we describe an efficient and new method for isolating those missed centromeric DNA elements. Flow-sorted human chromosome specific cosmid libraries were plated on agar plates and single colonies were picked up, inoculated individually in 96 well microtiter plates. Colonies were duplicated on to nylon membranes using 96 well replicators. These replicated membranes were hybridized at varying hybridization stringencies with human Cot-1 DNA, placental DNA and alpha satellites. Evaluation of the autoradiographic signal intensities enabled us to classify cosmids into three subgroups as strong, medium and weak intensities. FISH was performed to identify chromosomal locations of these cosmids. A substantial number of medium/weakly hybridizing cosmids were localized to the centromeric/pericentric regions of human chromosomes X, 8 and 17 (~34). Characterization of few of these centromeric cosmids by Southern hybridization, subcloning and sequencing confirmed the absence of alphoid sequences. Gamma satellite centromeric DNAs from chromosome X and 8 were successfully isolated using this approach. This method is useful for the systematic isolation of DNA sequences present in the human centromeric/pericentric regions. This newly isolated centromeric DNA may play a role in forming altered conformation that perhaps nucleate or stabilize normal centromeric structure.

**A complex derivative chromosome 8 with an inverted duplication of 8p21.3@p23.3 and a rearranged duplication of 8q24.13@qter characterized by FISH.** *Y.S. Fan<sup>1,2</sup>, V.M. Siu<sup>2</sup>*. 1) Cytogenetics Lab, London Health Sciences Ctr, London, ON., Canada; 2) Department of Pediatrics, London Health Sciences Ctr and University of Western Ontario, London, ON., Canada.

We observed a complex derivative chromosome 8 in a newborn boy who had a low birth weight, multiple congenital anomalies and dysmorphic facies. The der(8) was further characterized at age 18 months by a high resolution G-banding analysis, spectral karyotyping, and FISH with multiple DNA probes. The karyotype was described to be: 46,XY,der(8)(qter@p23.3::p23.3@p21.3::q24.13@qter), representing an inverted duplication of region 8p21.3@p23.3 and a duplication of region 8q24.13@qter which was rearranged into the short arm. This young child has manifested a broad nasal bridge, micrognathia, cleft lip, hydrocephalus, partial corpus callosum agenesis, Dandy Walker malformation, congenital heart defects, dysplastic kidneys, hydronephrosis, marked hypotonia and significant psychomotor retardation. Some of these features are commonly seen in cases with an inv dup(8p) and in cases with a partial trisomy of 8q. It is known that a deletion in the terminal region of 8p was present in all the cases with an inv dup(8p) examined. In our case, however, such a deletion was not detected. Given that the duplication of region 8p22@p23.3 is not or less clinically significant, we have assumed that the phenotypic anomalies of this case was mainly the effects of trisomy 8q24.1@qter and trisomy 8p21.3@p22 which has been commonly involved in all the cases with an inv dup(8p).

**Partial trisomy 18q due to a maternal insertion (2;18).** *L. Campora*<sup>1</sup>, *G. Zelaya*<sup>2</sup>, *D. Montanari*<sup>2</sup>, *J. Scheifer*<sup>2</sup>, *C. Barreiro*<sup>2</sup>, *M. Gallego*<sup>2</sup>. 1) Clinical Genetics, CENAGEM, Capital Federal, Buenos Aires, Argentina; 2) Clinical Genetics, Hospital Garrahan, Capital Federal, Buenos Aires, Argentina.

Insertional or interstitial translocations are relatively rare chromosome aberrations (1/5000). They result from three chromosome breaks, the first two release an interstitial segment of chromosome which is then inserted into the gap created by the third break, without reciprocal exchange. We report a one year old girl, the only daughter of a healthy and non-consanguineous couple. The maternal obstetric history included a spontaneous abortion of first trimester. Pregnancy and delivery had been uneventful. No neonatal complications occurred. The girl had severe mental retardation, hypotonia and seizures without visual following and poor response at sounds. Physical examination demonstrated enlarged forehead, epicanthal folds, strabismus, low nasal bridge, small nose with bulbous tip, high arched palate, malformed ears, brachydactyly, mild interdigital webbing, hyperextensible joints, congenital heart disease and pale ocular fundus. Brain MRI showed slight cortical atrophy; EEG, occipital spikes, BAEP and VEP, increase of latency and echocardiogram, ventricular septal defect. Chromosome analysis of the proband revealed 46,XX,der(2)ins(2;18)(p23;q21.3 q11.2)mat. FISH using two colors painting probes for chromosomes 2 and 18 confirmed the G-banded interpretation. The father's karyotype was normal, and the mother was carrier of a translocation between chromosomes 2 and 18: 46,XX,ins(2;18)(p23;q21.3 q11.2). Trisomy 18q due to insertional translocations are rare and the present case is the third described. Two regions must work in conjunction, the proximal one (18q12.1 q21.2) and the distal one (18q22.3 qter), to produce the classical phenotype of trisomy 18. In addition, the duplication of 18q12.3 q22.1 may be associated with more severe mental retardation. The clinical findings in our patient support this conclusions.

**FISH analysis of three cases of functional monosomy 10q26.3.** *J.M. Gastier<sup>1,2</sup>, B. Hamelberg<sup>1</sup>, J. Labanowska<sup>1</sup>, G.E. Herman<sup>3</sup>, D.W. Bartholomew<sup>1,3</sup>, G.D. Wenger<sup>1,2</sup>.* 1) Dept of Laboratory Med, Children's Hosp, Columbus; 2) Dept of Path, Ohio State Univ; 3) Children's Research Inst, Dept of Peds, Ohio State Univ.

Fewer than 30 cases of monosomy for distal 10q have been reported, and a consistent phenotype has not been described. We report the clinical findings in three new cases and describe FISH analysis used to confirm the karyotypes. Two of the cases have a terminal deletion [del(10)(q26.3)], while the other has translocation [t(X;10)(p22.3;q26.3)]. Chromosome 10 subtelomeric and chromosome Xp locus-specific FISH probes were utilized to characterize the breakpoints of the rearrangements. Case one is a five month old with failure to thrive, hypotonia, feeding intolerance, joint laxity, a prominent forehead, posteriorly rotated ears, but little facial dysmorphism. Cytogenetic analysis including FISH with chromosome 10 subtelomeric probes suggested the following karyotype: 46,XY,del(10)(q26.3).ish del(10)(q26.3)(tel 10p+,tel 10q-)de novo. Case two is a two year old referred for developmental delay, behavior problems, prominent ears and jaw, widow's peak, and no speech. Cytogenetic analysis revealed the karyotype 47,XYY,del(10)(q26.3).ish del(10)(q26.3)(tel 10q-). Case number 3 is a 16 month old female with developmental delay, occipital hair whorl, early hypotonia, no speech, staring episodes, sacral dimple, but little facial dysmorphism. Cytogenetic analysis suggested an abnormal 10q terminus. FISH analysis using chromosome 10 subtelomeric probes and probes for KAL and STS on Xp confirmed a translocation with the Xp breakpoint between STS and KAL [46,X,t(X;10)(p22.3;q26.3).ish t(X;10)(STS-,tel 10q+,KAL+;tel 10p+,tel 10q-,STS+,KAL-)de novo]. X inactivation studies revealed a random pattern in the patient's peripheral blood, suggesting that the phenotype may be due to inactivation of 10q26.3 sequences translocated to Xp. These cases contribute to the clinical characterization of a subtle cytogenetic abnormality in an attempt to better define a common phenotype. As subtelomeric FISH probes gain wider use, monosomy for chromosome 10q26.3 and small terminal deletions of other chromosomes may be observed more frequently, allowing for the report and definition of common clinical findings.

**De novo 46,XY/47,XY,r(12) karyotype in a male with dysmorphia and psychomotor retardation. Review of the literature.** V. Charpenel<sup>1</sup>, A. Ion<sup>2,1</sup>, L. Telvi<sup>1</sup>. 1) Cytogenetique Constitutionnelle et Moleculaire, St Vincent De Paul Hospital, Paris, France; 2) Medical Genetics, St George's Hospital Medical School, London, UK.

We describe a male patient harbouring a de novo 46,XY/47,XY,+r(12) chromosome complement. The child presented with psychomotor retardation and dysmorphic face. Initially, standard karyotype analysis using R and G banding techniques showed the presence of a supernumerary marker chromosome in about 30% of the examined metaphases. This marker could not be identified by routine cytogenetic techniques, including high resolution and FISH using total painting probes for the most frequent chromosomes involved in the living new born trisomies (21, 18, 8 and X). However, a MULTIFISH analysis demonstrated the presence of three signals specific for the chromosome 12, suggesting that the marker was a ring r(12). Karyotype performed from peripheral blood in both parents showed a normal chromosome complement. At present, the frequency of supernumerary marker chromosomes has been found to be around 1/2500 in amniocenteses samples (Warburton, 1991) and mosaicism in association with a normal 46,XX or 46,XY cell line has been reported in about 70 % of the investigated cases. The present report emphasises the importance of updated cytogenetic and molecular techniques in identifying the origin of marker chromosomes. At present, only a few cases with supernumerary r(12) have been reported. They all had de novo mosaicisms, associated with important developmental delay and severe mental retardation. A review of to date published supernumerary r(12) reports is presented, as well as a phenotype/genotype correlation.

**Deletion of candidate genes for AZF in an azoospermic man: confirmation by PRINS.** *J.S. Kadandale<sup>1</sup>, S.S. Wachtel<sup>2</sup>, P.R. Martens<sup>1</sup>, Y. Tunca<sup>1</sup>, R.S. Wilroy<sup>1</sup>, A.T. Tharapel<sup>1</sup>.* 1) Pediatrics, Univ Tennessee, Memphis, TN; 2) Ob-Gyn, Univ Tennessee, Memphis TN.

Among male patients evaluated for infertility, some 20% are affected with azoospermia or oligospermia. Cytogenetic investigations and molecular deletion analyses in these individuals have revealed that genes controlling spermatogenesis are located in the AZF (azoospermia factor) region at interval 6 of the Y chromosome, corresponding to sub-bands Yq11.22-q11.23. Microdeletions have been observed within the AZF region in some of these patients. Using a dual approach involving PRINS (primed in situ labeling) and conventional FISH, we studied a 27-year-old man referred for evaluation of azoospermia. Initial analysis of cultured blood lymphocytes revealed a 45,X/46,X,+mar karyotype, but QFQ-banding failed to identify a fluorescent area on the marker chromosome. On analysis with FISH, the marker was found reactive with probes AMELY and DYZ3, confirming that it was Y-derived. Subsequent FISH with dual color whole chromosome paint probes for X and Y chromosomes showed an Xp-Yp interchange. By PRINS, we then identified translocation of the SRY gene from its original location on Yp, to Xp, thus confirming the derivative nature of the X chromosome. PRINS studies with primers for RBM and DAZ, the two candidate genes for AZF, confirmed deletion of these genes in the patient but not in unaffected males. These observations resulted in a complex karyotype: 45,der(X),t(X;Y)(p22.3;p11.2)/46,der(X)t(X;Y)(p22.3;p11.2),prins der(X)(p22.3)(SRY+),del(Y)(q11.22q11.23)(RBM-,DAZ-). Loss of the der(Y) in about 8% of the cells during mitosis is a common characteristic of ring chromosomes. The formation of a ring in this instance could be due to the Xp-Yp interchange with subsequent deletion of the Y long arm, subsuming the AZF region. Detailed investigation of this patient, with PRINS, enabled us accurately to define the abnormality, and to postulate that azoospermia in this case had resulted from deletion of the RBM and DAZ genes. We conclude that PRINS is a useful method for the evaluation of male infertility, especially in cases of azoospermia.

**Directly Defining the Gene(s) for Genomic Disease: Use of the Sequence-Integrated BAC Resource to analyze a subtle deletion/inversion involving chromosome 8p22-23.3.** *Q-J. Liu<sup>1</sup>, X-N. Chen<sup>1</sup>, S. Gersen<sup>2</sup>, C. McKee<sup>2</sup>, M. Hummel<sup>3</sup>, S. Graham<sup>3</sup>, J.R. Korenberg<sup>1</sup>, G. Sun<sup>2</sup>.* 1) Medical Genetics Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA; 2) DIANON Systems, Inc. Stratford, CT; 3) Department of Pediatrics, West Virginia University, Morgantown, WV.

Cytogenetic aberrations of the distal short arm of chromosome 8 characterize a number of clinically defined disorders. However, neither the genotype/phenotype correlation nor the genomic structures that predispose to the defects are yet delineated.

We report the clinical & molecular analysis of a 23-year-old woman with mental retardation, seizures and scoliosis, all of which are common features reported in cases of 8p rearrangement. Cytogenetics and FISH studies with an 8p telomeric probe showed a deletion of the terminal and an inversion with a possible duplication involving 8p23. Parental chromosomes are normal. Using our Integrated BAC Resource (Korenberg *et al.* 1999), high-resolution multi-color FISH analysis was performed on metaphase and interphase cells. Ten BAC DNA probes mapping on 8p22 and 8p23 were tested including 5 BACs carrying unspecified locally repeated sequences. The results revealed: 1) B366 on 8p23.3 was deleted confirming routine cytogenetics; 2) B26G3 on 8p23.2 carrying repeated sequences detected a subtle partial deletion; 3) B1113 on 8p22 carrying repeated sequences was not only partially deleted but also involved in an inversion. No clear duplications were shown. The analysis of this case has gone beyond the simple genomic DNA sequence and demonstrates the ability to detect and study the subtle reorganization of the genomic material using the Integrated BAC Resource. By linking these results with gene, genetic and physical maps (STS, end sequence & fingerprint), we can move towards identification of genes that may be responsible for the phenotypes seen in this patient. In the current case, we have demonstrated that the phenotypes of mental retardation and scoliosis may be caused by haploinsufficiency rather than duplication of the gene(s).

**Clinical application of sequence-based single copy probes for FISH.** *J.H.M. Knoll<sup>1,2</sup>, P. Cazcarro<sup>1</sup>, P.K. Rogan<sup>1,2</sup>.*  
1) Section of Medical Genetics & Molecular Medicine, Children's Mercy Hospital, University of Missouri-Kansas City School of Medicine 64108; 2) Cytogenomix, Overland Park, KS 66213.

Commercial probes currently exist for the most common genomic rearrangements, however, these probes often do not permit analysis of rare breakpoints or less common aneuploidies. We have developed a technique that provides custom single copy probes for chromosome analysis (scFISH). scFISH relies on the availability of previously determined sequences in known disease intervals, and the ability to deduce the locations of single copy sequences in these intervals.

Typically, a genomic sequence of 100-300 kb was scanned to identify the precise locations of all repetitive sequence family members. The longest intervening single copy intervals were identified and amplified by long PCR. The purified amplicons were then labeled and hybridized by standard FISH procedures, except that suppression of repetitive DNA hybridization was unnecessary.

Specimens from patients with Prader-Willi, Angelman, duplication chromosome 15, DiGeorge and monosomy 1p36 syndromes were analyzed with probes developed adjacent to NDN (15q12), and from HIRA (22q11.2) and CDC2L1 (1p36.3) genomic sequences, respectively. The NDN probes consisted of three fragments, 4166 bp (70 kb downstream of NDN), 3544 bp (48 kb downstream) and 2290 bp (44 kb downstream) derived from GenBank accession AC006596. The HIRA probes were composed of 4 fragments, 5170 bp (IVS12 to IVS13), 3691 bp (IVS21 to IVS24), 3344 bp (IVS13 to IVS15) and 2848 bp (IVS2 to IVS4) from GenBank accession NT\_001039. The CDC2L1 probes comprised two fragments, 4823 bp (3' UTR) and 4724 bp (IVS11 to 3' UTR) from GenBank accession AL031282. These probes were used individually or in combination to detect sequences in either metaphase or interphase cells and to examine allele-specific replication. These probes detected the expected abnormality in each patient specimen analyzed. Detection of other contiguous gene syndromes and common translocations in hematopoietic malignancies will also be presented.

**Severity of developmental delay is associated with the proportion of cells with functional X disomy in female patients with mosaic for small ring X chromosomes.** *T. Kubota<sup>1</sup>, K. Wakui<sup>1</sup>, Y. Watanabe<sup>2</sup>, M. Yoshino<sup>2</sup>, N.*

*Okamoto<sup>3</sup>, T. Kida<sup>4</sup>, H. Ohashi<sup>5</sup>, Y. Fukushima<sup>1</sup>.* 1) Dept of Clinical and Molecular Genetics, Shinshu Univ School of Med, Matsumoto; 2) Dept of Pediatrics, Kurume Univ School of Med, Fukuoka; 3) Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka; 4) Div of Pediatrics, Hakodate Central Hospital, Hokkaido; 5) Div of Medical Genetics, Saitama Children's Med Ctr, Saitama, Japan.

Developmental delay (DD) not usually associated with Turner syndrome is seen in some females with mosaic for small ring X chromosomes [45,X/46,X,r(X)]. However, mechanisms of DD in these patients are not well understood. We have performed quantitative HUMARA X-inactivation assay by methylation-specific PCR using an automated sequencer. Of the 4 female patients analyzed, two patients with severe DD [46,X,r(X) lines are 73%, 87%, respectively] showed both maternal and paternal unmethylated (U) alleles derived from the active X and did not show methylated (M) alleles derived from the inactive X, suggesting that both normal X [nl(X)] and r(X) are active in all 46,X,r(X) cells (complete functional X disomy: CFXD). One patient with moderate DD showed both maternal and paternal U-alleles and one maternal M-allele, suggesting that both nl(X) and r(X) are active in some proportion of cells (~40%). The remaining patient with mild DD showed an U-allele and a M-allele (different allele size), suggesting that a nl(X) is active and an r(X) is inactive in all cells. These results suggest that the severity of DD may be associated with the proportion of cells with the functional X disomy in female patients with a small r(X). XIST locus on an r(X) was positive in three patients by FISH, but was negative in one patient with severe DD, in whom CFXD is likely to be caused by lack of the XIST locus. However, the remaining patient with severe DD preserved the XIST locus on an r(X), and did not show uniparental X disomy, suggesting no somatic duplication of an X chromosome. Therefore, CFXD in this patient may be caused by either defect of the XIST gene function or impairment of the putative X-chromosome counting process which both nl(X) and r(X) are counted to be active.

**The predictive value of FISH analyses for possible occurrence of Wilms tumor in aniridia patients with/without chromosome abnormalities around 11p13.** *R. Muto*<sup>1,3</sup>, *S. Yamamori*<sup>2</sup>, *M. Osawa*<sup>1</sup>, *H. Ohashi*<sup>3</sup>. 1) Department of Pediatrics, Tokyo Womens Med. Univ., Shinjuku-ku, Tokyo Japan; 2) Research department Mitsubishi Kagaku Bio-Clinical Laboratories, Inc. Tokyo Japan; 3) Division of Medical Genetics, Saitama Children's Medical Center, Saitama Japan.

Aniridia is an autosomal dominant condition caused by haploinsufficiency of the PAX6 gene at 11p13. The abnormalities of the PAX6 gene include mutations in the gene, position effect and gross deletions (cytogenetically visible or non-visible) around the gene. When gross deletions involve adjacent genes including WT1 (about 750 kb from PAX6), patients are predisposed to develop Wilms tumor and associated abnormalities (WAGR syndrome). We studied 17 patients with aniridia (10 are chromosomally normal and 7 abnormal) for possible deletion around 11p13 by FISH with four probes: PAX6, D11S2163, PER and WT1. Eight patients had gross deletions spanning the entire four loci, among whom 5 developed Wilms tumor, while none of the other 9 patients without detectable deletion have developed Wilms tumor. Four papers have been previously published to study microdeletions in the 11p13 region by means of molecular methods in aniridia patients. Out of a total of 101 patients in these five reports including this report, 29 patients had a deletion spanning from PAX6 to WT1 loci, of whom 14 developed Wilms tumor (48.3%). None of the other patients without deletion developed Wilms tumor. Risk assessment of Wilms tumor occurrence in aniridia patients by fine evaluation around the 11p13 region using FISH would be reliable and practical.

**Two cases of 46,XX SRY positive males: Unexpected results on molecular analysis of Y sequences with a molecular deletion detection screening panel.** *E. Mak-Tam, D.J. Allingham-Hawkins, A. Angelo, G. Rasiuk, J. Tzountzouris, P.R. Wyatt.* Genetics, North York General Hosp, Toronto, Ontario, Canada.

46,XX males occur with a frequency of about 1/20,000 births. The phenotype is heterogeneous ranging from normal male to genital ambiguity, but all have testicular development and are infertile. This variation is largely due to the genetic heterogeneity among the XX males. They can be classed as SRY, (sex determining region Y) positive, negative or true hermaphrodite. About 80% of XX males are positive for the SRY gene, which has been mapped to Yp11.3. The most common mechanism for XX male (and XY female) formation involves an aberrant X-Y exchange during paternal meiosis. Two cases were referred for infertility and hypogonadism respectively. The derivative X was not detected with routine G-Banding (500 band level), but FISH identified the presence of SRY in both cases. Molecular analysis using the Promega™ Y deletion detection screening panel for 18 sequence tag sites (STS) covering the four AZF regions was used to determine the extent of the translocated Y sequences. Analysis of case 1 not only showed positive for the SRY and ZFY (zinc finger protein, Y-linked) loci, but also an unexpected Yq locus AZFc (azoospermia factor c), distal to a deletion gap. This may indicate a more complex interchange or an inverted Y origin. The clinical, FISH and molecular data for the two cases will be presented. The increased availability of screening tools allows for more accurate delineation of rearrangements. In addition, clinical labs can provide more informative testing for referrals such as ambiguous genitalia.

**Chromosomal rearrangements identified by M-FISH, FISH and subtelomeric probes.** *C.B. Lozzio<sup>1</sup>, E.*

*Bamberger<sup>1</sup>, T. Ryan<sup>1</sup>, E. Ralston<sup>1</sup>, E. Holland<sup>1</sup>, W. Carter<sup>1</sup>, W. Russell<sup>2</sup>, I. Anderson<sup>1</sup>.* 1) Develop & Genetic Ctr, Med Ctr, Univ Tennessee, Knoxville, TN; 2) Vanderbilt University Medical Center, Division of Pediatric Endocrinology, Nashville, TN.

Two cases with marker chromosomes identified by M-FISH and one case with a subtelomeric deletion of the long arm of chromosome 2 are reported. M-FISH studies were performed using the Multicolor Spectra Vysion Assay from Vysis and the Applied Imaging Cytovision version 4.1 for UNIX with software for M-FISH. The subtelomeric deletion was detected with the Chromoprobe Multiprobe-T system from Cytocell. A mosaic for a small marker chromosome was found to be derived from chromosome 5 by M-FISH and this was confirmed by FISH studies with whole chromosome and centromeric probes for this chromosome. The child is a 2 years old non-dysmorphic male with developmental delay, tall stature and microcephaly. The finding that the extra marker is derived from chromosome 5 indicates that he has partial trisomy for the pericentric region of this chromosome. Another mosaic for a small marker was observed in a 14 years old female with short stature, menarche at 10 years and precocious adrenarche. She has a pericentric inversion of one of the X chromosomes and FISH studies showed that the X inactivation region XIST(Xq13) has moved to the short arm in the inverted X chromosome. The M-FISH studies revealed that the small extra marker is derived from chromosome 7 and FISH studies confirmed that this marker contains the centromere of chromosome 7. Thus, this child has partial trisomy for the pericentric region of chromosome 7. A cryptic subtelomeric deletion of the long arm of chromosome 2 was detected by the Multiprobe-T from Cytocell in a premature infant with multiple dysmorphic features, pulmonary hypoplasia and maternal history of polyhydramnios. Metaphase chromosomes in the amniotic cells cultures and in cultures of blood were normal at a 450 band level. These cases are examples of clinical applications of new molecular cytogenetic techniques that allow the identification and characterization of chromosomal rearrangements of clinical significance.

**Rx FISH in conjunction with G banding: One step solution to resolve complex de novo marker chromosomes and intrachromosomal rearrangements.** *S.P Naber, M. Karamove, C. Phillips, A. Nasir, R. Naeem.* Department of Pathology, Baystate Medical Center, Tufts University School of Medicine, Springfield MA.

In addition to SKY FISH and M FISH one of the recent advances in FISH technology is Rx FISH or multicolor multiband chromosome analysis. SKY and M FISH are reasonable approaches for identifying marker chromosomes but have limitations in identifying intrachromosomal changes such as inversions and insertions. In conjunction with G banded analysis, Rx FISH can be a useful tool to identify marker chromosomes and intrachromosomal rearrangements. We present two cases where we used G banding, routine FISH, and Rx FISH to identify a de novo complex chromosomal rearrangement and an intrachromosomal paracentric inversion insertion. The first case was a bone marrow sample from acute non-lymphoblastic leukemia with multiple translocations and a derivative chromosome. G banded analysis not able to identify and confirm all the chromosome aberrations; therefore routine FISH and Rx FISH were applied to resolve these rearrangements. The final karyotype was 45,XX, t (8; 12)(q12; p13), -15,der (17) t (15; 17)(q23; q22). The second case was a familial chromosomal abnormality with multiple family members inheriting the same marker 17 chromosomes. In addition to G banding and routine FISH, Rx FISH was applied to resolve this paracentric inversion insertion. G banded chromosome analysis has limitations in resolving marker chromosomes. Rx FISH, in conjunction with routine cytogenetics, proved to be a simple one-step solution for resolving complex as well as intrachromosomal rearrangements.

**Sex identification from bloodstains of normal persons and sex reverse cases using FISH and PCR.** *S.M. Tayel*<sup>1</sup>, *S.J. Abulhasan*<sup>2</sup>. 1) Genetics Unit, Anatomy Dep., Alex - Faculty of Medicine , Alexandria , Al Azarita, Egypt; 2) Kuwait Medical Genetics Center - Maternity Hospital, Kuwait.

Sex identification of dry blood and decomposed tissues is of crucial importance both in clinical and forensic medicine. Sixty phenotypically normal males (36) and females (24), and 7 cases of sex reverse; 3 phenotypic females with Swyer syndrome and the 46, XY karyotype, and 4 phenotypic Klinefelter's-like males with the 46, XX karyotype were subjected to sex identification by FISH and PCR using bloodstains. Sex identification using X/Y cocktail probe (DXZ1 & DYZ1, Oncor) and FISH has correctly identified the male sex in 91.69% of the interphase nuclei of the 36 males of the study, and in 92.29% of the cells of the 24 females and incorrectly identified the 3 females with Swyer syndrome as males and the 4 Klinefelter's-like males as females. The 60 normal persons of the study was correctly typed to their phenotypic sex by the 2 PCR methods used i.e. the single PCR reaction using the amelogenin sequence specific for the X and Y chromosomes and the multiplex PCR using SRY gene (male-specific) and the AR gene (X-specific). Out of the 7 cases with sex reverse, one Klinefelter's-like male was incorrectly identified as female due to absence of amplification of the SRY gene and the amelogenin male-specific 788 bp fragment. The present study demonstrates that both FISH and PCR techniques are fast, easy to perform, reliable and efficient for sex identification but PCR is more accurate. It also stresses that the sex identified is the genotypic sex which does not necessarily corresponds to the phenotypic one and in cases of doubt, sex reverse has to be thought-off and ruled out using different X-and Y-specific probes and PCR.

**Clinical and molecular-cytogenetic studies in seven patients with ring chromosome 18.** P. Stankiewicz<sup>1</sup>, I. Brozek<sup>2</sup>, Z. Hélias-Rodzewicz<sup>1</sup>, J. Wierzba<sup>3</sup>, J. Pilch<sup>4</sup>, E. Bocian<sup>1</sup>, A. Balcerska<sup>3</sup>, A. Wozniak<sup>2</sup>, I. Kardas<sup>2</sup>, J. Wirth<sup>5</sup>, T. Mazurczak<sup>1</sup>, J. Limon<sup>2</sup>. 1) Department of Medical Genetic, Institute of Mother and Child, Warsaw, Poland; 2) Department of Biology and Genetics; 3) Department of Pediatrics, Medical University, Gdansk, Poland; 4) Department of Pediatric Neurology, Silesian School of Medicine, Katowice, Poland; 5) Roper's Department, Max-Planck-Institute for Molecular Genetics, Berlin, Germany.

We report the results of detailed clinical and molecular-cytogenetic studies in seven patients with ring chromosome 18. Classical cytogenetics and FISH analysis with chromosome 18 painting probes identified five non-mosaic and two complex mosaic 46,XX,dup(18)(p11.2)/47,XX,dup(18)(p11.2),+r(18) and 46,XX,dup(18)(p11.32)/47,XX,dup(18)(p11.32),+r(18) karyotypes. FISH analysis was performed for precise characterization of the chromosome eighteen breakpoints using chromosome 18 specific short arm paint, centromeric, subtelomeric and a panel of fifteen Alu- and DOP-PCR YAC probes. The breakpoints were assessed with an average resolution of ~2.2 Mb. In all r(18) chromosomes the 18q terminal deletions ranging from 18q21.2 to 18q22.3 (~35 and ~9 Mb, respectively) were found whereas only in four cases the loss of 18p material could be demonstrated. In two patients the dup(18) chromosomes were identified as inv dup(18)(qterp11.32::q21.3qter) and inv dup(18)(qterp11.32::p11.32p11.1::q21.3qter)pat, respectively, with no evidence of 18p deletion. A novel inter-intrachromatid mechanism of formation of duplications and ring chromosomes is proposed. Although the effect of ring instability syndrome cannot be excluded, the phenotypes of our patients with characteristic features of 18q- and 18p- syndromes are compared and correlated with the analyzed genotypes. It has been observed that a short neck with absence of cardiac anomalies may be related to the deletion of the 18p material from r(18) chromosome.

**FISH as an initial screen for aneuploidy in spontaneous abortion specimens.** *A.J. Sobrino<sup>1</sup>, J.K. Kline<sup>2,3</sup>, D. Warburton<sup>1,3</sup>.* 1) Genetics Laboratory, New York Presbyterian Hospital, New York, NY; 2) New York State Psychiatric Institute, New York, NY; 3) Columbia University, New York, NY.

Culture of specimens from spontaneous abortion specimens has inherent problems that can lead to failure to obtain the fetal karyotype: lack of growth of in culture, contamination of the culture by microorganisms or overgrowth of maternal cells from the specimen. Interphase FISH on enzyme-digested fetal tissues before culture is one method of avoiding these problems. While a complete aneuploidy scan is theoretically possible, we have opted for a multiplex system that allows detection of aneuploidy for chromosomes 13,15,16,18,21,22, X and Y. This will diagnose not only trisomy for these chromosomes, but also triploidy, monosomy X and tetraploidy. Together these comprise 80% of the chromosome abnormalities in spontaneous abortions, and about 40% of early losses. Only those specimens in which aneuploidy is not detected by FISH need to be continued in culture.

Comparison of the results of this approach in our laboratory to standard cultures indicates that it is not only rapid but cost effective, since it avoided culturing in 42% of cases. It also enabled a diagnosis of aneuploidy in several cases where the culture failed to grow, or where the karyotype would have been read as normal female because of maternal cell growth.

**Increased nondisjunction in sperm identified as 'normal' by strict morphology in infertile patients: Implication for ICSI (intracytoplasmic sperm injection).** *H.M. Ryu<sup>1,2</sup>, W.W. Lin<sup>3</sup>, D.L. Lamb<sup>3</sup>, W. Chuang<sup>3</sup>, L.I. Lipshultz<sup>3</sup>, F.Z. Bischoff<sup>2</sup>*. 1) Dept OB/GYN, Samsung Cheil Hos, Sungkyunkwan Univ, Seoul, Korea; 2) Dept OB/GYN, Baylor College of Medicine, Houston, TX; 3) Dept Urology, Baylor College of Medicine, Houston, TX.

As part of the ICSI procedure, normal sperm are selected on the basis of motility and morphology. Although the incidence of aneuploidy among sperm with abnormal morphology has been evaluated, little is known regarding the genetic integrity of normal appearing spermatozoa among patients identified as infertile based on abnormal strict morphology analysis. The objective of this study was to determine the incidence of nondisjunction in morphologically normal sperm of infertile men who are candidates for ICSI. Method: Semen smears from eight men undergoing ICSI with abnormal strict morphology (<4% by Kruger's criteria) were obtained. For controls, semen smears from normal fertile men (n=6) were studied. Following standard hematoxyline staining, sperm with normal morphology were identified using Kruger's strict morphology criteria. In each case, the locations of 100-150 morphologically normal appearing sperm were recorded using an electronic microlocator. Slides were subsequently subjected to FISH for detection of chromosomes X, Y, and 18. Nuclei were then relocated and analyzed under the fluorescent microscope. Ploidy of each cell was determined according to the number of signals detected for each chromosome-specific probe. Results: Among the infertile group, aneuploidy was observed in 1.8 - 5.5% of the morphologically normal sperm as compared to 0 - 2.6% among the fertile control group. Statistically significant differences ( $p=0.004$ ) in the incidence of chromosome aneuploidy was observed. Conclusion: These results may help explain why some pregnancies fail among ICSI patients. Moreover, the results demonstrate that normal morphology is not an absolute indicator for the selection of genetically normal sperm. Therefore, ICSI patients need to be counseled that although morphologically normal sperm are being selected, there is still some risk for having a genetically abnormal offspring.

**Cryptic translocation 10pter;18qter as a cause of two different microdeletions in the offspring.** *M.S. Somer<sup>1</sup>, P. Tienari<sup>2</sup>, M. Kähkönen<sup>3</sup>*. 1) Medical Genetics, Family Federation of Finland, Helsinki; 2) Department of Neurology, Helsinki University; 3) Department of Clinical Genetics, Tampere University Hospital, Tampere, Finland.

The terminal 18q deletion is characterized by mild to moderate mental retardation, hypotonia, delayed CNS myelination, low IgA levels, susceptibility to autoimmune disorders, and typical dysmorphic features. We report a three-generation family with 5 males and 4 females with different grades of psychomotor retardation. Three of them had rheumatoid arthritis, two IgA deficiency, and one diabetes mellitus. Prometaphase study with resolution of 850 bands showed no abnormality, although deletion of 18qter was specifically looked for. Brain MRI of two patients showed severely delayed myelination at ages 8 months and 4 years, respectively. Myelin basic protein (MBP) gene and its neighboring polymorphic markers were studied in one and shown to be deleted based on segregation analysis. Finally, a telomeric deletion of 18q was verified with TelVysion 18q telomere probe in five of the six patients available for study. In healthy carriers of the family, this probe was shown to hybridize to terminal 10p, whereas the TelVysion 10p telomere probe hybridized to terminal 18q. One affected family member with a distinctively different phenotype and normal brain myelination was shown to have the counterpart translocation product with deletion of the telomeric 10p and trisomy of telomeric 18q region. It is now often possible to verify a clinically suspected chromosomal disorder with FISH. Two different mental retardation syndrome phenotypes within one family may be explained by different unbalanced karyotypes derived by segregation of a parental cryptic translocation.

**Chromosome analysis on fetal tissues: A revised protocol employing interphase FISH improves the success rate.**

*S. Weremowicz*<sup>1,2</sup>, *D.J. Sandstrom*<sup>1</sup>, *A. Thomas*<sup>1</sup>, *M. McH. Sandstrom*<sup>1</sup>, *C.C. Morton*<sup>1,2</sup>. 1) Brigham and Women's Hospital; 2) Harvard Medical School, Boston, MA 02115.

Our laboratory receives many requests for cytogenetic studies of tissues from SABs, some of which are autolyzed, precluding traditional metaphase chromosome analysis. In 1996 we revised our solid tissue protocol to include preparation of cells for possible FISH analysis. Fresh cells are saved in 3:1 methanol:acetic acid following disaggregation in 1ug/ml collagenase Type1A (Sigma #C9891) and 75 mM KCl treatment. In addition FISH studies can be pursued using paraffin-embedded tissues in cases in which fresh fixed cells were not prepared. Using these methods, 74 cases were tested including 30 with no growth, 19 with incomplete cytogenetic analysis, and 25 paraffin-embedded tissue samples. DNA probes (LSI13, D15Z, D16Z3, D18Z1, LSI21, DXZ1, DYZ1 and SRY, Vysis, Inc., Downers Grove, IL) were selected based on ultrasound or autopsy findings, and in cases with incomplete karyotypic analyses according to the chromosome(s) in question. FISH results were obtained in 28/30 (93%) of the no growth cases. In 13/28 (46%) cases, aneuploidies were revealed including four cases of trisomy 18, four of monosomy X, two of trisomy 21, one triploid and one each of trisomies 13 and 16. In 2/30 (7%) cases with no FISH result severe maceration may be a factor. Among 19 cases with incomplete karyotypic analyses, suspected chromosome abnormalities were found in six, the origin of a marker chromosome was identified in one, and in another case, a female karyotype (46,XX) was found in skin cells from a fetus with ambiguous genitalia. In the remaining 11 cases, FISH revealed disomy for the chromosome(s) in question. FISH results were obtained in 23/25 (92%) cases of paraffin-embedded fetal tissue. In 10/23 (44%) cases, aneuploidies were detected including three cases of trisomy 21, two of trisomy 13, two with monosomy X, two triploids and one case of trisomy 16. No FISH result was obtained in 2/25 (8%) cases.

Our results indicate that interphase FISH is an important supplement to routine karyotypic analysis of SABs and can provide valuable information for genetic counseling.

**Breakpoint mapping of an apparently balanced 2;8 translocation reveals a cryptic deletion on 2q in a child with autism.** *I. Borg*<sup>1,2</sup>, *K. Stout*<sup>3</sup>, *D.R. Sargan*<sup>1</sup>, *D. Morgan*<sup>4</sup>, *L. Willatt*<sup>4</sup>, *V. Kalscheuer*<sup>3</sup>, *N. Tommerup*<sup>5</sup>, *H.H. Ropers*<sup>3</sup>, *M.A. Ferguson-Smith*<sup>1</sup>. 1) Department of Clinical Veterinary Medicine, University of Cambridge, Cambridge, UK; 2) Medical Genetics Department, Addenbrooke's NHS Trust, Cambridge, UK; 3) Max-Planck Institute for Molecular Genetics, Berlin, Germany; 4) Cytogenetics Lab, Addenbrooke's NHS Trust, Cambridge, UK; 5) Department of Medical Genetics, IMBG, Copenhagen, Denmark.

Autism is a neurodevelopmental disorder characterised by abnormalities in social, communicative and behavioural functioning. The aetiology and the evidence suggest that the risks are likely to involve non-genetic, as well as genetic factors; the latter have probably the most powerful influence. The occurrence of chromosome abnormalities has been reported in association with a clinical phenotype of autism. Two International Consortia conducting a genome-wide scan of autism reported 2q as one of the potential susceptible regions in the search for candidate genes for autism. We report on a de novo balanced translocation  $t(2;8)(q36; q21)$ , in a male child with delayed developmental milestones and marked impairment in communication and social interaction. Repetitive, stereotyped activities and behaviour, formed part of the clinical picture. Minor dysmorphic features included upward slanting palpebral fissures and prominent antihelices. Several molecular cytogenetic techniques were employed in the search for cryptic chromosome abnormalities. YAC clones in the region of the breakpoint were selected and used as FISH probes; one of these was found to be deleted on 2q. Further YAC FISH is in progress to delineate the extent of the sub-microscopic deletion. Likewise we expect to narrow the search for autism susceptibility in the region of interest on 2q. The results present a step towards identifying genes predisposing to autism.

**Double Aneuploidy:Down's syndrome associated with Klinefelter's syndrome.** *F.A. Ali, S.S. Al Arrayed, H. Sanad, A. Al Abbasi.* Genetic department, Salmaniya Medical Complex, Manama, Manama, Bahrain.

The occurrence of double aneuploidy, i.e. the existence of two meiotic non-disjunction events is relatively rare. Although the association between double autosomal trisomy, such as trisomy 21&18 is extremely rare, rare cases of combination between Down syndrome and gonosomal trisomy has been reported. 8 year old Indian boy with Down and klinefelter syndrome is reported. The patient condition resulted from de novo trisomy-21 with extra X-chromosome (48,XXY,+21). The patient was born normally with birth weight, length and head circumference of 2590 gram, 45 cm and 31 cm respectively. The age of mother and father were 31 and 32 years old at the time of delivery. He had dysmorphic features of Down syndrome with imperforated anus, severe mental retardation, small phallus and bilateral undescended testicles but no congenital heart disease. The weight and hight were on the 3rd centile while the head circumference below the third centile. The patient developed hypothyroidism by the age of 6 years and was maintained on L-thyroxin. Testosterone level was pre-pubertal and failed to rise after HCG stimulation test.

**Molecular cytogenetic investigation of a supernumerary marker reveals a cryptic translocation in a prenatal sample.** *W.L. Golden<sup>1</sup>, T.E. Kelly<sup>1</sup>, S. Thiagarajah<sup>2</sup>, J. Boner<sup>2</sup>, K.W. Sudduth<sup>1</sup>, S.H. Burnett<sup>1</sup>, A.W. Lambert<sup>1</sup>, C. Jackson-Cook<sup>3</sup>.* 1) Department of Pediatrics, Univ of Virginia Health Sciences Ctr, Charlottesville, VA; 2) Martha Jefferson Hospital, Charlottesville, VA; 3) Department of Genetics, Medical College of Virginia, Richmond, VA.

A 36 year old prima gravida referred for prenatal diagnosis due to advanced maternal age and a MSAFP triple screen risk of 1/57 for Down syndrome underwent an amniocentesis at 22 weeks gestation. Standard GTG cytogenetic analysis revealed that the majority of cells (33/40) contained a small, supernumerary marker chromosome. Molecular cytogenetic analysis using SKY technology revealed that the marker originated from a chromosome 2. Subsequent whole chromosome paint and alpha-satellite analysis confirmed this finding. SKY analysis also revealed that there appeared to be a small amount of chromosome 12 material present on the short arm of one of the number 2 chromosomes. By SKY analysis there was no evidence of the reciprocal chromosome 2 material being present on either chromosome 12s. However, whole chromosome paints for 2 and 12 confirmed the finding of a portion of 12 on the short arm of 2 and revealed a small portion of chromosome 2 material on the long arm of chromosome 12. Even in retrospect this rearrangement is not apparent on standard GTG analysis. Standard and molecular cytogenetic analysis on the parents revealed that neither carried the t(2;12), however, the father was found on GTG analysis to have 3/200 cells with a supernumerary marker that appeared similar to that seen in the fetus. Counseling issues included the *de novo* nature of the t(2;12) as well as the significance of the frequency and distribution of what may be a familial marker. The couple opted to continue the pregnancy and at 39 1/2 weeks gestation an apparently normal female infant was delivered. Birthweight was 2807 gm with Apgars of 8 and 9. This case illustrates both the power and limitations of the methodologies available to the cytogeneticist for prenatal cases.

**The significance of a prenatally diagnosed del(10)(q23).** *J.E. Fox<sup>1</sup>, A.L. Zaslav<sup>2</sup>, S. Allan<sup>1</sup>, R. Kazi<sup>2</sup>, T. Shklooskaya<sup>3</sup>, D. Sohal<sup>3</sup>, S.M. Kleyman<sup>3</sup>, R.S. Verma<sup>3</sup>.* 1) Human Gen., Schneider Child Hosp, Long Island Jewish Medical Ctr, New Hyde Park, NY; 2) Dept of Pathology, Long Island Jewish Medical Center, The Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY; 3) Wyckoff Heights Medical Center, Brooklyn, NY, and New York Hospital/Weill Medical College of Cornell University, New York, NY.

The expression of fragile sites is highly variable and information is limited. We report a case of prenatal mosaicism for a deletion of chromosome 10(q23). It was suspected that this abnormality resulted from an inherited fragile site. In situ amniocentesis analysis was performed on a 27-year-old, East Indian female for an abnormal MSAFP. The karyotype was 46,XY,del(10)(q23)[9]/46,XY[45]. Chromosome analysis of parental blood grown in standard and in low-folate medium demonstrated the presence of the fragile site in 2/138 cells (standard) and in 6/50 cells (low-folate) in the mother. A repeat amniocentesis revealed 46,XY in 100 cells. A high-resolution ultrasound and fetal echocardiogram were performed at 22 weeks and neither revealed abnormalities. There are only three reports of prenatally diagnosed cases of del(10)(q23). Two cases apparently resulted from an inherited fragile site (Hsu, et al., 1996). One resulted in a normal live born. The other pregnancy was interrupted and the fetus appeared normal. The third case also resulted in a normal live born although no parental fragile site was detected. It appears that prenatally diagnosed mosaicism for a del(10q) represents culture artifact and is not clinically significant. Based on these findings the patient elected to continue the pregnancy. Since fragile site expressivity is variable and data is scarce, counseling should include the following recommendations: (1) cytogenetic analysis of parental blood grown in appropriate induction medium, (2) high-resolution ultrasound and fetal echocardiogram, and (3) postnatal confirmatory studies. Additional cases of prenatally diagnosed mosaicism of deletions are necessary to confirm the relevance of these findings.

**Familial pericentric inversion of chromosome 5 in a family with benign neonatal convulsion.** *D. Concolino<sup>1</sup>, M. Iembo<sup>1</sup>, M. Moricca<sup>1</sup>, E. Rossi<sup>2</sup>, O. Zuffardi<sup>2</sup>, P. Strisciuglio<sup>1</sup>*. 1) Department of Pediatrics, Faculty of Medicine University of Catanzaro ITALY; 2) Department of Biology and Medical Genetics University of Pavia ITALY.

The BFNC is an idiopathic autosomal dominant form of epilepsy characterized by spontaneous partial or generalized clonic convulsions beginning within the first months of life. A family is described in which the grandmother, the mother and the patient presented "benign" neonatal convulsions. The proband, a male, was a second child of unrelated parents, born at 40 weeks of gestation after an uneventful pregnancy. Apgar scores were 10 at 1 and 5 minutes. At delivery the weight, the length, the head circumference and the clinical examination were normal. In the third day of life he had five episodes of generalized clonic convulsions treated with phenobarbital (5mg/Kg/day). Routine laboratory and neurologic investigations were normal. At 8 months of age he was developmentally normal and continued to take phenobarbital. The mother and maternal grandmother appeared phenotypically and intellectually normal but reported a clear history of convulsions in neonatal age and afebrile seizures later in childhood. Chromosome analysis for proband and his family were performed from synchronized peripheral lymphocyte cultures. The proband's karyotype was interpreted as 46, XY, inv(5)(p15-q11.), the mother appeared to have the same rearrangement of chromosome 5. Moreover in the mother's family, the grandmother was carrier of inversion while other relatives had normal karyotypes. FISH experiments were performed to locate the breakpoints on chromosome 5 [inv5(p15.1,q11.2)]. In this report we describe a family carrying a pericentric inversion of chromosome 5 (p15.1,q11.2) presenting benign familial neonatal convulsions (BFNC). Loci for BFNC, based on the linkage analysis, have been mapped to human chromosomes 20q13.3 and 8q24 and recently a potassium channel gene, located on 20q13.3 was isolated and its mutations supposed to be responsible for BFNC. This report suggests the possibility of a new locus for BFNC on chromosome 5 and confirms the genetic heterogeneity of this disorder.

**A de novo duplication of marker chromosome inv dup(15).** *Y.H. Cho<sup>1</sup>, C.H. Lee<sup>1</sup>, S.H. Shim<sup>1</sup>, Y.J. Park<sup>2</sup>, H.C. Kwon<sup>2</sup>, W.I. Park<sup>2</sup>, H.J. Lee<sup>2</sup>.* 1) Dept Medical Genetics, Hanyang Univ Col Medicine, Seoul 133-791, Korea; 2) Department of Obstetrics and Gynecology, School of Medicine, Eulji University, Seoul 139-711, Korea.

During the cytogenetic study of a 40 years old woman referred for the evaluation of missed abortions, two identical marker chromosomes were detected (48, XX, +marx2). The markers were further evaluated with C-band and NOR-stain and her parents were karyotyped. The overall length of the marker chromosome was smaller than chromosome 21 and looked like metacentric chromosome. There was no G (+) band on both arms, and satellites were detected on both arms on NOR stain. Her father had one copy of the same marker chromosome (47, XY, +mar). The origin of the marker chromosome was evaluated by FISH. With D15Z1 probe (15p11.2) green signal was detected on both arms of the marker chromosomes. So the marker chromosomes were thought to be common harmless inv dup (15). The missed abortion history of the patient was thought to be unrelated with the marker chromosomes. This case may be the first report on the de novo duplication of inv dup (15).

**A maternal complex chromosome rearrangement ascertained through a mildly affected child with a del 13q. L.M.**

*Drummond Borg*<sup>1</sup>, *A. Kulharya*<sup>2</sup>, *V. Tonk*<sup>3</sup>, *J. Garcia-Heras*<sup>4</sup>. 1) Texas Dept Health, Bureau of Children's Health, Austin, TX; 2) Medical College of Georgia, Dept of Pediatrics, Augusta, GA; 3) Texas Tech Univ, Dept Pediatrics, Lubbock, TX; 4) Genetic Testing CTR, Texas Dept of HLTH, Denton, TX.

Carriers of complex constitutional chromosome rearrangements (CCRs) are usually ascertained after a the diagnosis of an unbalanced karyotype in malformed offspring, or if chromosome studies are done due to repeated pregnancy losses.

We report a child with an interstitial deletion of 13q that was inherited from a maternal complex translocation between chromosomes 2, 13 and 20.

A 2 1/2 month old girl received genetic evaluation due to unusual clinical features and a small size for her age. A physical exam showed partial right side facial palsy, craniofacial dysmorphism (flat facies, flat occiput, small eyes, flat nose, long philtrum, a thin upper lip, small mouth), short neck, widely spaced nipples, a reduced chest circumference and long fingers and toes. The weight was 8lbs 10 oz (3%), OFC 36 cm (- 2SD), and the height 21 1/2 inches (5%). A cytogenetic study identified a del(13)(q12q14). FISH showed that the retinoblastoma gene was not deleted. The mother carried a complex rearrangement involving chromosomes 2, 13 and 20 which was clarified by FISH with chromosome-specific libraries. The segment 13q12.1-q12.3 was translocated to band 2p13. The segment 2p13-p25 was attached to the segment 13q12.3-q14.3. This latter segment was translocated to band 20p13. The father was not available for chromosome studies.

The phenotype of this child is consistent with other proximal deletions of 13q not extending into band q32 (lack of major malformations, minor anomalies, growth retardation and retinoblastoma if the RB locus is deleted). The prognosis is more favourable and the phenotype is mild compared to the manifestations of deletions involving band q32 (major malformations and severe MR and growth retardation) or the most distal deletions q33-q34 (severe MR without gross malformations or growth retardation).

**Ring chromosome 17 with monosomy 17 associated with unusual severe malformations.** *C. Baldermann*<sup>1</sup>, *C. Taege*<sup>2</sup>, *A. Musil*<sup>2</sup>, *F. Rath*<sup>2</sup>, *I. Hansmann*<sup>1</sup>. 1) Institut fuer Humangenetik und Medizinische Biologie, Halle(Saale), Germany; 2) Institut fuer Pathologie; Halle(Saale) Germany.

We report on a premature female infant born at week 30 by caesarian section because of fetal bradycardia. The infant died 5 hrs pp. At autopsy severe craniofacial malformations were observed with microcephaly, hypertelorism, bilateral cheilognathopalatoschisis and dysmorphic ears as well as leftsided diaphragmatic hernia, cardiopulmonal malformation with agenesis of the lower lobe of the left lung, 2 ventricular septal defects and hypoplasia of the truncus pulmonalis. Genital anomaly with vagina and uterus duplex was present. Placental weight was too high and basal plate was too large in relation to gestational age. Maturation of villi was heterogeneous with areas of normal and large oedematous villi. Chromosome analysis of G-banded lymphocyte metaphases revealed a ring(17) in all 61 cells. In fibroblasts the ring(17) was confirmed in 36/40 cells. The remaining 4 cells (10%) disclosed monosomy 17 (45,XX,-17). FISH with probes specific for the short and long arm including subtelomeric regions was done. Signals were observed for each probe indicating that fusion of chromosome 17 arms was distal to the probe loci. Probes included that for Smith-Magenis (17p11.2) and Miller Dieker region (17p13.3), as well as for D17q25 (YAC659g5). To our knowledge there are only 10 documented cases of ring(17), 4 of them show features of Miller-Dieker syndrome and at least 2 presented with flecked retina suggesting that there may be a causal relationship between abnormalities of chromosome 17 and retinal pigment dysfunction. Several patients had mild nonlethal features in common such as growth, mental and motor retardation, microcephaly, mild facial dysmorphism, cafe au lait spots, seizures and hypotonia (ring chromosome 17 syndrome). The complex and lethal malformations of our new case has not been reported so far with ring(17). Our case has only minor clinical symptoms in common with those of the ring 17 chromosome syndrome. Explanations such as mosaicism for monosomy 17, altered gene function due to loss of telomeres and unmasking of a recessive mutation will be discussed.

**A new approach in interpretation of comparative genomic hybridization (CGH) profile analysis: existence of two patterns of shifts of ratio profiles for specific chromosomes and chromosomal regions within normal variations.**

*D.K. Kalousek, T.A. Loukianova, S.S. Tang, I.J. Barrett, E. Rajcan-Separovic.* Dept Path/Lab Med, Univ BC, British Columbia ChildrensHosp, Vancouver, BC., Canada.

CGH technology has proven to be a powerful molecular cytogenetic diagnostic tool. Despite many thorough descriptions of CGH technique, the use of new approaches in the interpretation of profiles are needed to improve the efficacy and utility of CGH as a clinical diagnostic method. Our audit of 552 CGH analyses known to have normal diploid complements illustrates a tendency for the image profiles of certain chromosomes and chromosomal regions to display a particular pattern of deviation. The CGH was performed with the test DNA directly labeled with FITC (green) and reference DNA with TRITC (red). Our study shows that there are two distinct patterns of deviations involving certain chromosomal regions and whole chromosomes. Chromosomal regions 1p32-pter, 12q24-qter, 16p, and chromosomes 17,19,20,22 show a statistically significant tendency to exhibit a green-to-red ratio profile  $<1$ , whereas chromosomal regions 3q, 4q, 5q, 6qcen-q24, 9p, 18q and chromosome 13 demonstrate a converse behaviour, green-to-red ratio  $>1$ . When multiple chromosomes display simultaneous deviation within a CGH profile, all chromosomes of the same pattern deviate to the same side and all chromosomes of opposite patterns deviate to opposite sides. The behaviour of profiles of these chromosomes is not random, but predictable due to innate differences between G-band light and dark regions (A/T and C/G rich respectively). Our observations provide a new approach in evaluation of the green-to-red ratio profiles within the threshold levels for gains and losses (ratio of 0.8-1.2). Any discordance in behaviour of chromosomal regions of a certain pattern must be considered significant and indicative of abnormal chromosomal complement. Confirmation of the abnormal finding by means of other cytogenetic molecular techniques should follow.

**Delineation of the dup 5q phenotype by molecular cytogenetic analysis in a patient with dup 5q/del 5p (Cri du chat).** *B. Levy*<sup>1</sup>, *T.M. Dunn*<sup>1</sup>, *J. Kern*<sup>2</sup>, *K. Hirschhorn*<sup>1</sup>, *N.B. Kardon*<sup>1</sup>. 1) Department of Human Genetics and Pediatrics, Mt Sinai Medical Ctr, New York, NY; 2) Department of Pediatrics, Flushing Hospital Medical Ctr, Queens, NY.

An infant girl presented with growth retardation, low set ears, prominent nose, short philtrum, microcephaly, low set nipples, significant VSD, bilateral clinodactyly of the 5th digits and a mewing cry. Cytogenetic studies of peripheral blood lymphocytes showed a 46,XX,add5p karyotype. Parental chromosome analysis revealed that the mother carries an apparently balanced pericentric inversion of chromosome 5, 46,XX,inv(5)(p15.2/3?q35.1?). In view of the patient's mewing cry, initial fluorescence in situ hybridization (FISH) studies using a commercial Cri du chat probe (D5S721, D5S23), which maps to 5p15.2, revealed signals on both the normal and derivative chromosomes. Further FISH analysis was performed to determine the nature of these rearrangements. Telomeric probes specific for 5p and 5q were used to confirm the pericentric inversion in the mother and demonstrated the loss of the terminal 5p region and a duplication of the terminal 5q region in the proband. Comparative genomic hybridization (CGH) was utilized to further refine both breakpoints in the recombinant chromosome 5, and clearly places them at 5p15.3 and 5q34. Therefore, the derivative chromosome found in the proband arose during a recombinant meiotic cross-over event in the mother leading to loss of material from 5p15.3@pter and a duplication of 5q34@qter. The presence of the cat-like cry appears to be the only specific feature that can be linked to the loss of 5p material. The remaining dysmorphic features in this infant appear to be due specifically to the duplication of the 5q sequences. The combination of FISH, CGH and cytogenetics has helped correlate the spectrum of clinical phenotypes found in cri du chat and 5q duplications with specific chromosome breakpoints. We have confirmed that the characteristic cry of the Cri du chat syndrome is due to the deletion of the most distal part of the classic del 5p. More importantly we have defined the duplication of 5q34@qter as a distinct clinical phenotype.

**Supernumerary Ring Chromosome 11 Mosaicism causing retinal colobomas.** *E.W. McPherson<sup>1,2</sup>, M.M.*

*Clemens<sup>1,2</sup>, S. Kochmar<sup>1,2,3</sup>, B. Gharaibeh<sup>1,2,3</sup>, U. Surti<sup>1,2,3</sup>.* 1) Magee-Womens Hosp, Pittsburgh, PA; 2) University of Pittsburgh; 3) Pittsburgh Cytogenetics Lab.

Ring chromosome 11, with clinical features similar to del 11q, has been reported in several patients, but we are aware of no previous descriptions of a supernumerary ring chromosome 11. We report an infant with a supernumerary ring 11 in 28% of her cells. Dandy-Walker variant was diagnosed prenatally, but the parents declined amniocentesis and the patient was born at term with a weight of 3081g, length of 48 cm and OFC of 32cm. She had an unusual appearance with marked hypertelorism, short downslanting palpebral fissures, down-turned mouth, thin lips, small nose and cupped ears. Eye exam showed bilateral retinal colobomas. She failed a hearing screen. Echocardiogram showed a small VSD which has been asymptomatic. MRI showed hypoplasia of the corpus callosum, increased fluid in the middle cranial fossa, migration abnormality and fetal prosencephalic vein. Despite gastroesophageal reflux, her postnatal growth has been normal. She was hypotonic as a neonate, but her development at 2 months appeared normal except for inconsistent visual fixation. Her karyotype was 47,XX,+ring11/46,XX. Parental chromosomes were normal. The family history was remarkable only for a stillborn sibling with no obvious malformations, who was not karyotyped. The supernumerary ring in our patient involves the middle 2/3 of the chromosome. She has mosaic trisomy for proximal 11p and proximal 11q and her clinical features overlap those of a previously reported patient with dup 11p12-13 who had minor dysmorphic features, retinal colobomas and mild developmental delay. The eye abnormalities may be attributable to duplication of the PAX6 gene. There is also overlap with a previously reported patient who had dup 11q13.3-14.2 with mild to moderate retardation and congenital heart disease. The larger duplication in our patient presumably explains her more significant dysmorphism. Complete trisomy 11 has never been reported in any liveborn individual. Our patient's mosaicism has allowed her to survive with a duplication of chromosome 11 larger than any previously reported.

**There is High malignancy risk in Mosaic Variegated Aneuploidy Syndrome.** *S. Jacquemont<sup>1</sup>, M. Boceno<sup>2</sup>, D. Genevieve<sup>4</sup>, J.M. Rival<sup>2</sup>, F. Mechinau<sup>3</sup>, A. David<sup>1</sup>.* 1) Unite de genetique clinique, Service de genetique medicale Hpital mere enfant, Nantes, France; 2) Unite de cytogenetique antenatal, Service de genetique medicale, Centre Hospitalier Universitaire de Nantes, France; 3) Service d'oncologie pediatrique, Hopital mere enfant, Nantes, France; 4) Service de genetique medicale, Hopital Necker-Enfants Malades, France.

14 cases of mosaic variegated aneuploidy (MVA) have been reported in the last 10 years. The phenotype of this rare syndrome has been quiet consistent : sever microcephaly, growth deficiency, mild dysmorphogenesis and mental retardation. We describe here a young boy who associates those clinical features, constitutional MVA and myelodysplasia with a monosomy 7 bone marrow clone. At the age of three, his myelodysplasia has transformed into an acute lymphoblastic leukemia and he died soon after. Hematological findings have never been described in the MVA syndrome. Patients described by Kadji et al [1998], Limwongse et al [1999] and us are the only 3 out of 14 cases (21%) with neoplastic findings. Nevertheless it is easily understandable that somatic cells suffering mitotic instability can at one point become malignant by increased expression of oncogenes or decreased expression (haploinsufficiency) of tumor suppressor gene. Indeed, multiple chromosome aneuploidy are commonly found in solid tumor and in hematological malignancies. More over, many reports mention very young patients (65% of the patients described are under 4 years old) and there long term-follow up might reveal malignancy. It is clear now that patients with MVA have a high malignancy risk. Therefore, if other cases of cancers and hemopathies are reported, MVA could become a neoplastic predisposing syndrome.

**Fragile site 16(q22): is there a phenotypic consequence?** *A. Hing, K. Leppig.* Div Genetics & Dev, Univ Washington, Seattle, WA.

The fragile site at 16q22 [fra(16)(q22)] is rare fragile site, sensitive to distomycin, results from an amplification of an AT-rich minisatellite repeat and is thought to be without phenotypic sequelae. We report a four month old female with microstomia, bilateral cleft lip, cleft palate, micrognathia, broad thumbs and clinodactyly. Routine cytogenetic analysis performed on peripheral blood lymphocytes showed expression of the fragile site at 16q22 in 41 of 101 metaphase cells examined, with six of the metaphase cells showing a deletion of 16q22 to qter. Family history is positive for a paternal aunt and cousin with oral clefting.

Oral clefting has been characteristic of other patients with fra(16)(q22) and an abnormal phenotype. A family reported by Bettex (et al. *Eur J Pediatr Surg* 8:4-8, 1998) describes a three generation family with cleft palate, microstomia, hypoplasia of the mandible and partial anodontia, segregating with fra(16)(q22). Another family reported by Dummer (et al., *Am J Med Genet* 16:277-284, 1983) described two sibs with fra(16)(q22), one with cleft palate and brachydactyly, and the other with three cranial fontanelles, congenital heart disease, and syndactyly of toes 2-3. Their healthy mother also had fra(16)(q22). Patients with isolated deletions involving 16q22.1-q24.1 (Callen et al., *J Med Genet* 30:828-832, 1993) have anomalies that include oral clefting. Prescott (et al., *Hum Genet* 106:345-350, 2000) has identified 16q22-24 as one of nine areas of interest by non-parametric linkage scores for nonsyndromic cleft lip with or without cleft palate.

The presentation of this patient and review of literature suggest that susceptibility genes for orofacial clefting may reside on chromosome 16q22 and a possible causal relationship between fra(16)(q22) and the development of orofacial clefts.

**Tricuspid atresia in mosaic tetrasomy 8p.** P.R. Koduru, R. Schiff, A. Yenamandra, E. Arnold, M.G. Bialer. Dept Pathology and Pediatrics, North Shore Univ Hosp/NYU School of Medicine, Manhasset, NY.

A 5 mo old girl from the Dominican Republic was seen for evaluation and treatment of congenital heart disease (CHD). She had presented with breathing difficulties at 1 day of age and a chest X-ray at 1 wk revealed vertebral anomalies. She had poor weight gain and tired during feeding. Admission weight was 3.64 kg (<<5%), length 60 cm (5%) and OFC 38.8 cm (5%). Dysmorphology exam was significant for large anterior fontanelle, unfolded right ear with soft cartilage, mild 5th finger clinodactyly, hypoplastic proximal phalanx of left 5th finger, and 2nd toe overriding 3rd bilaterally. Chest X-ray revealed butterfly and hemivertebrae involving T6-10. Ribs were somewhat irregular. Echocardiography demonstrated tricuspid atresia, a non-restrictive atrial defect, and a very restrictive bulboventricular foramen (VSD). Oxygen saturation was in 50's-60's. Head ultrasound showed agenesis of the corpus callosum (ACC). Chromosome analysis revealed 12/62 cells with a large metacentric marker chromosome. Banding pattern and fluorescence *in situ* hybridization with a chromosome 8 specific painting probe WCP8 (Vysis Inc.) proved the marker to be derived from 2 copies of the short arm of chromosome 8 (mos 47,XX,+mar[12]/46,XX[50].ish i(8)(p10)(WCP8+)). She underwent atrial septectomy and bidirectional right superior vena caval to pulmonary artery anastomosis. Her post-operative course was complicated by RSV bronchiolitis, thrombosis of the left innominate vein causing multiple pulmonary emboli, and several episodes of bacterial sepsis. She died at almost 7 mo. Mosaic tetrasomy 8p has been described in 11 previous cases in the world literature. Including this case, 6/12 (50%) have had CHD. Tricuspid atresia has not been previously reported in this condition, but mitral atresia has been seen once. Vertebral segmentation defects have been seen in 9/11 (81%) and ACC in 7/9 (78%) individuals studied. Mild-moderate mental retardation has been reported in 6/7 surviving individuals (Am J Med Genet 1997;73:330). Additional cases will be helpful in delineating the features of this syndrome.

**Inherited chromosome Xp22.3 deletion: Discordant phenotype in mother and daughter.** *B. Mouron*<sup>1,3</sup>, *M.L. Begleiter*<sup>1,3</sup>, *R. Rinaldi*<sup>2,3</sup>, *M.G. Butler*<sup>1,3</sup>, *J.H.M. Knoll*<sup>1,3</sup>. 1) Section of Medical Genetics and Molecular Medicine; 2) Section of Pediatric Rehabilitation Medicine; 3) Children's Mercy Hospital and the University of Missouri Kansas City School of Medicine, 64108.

Terminal deletions of the X chromosome short arm are often associated with short stature and occasionally with mental retardation. We present the chromosomal findings on a 34 month old female who was referred because of small size (<5<sup>th</sup> %ile for height), facial dysmorphism and developmental delay, and on her mother with short stature (height 154cm, 5<sup>th</sup>%ile) and normal intelligence. Routine cytogenetic analysis of peripheral lymphocytes from both individuals showed similar deletions of one X chromosome at Xp22.3. FISH analysis with chromosome Xp22.3 specific probes for the Kallman gene (KAL1), steroid sulfatase gene (STS) and the Xp subtelomeric region demonstrated 46,X,del(X)(p22.3). ish del(X)(p22.3)(DXZ1+,KAL1+,STS-,TELXp-). The KAL1 locus was intact, but STS and the subtelomeric sequence were deleted. Such a deletion in males would result in an abnormal phenotype including ichthyosis, whereas, in females, a normal phenotype would be likely. The patient's father was normal and therefore was unlikely to have transmitted a recessive X-linked gene unmasked by the deletion. In deletion positive females with clinical abnormality, the abnormality may be due to preferential X chromosome inactivation of genes or a reduction in gene expression for those genes that escape inactivation (ie. STS and KAL1). We are evaluating possible skewed X-inactivation by replication banding and allele- specific replication timing.

**Prenatal diagnosis and characterization of an unbalanced whole arm translocation, der(18;22)(q10;q10), resulting in monosomy for 18p.** *E.M. McGhee<sup>1</sup>, Y. Qu<sup>2</sup>, P.D. Cotter<sup>1,3</sup>*. 1) Dept Pediatrics, Medical Genetics, University of California, San Francisco, San Francisco, CA; 2) Chapman Institute of Medical Genetics, 5300 East Skelly Drive, Tulsa, OK; 3) Division of Medical Genetics, Children's Hospital Oakland, 747 Fifty Second Street, Oakland, CA.

Monosomy for the short arm of chromosome 18 is one of the most frequent autosomal deletions observed. As many as 16% of cases were reported to be due to an unbalanced whole arm translocation resulting in monosomy 18p. The origin and structure of these derivative chromosomes was reported in only a few cases. We report the prenatal diagnosis and characterization of a new case of monosomy 18p due to an unbalanced whole arm translocation. Amniocentesis was performed at 16 weeks of gestation on a 34 year old woman who was initially referred for advanced maternal age and holoprosencephaly identified by ultrasound. Karyotype analysis showed an unbalanced whole arm translocation between the long arm of one chromosome 18 and the long arm of one chromosome 22, 45,XX,der(18;22)(q10;q10), in all metaphases. In effect, the fetus had monosomy for 18p. Parental karyotypes were normal, indicating a de novo origin for the der(18;22). FISH analysis was performed with alpha satellite probes D18Z1 and D14Z1/D22Z1 to identify the origin of the centromere on the der(18;22). Signal was observed with both probes, indicating that the der(18;22) was a dicentric chromosome. Genotyping of the fetus and her parents with chromosome 18p STS marker D18S391 showed only the paternal 187 bp allele was present in the fetus, indicating the chromosome 18 involved in the der(18;22) was maternally derived. While familial whole arm translocations were more likely to be monocentric, this case and previous reports demonstrate that de novo unbalanced whole arm translocations are most often dicentric rearrangements. Loss of the reciprocal translocation product, resulting in monosomy for 18p, is likely a result of instability due to little or no centromeric material on that derivative chromosome.

**Complex counseling issues associated with a balanced, nonreciprocal 12;15 translocation.** *K.A. Kaiser-Rogers<sup>1</sup>, K.K. Phillips<sup>2</sup>, C.M. Powell<sup>1</sup>, M.I. Roche<sup>1</sup>, K.W. Rao<sup>1,2</sup>.* 1) Dept Pediatrics, Univ North Carolina, Chapel Hill, NC; 2) Dept Pathology, Univ North Carolina, Chapel Hill, NC.

An unusual, balanced, nonreciprocal 12;15 translocation was detected in a phenotypically normal 30 year old woman ascertained because of multiple pregnancy losses. This patient's balanced karyotype [45,XX,der(12)t(12;15)(q24.33;q11.2)] contains 45 rather than 46 chromosomes and the entire long arm of one chromosome 15 homologue appears to have been translocated to the distal long arm of chromosome 12. A chromosome 15 a-satellite FISH probe did not hybridize to the der(12) chromosome, while the most proximal Prader-Willi (PWS)/Angelman syndrome (AS) probes did, suggesting that this chromosome is monocentric with the chromosome 15 breakpoint lying proximal to the PWS/AS region. Subtelomeric and pan telomeric probes hybridized to the derivative chromosome showing that little, if any, DNA was lost from the distal long arm of chromosome 12. No evidence of mosaicism was seen in the 100 lymphocytes that were examined.

The genetic counseling issues involving this translocation are complex. This patient is at increased risk for conceiving pregnancies with unbalanced karyotypes secondary to chromosome malsegregation. In this case, monosomy or trisomy for chromosome 12 or 15 could occur; however, these are lethal abnormalities and her risk for having live-born children with these karyotypes is low. Since malsegregation followed by correction can result in an abnormal phenotype secondary to uniparental disomy (UPD), this issue was also discussed. Trisomy correction could produce a fetus with maternal UPD for chromosome 12 or 15. Although no UPD 12 cases have been reported, maternal UPD 15 causes PWS. Similarly, monosomy correction would result in paternal uniparental isodisomy (UPiD) 15 and AS. The risk of inheriting a recessive disorder secondary to UPiD was also considered. Finally, the tendency for familial translocations involving the PWS/AS region to produce deletions involving proximal chromosome 15 was discussed. These deletions appear to arise by unequal crossing over; the consequence of such a deletion in this patient's offspring would be AS.

**Subtelomeric testing for cryptic chromosomal rearrangements in 68 patients with idiopathic mental retardation and dysmorphism.** *X.L. Huang<sup>1</sup>, H.E. Wyandt<sup>1,2</sup>, J.M. Milunsky<sup>1,3</sup>*. 1) Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Pathology, Boston Univ Sch Medicine, Boston, MA; 3) Pediatrics, Boston Univ Sch Medicine, Boston, MA.

Sixty-eight patients have been referred to our center for subtelomeric testing. In the course of these studies we used either the subtelomeric Cytocell 41-probe device (Rainbow Scientific, Windsor, CT) or a panel of 41 individual TelVision probes (Vysis, Downers Grove, IL). Individual probes from either source were used when some probes had to be repeated. The majority of cases were first studied by high-resolution chromosome banding. In some cases, other tests were also done to rule out possible causes of mental retardation (mr) and/or dysmorphic features. Of 23 patients examined by one of us (JMM), 12 have moderate to severe mr and 11 have mild mr that eluded explanation by other testing. From this group, three (13%) have *de novo* deletions of subtelomeric sequences. Case 1, a 10.5 y.o. male with a terminal deletion in 1p36 has severe mr with lack of language, self-abusive behavior, hypotonia as an infant, esotropia, growth delay, cerebral atrophy and dysmorphism. Case 2, a 2 y.o. male with a subterminal deletion in 9q34 has severe mr, central apnea, hypotonia, optic nerve atrophy, multiple dysmorphic features, multiple cardiac defects and bilateral hearing loss. Case 3, an 18 y.o. male with deletion in 10q26, has moderate mr, autistic behavior, bipolar disorder with multiple suicide attempts and dysmorphism. Of 45 cases sent from other clinics, one (Case 4), an 18 mo female with severe mr, hypotonia, gastroesophageal reflux and failure to thrive, has deletion in 2q37. The clinical details of all four cases will be presented. Case 1 represents a well-described subtelomeric deletion. Cases 2, 3 and 4 represent less frequently described deletions. The finding of these four cases is consistent with previously reported series and confirms that subtelomeric FISH testing is appropriate, especially for those cases with unexplained moderate to severe mr.

**A case of complete tetrasomy 12p versus mosaic tetrasomy 12p (Pallister-Killian syndrome).** *M.C. Lowery<sup>1,2</sup>, R.L. Young<sup>2</sup>, A. Li<sup>1</sup>, M. Fowler<sup>1</sup>, L.A. Prouty<sup>2</sup>, M. Lucas<sup>3</sup>, H. Chen<sup>2</sup>.* 1) Dept. Pathology; 2) Dept. Pediatrics; 3) Dept. Obstetrics & Gynecology, Louisiana State Univ Health Sciences Center, Shreveport, LA.

Pallister-Killian syndrome, or mosaic tetrasomy 12p, is a relatively rare syndrome that is clinically manifested by profound mental deficiency and multiple congenital anomalies. The syndrome exhibits tissue-specific mosaicism where a supernumerary isochromosome 12p is marked in fibroblasts but virtually absent in peripheral blood. Very few cases, if any, show total tetrasomy 12p. We report an isolated clinical case of a 18 year-old prima gravida who presented to the hospital in labor. Prenatal ultrasound revealed polyhydramnios, diaphragmatic hernia, short limbs, and short neck. Although the possibility of Pallister-Killian was suspected, amniocentesis was not performed because of late gestation and the patient being in labor. At birth, the infant was found to have hypertelorism, short neck, short limbs, and diaphragmatic hernia. In spite of resuscitation, the infant expired and an autopsy was performed. Death was attributed to pulmonary hypoplasia secondary to diaphragmatic hernia. Cytogenetic analysis on tissue from the infant revealed all cells with i(12p). Fluorescence in situ hybridization (FISH) was performed using a pericentromeric probe (CEP12/SpectrumOrange, Vysis) and a whole chromosome paint probe (WCP/SpectrumOrange, Vysis) for chromosome 12. FISH confirmed 4 copies of the chromosome 12 centromeric region in all interphase and metaphase cells analyzed. WCP analysis confirmed that structurally the der(12) was comprised of all 12 material. This case documents complete tetrasomy of 12p and that survival to term is possible.

**Deletion of 2q37 and duplication of 10q24: Report of two cases in the same family and literature review. A.**

*Wiktor<sup>1</sup>, G.L. Feldman<sup>1,3</sup>, E. Bawle<sup>1,2</sup>, P. Czarnecki<sup>1</sup>, J. Conard<sup>2</sup>, D.L. Van Dyke<sup>1</sup>.* 1) Department of Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Division of Genetic and Metabolic Disorders, Children's Hospital of Michigan, Detroit, MI; 3) Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, MI.

Two patients (first cousins, once removed) with dysmorphic features and developmental delay have an unbalanced translocation resulting in loss of 2q37.3-qter and duplication 10q24.1-qter. The patients were ascertained independently and it was initially unknown that they were related to each other. Cytogenetic and fluorescent in situ hybridization (FISH) analysis identified a der(2)t(2;10)(q37.3;q24.1) karyotype. Patient 1 is an 18 year old severely mentally impaired male with dolicocephaly, high arched palate, flat nasal bridge, acquired total alopecia, prominent ears, joint contractures and a prominent scapula. The family was lost to follow-up for 5 years after the initial visit. After the association with patient 2 was identified, the family was able to be recontacted. The mother is an obligate carrier and the only sibling had a 46,XX karyotype. Patient 2 is a 12 month old female with craniosynostosis, flat nasal bridge, low set and posteriorly rotated ears with delayed development of approximately 2 months. A positive family history was initially denied by the family. After the karyotype results became known, the family history was provided. The father's karyotype is 46,XY,t(2;10). Previously described features of patients with deletions of chromosome 2q37 include moderate mental retardation, depressed nasal bridge and hand and feet abnormalities. Duplication 10q is characterized by mental and growth retardation and dysmorphic features, including short palpebral fissures, hypertelorism, malformed ears and broad nasal bridge. This is the first report of patients with the both loss of 2q and duplication of 10q. Both patients described have unusual phenotypic features not previously reported in patients with a 2q deletion or 10q duplication. These patients emphasize the importance of understanding genetic information and risks, and sharing it among their extended family.

**Ring X chromosome and male infertility - Report of a case 45,Y/46,Y,r(X).** *G. Quenum<sup>1</sup>, M. Freund<sup>1</sup>, M. Stelandre<sup>1</sup>, A. Dubucq<sup>1</sup>, L. Salens<sup>1</sup>, J. Sartenaer<sup>3</sup>, S. Decooman<sup>2</sup>, Ch. Verellen-Dumoulin<sup>1</sup>.* 1) Dept Genetics, UCL Saint-Luc Hospital, BRUSSELS, BELGIUM; 2) Dept Gynecology, UCL Saint-Luc Hospital, BRUSSELS, BELGIUM; 3) Gynecology 42, rue Jules DESTREE 6000 CHARLEROI, BELGIUM.

Ring X chromosomes are usually small, present as a mosaic in patients with Turner syndrome. In male patients, large ring X has been reported only once associated to short stature in a 15 years old boy. We report on a second patient, the first known for his infertility, with severe oligozoospermia and short stature. The karyotype showed a large X ring with apparently no deletion on G banding. The ring was also present on fibroblast culture. Using whole chromosome painting and subtelomeric probes we demonstrated by FISH that the subtelomeric regions were preserved. To our knowledge, telomere-to-telomere fusion has not been described for X ring chromosomes. Different lymphocyte culture times (48 h, 72 h, 96 h) showed that the ring was unstable and lost in 7% of cells in cultures of more than 48 hours with a karyotype 45,Y. Short stature could be related to the instability of the ring. The ring seems to have been inherited from his mother whose karyotype revealed 73 cells 45,X, 26 cells 46,XX and a unique 46,X,r(X) cell. In spite of her karyotype she had four pregnancies without any problem. The status of fertility of patients with ring chromosome is not well known, however, azoospermia has been previously described as the only feature in some reports of male adults with a ring 21. This is the first report of a male patient whose infertility could be related to the presence of a ring X chromosome, and the first demonstration by FISH analysis of the preservation of subtelomeric sequences for a ring X chromosome.

Program Nr: 857 from the 2000 ASHG Annual Meeting

**Assessment of subtelomeric regions of children with autism: Detection of a 2q deletion.** *D.J. Wolff, K. Clifton, J. Charles.* Departments of Pathology/Laboratory Medicine, Medical Laboratory Sciences and Pediatrics, Medical University of South Carolina, Charleston, SC.

Autism is a behaviorally defined syndrome characterized by difficulties in socializing, communicating, and by the presence of stereotypical behaviors. The disorder is a complex genetic trait with no known predisposing genes. We have utilized a multiprobe system that includes probes for the subtelomeric regions of all of the chromosomes to screen for cryptic cytogenetic abnormalities in ten children with a diagnosis of autism and a previous normal standard cytogenetic analysis. An apparent deletion of 2q was detected in one patient. A targeted high resolution study revealed a subtle abnormality on one chromosome 2 homologue. This patient's mother's chromosomal analysis and subtelomeric assessment were normal and the father was unavailable. There have been several reports of children with dysmorphic features, autistic behaviors and deletions of 2q detectable by standard techniques. It may be that the distal region of 2q harbors a gene or genes important for normal brain function. Further studies are underway to define the extent of the deletion in this patient. Also, the pilot project is being extended to include additional autistic children to determine if deletions of 2q are a consistent finding and/or to potentially discover new regions that may include genes important in autism. The results of our study suggest that subtelomeric deletions may be involved in the pathogenesis of a significant percentage of autism cases (10% of our unselected pilot population).

**Complex chromosomal rearrangements in a 1p36 deletion syndrome child with a cryptic interstitial deletion.** C.-H. Tsai<sup>1</sup>, J. Yu<sup>2</sup>, T. Gilfillan<sup>2</sup>, L. Meltesen<sup>2</sup>, B. Hirsch<sup>3</sup>, L. McGavran<sup>2</sup>. 1) Division of Genetics Services, The Childrens Hospital, Denver, University of Colorado Health Sciences Center, CO; 2) Colorado Genetics Laboratory, Departments of Pathology & Pediatrics, UCHSC & TCH; 3) University of Minnesota Medical School.

We report a girl with a distal 1p36 deletion phenotype and a complex rearrangement of 1p resulting in a cryptic deletion. Born at term and appropriately grown, she was hypotonic and had torticollis, and left iris and inferior retinal coloboma. In utero, mildly decreased fetal movement had been noted. Screening demonstrated hearing loss. Brain MRI showed right plagiocephaly and mildly delayed myelination. At 18 months physical examination revealed prominent forehead, mid-face hypoplasia, flat nasal bridge, deep-set eyes with hypertelorism, high-arched palate and bilaterally short fifth fingers. Growth parameters were between 25th to 50th percentile, and she was hypotonic with decreased muscle bulk. Other findings included hypothyroidism, thrombocytosis, multiple ear and respiratory infections, and global developmental delay. High resolution cytogenetic studies revealed an abnormality of 1p34->pter. Parental cytogenetic studies were normal. FISH studies showed an unexpected reciprocal translocation of subtelomeric sequences between 1p and 16p, and loss of D1Z2 sequences on the der(1). We constructed a mini-paint microdissection probe for bands 1p36.1-1p36.3. It hybridized more proximally on the der(1p) and gave a smaller signal, consistent with an inversion and deletion of part of these bands. The karyotype is 46,XX,der(1)del(1)(p36.2p36.3)inv(1)(p36.3p36.1),t(1;16)(pter;pter). Heteromorphisms of 1qh show the der(1) to be of paternal origin. As a result of the initial cytogenetic findings, a diagnosis of 1p36 deletion syndrome was confirmed by closely comparing the phenotypes of reported 1p36 deletion cases and extensive molecular cytogenetic studies to prove a deletion in this complex rearrangement. This case illustrates the importance of recognizing characteristic physical features and aggressive laboratory confirmation to provide accurate syndromic diagnosis.

**Euchromatic 16p+ heteromorphism: a rare variant or chromosomal abnormality:.** *T. Shklovsky, S.M. Kleyman, M.J. Macera, R.S. Verma.* Department of Molecular Medicine & Genetics, Wyckoff Heights Medical Center, Brooklyn New York Hospital/Weill Medical College of Cornell University, New York, N.Y.

Chromosomes 1, 9 and 16 display the highest morphological variation due to the presence of a heterochromatic block in the secondary constriction region [qh]. Numerous types of variations of chromosome 9 have been observed. The qh region of chromosome 1 also displays an additional G-negative band that is inherited by progeny. The rarest variant is chromosome 16 where the short arm has additional G-negative material and thus presents as a metacentric chromosome. There are a number of reports that suggest that these morphological variations have no clinical significance because minor malformations observed in these patients are not observed in normal family members with the same variant chromosome. Recently, we were referred a newborn male with a high-arched cleft palate and micrognathia. A clinical diagnosis of Pierre-Robin syndrome was suspected. Cytogenetic findings by GTG-banding revealed: 46,XY[135]/46,XY,16p+[5]. i.e. an enlarged short arm of chromosome 16 was noted in 5 cells. FISH with a whole chromosome painting probe for 16 (Vysis) gave a positive signal over the entire der(16), confirming that the additional material was derived from chromosome 16. The mosaic cell line was most likely caused by post-zygotic mutation. It has been hypothesized that its origin is similar to that of facultative heterochromatin of the inactive X-chromosome and may have differential regulation of gene activity [Monk, 1987; Thompson et al, 1990]. At present, the parents are not available for cytogenetic evaluation. This heteromorphism was first noted by Thompson and Robert (1987) and confirmed by many investigators, although, not in a mosaic state. The possibility exists that this mosaic may be an artifact due to cultural conditions. This case is the first one that presented with severe malformations. Genetic counseling of de novo cases is very difficult especially if they are ascertained via genetic amniocentesis.

**A range of phenotypes in three patients with a karyotype of 45,X/46,X,idic(Y)(q11.2).** *A.L. Zaslav<sup>1</sup>, J. Jacob<sup>1</sup>, S. Allan<sup>2</sup>, D. Blumenthal<sup>2</sup>, J.E. Fox<sup>2</sup>, P. Papenhausen<sup>3</sup>.* 1) Dept Pathology, Long Island Jewish Medical Ctr, New Hyde Park, NY; 2) Dept of Pathology, Long Island Jewish Medical Center, The Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY; 3) Laboratory Corporation of America, Research Triangle, North Carolina.

Patients with a 45,X cell line and an idic(Y) are uncommon. Reported phenotypes include: Turner syndrome (TS), virilized female, normal male, and males with ambiguous genitalia (AG). We report 3 cases demonstrating this variability. Case 1: a 33 y female had amniocentesis for AG at 32 wk US. The karyotype was 45,X[28]/46,X,?Y[1]. Interphase FISH analysis revealed an idic(Y)(q11.2) in 9 of 315 nuclei. Postnatal studies revealed a 38 wk baby with AG and features of TS. Postnatal cytogenetics on blood revealed 45,X[48]/46,X,idic(Y)(q11.2)[17]. Interphase FISH analysis revealed 45,X/46,X,idic(Y) in the following ratios: blood (55/10), tissue (110/6), and left gonad (50/3). Molecular analysis using 4 long arm spermatogenesis Y probes demonstrated the presence of DYS275, SYS209 and deletion of DAZ and SPGY. The dual presence by FISH of centromeres and SRY loci confirmed the idic(Y). Case 2: a 37 y female had amniocentesis for AMA. Cytogenetics and FISH revealed a de novo 46,X,idic(Y)(q11.2)[15]/45,X[10].ish idic(Y)(q11.2)(SOCEPY++). Molecular analysis using the same Y probes as in Case 1 demonstrated the absence of DYA209, DAZ, and SPGY. Two centromeres and SRY loci found by FISH confirmed the idic(Y). High-resolution US and postnatal clinical evaluation revealed a normal appearing male. Case 3: a 17 y female was referred for delayed puberty and short stature. A karyotype of 46,X,idic(Y)(q11.2)/45,X was seen in blood (94/6), skin (48/52), and left ovary (2/48). The low percentage of Y bearing gonadal cells justified the phenotype. These 3 cases demonstrate the wide range of variability among patients with this karyotype. Sexual development in patients with this abnormality depends on the gonadal cell line distribution and the genes deleted on the idic(Y). With current technology, correlation of phenotypic, cytogenetic, and molecular data will be useful in predicting fertility and phenotypes.

**The 22q11.2 Deletion: Parental Origin and Meiotic Mechanism.** *S.C. Saitta, D.A. Driscoll, E.F. Rappaport, D.M. McGinn, E.H. Zackai, B.S. Emanuel.* Dept Human Genetics, Childrens Hosp Philadelphia.

Microdeletions of 22q11.2 are associated with velocardiofacial/DiGeorge syndrome (VCFS/DGS). It is the most frequently occurring deletion syndrome in humans with an estimated incidence of 1:4000 live births. The molecular mechanism by which the deletion occurs is largely unknown. Analysis of our patients by fluorescence in situ hybridization (FISH) demonstrates a standard deletion of ~3 Mb in 80-90% of patients. The overwhelming majority of deletions occur as de novo lesions indicating an extremely high mutation rate within this genomic region. The 22q11 deletion interval contains at least four large low copy repeats (22-LCRs) which coincide with the recurrent deletion endpoints (DEPs), strongly implicating them in the events leading to deletion. In order to further investigate the meiotic mechanism of deletion formation, we have examined families in which de novo standard 22q11.2 deletions occurred. We used 5 microsatellite markers within the deletion to determine the parental origin of the deleted allele in 59 cases. Thirty were of paternal origin, while 29 were of maternal origin, demonstrating no bias. For further analysis we designed PCR primers for polymorphic markers F8VWFP and D22S420, which flank the proximal standard DEP, and markers D22S257 and TOP1P2, flanking the distal DEP to amplify genomic DNA from ten 3-generation families. Segregation analysis using grandparental haplotypes and one proximal and one distal marker, was consistent with a meiotic interchromosomal cross-over event in at least two informative families. This is in agreement with ten previously published cases which indicated such events as leading to the deletion. Our study is the first in which the size of the deletion has been determined as part of the analysis. We are currently analyzing the remaining families and collecting additional ones in an effort to understand the meiotic recombination events which lead to the deletion.

**Prenatal detection of an analphoid marker chromosome; recommended adjunctive testing.** *P.R. Papenhausen<sup>1</sup>, R. Wiltshire<sup>2</sup>, J.H. Tepperberg<sup>1</sup>, P.N. Mowrey<sup>1</sup>, I.K. Gadi<sup>1</sup>, K.K. Phillips<sup>1</sup>.* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Pk, NC; 2) Dept Pathology, Duke U Med Cnt, Durham, NC.

Reports of marker chromosomes without standard alphoid centromere associated repeats have escalated due to the increasing availability of FISH techniques to quickly resolve chromosomal origin. A 37 yo G2PO woman referred for amniocentesis for AMA revealed a non-mosaic 47,XX,+mar karyotype. Level II US and an echocardiogram were normal. The de-novo marker was C-band negative, analphoid in systematic analysis (Cytocell), and appeared to be a small ring (1/4 size of chr. 21). Origin was determined by systematic paint probe analysis (Cytocell), revealing chromosome 10 positivity consistent with complete unique sequence (euchromatin) content. Previous reports (40) of analphoid markers with neocentromeres (neos) have included three cases derived from chromosome 10. The locations of neos appear to cluster at specific sites on select chromosomes #13(q32), #15(q25), #3(q27). The frequent involvement of telomeric regions suggests that the use of subtelomere probes will be helpful to further characterize such markers, followed by regional cosmid probes. Localization efforts will include CGH, which could benefit from the frequent inverted duplication structure of analphoid markers, yielding partial tetrasomy levels. We will also perform microdissection/reverse FISH to the patient's metaphase chromosomes. If both chr 10 homologues (and marker) are positive, this will offer exclusion of a balanced deletion/marker generation that has been reported in 7 cases. No deletion of a chr.10 homologue could be visualized in the present case, so the risk of anomalies/MR due to partial trisomy or tetrasomy is substantial. The present array of ancillary tests allows increasingly valuable tools for prognosis. Standardizing such testing to allow reasonable clinical comparisons will be necessary before defined risks can be generated.

**Molecular Analysis of Syndromic Congenital Heart Disease by Using Short Tandem-Repeat Polymorphic**

**Markers.** *Y.R. Shi<sup>1</sup>, K.S. Hsieh<sup>5</sup>, J.Y. Wu<sup>1,3</sup>, C.C. Lee<sup>1,4</sup>, C.H. Tsai<sup>1,2</sup>, F.J. Tsai<sup>1,2,3</sup>.* 1) Department of Medical research, china medical college hospital, Taichung, Taiwan; 2) Department of Pediatrics, Veterans General Hospital, Haohsiung, Taiwan; 3) Medical Genetics department, China Medical College Hospital, Taichung, Taiwan; 4) Neurology department, China Medical College Hospital, Taichung, Taiwan; 5) Pediatrics department, China Medical College Hospital, Taichung, Taiwan.

Velocardiofacial syndrome (VCFS), DiGeorge syndrome (DGS) and CATCH22 are developmental disorders characterized by conotruncal heart defects. Most of them have hemizygous deletions within chromosome 22q11, suggesting that haploinsufficiency in this region are responsible for their etiologies. To effectively understand the molecular basis for the chromosomal deletions, we designed a semi-quantitative fluorescent PCR using 11 highly polymorphic markers located in 22q11 to do genotyping analysis on ten probands (five VCFS, two DGS and three CATCH22) and their unaffected relatives. We found two VCFS, two DGS and two CATCH22 patients have a 3-Mb deletion. One patient with CATCH22 had a 1.5-Mb deletion and a crossover occurred in the same interval at the other allele. These results suggested that the specific regions in 22q11 are susceptible to rearrangement and the deletions might be the genetic etiology of these three syndromes. It also revealed that the deletion size is not correlated with the severity of the clinical manifestations.

**Identification of extra material on the long arm of chromosome 5(q33-qter) by FISH technique.** *V. Jobanputra<sup>1</sup>, M.J. Macera<sup>2</sup>, A. Kriplani<sup>1</sup>, R.S. Verma<sup>2</sup>, K. Kucheria<sup>1</sup>.* 1) Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Division of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn-New York Hospital/Weill Medical College of Cornell Medical Center, New York, NY.

A 28 year-old, gravida 4, para 3 with poor obstetric history presented with severe oligohydramnios with bilateral polycystic kidney disease in the fetus. Cytogenetic analysis performed from the cord blood sample of the fetus showed the presence of additional material on the long arm of chromosome 5 in 25% of the metaphases analyzed. This additional material was suspected to be the bands 5q33-qter. Nevertheless, the initial impression cannot be related to a specific clinical presentation as variable features are associated with these bands. In an attempt to verify this duplication, the FISH technique, using a whole chromosome painting probe specific for chromosome 5 (wcp5, Vysis), was applied to metaphases from fetal tissue. Hybridization signals were detected over the entire derivative chromosome 5, confirming that the additional material was indeed 5q33-qter. The karyotype was rewritten as 46,XY/46,XY,dup(5)(q33q35).ish(wcp5+). Since the duplicated segment is very small, the clinical findings observed in this case may be associated with these chromosomal bands. Although patients with dup5(q11-15) have been reported to have renal and urinary tract abnormalities, these abnormalities have not been previously reported in association with dup5(q33-qter). A review of other cases with variable duplicated segments has been tabulated in an effort to establish a genotype/phenotype relationship.

**Cryptic subtelomeric translocation t(2;16)(q37;q24) segregating in a family with unexplained stillbirths. D.**

*Giardino<sup>1</sup>, P. Finelli<sup>1</sup>, G. Gottardi<sup>1</sup>, D. Clerici<sup>2</sup>, E. Briscoli<sup>3</sup>, L. Larizza<sup>1,4</sup>.* 1) Laboratorio di Citogenetica, Auxologico Inst, Milan, Italy; 2) Dipartimento di Neonatologia, ICP, Milan, Italy; 3) Dipartimento Laboratori, Servizio Genetica Medica, ICP, Milan, Italy; 4) Dipartimento di Biologia e Genetica, Universit degli Studi, Milan, Italy.

We report on a familial submicroscopic translocation affecting the subtelomeric regions of chromosomes 2q and 16q. The index case, a six month-old male, presented with mild craniofacial dysmorphisms and psychomotor retardation. A conventional karyotype, performed at birth, did not reveal chromosome abnormalities. As family history showed along three-generations stillbirths and the presence in a few liveborns of mild non specific dysmorphic features, suggesting segregation of a familial translocation, a FISH study with chromosome-specific subtelomeric probes was performed. FISH analyses identified a familial cryptic translocation t(2q;16q), with an unbalanced form in the proband and a balanced form in the mother and the maternal grandfather. The unbalanced rearrangement leads to trisomy of the telomeric region of chromosome 16q and the concurrent monosomy of the distal region of chromosome 2q. An unbalanced form of the translocation is suggested by the family tree to underlie the observed stillbirths. The unbalanced translocation seen in the proband is inferred to have been present in a maternal aunt who also had the craniofacial dysmorphisms of the index case and deceased at 14 months of age. The grandfather, a balanced translocation carrier, is affected by late onset macular degeneration (MD) and, as a consequence, either of the chromosomal areas involved in the translocation may be a candidate region for a MD determining gene. To map precisely the translocation breakpoints, FISH analyses with YACs and PACs are in progress. The identification of the cryptic subtelomeric translocation segregating in this family is also of practical relevance, allowing us to offer prenatal diagnosis to the currently pregnant probands mother.

**Chromosome 22q11.2 deletion in 6 infants with several clinical phenotypes.** *V. Catala<sup>1</sup>, E. Cuatrecasas<sup>1</sup>, T. Vendrell<sup>2</sup>, A. Plaja<sup>2</sup>, M. Crespo<sup>1</sup>, J. Colomer<sup>1</sup>, C. Mediano<sup>2</sup>, E. Sarret<sup>2</sup>, A. Seres<sup>1</sup>.* 1) Prenatal Genetics, Barcelona, Spain; 2) Unitat de Genetica, Hospital Materno Infantil Vall d'Hebron, Barcelona, Spain.

Chromosome 22q11.2 microdeletions are associated to different syndromes with a wide spectrum phenotypes. 50 infants with clinical features suggesting a possible 22q11.2 deletion were studied by FISH using TUPLE-1 probe (Vysis). Deletions were observed in 6 cases. Patient 1, aged 3, displayed minor facial features, hypocalcaemia and interrupted aortic arch. Both parents were cytogenetically normal. Patient 2 had dysmorphic face and a congenital conotruncal cardiac defect leading to a neonatal dead. The 22q11.2 deletion was observed in mosaic (89%). Patient 3 showed a retardation of growth and development and facial features, but had a normal heart. The 22q11 deletion was observed in the 60% of the analysed cells. Parents were cytogenetically normal. Patient 4 displayed an interrupted aortic arch. Both parents were normal. Patient 5 showed a truncus arteriosus and minor dysmorphic face. The mother was found to carry the 22q11.2 deletion. She displayed minor facial features and nasal speech and had a normal heart. The other son of the couple was studied by FISH showing no deletion. Patient 6 displayed immunopathy, dysmorphic face and a congenital cardiopathy. Both parents showed a normal karyotype.

**Microdeletion of chromosome 17p13 in isolated lissencephaly sequence (ILS).** *M.I. Melaragno, D. Brunoni, M.F. Galera.* Escola Paulista de Medicina, Sao Paulo Federal University, Sao Paulo, Brazil.

Classical lissencephaly is a brain malformation manifested by a smooth cerebral surface due to an arrest in the neuronal migration. It has been observed in association with the Miller-Dieker syndrome (MDS) or as isolated lissencephaly sequence (ILS). Literature shows that visible or submicroscopic deletions of 17p13.3 are found in about 90% of MDS patients whereas submicroscopic deletions occurring at the same locus are found in 10 to 30% of patients with ILS. A gene known as LIS1 was mapped to 17p13.3 and it has been responsible for classical lissencephaly. The present study focuses on clinical and cytogenetic aspects in ten patients with ILS. Cytogenetic analyses have been performed from lymphocyte cultures. Fluorescent in situ hybridization (FISH) was carried out on metaphase chromosomes using D17S379 Miller-Dieker region probe (Oncor) which hybridizes to specific sequences in 17p13.3. Chromosome 17q21 control probe (RARA) was used along with in order to facilitate chromosome identification. All the ILS patients showed apparently normal karyotypes using G-banding at 550-bands level resolution. However, FISH revealed deletion involving band 17p13 in one of them. The deletion was de novo, since signals on both chromosomes 17 in the patients parents karyotypes were present. No distinct difference was found between the clinical features of the patient with deletion and those with normal karyotype. Although FISH analysis has proved to be the most rapid and sensitive method of detecting deletion, it is not useful for the majority of the patients with ILS, as a considerable number of them (about 40%) presents point mutations or other subtle alterations of the locus LIS1. These findings emphasize the need to investigate not only the presence of molecular cytogenetic deletions but also the presence of mutations through molecular studies (FAPESP; CNPq, Brazil).

**Adeno-Associated Virus rep/cap genes map to the active X chromosome and undergo episomal amplification in a HeLa based AAV producing cell line.** *F. Lu<sup>1</sup>, J.M. Wilson<sup>2</sup>, N.B. Spinner<sup>1</sup>, G. Gao<sup>2</sup>.* 1) Division of Human Genetics, Dept of Pediatrics, Univ. of Penn School of Medicine, Philadelphia, PA; 2) Institute for Human Gene Therapy, Univ. of Penn School of Medicine, Philadelphia, PA.

Recombinant adeno-associated virus (AAV) is one of the most promising vectors for gene therapy. HeLa cells that contain the AAV rep/cap genes, are uniquely capable of serving as packaging cell lines for the AAV vector. We have studied the AAV packaging line, B50, a HeLa based cell line that has the AAV rep/cap genes stably integrated to understand the basis for this selective suitability of HeLa cells. Using fluorescence in situ hybridization (FISH) we mapped a single integrated rep/cap site to one of the two X chromosomes in the B50 genome. This was confirmed by dual-color FISH with a pericentromeric X chromosome probe. The rep/cap gene integrated into Xq26-27. Of interest, this integration site is in the vicinity of a global transcript activator (hSNF2L) that contains a Rep recognition sequence (RRS). This suggests that the Rep protein may play a role in this site-specific integration. In order to determine if the X chromosome containing the rep/cap genes was the active X, we carried out FISH to detect the replication pattern of the Xist gene. We studied 92 interphase nuclei and metaphase chromosomes. Twenty two percent of nuclei gave an asynchronous pattern of Xist gene hybridization. This is consistent with a difference in the replication timing of this gene on the two homologues. All of those cells with an asynchronous pattern had a doublet hybridization signal on the X chromosome without the rep/cap gene integrated. This is consistent with the X chromosome containing the rep/cap genes being the active X chromosome. We studied B50 cells after infection with adenovirus (AV) to analyze the effect on the rep/cap gene. Our results demonstrate that AV infection leads to the amplification of rep/cap gene episomally. Distinct images of the amplified rep/cap gene could be visualized in the cytoplasm 36 hours after AV infection. Rep/cap gene amplification may be a crucial requirement for AAV packaging.

**Individual and chromosome specific differences in telomere length and age-related somatic cell aneuploidy frequencies: A twin study.** *N.T. Leach, L.A. Corey, C.K. Jackson-Cook.* Human Genetics, VCU-MCV, Richmond, VA.

An increased frequency of sex chromosomal aneuploidy in lymphocytes is correlated with aging, especially in females. However, the frequency of age-related autosomal aneuploidy in various tissues is unclear. Also, the contribution that genetic and/or environmental factors make to age-related aneuploidy is not known. To gain this information, we determined the frequency of aneuploidy for a subset of chromosomes in lymphocytes (X,3,5,9,13,16,17 and 21) and buccal mucosa cells (X,17) using FISH. To date, we studied 10 female twin pairs ranging in age from 45 to 58 y.o. In lymphocytes, chromosomes X (3.9%) and 17 (3.2%) showed the highest level of loss, with chromosome 13 (0.6%) showing the lowest loss frequency. No clear association between chromosome size and its loss frequency was detected. Levels of chromosomal gain ranged from 1% (X chromosome) to 0.3% (chromosomes 9 and 17). The frequency of X chromosomal loss and gain was significantly lower ( $p < 0.001$ ) in buccal mucosa cells compared to lymphocytes. In contrast, for chromosome 17 the difference in loss frequencies between tissues was less pronounced ( $p = 0.03$ ), with no difference in chromosomal gain being seen ( $p = 0.8$ ). Individual specific frequencies in somatic cell aneuploidy frequencies were also noted between females, with co-twins being more similar to one another than unrelated individuals. A potential association between aneuploidy frequencies and chromosome specific telomere length was determined for each chromosome arm using a semi-quantitative analysis of the intensities of a PNA pantelomeric probe. It may not be fortuitous that chromosome 17 (especially 17p) has been shown to have a small average telomere length and was also noted to have an increased level of somatic cell aneuploidy. This finding is of particular interest since loss of chromosome 17 has been observed in many types of cancer. In summary, we noted differences in the level of age-related aneuploidy between chromosomes and between individuals. Further studies to better define the role that genetic and environmental factors play in age-related aneuploidy should provide insight as to the clinical significance of this phenomena.

**Fast-FISH using repeat sequence-depleted painting probes from microdissected DNA.** *H. He<sup>1</sup>, W. Huang<sup>1</sup>, L. Scheller-Malin<sup>1</sup>, X.Y. Guan<sup>2</sup>.* 1) American Lab Technologies, Inc, Rockville, MD; 2) Department of Clinical Oncology, University of Hong Kong, Hong Kong, China.

There is currently an increasing demand by researchers and clinicians for high quality FISH painting probes that aid in the diagnosis of cancer and hereditary diseases. We have designed a novel method of removing repetitive sequences from microdissected probes resulting in products that are more specific and are easier to use. We named our repetitive sequence-depleted probes "ReSeD Probes". We tested our ReSeD probes of 5p, 9q, 12p, 15q and a few band specific probes in Fast-FISH. When used on metaphase chromosomes and interphase cells, the ReSeD probes produced strong, uniform, and specific hybridization signals with little background staining in only 30 minutes of hybridization. Dual-color Fast-FISH also produced comparable results. These new probes will make Fast-FISH a useful tool for the research and clinical community and allow faster turn around time for individual FISH cases.

**Molecular and cytogenetic studies in Ambras syndrome.** *M. Tadin<sup>1</sup>, E.P. Braverman<sup>5</sup>, C-Y. Yu<sup>1</sup>, J.A. Frank<sup>1</sup>, F.A.M. Baumeister<sup>3</sup>, S. Cianfarani<sup>4</sup>, A.M. Christiano<sup>1,2</sup>, D. Warburton<sup>1</sup>.* 1) Department of Genetics and Development, Columbia University, New York, NY; 2) Department of Dermatology, Columbia University, New York, NY; 3) Dr. v. Haunersches Kinderspital der Universität München; 4) Department of Pediatrics and Public Health, University 'Tor Vergata', Rome, Italy; 5) School of Allied Health, University of Connecticut.

Ambras syndrome (AMS) is a unique form of congenital universal hypertrichosis. In patients with this syndrome the whole body is covered with fine, long vellus hair, except for areas where no hair normally grows. There is accompanying facial dysmorphism and abnormalities of the teeth, including retarded first and second dentition, and absence of teeth. No metabolic or endocrine defect has been detected. Multiple affected family members suggest a genetic basis for the syndrome. An inversion of chromosome 8 has been found in two isolated cases. These inversions have a breakpoint in band q22 in common, suggesting that this region (8q22) contains the gene which causes AMS. Using chromosomal FISH analysis we have narrowed the breakpoint interval to about 500 kb in one of the patients. We also performed loss of heterozygosity (LOH) analysis to check for possible microdeletions that are not evident at the cytogenetic level. A deletion of about 1 Mb was detected in the other patient in the vicinity of the previously defined 500 kb inversion interval. We are currently saturating the region with additional microsatellite markers to determine the borders of the deleted interval. We anticipate that these combined approaches will further narrow the interval and lead to the identification of the Ambras syndrome gene.

**A case with an extra large inverted duplicated chromosome 15.** *S.-D. Cheng*<sup>1</sup>, *S.-P. Lin*<sup>2</sup>. 1) Department of Anatomy, College of Medicine, Chang Gung University, Kweishan, Taiwan; 2) Division of Genetics, Department of Pediatrics, MacKay Memorial Hospital, Taipei, Taiwan.

The proximal region in the long arm of chromosome 15 (15q11q13) has been known to be related to the Angelman syndrome (AS) and Prader-Willi syndrome (PWS). The increase of the copy number of the region, depending on the size, may also create abnormalities to the phenotype. With fluorescence *in situ* hybridization (FISH) method combined with quantitative Southern analyses, we detected a proband with an extra large inverted duplicated chromosome 15 (inv dup(15)). Under DAPI staining an extraordinarily long segment is revealed between two centromeres of the inv dup(15). We tested with FISH with lambda clones of 34-10 (D15S9), 116 (GABRB3) and IR10-1-45 (D15S12) individually. Each of the three probes revealed four copies of the signals on each sister chromatid of the inv dup(15). Together with two copies of each locus on the normal chromosomes 15, the proband has six copies totally in her genome. The quantitative Southern analyses with PhosphorImager indicated that the copy number of p3-21 (D15S10) locus of proband is 2.27 times, and that of p189-1 (D15S13) is two-fold than that of a normal female after normalization with probe 87-15 (DXS164). The proband at her age of 12 featured short stature, hypertelorism, upward slant of palpebral fissures, thin upper lips, mildly dysplastic ears, and simian crease of right hand. She had developmental delay with mental retardation and poor language ability. Other than emotional instability and hyperactivity, she also had neurofibromatosis type I, which is inherited from her mother.

**An *In Situ* Hybridization-Based Strategy to Detect Neuronal Patterns of Genomic Imprinting in the Autism**

**Candidate Region of Chromosome 15q11-q13.** R.A. Kesterson<sup>1</sup>, E.L. Nurmi<sup>1</sup>, D.K. Johnson<sup>2</sup>, J.S. Sutcliffe<sup>1</sup>. 1) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 2) Mammalian Genetics and Development Section, Oak Ridge National Laboratory, Oak Ridge, TN.

Reciprocal patterns of genomic imprinting are involved in the etiology of genomic disorders associated with human chromosome 15q11-q13. Paternal deletions of 15q11-q13 are associated with Prader-Willi syndrome, while maternal deletions of a common region are associated with Angelman syndrome. Interstitial duplications or triplications using similar homologous breakpoints, or "duplicons", and inverted duplications utilizing more distal breakpoints are associated with autism-spectrum phenotypes, possibly in a maternal-specific manner. An autism candidate region has been suggested based on the duplications, as well as linkage and linkage disequilibrium data in a common area. Given the possible involvement of genomic imprinting in the etiology of autism susceptibility in the chromosome 15 region, we are assessing positional and functional candidate genes in this region for neuronal patterns of genomic imprinting using an *in situ* hybridization-based strategy for their murine orthologs. Mice with large deletions encompassing the p locus are hemizygous for genes within the autism candidate region. Using mice with reciprocal maternal or paternal deletions, or controls, we hybridized brain sections with probes corresponding to a cluster of GABA<sub>A</sub> receptor subunit genes (*Gabrb3*, *Gabra5*, and *Gabrg3*), and the p locus. Our initial studies have revealed that these genes do not show complete allele-specific silencing within the brain. We are currently exploring the possibility of more subtle allelic differences in expression. It is feasible that genes within this region may show complex imprinting effects as evidenced by maternal-biased expression of *Ube3a* within certain brain regions. This experimental strategy provides greater sensitivity to detect genomic imprinting in this region compared to northern-based approaches which may not detect subtle patterns of parental-specific expression.

**Molecular analysis of Severe Mental Retardation associated 16p-chromosomal breakpoint.** *K. Bhalla, H. Eyre, A. Gardner, G. Kremmidiotis, G.R. Sutherland, D.F. Callen.* Department of Cytogenetics and Molecular Genetics, The University of Adelaide, Women's & Children's Hospital, Adelaide, Australia.

Identification of families with mentally retarded males has led to the mapping and cloning of a number of X-linked recessive loci and relevant genes for mental retardation. However, there has been little progress in the identification of autosomal genes for mental retardation. We have exploited a *de novo* balanced translocation, 46,XY,t(1;16)(q12;p13.3) in a patient with severe intellectual retardation. We have generated a somatic cell hybrid containing the der(16) of this translocation, designated as CY196. Since the chromosome 1 breakpoint was shown to be within 1q heterochromatin, we propose that this translocation either disrupts a gene on chromosome 16 or alters expression of a gene in the near vicinity by a position effect of the chromosome 1 heterochromatin. Preliminary work in the vicinity of the breakpoint identified *C16orf5*, a novel proline rich gene, highly expressed in the brain. The YAC pulse field map of the region placed this gene distal to CY196. A PAC/BAC contig was then constructed across the chromosome 16 breakpoint. FISH analysis with these clones to the metaphase chromosome identified a PAC clone spanning the breakpoint. The PAC was sequenced and analysis indicates that the region surrounding the breakpoint is repetitive with very few matches to expressed sequences (ESTs) or computer predicted exons. *C16orf5* is the closest gene to the breakpoint and is highly expressed in the brain. Quantitative RT-PCR analysis suggests that the expression of the *C16orf5* transcript is reduced in the patient. We propose that the mental retardation of the translocation patient is the result of reduced expression of this brain specific transcript due to the position effect of the adjacent translocated chromosome 1 heterochromatin. Mutation analysis in the candidate gene will now be carried out to show its involvement in mental retardation.

**Simultaneous Detection of Three Different Chromosomes in Multi-PRINS Using only two types of labeled nucleotides.** Yan J, Bronsard M, Drouin R. Department of Medical Biology, Division of Pathology, Faculty of Medicine, Universit Laval, Hpital Saint-Franois d'Assise, CHUQ, Qubec, Qubec, Canada. *J. Yan, M. Bronsard, R. Drouin.* Dept Medical Biol, Laval Univ, CHUQ Hop.St-Francois d'Assise, Quebec, Quebec, Canada.

In multi-PRINS technique, the blocking step using ddNTP incorporated by a DNA polymerase is an important procedure that can block the free 3-end generated in the last PRINS reaction, thus avoiding the next PRINS reaction to use it as a primer to perform a spurious elongation at non-desired sites. However, in our tests, omission of the blocking step never affected the correct identification of two chromosomes because the signals from the second PRINS reaction site always showed the pure original color. Taking advantage of the color mixing and creating a new color, we successfully performed a multi-PRINS technique to obtain a third color for simultaneous detection of three chromosomes in the same cell. By arranging the incorporation order of the labeled nucleotides either in bio-dig-bio or in dig-bio-dig, two most common labeled nucleotides, biotin- and digoxigenin-dUTP, were alternatively incorporated in the newly synthesized DNA strand during three sequential PRINS reactions. Two detection systems were coupled with the incorporation order: 1) avidin-fluorescein mixed with anti-dig-rhodamine was used for bio-dig-bio incorporation order and 2) anti-dig-fluorescein mixed with avidin-rhodamine was used for dig-bio-dig incorporation order. Three different chromosomes can be identified as yellow, red and green color signals, respectively. We measured the relative intensity of the two original red and green color elements. The results showed that a red signal can contain up to 38% of green color and still appears red, whereas a fluorescent signal must contain at least 43% of green color to generate the yellow color. A green signal can contain up to 12% of red color and still retain its green color. The entire procedure could be completed in less than 90 minutes because the blocking step is omitted. We believe that this multi-PRINS technique is a practical and efficient way to simultaneously detect three or more chromosomes.

**Towards a Full Karyotype Screening of Interphase Cells: 'FISH and Chip' Technology.** *H.U. Weier<sup>1</sup>, J. Fung<sup>1,2</sup>, S. Munné<sup>3</sup>, R.A. Lersch<sup>1</sup>, H.B. Hsieh<sup>1</sup>, X.N. Chen<sup>4</sup>, J. Korenberg<sup>4</sup>, R.A. Pedersen<sup>2</sup>.* 1) Lawrence Berkeley Natl. Laboratory, Berkeley, CA 94720; 2) Department of Ob/Gynecology and Reproductive Sciences, UCSF, CA 94143-0720; 3) St. Barnabas Medical Center, Livingston, NJ 07052; 4) Medical Genetics Birth Defects Center, UCLA, CA 90048.

Translocations carriers have an elevated risk of producing aneuploid germ cells due to disturbed homologue pairing. The resulting numerical chromosome aberrations lead to spontaneous abortions, stillbirth or severe deficiencies and disease. Our laboratories develop technologies to study the chromosomal composition of single interphase cells, e.g., blastomeres. Our work is facilitated by access to large insert genomic DNA libraries, physical maps or collections of cytogenetically mapped DNA probes. Most breakpoint-specific probe sets for interphase cell analyses of patient cells are prepared within a few weeks. Once optimized, these probe sets allow to rapidly determine the number of normal and derivative chromosomes in somatic or germ cells from the carriers as well as their offspring. So far, however, these procedures failed to produce the desired increase in pregnancy rates. Our concern is that gain or loss of other chromosomes due to impaired homologue pairing remains undetected in these assays. Most fluorescence in situ hybridization (FISH) studies using filter-based microscope systems were limited to simultaneous use of 3-4 differently labeled probes. Spectral Imaging (SIm) now allows an investigator to discriminate an increased number of probes by exciting fluorescence over a broad spectral range and recording the emission spectrum with an interferometer. SIm allows to interrogate a much larger number of targets thus producing a more comprehensive picture of the chromosomal composition of cells. Using mostly YAC/BAC probes for analyses of blastomeres, we are building panels of probes to simultaneously score 10 chromosomes. Further increases in the number of probes are complicated by spatial overlap of chromosome domains. We are presently investigating a complementing strategy, in which the DNA probes are immobilized and DNA from the embryonic cells is hybridized to such a DNA Chip in a quantitative manner.

**Interphase FISH analysis on uncultured cells for prenatal diagnosis.** *H. Bruyere, S. Masui, D. Dowsley, D.E. McFadden, T. Pantzar, E. Separovic, F.J. Dill, D.K. Kalousek.* Cytogenetics Laboratory, Department of Pathology, Children's & Women's Health Centre of BC, Vancouver, BC, Canada.

Interphase fluorescence in situ hybridization (FISH) on uncultured amniocytes with a commercially available cocktail of specific probes for chromosomes 13, 18, 21, X and Y is currently being assessed for its use as an alternative or an adjunct to conventional cytogenetics in prenatal diagnosis. It is helpful for rapid confirmation of the most common aneuploidies when the patient is near the legal limit for termination of pregnancy or in late pregnancy when decisions regarding the delivery of fetuses with ultrasound abnormalities are made. FISH analysis is performed along with conventional cytogenetic analysis on amniotic fluid. Among 250 cases analyzed during a 28-month period, 38 common aneuploidies and 3 triploidies were detected. In 9 pregnancies with chromosomal structural abnormalities, FISH showed an abnormal result in 3 cases: 1) An extra derivative chromosome 18 presented as a trisomy 18. 2) An unbalanced robertsonian translocation was correctly interpreted as a trisomy 21. 3) Two cell lines involving missing X chromosome and a rearranged X chromosome were identified. The 6 remaining cases involved an interstitial deletion of chromosome 17q, three 22q11 microdeletions, a paternally inherited balanced translocation between chromosomes 14 and 21 and a derivative chromosome 22 resulting from the abnormal segregation of a maternal balanced translocation previously undiagnosed. Our results show that interphase FISH analysis on uncultured amniocytes is a valuable tool for the rapid detection of the most common aneuploidies. Although this test is not designed to detect structural rearrangements, it may show an abnormal result when the structural abnormality involves one of the 5 chromosomes tested.

**Mosaic triple trisomies isolated to amniocytes.** *T. Creeden<sup>1</sup>, D. Day-Salvatore<sup>1</sup>, L. Sciorra<sup>1</sup>, S. Finkernagel<sup>1</sup>, T. Kletz<sup>1</sup>, E. Guzman<sup>2</sup>.* 1) Division of Clinical Genetics, UMDNJ-Robert Wood Johnson Medical School and Saint Peter's University Hospital, New Brunswick, NJ; 2) Division of Maternal Fetal Medicine, UMDNJ-Robert Wood Johnson Medical School and Saint Peter's University Hospital, New Brunswick, NJ.

We report the prenatal detection of a mosaic triple trisomy, 46,XX/49,XX,+13,+17,+20, in amniocyte culture. Repeat amniocentesis demonstrated the same mosaic triple trisomy results while placental biopsy and percutaneous umbilical blood sampling yielded normal non-mosaic female karyotypes. Targeted level II ultrasonography revealed normal fetal anatomy and appropriate fetal growth. A healthy female infant was delivered at term; postnatal chromosome analysis of lymphocytes and fibroblasts were normal. We postulate that this triple trisomy may be confined to the fetal kidneys or bladder, as this would explain the presence of the trisomic cells in amniotic fluid only. Postnatal renal ultrasounds were reported as normal. Urine sediment chromosome analysis was attempted, but failed to yield results. This is the second reported case of mosaic triple trisomy; the previous case was 46,XY/49,XY,+13,+20,+21 and resulted in a phenotypically and karyotypically normal live born infant. Trisomy 20 has been confined to the placenta or other fetal organs, such as kidney or gut, and results in a normal outcome in the majority of cases. This case provides further evidence that mosaic triple trisomies, involving chromosome 20, may be an extension of the benign isolated trisomy 20 mechanism.

**Clinical associations of women experiencing recurrent spontaneous abortion (RSA) and exhibiting skewed X chromosome inactivation (XCI).** *C.L. Beever<sup>1</sup>, M.D. Stephenson<sup>2,3</sup>, V. Popovska<sup>2</sup>, R. Jiang<sup>1</sup>, K.K. Sangha<sup>1</sup>, K. Ochnio<sup>1</sup>, C.J. Brown<sup>1</sup>, W.P. Robinson<sup>1,3</sup>.* 1) Dept. of Medical Genetics; 2) Dept. of Obstetrics & Gynaecology, Univ British Columbia; 3) Children's & Women's Hospital & Health Centre of B.C., Vancouver, BC, Canada.

RSA, defined as 3 or more consecutive losses under 20 weeks gestation, is estimated to affect 1-2% of couples trying to have a family. Skewed XCI, scored as  $\geq 90\%$  inactivation of one X allele, is significantly increased in women experiencing RSA. To identify the cause of this association, XCI status in blood was determined using a methylation sensitive assay at the androgen receptor locus and correlated with clinical features in RSA women. 19% of the RSA women (n=113) were found to have skewed XCI compared to 5% of controls (n=111) (p=0.001). Preliminary studies of buccal samples from a subset of the RSA women showed that skewed XCI can be present in both blood and buccal cells. If RSA and skewed XCI were the result of women being carriers of X-linked lethal mutations, we would expect an excess of male abortuses and an excess of female livebirths in those women with skewed XCI. However, 2 of 3 karyotyped abortuses and 7 of 10 livebirths were male. If RSA and skewed XCI were the result of maternal germline trisomy mosaicism, we would expect an excess of age-independent aneuploid losses from RSA women with skewed XCI. Although 10 of 14 karyotyped abortuses from the skewed XCI women were aneuploid as compared to 30 of 73 abortuses from the non-skewed XCI women (p=0.02), increased maternal age was associated with aneuploid losses in both the skewed and non-skewed groups of women with RSA. Of the 17 couples with RSA and skewed XCI who completed clinical investigations, 8 were classified as having autoimmune-associated RSA, 8 with unexplained RSA and 1 with anatomical-associated RSA. Although preliminary data show this is not statistically significant compared to the non-skewed group, the trend towards an increased rate of autoimmune-associated and unexplained RSA couples is of interest. Further studies will clarify these associations and assist in the management of couples with this complex reproductive problem.

**X/Autosomal translocations in the Xq region associated with premature ovarian failure fall both within and outside genes.** *L.M. Herrera<sup>1</sup>, S. Mumm<sup>2</sup>, A. Forabosco<sup>3</sup>, P.W. Waeltz<sup>1</sup>, L. Ruini<sup>3</sup>, R. Nagaraja<sup>1</sup>, T. Esposito<sup>3</sup>, M. Rocchi<sup>4</sup>, D. Schlessinger<sup>1</sup>.* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Division of Bone and Mineral Disease, Washington University School Medicine and Barnes-Jewish Hospital, St. Louis, Missouri; 3) Department of Morphology and Legal Medicine Sciences, University of Modena and Reggio-Emilia, Modena, Italy; 4) Istituto di Genetica, Bari, Italy.

Premature ovarian failure (POF), which affects 1% of women, is characterized by a cessation of ovarian function before the age of 40 years. POF has been linked to X-chromosome abnormalities, including X/autosome balanced translocations. Mapping of breakpoints has shown that they tend to concentrate in a large "critical region" (Xq13-Xq26), that is inferred to be required for the maintenance of ovarian function and normal reproductive lifespan. To account for X involvement in POF, one model predicts that breakpoints interrupt specific genes involved in ovarian development; a second model predicts that defects in meiotic pairing provoked by the rearrangements in X chromosome result in excessive apoptosis of follicles. For the second model, breakpoints might fall inside or outside of genes. Three translocations located at the borders of the critical region were analyzed (one in Xq13.3, and two in Xq26). Patient chromosomes were isolated in somatic cell hybrids, breakpoints were mapped, and sequence analysis was carried out. The Xq13.3 breakpoint falls in a region that is essentially totally comprised of repeat sequences, with a low GC content and no gene within 40kb in either direction. One breakpoint in Xq26 maps in a highly transcribed region, and when fully analyzed, interrupts a gene that encodes a widely-expressed member of the ETS transcription factor family. The third breakpoint falls in uncloned DNA, though in a gene-poor region. The analyses suggest that POF can result from breaks both within and outside of genes, increasing the possibility that a disturbance of X chromosome dynamics, perhaps related to X-inactivation, may be involved in the etiology of the condition.

**Satellite-like Projection of Chromatin - a possible marker for anticipation of fragile sites, detected in a case of Fanconi Anemia.** *P.F. Madon, A.S. Athalye, D.J. Naik, V.C. Sarangdhar, F.R. Parikh.* Dept.of Assisted Reproduction & Genetics, Jaslok Hospital, Bombay, India.

A satellite-like projection of chromatin situated along the length of the outer margin of some chromosomes, has occasionally but consistently been observed during routine cytogenetic analysis. This marker is more commonly seen while screening for fragile sites, when blood is cultured in a low folic acid medium. It has also been observed in the fuzzy outline of some chromosomes in leukemia patients. Its appearance is similar to the stalk and satellite of acrocentric chromosomes. On further analysis it was observed that the location of this marker was mainly confined to G-light band regions and corresponded with fragile sites. However no visible chromatid gap was seen. Recently, while analysing the results of the Mitomycin C (MMC) chromosome stress test in a 2 year old boy from Bhopal suspected to have Fanconi Anemia, this satellite-like marker was noticed in 2% of 400 metaphases. In some cells, the location of this marker was at the same site at which chromatid breaks were observed. The child had congenital bilateral syndactyly of all digits on the hands and distal triphalangeal thumbs. MMC tests showed 88% breaks and 10% radials in cultures at a final concentration of 80ng/ml MMC as compared to 38% breaks and 2% radials in his parents. He was diagnosed as having Fanconi Anemia though he did not have other clinical manifestations at this age except a low Hb count of 10g/dl. We hypothesize that this marker could help in early identification of hotspots of fragile sites even before the unstained gap is visible. This could have important implications as fragile sites are known to play an integral role in tumorigenesis as they often occur at the site of cellular proto- oncogenes. Further studies using different fragile site inducing agents, CGH and scanning electron microscopy are indicated. Similar markers have been reported to be linked with DNA amplification of oncogenes, nucleolar organising regions and double or single minutes. Chromosome microdissection if possible and molecular analysis may help to characterize this marker and develop a means to anticipate cancer. >>>>.

**Complex chromosomal rearrangement and review of familial cases.** *G.S. Sekhon<sup>1</sup>, M.S. Williams<sup>2</sup>, K.J. Thompson<sup>1</sup>, M.K. Sharifi<sup>1</sup>.* 1) Div Clinical Gen, Waisman Ctr, Univ Wisconsin, Madison, WI; 2) Dept. of Pediatrics, Gundersen Lutheran Medical Center, LaCrosse, WI.

A familial case of complex chromosomal rearrangement (CCR) was ascertained through a male newborn infant with respiratory distress and multiple congenital anomalies including wide sagittal suture, flat occiput, bifid uvula, short thumbs, clinodactyly and camptodactyly of the fifth fingers, bilateral hip dislocations, small penis, undescended testes, and a two vessel cord. Neurological examination identified an unusual cry and abnormalities of muscle tone. CT of the head demonstrated a Dandy-Walker variant. No renal or cardiac anomalies were present. The mother had a balanced reciprocal translocation involving chromosome 1, 4, and 9. The karyotype is: 46,XX,t(1;9;4)(q44;q32;q33). The malsegregation of the CCR resulted in partial duplication of chromosome 4 and 9 and a tiny deletion of 1q terminus resulting in karyotype: 47,XY,der(1)t(1;9;4)(q44;q32;q33),+der(9)t(1;9;4)(q44;q32;q33)mat. A review of 40 familial cases of CCRs led to the following: 1) familial CCRs have fewer chromosomes involved and fewer breakpoints than de novo CCRs, 2) there is an excess of balanced female carriers among the offspring of index carriers, 3) familial transmission is usually through female carriers although the origin of de novo abnormality is frequently paternal, 4) meiotic segregation resulting in abnormal liveborn infant is usually due to adjacent 1 segregation, followed by 4:2 segregation.

**Gene expression analysis of developing mouse utricle by oligonucleotide array and implication in deafness gene identification.** Z. Chen<sup>1,2</sup>, K. Karimi<sup>3</sup>, D. Zhang<sup>1,4</sup>, M. Rivolta<sup>5</sup>, R. MacDonald<sup>1</sup>, M. Holley<sup>5</sup>, J. Corwin<sup>3</sup>, D. Corey<sup>1,2,4</sup>. 1) Neurology Dept, Massachusetts General Hosp, Boston, MA; 2) Dept. of Neurobiology, Harvard Medical School, Boston, MA; 3) Dept. of Otolaryngology-HNS and Neuroscience, University of Virginia School of Medicine, Charlottesville, VA; 4) Howard Hughes Medical Institute; 5) Dept. of Physiology, School of Medical Sciences, University of Bristol, UK.

Microarray technology utilizes a massively parallel approach to study gene expression at the global level. This approach is particularly suited to investigate the expression pattern of the inner ear, where limited tissue and inaccessibility has traditionally hampered study on its development and function. The utricle is one of two vestibular organs in the inner ear that detects gravity and linear acceleration of the head. With a relatively simple organization, it is a useful model for other hair-cell organs such as the cochlea and semicircular canals. Using oligonucleotide array technology, we studied the gene expression profile of the mouse utricle during developmental stages critical for maturation of hair cell function. Oligonucleotide array analysis is sufficiently sensitive to detect genes expressed in the hair cells (~1,000 hair cells per utricle). Cluster analysis revealed genes involved in pathways important to the development and function of the utricle. Enzymatic and pharmacological approaches were employed to select different cell populations for oligonucleotide analysis, which allows the identification of cell-type-specific pathways in the multicellular environment. Cell lines derived from mouse utricle showed expression profiles similar to that of utricle, suggesting that it can be used to study genes specifically expressed in the utricle. Most known deafness genes were found in the clusters representing the mature utricle, suggesting that these clusters may contain additional genes for inherited hearing loss. The ability to cluster disease genes in a particular tissue will have an important implication for disease gene identification in general.

**SLC5A3 GENE EXPRESSION REGULATES FETAL MYO-INOSITOL LEVELS.** *R. Buccafusca, S. Wu, J. Golden, K. McVeigh, G. Berry.* Pediatrics, University of Pennsylvania, Philadelphia, PA.

A Na<sup>+</sup>/myo-inositol cotransporter such as the SLC5A3 protein is responsible for Na<sup>+</sup> and energy dependent concentrative uptake of myo-inositol in certain mammalian tissues. The synthesis of membrane phosphoinositides such as phosphatidylinositol-4,5-bisphosphate, phosphatidylinositol-3-phosphate and phosphatidylinositol-anchored proteins is dependent on an adequate concentration of cellular myo-inositol. During fetal life, myo-inositol is maintained at much higher concentrations in blood and spinal fluid than in the adult mammalian organism. In order to assess the importance of the SLC5A3 gene in fetal-placental homeostasis of Ins, we generated SLC5A3 (-/-) and (+/-) mice by targeted gene inactivation and studied the effect on gene expression and fetal Ins levels. The SLC5A3 (-/-) mice die shortly after birth, manifest no SLC5A3 mRNA and have a 80-90% reduction in whole fetal Ins levels. The gene is highly expressed in fetal and placental tissues. Carriers demonstrate intermediate tissue Ins levels and SLC5A3 mRNA levels that persist into adult life. The homozygous SLC5A3 null mutation is lethal probably because of severe Ins deficiency as the SLC5A3 gene is essential for maintenance of the Ins concentration gradient in the fetal-placental unit. The consequences of SLC5A3 underexpression in the carrier state remain to be determined.

**Expression pattern of the NOGGIN gene during human bone development fits with the clinical spectrum of proximal symphalangism and multiple synostosis syndrome but not with spondylocarpotarsal synostosis.** *J. Augé<sup>1</sup>, V. Cormier-Daire<sup>1</sup>, J. Amiel<sup>1</sup>, S. Audollent<sup>1</sup>, J. Martinovic<sup>1</sup>, F. Encha-Razavi<sup>1</sup>, D. Esnault<sup>1</sup>, S. Lyonnet<sup>1</sup>, A. David<sup>2</sup>, A. Munnich<sup>1</sup>, M. Le Merrer<sup>1</sup>, M. Vekemans<sup>1</sup>, T. Attié-Bitach<sup>1</sup>.* 1) Dep de genetique INSERM-U393, Hopital Necker-Enfants Malades, Paris, France; 2) Service de génétique médicale, CHU Hopital Mère Enfant, Nantes, France.

Recently NOGGIN mutations have been identified in two autosomal dominant disorders both characterized by multiple joint fusion: proximal symphalangism (SYM1) and multiple synostose syndrome (SYN1). Interestingly, the *noggin*<sup>-/-</sup> mutant mice present joint vertebral body fusion and synostoses of proximal large joints, both features being reminiscent of spondylocarpotarsal synostosis syndrome or synspondylism in human. Therefore, in order to assess the role of NOGGIN in joint fusion syndromes, we sequenced the NOGGIN gene in 5 cases of SYM1, SYN1 or synspondylism and performed in situ hybridization studies of NOGGIN during human development. A 12 bp NOGGIN deletion was identified in a SYN1 case and a missense mutation (P35S) was found in a SYM1 case also presenting with complete absence of distal phalanga. Accordingly, the NOGGIN gene was expressed in cartilage of all bones examined, namely phalangeal, carpal, tarsal, rib and vertebral bones. NOGGIN was also strongly expressed in perichondrium of distal phalanges, medial carpal bones and cubitus, but not in vertebral perichondrium. Consistent with these results, we failed to find any NOGGIN mutation in three patients with synspondylism. This study confirms the involvement of NOGGIN in SYN1 and SYM1 and suggests that NOGGIN is not associated with synspondylism in humans.

**Neuronal migration defects in Lis1 mutant mice are accompanied by abnormalities in cell Proliferation and survival**  
*Lis1*. M.J. Gambello<sup>1,2</sup>, A. Wynshaw-Boris<sup>1</sup>. 1) Department of Pediatrics, UCSD School of Medicine, San Diego, CA; 2) HHMI Physician Fellow, UCSD, San Diego, CA.

Haploinsufficiency of the LIS1 gene plays a major role in the etiology of two human neuronal migration disorders characterized by classical lissencephaly: Miller-Dieker syndrome and isolated lissencephaly sequence. Mice heterozygous for a Lis1 null allele (HET) exhibit a cell autonomous in vivo and in vitro neuronal migration defect. To understand the pathogenesis of classical lissencephaly, a developmental analysis was done in HET and compound heterozygous mice (CH) containing a null and a hypomorphic allele. BrdU birthdating in Lis1 mutant mice demonstrate a slowing of neuronal migration proportional to Lis1 reduction. The preplate of Lis1 mutant mice is split into the marginal zone and subplate by invading cortical plate neurons, however in the CH the subplate remains diffuse, suggesting that some neurons failed to migrate out of this zone. By E15.5 CH brains are smaller than wildtype brains suggesting a defect in proliferation and/or cell survival. Analysis of neural precursor proliferation of E15.5 embryos by BrdU pulse labeling reveal a 20 and 40% reduction in absolute number of proliferating cells in HET and CH mice respectively, but a similar mitotic index in all three genotypes. Finally, histologic analysis reveals more pyknotic nuclei in embryonic and postnatal CHs suggesting increased apoptosis. To further assess the possibility of cell cycle defects, mitotic figures were identified by immunohistochemistry. In wildtype brains most mitoses are seen along the ventricular lumen with few in the subventricular zone. The CH shows fewer neuroblasts in M phase along the ventricular lumen, and more M phase cells scattered throughout the thinner ventricular zone. This may represent a defect of interkinetic nuclear migration and/or be reflective of cell cycle dysregulation. These development analyses of Lis1 mutants demonstrate a tripartite role for Lis1 in the pathogenesis of classic lissencephaly involving delayed neural migration, cell proliferation, and apoptosis. *LIS1Lis1Lis1Lis1*

**Ectopic over-expression of the dosage dependent gene, ZIC2, in transgenic mice results in severe CNS malformation.** *L.Y. Brown, S. Brown.* Obstetrics and Gynecology, Columbia University, New York, NY.

*Zic2* is zinc finger transcription factor which is one of the vertebrate homologues of the *Drosophila* odd-paired or *opa* gene. That *Zic2* has a critical role in CNS development has been demonstrated by the fact that heterozygous mutations in humans result in holoprosencephaly (HPE) and diminished gene dosage results in a similar phenotype in mice. In addition, chromosome 13 q32 deletions which include *ZIC2* result in severe brain malformations. All of these observations demonstrate that brain development is exquisitely sensitive to the level or dosage of *Zic2* protein present, although the developmental pathway in which *Zic2* functions is unknown. Because *Zic2* is dosage sensitive, we sought to test the hypothesis that increased levels of *Zic2* protein during development may also result in brain malformation and that increased *Zic2* dosage may be part of the basis for the developmental defects caused trisomy 13 and distal chromosome 13 duplications. To this end, we placed the *ZIC2* cDNA under the regulation of the enhancer elements of the neurofilament protein, nestin and introduced this construct into mouse oocytes by pronuclear injection. Injected pronucleii were transferred to foster mothers in order to generate transgenic mice. Foster mothers were sacrificed at day 12.5 and day 14.5 of gestation and embryos were inspected grossly and analyzed by serial sectioning and in-situ hybridization. All embryos which expressed the transgene were multiply malformed. Malformation ranged from exencephaly in the most severe cases to distortions of the spinal cord and forebrain structures in less severe cases. All of the malformations seen were likely to be lethal. Analysis of transgenic embryos showed an over abundance or over proliferation of neural tissue in response to transgene expression, whereas the basic patterning of CNS structures, in general, remained intact. This result suggests that *ZIC2* has a role in proliferation and or maintenance of specific pre-neuronal cells of the CNS. Current experiments are directed towards a more refined model of *ZIC2* overdosage and towards understanding of the pathway through which *ZIC2* acts.

*opa.*

**Comparative expression of the SHH, GLI3 and JAG1 genes in normal and neural tube defects human embryos.**

*I. Kirillova*<sup>1,2</sup>, *I. Novikova*<sup>2</sup>, *L. Galaganova*<sup>2</sup>, *J. Augé*<sup>1</sup>, *S. Audollent*<sup>1</sup>, *C. Crosnier*<sup>3</sup>, *D. Esnault*<sup>1</sup>, *F. Encha-Razavi*<sup>1</sup>, *T. Attié-Bitach*<sup>1</sup>, *M. Vekemans*<sup>1</sup>. 1) Dep de Genetique INSERM-U393, Hopital Necker-Enfants Malades, Paris, France; 2) Institute of Hereditary Diseases, Minsk, Belarus; 3) INSERM-U347, Kremlin Bicetre, France.

SHH, GLI3 and Jagged1 (JAG1) are known to be important determinants of early development in several species. In humans their mutations are associated respectively with holoprosencephaly, Greig, Pallister-Hall and Allagille syndromes. Here we analysed their central nervous system (CNS) expression pattern in normal as well as in 5 neural tube defects (NTD) human embryos. In normal embryos (CS 12 to 21), GLI3 is expressed in the dorsal part of the neural tube in an opposite manner to the SHH gene which is expressed in the ventral part of the CNS and in the floor plate. The JAG1 gene is expressed in a ventral region of the neural tube flanking the floor plate, in a dorsal region flanking the roof plate as well as in two middle strips at and below the sulcus limitans. In the cranial region of the NTD embryos, additional domains of expression of the GLI3 and JAG1 gene are observed. In the thoracic region, where several expression domains of the SHH gene are observed, GLI3 expression is abnormally detected in the floor plate. Also additional domains of JAG1 expression are still observed in this region. In the caudal region SHH gene expression is displaced suggesting a vertical floor plate. A symmetrical GLI3 gene expression is observed on either side of the closed neural tube but an asymmetrical (or absent) pattern of expression is observed in the open one. Further studies are necessary to identify genes that are differentially expressed between normal and NTD embryos. For example, large-scale gene expression studies using microarray techniques should contribute to our understanding of the pathogenesis of neural tube defects in humans.

**Novel polymorphisms in the upstream region of VIPR2 gene suggest a possible role in gastrointestinal problems and stereotypical behaviors in autism.** *E. Asano<sup>1</sup>, H. Kuivaniemi<sup>2</sup>, M. Huq<sup>1</sup>, G. Tromp<sup>2</sup>, M. Behen<sup>1</sup>, R. Rothermel<sup>1</sup>, J. Herron<sup>1</sup>, D.C. Chugani<sup>1</sup>.* 1) Children's Hosp. of Michigan, Wayne State Univ., 3901 Beaubien St., Detroit, MI; 2) Center for Molecular Medicine and Genetics, Wayne State Univ., Scott Hall 3106, 540E. Canfield Ave., Detroit, MI.

We investigated the vasoactive intestinal peptide receptor type 2 (VIPR2) gene as a candidate gene for autism because: (1) VIPR2 gene is mapped near the region on 7q with suggested linkage to autism, (2) VIPR2 is expressed in embryonic brain, (3) VIP has neuroprotective actions, and (4) many autistic children have gastrointestinal problems. We searched for mutations in the VIPR2 gene in autistic patients and identified a novel seven-nucleotide deletion in the promoter region. We also found nine novel single-nucleotide polymorphisms (SNPs): four in the promoter region, one in the 5' UTR, and four in the coding region, none of which changed an amino acid. Three polymorphisms in the upstream region were studied in detail and there was no significant difference in the frequencies between the autistic group (N=15) and unrelated controls (N=52). Autistic subjects who were heterozygous for the seven-nucleotide polymorphism, however, had gastrointestinal problems more frequently than those with homozygous insertion or deletion genotype (Fishers exact test,  $p=0.028$ ). Conversely, autistic patients with GG genotype for the A-G SNP of the 5' UTR had gastrointestinal problems more frequently than those with AG or AA genotypes ( $p=0.030$ ). Moreover, there was a correlation between the genotypes for the C-T SNP of the promoter region and the severity of stereotypical behavior as ranked by Gilliam Autism Rating Scale (Spearman's rank order test,  $p=0.039$ ). These preliminary results suggest that VIPR2 may be a modifier locus for autism altering the presence or severity of gastrointestinal problems and stereotypical behaviors.

**Aristaless Related Homeobox (ARX) Gene is Expressed in a Subset of Neuronal Precursor Cells and Post-Mitotic Neurons in Human Fetal and Adult Brain.** R. Ohira<sup>1</sup>, Y.-H. Zhang<sup>2</sup>, W. Guo<sup>2</sup>, K. Dipple<sup>2</sup>, S.L. Shih<sup>2</sup>, J. Doerr<sup>3</sup>, B.-L. Huang<sup>2</sup>, L.J. Fu<sup>4</sup>, A. Abu-Khalil<sup>4</sup>, D.H. Geschwind<sup>4</sup>, E.R.B. McCabe<sup>2</sup>. 1) Human Genetics; 2) Pediatrics; 3) Microbiology and Molecular Genetics; 4) Neurology, UCLA, Los Angeles, CA.

Arx is a homeobox-containing gene with a high degree of sequence similarity between mouse and zebra fish (Miura et al, *Mech Dev* 65:99, 1997). Arx is expressed in the forebrain and floor plate of the developing central nervous systems (CNSs) of these vertebrates and in the presumptive cortex of fetal mice. Our goal was to identify genes in Xp22.1-p21.3 involved in human CNS development. Our in silico search for candidate CNS developmental genes noted that annotation of a human Xp22 PAC (RPC11-258N20) sequence (GenBank No. AC002504) identified putative exons consistent with an Arx homologue in Xp22. Northern blot analysis showed that human ARX was expressed in fetal and adult brain, and we also observed increased levels of expression in placenta and in adult heart, skeletal muscle, liver and kidney. In situ hybridization with an ARX anti-sense cRNA probe onto human brain sections at various developmental stages (fetal-adult) showed highly restricted expression patterns that differed from those reported in mouse. Embryonic expression was highest in neuronal precursors in the germinal matrix and a subset of post-mitotic neurons in the cortex and hippocampus. ARX marked a discrete subset of cortical neurons in the adult. The expression pattern suggests that ARX is involved in the differentiation and maintenance of specific subsets of neuronal phenotypes in the human CNS. We also mapped the murine Arx gene to the mouse genome using a mouse/hamster radiation hybrid panel to determine whether Arx and ARX are orthologues or simply members of the same gene family. Arx mapped to the murine X chromosome in the region containing Dmd, Gyk and Zfx and syntenic with the ARX locus. We conclude that ARX is the human orthologue of murine Arx and is an Xp22 gene involved in human fetal brain development. We speculate that ARX is a candidate gene for X-linked mental retardation and/or structural brain abnormalities.

**Abnormal signalling pathway caused by FGFR 3 mutations in the cartilage of Achondroplasia and Thanatophoric Dysplasia patients.** *L. Legeai-Mallet, C. Benoist-Lasselin, V. El Ghouzzi, A. Munnich, J. Bonaventure.* Genetique INSERM U393, Hopital Necker, Paris, France.

Achondroplasia (ACH), and Thanatophoric Dysplasia (TD) type I and II, three autosomal dominant chondrodysplasias of increasing severity, have been ascribed to recurrent missense mutations in different domains of the Fibroblast Growth Factor Receptor 3 (FGFR 3). Some of these mutations have been demonstrated to induce constitutive activation of the receptor through a ligand-independent process, but the mechanisms by which FGFR 3 mutations alter bone growth in human are still unclear. Here we show by immunostaining analyses of cartilage sections from ACH and TD I and II patients that overexpression of the mutant receptor was associated to an activation of the Signal transducers and activators of transcription Stat 1 and Stat 5a protein levels in the pre-hypertrophic and hypertrophic chondrocytes of both ACH and TD patients. Expression of the cyclin dependent kinase (cdk) inhibitor p21CIP1, one of the targets for Stat 1/5a was also increased to various extents pending on the severity of the disease. By contrast expression of collagen type X, a specific marker of hypertrophic cells, was dramatically reduced especially in TD I samples, being restricted to the last row of chondrocytes. Evaluation of apoptosis by using the TUNEL assay and quantifying annexin V positive-cells revealed that the number of apoptotic cells in primary cultured chondrocytes derived from the cartilage of control and TD patients raised from < 1% to 5%. We conclude that gain of function mutations in the FGFR 3 gene lead to activation of the Stat pathway by promoting phosphorylation and translocation of Stat 1 and Stat 5a into the nuclei of patient chondrocytes. We speculate that binding of the Stat 1/5a transcription factors to the promoter of the target gene p21CIP1 would induce overexpression of the protein in the cartilage growth plate and premature cell death of abnormally differentiated chondrocytes, thus resulting in growth retardation of long bones.

**Two novel retinoic acid-sensitive genes isolated by an induction gene trap approach.** *M. Schlicker<sup>1</sup>, D. Barthelmes<sup>1</sup>, K. Recker<sup>1</sup>, W. Wurst<sup>2</sup>, I. Hansmann<sup>1</sup>.* 1) Humangenetik und Med Biol, Martin-Luther Univ, Halle/Saale, Germany; 2) Molekulare Neurogenetik, GSF, Neuherberg, Germany.

In man and mammals prenatal exposure to the teratogens retinoic acid (RA) and/or retinoids (RX) results in characteristic congenital anomalies including cardiac and craniofacial malformations. Incidence and pattern of the malformations apparently depends on dose and stage of exposure. Yet, the respective molecular mechanisms as well as the genes involved are more or less unknown. RA/RX signalling is mediated by intracellular RA/RX binding proteins and nuclear receptors that activate target genes containing RA-binding elements (RAREs). Based on a retinoic acid-induced gene trap approach (Forrester et al., 1996) we set up a strategy to identify RA/RX downstream genes of mouse and human development that are possible candidate genes to be involved in the generation of congenital malformations. By RACE-PCR of trapped ES clones we identified two novel genes that are expressed in early brain and/or heart. In northern analyses a cDNA fragment of the 1st gene (EScD-1) identifies a brain-specific 6 kb transcript in embryonic midbody (10d p.c.) and adult heart. The 2nd gene (EScD-2) is expressed in fetal brain (2.5 kb) and heart (1.4 kb). By screening of mouse and human Marathon-cDNA libraries we identified about 2 kb (EScD-1) and 1.4 kb (EScD-2) of the respective cDNA sequences including the polyA-tails. The mouse and human sequences of the genes share homologies of 96 % (EScD-1) and 98 % (EScD-2). Searches for human homology revealed that the human gene EScD-2 is represented within human BAC and cosmid sequences mapping to chromosome 16p13.3. Breakpoints within that chromosome segment are known to be associated with cardiac anomalies. Using EScD-1 cDNA primers we isolated a human BAC clone and localized the respective gene on chromosome segment 7q32 by FISH. The detailed analysis of the expression patterns of EScD-1 and EScD-2 by whole mount in situ hybridization and the study of the mouse gene trap phenotypes will give information about the involvement of the two genes in human early development and specific disorders of brain and/or heart. (Supported by DAAD and DFG).

**Generation of novel models of congenital anomalies using ENU mutagenesis.** *B.J. Herron<sup>1</sup>, K.S. Simms<sup>1</sup>, H. Peters<sup>1</sup>, W. Lu<sup>1</sup>, S. Liu<sup>1</sup>, M. Justice<sup>2</sup>, D. MacDonald<sup>3</sup>, D.R. Beier<sup>1</sup>.* 1) Genetics Division, Brigham & Women's Hospital/Harvard Medical School, Boston, MA; 2) Baylor University Medical Center, Houston TX; 3) Wichita State University, Wichita, KA.

The generation of models of congenital malformation syndromes can be useful both for the identification of genes important to mammalian development and for understanding the molecular basis of birth defects. We are presently using a systematic approach to screen embryos derived from mice mutagenized with ENU for recessive phenotypes similar to human congenital defects. We use a backcross breeding scheme in which third generation progeny are evaluated at embryonic d18.5. In this manner we identify defects in organogenesis that are consistent with survival *in utero* nearly full term, but which may cause post-natal lethality. Affected progeny from these lines are used directly in genetic mapping utilizing our previously described method of interval haplotype analysis. With this strategy, we are able to localize the mutation to a single linkage group by genotyping 9-10 probands using only 60 markers.

The main component of the mutation screen is a gross assessment of major organs after dissection, followed by a more detailed analysis for anomalies of kidney and brain (by histological examination), and skeleton (by bone stains). Our screening employs a hierarchical strategy in which each familial cohort is analyzed for abnormalities in at least 3 litters. Families for which a significant anomaly is found (about 70%) are further tested by examining 3-6 additional litters for reproducibility of the phenotype. The yield of abnormal phenotypes that appear to segregate in a Mendelian fashion is presently 20% of fully tested families. The spectrum of phenotypes found to date is remarkably varied, and includes developmental disorders of heart, palate, pancreas, kidney, skeleton, muscle and brain. Many of these disorders are similar to human malformation syndromes. Our results demonstrate that a recessive screen can be extremely productive for the purpose of generating abnormal developmental phenotypes and can be readily managed even in a small laboratory.

**Role of VAX1 and VAX2 in Holoprosencephaly.** J.D. Karkera<sup>1</sup>, Y. Du<sup>2</sup>, E. Roessler<sup>1</sup>, S. Banfi<sup>3</sup>, A. Ballabio<sup>3</sup>, M. Muenke<sup>1,2</sup>. 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia; 3) Telethon Institute of Genetics and Medicine, Milan, Italy.

In order to study the genetic mechanisms of forebrain and eye morphogenesis we have selected two genes from the *Ems/Not* family, *VAX1* and *VAX2*. Recently, a murine *VAX1*<sup>-/-</sup> study displayed defective cleavage of the dorsal forebrain into bilateral vesicles resulting in holoprosencephaly (HPE). There also was a failure of choroid fissure fusion leading to optical coloboma. Similarly, overexpression of *VAX2* in *Xenopus* leads to enlargement of the optic stalk and aberrant folding of the ventral retina towards the brain. We have determined the intron-exon junction of human *VAX1* and *VAX2*. The alignment study of *VAX1* and *VAX2* at the protein level suggests that there is a high degree of conservation of the homeodomain region and these proteins are phylogenetically highly homologous. We are in the process of screening for mutations in these genes in HPE patients. The preliminary data obtained thus far: two missense and two silent mutations in *VAX2*. Both these missense mutations detected are conserved in murine and *Xenopus*. Meanwhile, the normal DNAs will be screened to ascertain whether these changes reflect common polymorphism or novel changes. The DNAs from the respective pedigrees will then be tested for the presence of these particular mutations and further functional studies will be conducted in the early *Xenopus* embryos to evaluate the effect of the mutant *VAX2* molecule.

**Tracheoesophageal fistula, lung hypoplasia and congenital diaphragmatic hernia: a common pathogenesis of foregut malformation?** *C.P. Torfs<sup>1</sup>, M.F. van Dooren<sup>2</sup>, D. Tibboel<sup>2</sup>*. 1) CA Birth Defects Monitoring Program, Emeryville, CA; 2) Sophia Childrens Hospital, Rotterdam, The Netherlands.

Three severe birth defects, congenital diaphragmatic hernia (CDH), tracheoesophageal fistula (TEF) including esophageal atresia and stenosis, and lung hypoplasia (LH) have traditionally been analyzed separately in epidemiological studies. However, recent experimental results in animals have suggested that some common embryological pathways may be shared by the three defects that originate from the budding of the ventral endoderm. Several researchers now postulate that LH may precede or occur concurrently with DH. Experimentally, mutations in several candidate genes such as *Gli2*, *Gli3*, *shh*, *RARab*, *GATA6*, *adrift*, and *HNF-2B* result in the occurrence of one or a combination of these defects. Furthermore, the defects also share environmental risk factors such as vitamin A deficiency and exposure to PHAHs, for example, nitrofen. To evaluate these hypotheses, we studied the prevalence of the combination of these defects in a population of 3,318,966 live and stillbirths in California from 1983 to 1996: There were 493 CDH cases (excluding Morgagni hernia), 893 TEF cases, and 646 LH cases. Of these, 53 (0.2 per 1,000) had TEF + LH and 18 (0.01 per 1,000) had CDH + TEF + LH, a prevalence that is statistically different from the expected ( $P < 10^{-6}$  and  $P < 10^{-6}$  respectively). Both combinations had, respectively: a male predominance (51% and 56%), a high mortality rate (94% and 85%) and high co-occurrence of multiple associated congenital anomalies, among them: heart defects (76% and 78%), limb reduction defect (34% and 33%), anal atresia, stenosis or imperforate anus (51% and 33%), kidney defects (53% and 6%), genital defects (66% and 50%), CNS defects (41% and 39%), vertebral or rib defects (72% and 57%), digestive tract defects (56% and 41%), and orofacial clefts (11% and 15%). Both groups had 11% of trisomies; all but one were trisomy 18. These observations suggest that mutations in genes crucial to foregut development may result in these combinations of congenital anomalies.

**Folate and congenital defects: expression of methylenetetrahydrofolate reductase (*Mthfr*) in early development and effect of folate supplementation in curly-tail (*ct*) mice.** P. Tran<sup>1</sup>, Z. Chen<sup>1</sup>, P. Bagley<sup>2</sup>, J. Selhub<sup>2</sup>, T. Bottiglieri<sup>3</sup>, R. Rozen<sup>1</sup>. 1) Human Genetics, Pediatrics & Biology, McGill University, Montreal, Quebec, Canada; 2) Tufts University, Boston, USA; 3) Baylor University Medical Centre, Dallas, USA.

Folate deficiency is associated with increased risk for neural tube defects (NTD), orofacial clefts (OFC), and congenital heart defects. Periconceptional folate supplementation reduces the occurrence of these anomalies. To investigate the role of folate in early development, we performed two studies: a) we examined the transcriptional expression pattern of *Mthfr* at the time of neural tube closure and b) we assessed the impact of maternal folate supplementation on NTD incidence in the *ct* mouse. MTHFR produces 5-methyltetrahydrofolate, the main circulatory folate derivative. Severe deficiency of MTHFR causes abnormalities of the central nervous system (CNS) and vasculature, while mild deficiency is associated with increased risk for NTD, cardiovascular disease, and possibly for OFC. In situ hybridization of day 8.5, 9.5 and 10.5 C57Bl/6J embryos using an *Mthfr* riboprobe revealed expression in the head, optic eminence, branchial arches, heart and ventral area. From day 8.5 to 10.5, *Mthfr* expression increased notably and progressed rostro-caudally along the ventral region. The expression pattern is compatible with the types of defects seen in our recently-generated knockout mice for *Mthfr* and with the proposed impact of MTHFR on CNS, vascular and orofacial development in humans.

The *ct* mouse is a murine model for NTD, in which 30%-60% of mice are afflicted with tail flexion defects. Data regarding the folate-responsiveness of *ct* mice are inconclusive. Female *ct* mice were administered a folate-supplemented diet at 4 weeks of age, then mated after 8 weeks on diet. Folate levels in maternal livers and in brains of pups reflected the increased folate in the diet. Tail flexion defects were reduced by 25% ( $p=0.03$ ) in 8 day-old pups. Our studies support the important role of folate in early development.

**Characterization of the *Nsdhl* Gene Involved in X-linked, male lethal Chondrodysplasias.** X. Wang<sup>1</sup>, Q. Ma<sup>1</sup>, W. Zhao<sup>1</sup>, T. Fox<sup>1</sup>, J. Hayes<sup>1</sup>, B. Cattanaach<sup>2</sup>, J. Peters<sup>2</sup>, G.E. Herman<sup>1</sup>. 1) Children's Res. Inst., Molecular, Cellular, and Developmental Biology Program, and Depts. of Pediatrics and Pathology, Ohio State U, Columbus, OH; 2) Mouse Genome Centre, Harwell, UK.

*Nsdhl* is a novel 3 $\beta$ -hydroxysteroid dehydrogenase that we have recently shown is involved in the removal of C-4 methyl groups in the cholesterol biosynthetic pathway. Mutations in this gene are associated with the X-linked, male lethal mouse mutations bare patches (*Bpa*) and striated (*Str*) and with human CHILD syndrome. *Bpa* mice have a skeletal dysplasia, cataracts, and early psoriatic/ichthyosiform skin changes. The skin changes resolve producing striping of coat. Milder *Str* alleles are normal in size and have a striped coat. Affected human females with CHILD syndrome demonstrate striking unilateral ichthyosiform erythroderma and limb reduction defects. We have now detected missense mutations, V53D and A94T, in conserved amino acids in two additional *Bpa* alleles. The latter mutation is identical to a missense mutation found by Konig et al. (AJMG, 90:339-346, 2000) in 2 unrelated CHILD patients. Thus, differences in the phenotype between *Bpa* mice and CHILD syndrome cannot be completely explained by different types or sites of mutations. The human and mouse NSDHL proteins have a variant form of a Type I ER membrane localization signal, a carboxy terminal RKDK (mouse) and RRVK (human) and one predicted membrane-spanning domain. Using a GFP-tagged NSDHL fusion protein, we have confirmed the expected subcellular localization of the enzyme to the ER membrane. Finally, *Str* male embryos die in midgestation (10.5-2.5 day pc). Placentas from affected male and female *Str* embryos at day 10.5 are smaller than those of normal littermates (p<0.01) and the labyrinthine layer of the placenta appears thinner and disorganized in some affected embryos. In the mouse, the normal paternal X is inactivated in most extraembryonic tissues. Placental abnormalities may contribute to the lethality of the mutation. However, the finding of similar defects in affected male and female placentas suggests that other fetal factors still to be determined must contribute significantly to the eventual male lethality.

**Ahch Expression in Murine Embryonic Stem Cells Supports Role Early in Development Prior to Differentiation of Steroidogenic Axis.** *R.C. Clipsham<sup>1</sup>, Y.-H. Zhang<sup>2</sup>, B.-L. Huang<sup>2</sup>, E.R.B. McCabe<sup>1,2</sup>.* 1) Molecular Biology Institute; 2) Dept Pediatrics, UCLA Sch Medicine, Los Angeles, CA.

Ahch is the murine homologue of DAX1, a gene that, when mutated, is responsible for adrenal hypoplasia congenita and hypogonadotropic hypogonadism, and, when duplicated, is associated with XY sex reversal. Ahch and DAX1 are known to be expressed in the hypothalamus, pituitary, adrenal cortex and gonads. The purpose of these investigations was to determine whether Ahch was expressed in murine embryonic stem (ES) cells and played a role in development prior to differentiation of the steroidogenic axis. We examined expression by northern blot hybridization and expressed sequence tag (EST) database searches. Ahch was expressed in undifferentiated cultured 129/SvJ ES cells. Preliminary data suggested decreased expression following removal of leukocyte inhibitory factor (LIF), a condition that permitted ES cell differentiation. We are currently examining Ahch expression in cultured ES cells stimulated to differentiate by an alternative mechanism to determine whether or not the observation of decreased Ahch expression is a specific consequence of LIF removal or a general feature of ES cell differentiation. Two other genes, SMRT and NCoR, that code for proteins known to interact with Ahch/DAX1, were also expressed in ES cells. Search of murine EST databases with 20kb of murine genomic sequence containing both Ahch exons identified numerous ESTs from ES cells with 100% matches in the 3' untranslated region. We conclude that Ahch is expressed in undifferentiated ES cells. The expression in these cells of genes coding for proteins known to interact with Ahch/DAX1 is consistent with a functional role for Ahch in undifferentiated ES cells. We speculate that Ahch has a role early in embryogenesis that precedes its later role in the development of the steroidogenic axis.

**Midkine is expressed early in rat fetal adrenal development.** *P. Dewing*<sup>1</sup>, *S. Ching*<sup>1</sup>, *Y.-H. Zhang*<sup>1,2</sup>, *B.-L. Huang*<sup>1,2</sup>, *E.R.B. McCabe*<sup>1,2</sup>, *E. Vilain*<sup>1,2,3</sup>. 1) Dept of Human Genetics, UCLA, Los Angeles, CA; 2) Dept of Pediatrics, UCLA, Los Angeles, CA; 3) Mattel Children's Hospital at UCLA, Los Angeles, CA.

Adrenal gland development is complex and poorly understood at the molecular level. Only a subset of patients with adrenal hypoplasia congenita (AHC) carry mutations in DAX1, a member of the nuclear hormone receptor superfamily. Therefore we set out to identify other candidate genes responsible for AHC by characterizing genes involved in fetal adrenal development. To identify these genes, we studied differential gene expression in embryonic rat adrenals comparing 13-14 with 15 dpc, since these two time points encompassed a period of major morphological change. Fetal rat adrenals were dissected, cDNAs prepared and suppressive subtractive hybridization performed. We isolated 192 clones of putatively differentially expressed clones. Approximately 400bp of each of the clones were sequenced and the most relevant putative developmental genes were examined.

A member of the PTN/MK (pleiotrophin/midkine) heparin-binding protein family was selected for initial study. This is a family of extracellular heparin-binding proteins involved in regulation of growth and differentiation. Midkine(MK) was originally cloned in search for genes transcribed during retinoic acid-induced differentiation. Its expression is ubiquitous at 7-9 embryonic days in the mandible/maxilla, lungs, caudal sclerotomes, limbs and brain ventricles, but limited to the kidney at day 15.

We obtained full length transcript by 5' Rapid Amplification of cDNA Ends (RACE) and performed northern analysis on rat adrenal RNA from fetuses at 13, 14, 15, 17, 19 dpc and newborns. Results from those analyses demonstrated the highest MK expression at days 13 and 14 followed by a moderate decrease of expression during the fetal stages thereafter. At the newborn stage, however, MK expression is nearly undetectable. Our results indicate that MK has a very specific pattern of fetal expression in the adrenals. We conclude that MK is involved early in fetal development of the rat adrenal. Therefore, MK is a candidate genes for AHC not due to DAX1 mutations.

**Mis-expression of human cytochrome P450 (CYP2D6\*17) in the *Drosophila* wing results in wing patterning defects.** *L.T. Reiter*<sup>1</sup>, *B. Biehs*<sup>1</sup>, *D. Ang*<sup>1</sup>, *M. Oscarson*<sup>2</sup>, *E. Bier*<sup>1</sup>. 1) UCSD, La Jolla, CA; 2) Karolinska Institutet, Stockholm, Sweden.

Cytochrome P450s (C-P450) are a group of mixed function monooxygenases that metabolize drugs and toxins in both humans and *Drosophila*. It is estimated that human C-P450 *CYP2D6* is responsible for the metabolism of over 30 clinically relevant drugs like debrisoquine, commonly used for the treatment of hypertension. C-P450s may also be involved in the synthesis of small signal molecules during development as suggested by the finding that mutations in human *CYP1B1* lead to primary congenital glaucoma (PCG). We have begun analyzing the roles of *CYP2D6* and *CYP1B1* during development. This analysis is twofold: mis-expression of wild-type and mutant forms of these proteins in the *Drosophila* wing using the GAL4-UAS system and mutagenesis of the *Drosophila* gene encoding the homologue of *CYP2D6*, *CYP1B1*, *CYP21* and *CYP17*, known as *cyp18*. cDNAs encoding the wild-type human *CYP2D6* gene, a putatively non-heme binding mutant form *CYP2D6-T107A* (*CYP2D6\*17*), and wild-type versions of human *CYP1B1* and *Drosophila cyp18* were placed under the control of the yeast upstream activator sequence (UAS) and introduced into the fly genome. Mis-expression of wild-type UAS-*CYP2D6* driven by the yeast GAL4 transactivator results in a few ectopic wing veins and reduction of endogenous *cyp18* expression in the developing wing disk. Mis-expression of *CYP2D6\*17* induces a significant amount of ectopic vein formation between L2 and L3 and squares off the wing margin. Misexpression of *CYP2D6\*17* also alters endogenous *Drosophila cyp18* expression within the wing pouch. These results suggest that the human C-P450s are able to disrupt the normal *cyp18* expression pattern by binding to and/or modifying the signal molecules synthesized by *cyp18*. Attempts to disrupt the *cyp18* gene via a PCR based P-element mutagenesis scheme are underway. We expect that these studies in *Drosophila* will lead to a mechanistic understanding of the process by which human C-P450 mutations result in disorders such as PCG (*CYP1B1*) and adrenal hyperplasia (*CYP17* and *CYP21*).

**Notch1, Notch2, Notch3 and Notch4 are expressed in the developing mouse liver.** *R.J Oakey<sup>1</sup>, N.B. Spinner<sup>1</sup>, D.A. Piccoli<sup>2</sup>, K.M. Loomes<sup>1,2</sup>.* 1) Division of Human Genetics, CHOP, Philadelphia, PA; 2) Division of Gastroenterology, CHOP, Philadelphia, PA.

Introduction: Alagille syndrome (AGS) is an autosomal dominant disorder characterized by paucity of the intrahepatic bile ducts in combination with developmental abnormalities of the heart, eye, skeleton, face and kidney. Mutations in human Jagged1, a ligand in the Notch intercellular signaling pathway, have been found to cause AGS. We have demonstrated previously that Jagged1 expression in the developing mouse and human liver co-localizes with the primitive bile duct cells or ductal plate. In order to determine which of the Notch receptors interacts with Jagged1 in the liver, we have assayed expression of the Notch genes during development. Methods: RNA and serial sections were generated from staged mouse embryos and developing mouse livers. Expression of Notch1, Notch2, Notch3 and Notch4 was assayed by RT-PCR and in situ hybridization. Results: Notch1,2,3 and 4 are expressed at all stages assayed in the mouse from 7.5 days post coitum (dpc) to 14.5 dpc. Notch1,2,3 and 4 are expressed in embryonic liver at 13.5 dpc, the stage at which bile duct development begins. All four mouse Notch genes are also expressed in 10 day postnatal liver, 3 week old liver and adult liver. In situ hybridization studies show a diffuse pattern of expression in the liver at 12.5 dpc, 14.5 dpc and newborn liver for Notch1,2 and 4. Mouse Notch3 is expressed in the newborn liver in a ring-like pattern surrounding the vascular structures, similar to the expression pattern of Jagged1 at the same stage. Conclusions: All four Notch genes are expressed in the mouse liver from mid-gestation through adulthood. One or all of these Notch receptors could interact with the ligand Jagged1 during liver and bile duct development. Mouse Notch3 mRNA is spatially localized with Jagged1 in the neonatal liver as shown by in situ hybridization. This specific expression pattern may imply a role for mouse Notch3 in signaling during bile duct development. Functional studies are necessary to define further the specific ligand-receptor relationships involved in bile duct development.

**Activin signaling and gene dosage: evidence for both endocrine and autocrine/paracrine effects *in vivo*.** C.W. Brown<sup>1</sup>, D.E. Houston-Hawkins<sup>1</sup>, M.M. Matzuk<sup>2</sup>. 1) Department of Molecular and Human Genetics; Baylor College of Medicine, Houston, TX; 2) Departments of Pathology, Molecular and Cellular Biology, Molecular and Human Genetics; Baylor College of Medicine, Houston, TX.

Activins A and B (dimers of bA or bB subunits) are TGF- $\beta$  superfamily members that play critical roles in reproduction and development. Recently, we have shown that activin bB is sufficient to rescue the phenotypes of activin bA null mutant mice, by creating knock-in mice that produce activin bB at sites where activin bA is normally expressed. However, novel phenotypes were observed, suggesting that despite overlapping functions *in vivo*, the activins are not entirely functionally interchangeable. To further assess the influences of gene dosage and endocrine versus autocrine/paracrine effects, we have produced mice that express activin bB from the activin bA locus, but not from the wild type activin bB locus. Similar to activin bB knockout mice, double homozygous mutant mice [actbA<sup>BK/BK</sup>; actbB<sup>-/-</sup>] have eyelid closure defects. Thus, despite its widespread expression during embryonic development, including the developing orbit, activin bB produced in an activin bA expression pattern cannot rescue the eyelid closure defects of the activin bB knockout mouse. In contrast to both actbB<sup>-/-</sup> knockout mice and homozygous activin bB knock-in (BK/BK) mice, which are viable and fertile, the double homozygous mutant mice generally do not live beyond the first week. Those that survive have profound somatic and gonadal growth deficiencies, delayed hair growth, and enlargement of the external genitalia. The phenotypic characteristics of the double mutant mice support the hypothesis that critical developmental functions, including survival beyond the neonatal period and somatic growth, are supported by both activins A and B in a dose-dependent fashion, although activin A plays a more important role in this context. In contrast, specific processes such as eyelid fusion are exquisitely sensitive to correct spatio-temporal activin expression, consistent with autocrine/paracrine roles for the activins. We will discuss the mechanisms by which activins influence the growth and fertility phenotypes of the knock-in mice.

***Chx10-1*, a rapidly evolving murine homologue of the paired-like homeodomain transcription factor *Chx10*. R.L.**

*Chow*<sup>1</sup>, *B. Snow*<sup>1</sup>, *J. Novak*<sup>1</sup>, *J. Looser*<sup>1</sup>, *C. Freund*<sup>1</sup>, *B. Chang*<sup>2</sup>, *M. Davisson*<sup>2</sup>, *B. Taylor*<sup>2</sup>, *L. Ploder*<sup>1</sup>, *R.R. McInnes*<sup>1</sup>.

1) Program in Developmental Biology, Research Institute, Hospital for Sick Children, Toronto, ON, Canada; 2) The Jackson Laboratory, Bar Harbor, ME.

The homeodomain (HD) transcription factor CHX10 is essential for eye development. *Chx10* loss-of-function mutations cause the ocular retardation mutation in mice, and similar *CHX10* alleles in humans lead to microphthalmia and blindness. To identify *Chx10* homologues, we conducted a low-stringency cDNA library screen and isolated a murine homologue, *Chx10-1*. The *Chx10-1* predicted protein is closely related to CHX10 and VSX1 (a *Chx10* homologue in human) in the conserved HD/CVC domains (86% and 93% identical, respectively), but outside these domains, the identity is < 63%. *Chx10-1* and *VSX1*, appear to be orthologues, however, since (i) they map to regions of conserved synteny in mouse and human (*Chx10-1* to chr. 2, close to *coloboma* and *blind sterile*, *VSX1* to chr. 20p11-q11), and (ii) we have not identified a *VSX1* orthologue in mouse nor a *Chx10-1* orthologue in human, despite careful screening. To start defining the function of *Chx10-1*, we examined its expression. RNA blots of adult mouse tissues showed a 3.4 kb *Chx10-1* mRNA in retina but not in 7 other tissues. Both *Chx10* and *Chx10-1* are expressed in retinal progenitor cells at E15.5 but, whereas differentiating ganglion cells upregulate *Chx10-1*, their formation is associated with extinction of *Chx10*. *Chx10-1* is also expressed in the lens epithelium, developing Harderian glands and eyelids. In the mature retina, *Chx10-1* transcripts are restricted to the inner nuclear (INL) and ganglion cell layers; outside the eye expression is most prominent in the developing nasal epithelium. We conclude that (i) *Chx10-1* is a member of the CVC domain group of paired class homeodomain proteins, (ii) the overlapping expression of *Chx10* and *Chx10-1* in the INL may specify the cells of this layer, (iii) *Chx10-1* is a strong candidate gene for *coloboma* and *blind sterile*, and mutations in *Chx10-1* may cause defects in the neural retina and optic nerve, (iv) *Chx10-1* and human *VSX1* may be rapidly diverging orthologues partly responsible for eye speciation in mouse and man.

**Genetic interactions of *Pitx2* with *Lhx3* and *Lhx4* in pituitary development.** P. Eswara<sup>1</sup>, H. Suh<sup>2</sup>, A.L. Radak<sup>1</sup>, P.J. Gage<sup>1</sup>, S.A. Camper<sup>1,2,3</sup>. 1) Dept Human Genetics; 2) Neuroscience Program; 3) Dept of Internal Medicine, University of Michigan, Ann Arbor, MI.

Mutations in the homeodomain transcription factor PITX2 lead to Rieger syndrome (RGS), a dominant haploinsufficiency disorder with early onset glaucoma, iris hypoplasia, tooth defects, and umbilical hernia (1). Heart defects and pituitary-based growth insufficiency are occasionally found. Mice heterozygous for a *Pitx2* null allele exhibit a low frequency of RGS features (2). The variable phenotype in both humans and mice suggests the possibility of genetic background effects. To assess this, we transferred the *Pitx2* null allele to four inbred strains. At generation N3, no obvious tooth or growth defects were observed, and analysis of the eyes is in progress. We tested interaction of *Pitx2* with *Lhx3* and *Lhx4*, two LIM homeobox genes that are required for pituitary organogenesis. Both *Lhx3* and *Pitx2* mutants have arrested pituitary development after initial formation of Rathke's pouch (2, 3). *Lhx4* mutants have a milder pituitary phenotype (4). The functions of *Lhx3* and *Lhx4* overlap and the dosage of each gene influences pituitary organogenesis. To determine whether *Pitx2* function overlaps with that of either of these genes we bred *Lhx3*<sup>+/-</sup> and *Lhx4*<sup>+/-</sup> mice to *Pitx2*<sup>+/-</sup> mice. The F1 double heterozygotes from both the crosses were viable, fertile and obtained in Mendelian ratios. Preliminary analysis of embryos from *Lhx3*<sup>+/-</sup>, *Pitx2*<sup>+/-</sup> intercross and *Lhx4*<sup>+/-</sup>, *Pitx2*<sup>+/-</sup> intercross suggested that the *Lhx3*<sup>-/-</sup>, *Pitx2*<sup>-/-</sup> and *Lhx4*<sup>-/-</sup>, *Pitx2*<sup>-/-</sup> embryos are more severely affected than either of the single mutants. Because mutations in *LHX3* cause combined pituitary hormone deficiency (CPHD) (5), and both *Lhx4* and *Pitx2* overlap functionally with *Lhx3*, interactions between these genes could contribute to CPHD.

**Autosomal dominant polycystic kidney disease: More than a renal disease.** *J. Horst<sup>1</sup>, P. Pennekamp<sup>1</sup>, W. Bloch<sup>3</sup>, B. Skryabin<sup>2</sup>, K. Addicks<sup>3</sup>, B. Dworniczak<sup>1</sup>*. 1) Institute of Human Genetics, University of Muenster, Germany; 2) Institute of Experimental Pathology, University of Muenster, Germany; 3) Institute I of Anatomy, University of Cologne, Germany.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most frequently inherited monogenic diseases and affects up to 1:1000 individuals worldwide. It is characterized by progressive development and enlargement of fluid filled cysts in the kidneys that frequently result in chronic and end-stage renal failure. Approximately 8-12% of all patients requiring haemodialysis suffer from this disease. However it is not only restricted to the kidneys but can also manifest as a multisystem disorder, with symptoms including arterial hypertension, hepatic cysts, cardiovascular valve abnormalities, pancreatic cysts, cerebral aneurysms and colonic diverticuli. To analyse the function of the ADPKD genes in more detail we at first characterised the mouse *Pkd2* gene, analysed its expression pattern in comparison to *Pkd1* during development and secondly created a mouse model for ADPKD2 by homologous recombination. Using conventional gene targeting technologie we replaced exon one of the *Pkd2* gene by the *LacZ* gene. Beside some single episodes like sudden death due to most probably bleeding into the thoracic region of pregnant heterozygous mice and cysts in the testicle region of one male chimaera heterozygous *Pkd2* knockout mice do not show any phenotype so far, whereas the homozygous *Pkd2* mutant mice are not viable and die pre- or perinatally between day 13.5 and birth with multiple defects. These defects include the previously described bilateral cystic kidneys, cysts in the pancreas, hypoplasia of the lungs, whole body oedema with bleedings and heart defects. In addition semithin sections and electron microscopy revealed a massive involvement of microvessels during the pathogenesis of ADPKD with defects in the endothelium. In contrast to other groups we were able to detect defects of the liver and biliary ducts like necrosis and morphological changes in the biliary epithelium. Confirmation of previously published results and additional information will be presented.

**Global analysis of gene expression patterns during differentiation of embryonic stem cells.** *S.A. Jaradat, T. Tanaka, L. O'Neill, K. Boheler, M.S.H Ko.* Lab Genetics, NIH/NIA, Baltimore, MD.

Mouse embryonic stem (ES) cells are pluripotent cells derived from the inner cell mass of the pre-implantation mouse embryo. Pluripotency of ES cells can be sustained in vitro in the presence of leukemia inhibitory factor (LIF). The mechanisms underlying the maintenance of ES cell differentiation when LIF is withdrawn remain elusive. To further our understanding of the pathway(s) controlling ES cell pluripotency, we examined gene expression patterns on a genomic scale, using a cDNA microarray. For this purpose, we constructed a microarray containing 15,000 mouse cDNAs, 50% of which were derived from early developmental stages. We compared gene expression in ES cells in the presence of LIF with gene expression at various time points post LIF withdrawal (4, 8, 18, 24, 36 hours and embryoid bodies). A hierarchical clustering program grouped the 15,000 genes on the basis of their expression profiles over time. A distinct cluster contained genes that were sharply down regulated 4 hours post LIF removal. This category contains well characterized genes, such as Stat1, Oct-4, Rex-1 and SOX-2, that are expected to be down regulated by LIF withdrawal. A second cluster consisted of genes upregulated during differentiation included genes such as e-Hand, which is important in heart development. Two general clusters are emphasized in this abstract, but there were also further subdivisions of genes whose expression, showed sharp upregulation or downregulation during differentiation. Novel gene clusters observed in this study, provide a starting point to assess regulatory factors and mechanisms leading in early differentiation. *stat1oct-4Rex-1Sox-2e-Hand.*

**Developmental role for ataxin-2 and the fox-1 homolog A2BP1.** *T.-R. Kiehl<sup>1</sup>, A. Nechiporuk<sup>2</sup>, D.J. Luthringer<sup>3</sup>, S.-M. Pulst<sup>1</sup>.* 1) Dept. of Neurology, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Dept. of Human Genetics, Howard Hughes Medical Institute, University of Utah, Salt Lake City, UT; 3) Dept. of Pathology, Cedars-Sinai Medical Center, Los Angeles, CA.

Ataxin-2, the gene product of the human spinocerebellar ataxia type 2 (SCA2) gene, is a protein of unknown function. It interacts with ataxin-2-binding-protein 1 (A2BP1), a member of a novel family of putative RNA binding proteins. Both are highly conserved among species, with orthologs in mouse, fly and worm. A2BP1 has 29.8 % aa identity to its worm ortholog, fox-1. Fox-1 is known to be a numerator element, but its role in development was unknown. Using RNA interference, we show that both proteins play a role in early embryonic development in the worm. There was a marked reduction in the number of embryos, with an average of 11 offspring per worm observed in the *atx-2*(RNAi) group, 94 in the *fox-1*(RNAi) group and 250 in the control. We generated an ataxin-2 null mouse. Animals are viable with no gross anatomic defects. There is no reduction in fertility or segregation distortion with an average of 6.8 mice (SD=1.32) per litter in the wild type and 6.25 (SD=1.26) in the homozygous knockout group. Deletions or loss of function mutations involving either gene are not known in humans. We stained a human ovary specimen containing a large number of primary follicles and oocytes with antibodies to ataxin-2 and A2BP1. There was strong overall staining for ataxin-2 both in follicles and in the surrounding stroma. For A2BP1, we observed highly specific staining in the oocyte and in the zona pellucida. Staining was confined to the cytoplasm of the oocyte whereas the nucleus was spared. This is consistent with observations in neuronal and non-neuronal cell types showing that both ataxin-2 and A2BP1 colocalize with the trans-golgi network. It is also compatible with previous findings implicating the worm orthologs *atx-2* and *fox-1* in embryonic development. Since both have RNA-binding properties, a function in RNA distribution or processing is plausible. Further studies will elucidate the role of these proteins in mammalian embryonic development and assess possible implications for human reproductive medicine.

***Lmx1b* regulates type IV collagen gene expression and underlies renal dysplasia in nail patella syndrome. R.**

Morello<sup>1</sup>, G. Zhou<sup>1</sup>, P. Thorner<sup>2</sup>, K. Oberg<sup>3</sup>, B. Lee<sup>1</sup>. 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Div. of Pathology, Hospital for Sick Children, Toronto, Canada; 3) Dept. of Pathology, Loma Linda Univ., Loma Linda, CA.

Nail patella syndrome (NPS) is a dominantly inherited skeletal dysplasia associated with nephropathy and is caused by mutations in the LIM homeodomain transcription factor *LMX1B*. Patients with NPS have nephropathy associated with albuminuria, and ultrastructural abnormalities of glomerular basement membranes (GBM), and of podocyte foot processes. Among the components of the glomerular filtration barrier is a specialized basement membrane (BM) that, in humans and rodents, undergoes a developmental switch of extracellular matrix expression. This switch occurs from the expression of the  $\alpha 1$  and  $\alpha 2$  subunits of type IV collagen together with the b1 form of laminin during the fetal life to the expression of the  $\alpha 3$ ,  $\alpha 4$  and  $\alpha 5$  subunits of type IV collagen and the S-laminin isoform, in late fetal and adult life. We hypothesized that *Lmx1b* may regulate matrix expression during GBM development. We observed reduced expression and absence of mRNA for *Col4a3* and *Col4a4*, respectively, in *Lmx1b*<sup>-/-</sup> newborn mouse kidneys compared to wild-type littermates. The glomeruli as well as the cells secreting these extracellular molecules are preserved, as shown by appropriate expression of *sFrp2* and *Col4a1*. Moreover, LMX1B is able to bind to a putative enhancer-like sequence for *COL4A3* and *COL4A4* that we identified at the 3' end of the first intron of *COL4A4*. These genes are arranged in a head to head fashion and are transcribed in opposite directions in coordinate fashion. Finally, LMX1B can upregulate the reporter activity of a construct containing this enhancer-like element positioned upstream of a minimal promoter. These data together, identify *COL4A4* as the first downstream target of *LMX1B* described to date and suggest that a disruption of GBM morphogenesis underlies the renal dysplasia observed in NPS. Moreover, the abnormal podocyte architecture in NPS patients and *Lmx1b*<sup>-/-</sup> mice may point to more global dysregulation of podocyte development.

**FGF-10 Initiates Ocular Gland Morphogenesis.** *P.A. Overbeek, V. Govindarajan.* Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX.

**Purpose:** FGF-10, a member of the fibroblast growth factor family, is thought to mediate epithelial-mesenchymal interactions in different organ systems. The purpose of this study was to test whether FGF-10 regulates normal ocular development. **Methods:** An  $\alpha$ A-crystallin promoter was used to obtain lens-specific expression of FGF-10 in transgenic mice. Expression of FGF-10 in transgenic and wild type mice was examined by in situ hybridizations using <sup>35</sup>S-labelled riboprobes. Lacrimal gland development was studied using transgenic mice that express lacZ driven by a 5 kb Pax-6 promoter. Ocular morphogenesis in wild type, transgenic, and FGF-10 knock-out mice was analyzed by standard histological techniques. **Results:** Lens-specific expression of FGF-10 induced proliferation of the corneal epithelial cells followed by inward growth and invasion of the corneal stroma. The corneal epithelium subsequently differentiated into gland-like structures that resemble the lacrimal and Harderian glands. Endogenous expression of FGF-10 was seen in the mesenchymal cells surrounding both the lacrimal and Harderian gland primordia during initiation of glandular development. In addition, lacrimal and Harderian glands were not induced in FGF-10 null fetuses. **Conclusions:** FGF-10 is both necessary and sufficient for induction of ocular gland differentiation. FGF-10 expression in the perioptic mesenchyme acts to alter the fate of the adjacent epithelial cells in the conjunctiva and to initiate glandular development. Supported by NIH grants EY10448 and EY10803.

**Localization of angiotensinogen-expressing cells in the fetal kidney: Clues into the role of Angiotensin in Renal Development.** *M.C. Prieto*<sup>1,2</sup>, *S. Dipp*<sup>2</sup>, *S. Meleg-Smith*<sup>3</sup>, *S.S. El-Dahr*<sup>2</sup>. 1) Physiology Department, Tulane University School of Medicine, New Orleans, LA; 2) Pediatrics Department, Tulane University Medical Center, New Orleans, LA; 3) Pathology Department, Tulane University School of Medicine, New Orleans, LA.

The epithelial anlagen in the developing kidney undergo a process of centrifugal maturation characterized by intense proliferation and segmental patterning followed by structural and functional differentiation. The renin-angiotensin system is essential for normal renal growth and functional maturation. However, the precise developmental stage(s) of nephrogenesis that are regulated by angiotensin II are not completely known. To gain further insights into the developmental role of intrarenal angiotensin II, we examined the localization of its precursor, angiotensinogen (Ao), in the rat fetal kidney utilizing immunohistochemical techniques. Distinct expression of Ao in the tubular epithelium was not apparent until segmental nephron patterning was established on E16. At this stage, Ao was expressed at low levels in ureteric bud ampullae, but not in the metanephric-derived epithelial anlagen. A marked induction in the abundance of Ao coincided with terminal epithelial differentiation. On E17, Ao was expressed in the mesangium of cup-shaped glomeruli and the proximal tubular brush border. The classical adult localization pattern of Ao in well differentiated proximal tubules was clearly established by E18-E19. Immunostaining for the DNA replication factor, proliferating cell nuclear antigen (PCNA), revealed that the distribution of cyclin cells was confined to the metanephric mesenchyme, the branching ureteric buds, and the epithelial anlagen. In contrast, Ao-containing tubular epithelial cells were PCNA-negative. These results demonstrate that expression of Ao correlates spatiotemporally with terminal epithelial differentiation. This pattern of developmental expression infers that intrarenally produced angiotensin II regulates differentiated tubular functions and may be important for the maintenance of the differentiated tubular epithelial phenotype.

**Perturbation of the developing chick embryo using antisense to fibrillin-1.** *S. Plaza*<sup>1</sup>, *G. Zhou*<sup>1</sup>, *S. Belleh*<sup>1</sup>, *S.V. Vinogradov*<sup>2</sup>, *A.V. Kabanov*<sup>2</sup>, *M. Godfrey*<sup>1</sup>. 1) Ctr for Human Molecular Genetics; 2) Dept Pharmaceutical Science, Univ Nebraska Med Center, Omaha, NE.

Mutations in fibrillin-1 (FBN1) a microfibrillar glycoprotein with a ubiquitous distribution, are known to cause the Marfan syndrome (MFS). Given the pathophysiology of MFS, it has been hypothesized that fibrillin-1 plays primarily a "load bearing" function in the extracellular matrix. However, it has been shown that fibrillin-1 is expressed as early as the primitive streak in the developing chick embryo. Since "load bearing" is not a critical function at that stage of development, we used an antisense approach to target fibrillin-1 during early chick development. Our initial studies were focused on getting antisense oligonucleotides into the embryo. Using fluorescence tagged oligonucleotides, we observed a greater accumulation of oligonucleotide in the embryo if the oligonucleotides were bound to cationic block copolymers of polyethyleneglycol and polyethylenimine.

Block copolymer bound phosphorothioate antisense oligonucleotides were inoculated into eggs four hours post fertilization. Additional inoculations of oligonucleotides or controls were at 24, 48, 72, 96, and 120 hours of fertilization. 50ml of a 10mM concentration of oligonucleotide was used per inoculation. Control eggs were inoculated with equivalent volumes of PBS, copolymer alone, antisense oligonucleotides without copolymer, and sense oligonucleotide with copolymer. At 6 days, normal chick embryos should be at Hamburger and Hamilton stage 29. All control embryos were at normal stages despite inoculation with various compounds. The embryos inoculated with antisense to fibrillin-1 without copolymer were also normal. Embryos inoculated with antisense to fibrillin-1 with the block copolymer showed a range of abnormalities ranging from delay in development to gross morphological abnormalities. A similar trend is seen after a three day incubation. These studies point to the critical role fibrillin-1 must play in early embryogenesis and the greater efficiency and efficacy of block copolymer bound antisense oligonucleotides.

**High throughput screening of the genes related with postnatal development of rat cerebellum.** *Y.H Kang, H. Kim, I.J. Rhyu, C.M. Kim, Y.S. Suh, S.H. Park.* Institute of Human Genetics, Dept. of Anatomy, Korea Univ. Coll of Medicine, Seoul, Korea.

To clone the genes related with postnatal development of cerebellum, we screened developmentally differentially expressed genes from rat brain with ordered differential display PCR (ODD-PCR) and cDNA microarray. The expression patterns of cloned genes in the developing rat cerebellum were investigated with *in situ* hybridization histochemistry. In this experiment, we screened developmentally expressed genes from 12 cDNA pools (E12, E14, E16, E18, E20, P0, P3, P7, P12, P18, P25, and adult rat brain) with ODD-PCR. Among 20000 developmentally differentially expressed cDNA bands, 3000 cDNAs were subcloned into T easy vector, sequenced, and searched. 1500 clones were novel genes showing very low sequence homology with registered genes, 820 clones were homologous with registered genes, and 680 clones were almost identical with registered genes. The expression patterns of these genes in the postnatal cerebella were investigated by cDNA microarray. While the majority of transcripts were expressed at the similar level from postnatal day 3 (P3) cerebellum to adult cerebellum, more than 100 mRNAs were modulated during postnatal development of cerebellum. *In situ* hybridization histochemistry was performed to see the expression of screened genes in the tissue sections of developing rat cerebellum. More than 60 genes encoding doublecortin, vimentin, VAMP-1, glutamate receptor subunit, myelin basic protein, and etc showed specific expressional changes. A possible roles of these known genes in the postnatal development of cerebellum will be discussed.

***Zic3*-deficient mice manifest defects in left-right axis development.** *S.M. Purandare*<sup>1</sup>, *M. Gebbia*<sup>1</sup>, *M.T. Bassi*<sup>1</sup>, *K.M. Kwan*<sup>2</sup>, *H. Vogel*<sup>1</sup>, *R. Behringer*<sup>2</sup>, *B. Casey*<sup>1</sup>. 1) Dept Pathology, Baylor Col Medicine, Houston, TX; 2) Dept Molecular Genetics, Univ Texas MD Anderson Cancer Center, Houston, TX.

A cascade of asymmetric gene expression initiated at the vertebrate node controls the positioning of the heart and other organs along the left-right (LR) axis. Previously we found that some cases of LR anomalies are associated with mutations in *zinc finger in cerebellum 3* (*Zic3*), a gene on the human X chromosome. A targeted deletion of murine *Zic3* was engineered in order to begin elucidating the role of this transcription factor in mammalian LR specification. All *Zic3*-null mice that survive intrauterine development have a kinked tail. Approximately 25% manifest, alone or in combination, malformations of the central nervous system (CNS), the axial skeleton, and the left-right (LR) axis. Similar to the human phenotype, LR anomalies were of random, indeterminate sidedness (*situs ambiguus*). Malformations of the CNS (exencephaly accompanied by agenesis of the cerebellum) and those of the axial skeleton (unilateral homeotic transformations) appeared independently of LR-axis anomalies and with equal frequency. Symmetric *nodal* expression at the node in *Zic3*-deficient mice begins appropriately but disappears rather than becoming left-dominant as in the wild type. Subsequent expression of *nodal* and the downstream gene *Pitx2* in the lateral plate mesoderm is randomized rather than consistently left-sided. These results suggest a role for *Zic3* in murine LR development by helping to maintain *nodal* expression at the node.

**Limb and CNS malformations in *Lhx2*<sup>-/-</sup>:*Lhx9*<sup>-/-</sup> mutant embryos.** C.A. Wassif<sup>1</sup>, Y. Zhao<sup>2</sup>, S. Mackem<sup>3</sup>, H. Westphal<sup>2</sup>, F.D. Porter<sup>1</sup>. 1) HBD/NICHD/NIH, Bethesda, MD; 2) LMGD/NICHD/NIH, Bethesda, MD; 3) NCI/NIH, Bethesda, MD.

*Lhx2* and *Lhx9* are two closely related LIM/Homeobox genes with overlapping, but distinct developmental expression patterns. In order to determine the developmental functions of these genes, we disrupted both genes in ES cells. *Lhx2* is necessary for forebrain and eye development, as well as definitive erythropoiesis. *Lhx9* is necessary for gonad formation. Both *Lhx2* and *Lhx9* are co-expressed in the progress zone of the developing limb, and *Apterous*, the drosophila homolog of *Lhx2* and *Lhx9*, is necessary for normal wing development. Neither *Lhx2*<sup>-/-</sup> nor *Lhx9*<sup>-/-</sup> embryos have any limb malformations. *Lhx2* and *Lhx9* are also coordinately expressed in the developing midbrain. Hence we proposed that the combined mutant embryos would have a limb defect, and additional CNS defects beyond those seen in the *Lhx2*<sup>-/-</sup> embryos. In the midbrain of *Lhx2*<sup>-/-</sup>:*Lhx9*<sup>-/-</sup> embryos we find that the diencephalon is hypoplastic with dilatation of the third ventricle. The limbs of *Lhx2*<sup>+/-</sup>:*Lhx9*<sup>+/-</sup>, *Lhx2*<sup>+/-</sup>:*Lhx9*<sup>-/-</sup>, and *Lhx2*<sup>-/-</sup>:*Lhx9*<sup>+/-</sup> mice develop normally. However, both the fore and hind limbs of the *Lhx2*<sup>-/-</sup>:*Lhx9*<sup>-/-</sup> mice fail to develop properly. Although the limb buds of the mutant embryos are smaller, the AER appears normal. Analysis of alizarin and alcian blue stained embryos demonstrated that the mutant limbs have a progressive loss of normal structures in the proximal to distal axis. The humerus and the femur are relatively normal. The bones of the zygopodium are present, but markedly shortened and malformed. The malformed limbs then terminate in two shortened phalangeal elements. This phenotype is consistent in eight double mutant mice evaluated to date. *In situ* analysis of the expression patterns of genes involved in limb development and BrDU analysis is in progress. Based on our prior knowledge that both *Lhx2* and *Lhx9* are important for cellular proliferation in other developmental fields, we propose that these two genes are functionally redundant but necessary for the proliferation of cells in the progress zone of the developing limb. Lack of this cellular proliferation leads to the progressive loss of limb structures in the proximal to distal axis.

**Gene expression profiles from early stages of human craniofacial development.** *L.Q Zhang<sup>1</sup>, T. Attié-Bitach<sup>2</sup>, Y. Korshunova<sup>3</sup>, J. Cai<sup>1</sup>, D. Messina<sup>3</sup>, J. Augé<sup>2</sup>, M. Vekemans<sup>2</sup>, E.W Jabs<sup>1</sup>, M. Lovett<sup>3</sup>.* 1) Johns Hopkins University, Baltimore, MD; 2) Hospital Necker Enfants Malades, Paris, France; 3) Washington University School of Medicine, St. Louis, MO.

The Craniofacial and Oral Gene Expression Network (COGENE) is employing micro-cDNA methods, serial analysis of gene expression (SAGE), Affymetrix chip analyses and subtractive cDNA techniques to analyze gene expression in early human development and especially in microdissected, embryonic craniofacial structures. We have generated cDNA libraries from a 26-day conceptus (4mm crown rump), from fourth week rhombomeres (numbers 1 through 4) and from third week 1st pharyngeal arch as the first steps in this project. DNA sequencing of several hundred clones from each of these libraries indicates that ~20% of cDNAs encode proteins involved in protein synthesis or cell division, reflecting the enormous growth and proliferation that is occurring during these stages. Interestingly, these sequences also include multiple copies of cDNAs encoding putative tumor suppressors and proto-oncogene products such as DOC-1, JUND, QM and AF1q as well as transcription factors such as PLZF and ILF3. These analyses were validated and extended by a modified micro-SAGE method. Sequencing of 50,864 SAGE tags from the 26-day conceptus, yielded 20,133 different 10-bp tags, 12,193 of which matched known genes or ESTs. The remaining 7940 (39%) tags presumably represent novel genes. 14,908 tags were found once, while 5,225 tags occurred multiple times, ranging from 2 to 620 times. In agreement with the cDNA analyses, the most highly expressed class of transcripts (18% of all tags) were from genes encoding ribosomal proteins. Included among the 20 most highly expressed transcripts were 1 glutamate receptor gene, 2 cystatin C genes, 2 CD74 antigen genes, 1 translation elongation factor, 1 epsilon 1 hemoglobin gene, 1 ATPase, 2 ESTs and 1 non-matching tag. The unique libraries and the data derived in this project will provide new insights into which specific genes and pathways are being expressed during human craniofacial and oral development and are accessible at <http://hg.wustl.edu/lovett/projects/cogene>.

**Mutations of *PVRL1*, encoding a cell-cell adhesion molecule/Herpesvirus receptor, in cleft lip/palate-ectodermal dysplasia.** R.A. Spritz<sup>1</sup>, K. Suzuki<sup>1</sup>, D. Hu<sup>2</sup>, T. Bustos<sup>3</sup>, J. Zlotogora<sup>4</sup>, A. Richieri-Costa<sup>5</sup>, J.A. Helms<sup>2</sup>. 1) Univ. Colorado Health Sci Ctr, Denver, CO; 2) Univ California San Francisco, CA; 3) Univ Central de Venezuela, Caracas; 4) Hebrew Univ, Jerusalem, Israel; 5) HRAC-USP, Bauru, Brasil.

Cleft lip  $\pm$  cleft palate (CL/P), is among the most common birth defects, occurring in 0.4 to 2.0 per 1000 liveborns. About 70 percent of CL/P is non-syndromic, but CL/P also occurs in many single-gene syndromes. We have positionally cloned the gene for CLPED1, an autosomal recessive CL/P-ectodermal dysplasia (ED) syndrome (ED4; Margarita Island ED; Zlotogora-Ogur syndrome), characterized by CL/P, hidrotic ED, developmental defects of the hands, and in some cases, mental retardation. We identify the CLPED1 locus as *PVRL1*, encoding an immunoglobulin-related transmembrane cell-cell adhesion molecule, part of the NAP cell adhesion system. In addition, *PVRL1* is the principal receptor for cellular infection by HSV1 and HSV2. We identified 3 independent null-mutant alleles in patients with different clinical forms of CLPED1, not previously realized to be allelic. A W185X nonsense mutation is ubiquitous on Margarita Island, at a high heterozygote frequency (1/26), possibly the result of resistance to infection by HSV1 and HSV2. In mouse embryos, we find that *PVRL1* is expressed in day e15-15.5, primarily in medial edge epithelium of the palatal shelves, the ectodermal component of tooth buds, olfactory epithelium, and skin surface epithelium, consistent with the phenotype of CLPED1. *PVRL1* may also provide clues to other types of CL/P. The high frequency of CLPED1 carriers on Margarita Island may contribute to the high frequency of non-syndromic CL/P on the island. Furthermore, two close *PVRL1* paralogues, *PVR* and *PVRL2*, likewise encode Ig-class cell adhesion molecules that serve as viral receptors and are both located in chromosome segment 19q13.2-q13.3 nearby *BCL3*, the position of OFC3, one of several non-syndromic CL/P susceptibility loci mapped in humans. We are currently studying genetic variation of *PVRL1*, *PVRL2*, and *PVR* in patients with non-syndromic CL/P, including families exhibiting apparent linkage to OFC3.

**Perinatal Development of Endothelial Nitric Oxide Synthase Deficient Mice.** *L.A. Hefler<sup>1</sup>, C.A. Reyes<sup>2</sup>, B.B. Leibman<sup>1</sup>, W.E. O'Brien<sup>3</sup>, A.R. Gregg<sup>1,3</sup>.* 1) Obstetrics & Gynecology, Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The purpose of this study was to evaluate the influence of endothelial nitric oxide synthase (eNOS) deficiency on fetal growth, perinatal survival, and limb development in a mouse model with a targeted mutagenesis of the *Nos3* gene. Wild type (*Nos3<sup>+/+</sup>*) and eNOS deficient fetuses (*Nos3<sup>-/-</sup>*) were evaluated on gestational day (E) 15 and E17, newborn pups were observed on day1 of life (D1). For the evaluation of postnatal development, a breeding scheme consisting of *Nos3<sup>+/-</sup>* x *Nos3<sup>+/-</sup>* and *Nos3<sup>-/-</sup>* x *Nos3<sup>-/-</sup>* mice was established, offspring was observed for 3 weeks. Southern blotting was used for genotyping. No significant difference in fetal weight, crown-rump-lengths (CRL), and placental weight was seen between *Nos3<sup>+/+</sup>* and *Nos3<sup>-/-</sup>* fetuses on E15. By E17, *Nos3<sup>-/-</sup>* fetuses showed significantly reduced fetal weights, CRL, and placental weights. This difference in body weight was also seen throughout the whole postnatal period. In pregnancies of *Nos3<sup>-/-</sup>* females, the average number of pups alive on D1 was significantly decreased compared to either E15 or E17. Placental histology revealed no abnormalities. On E15, E17, and D1 *Nos3<sup>-/-</sup>* fetuses demonstrated focal acute hemorrhages in the distal extremities among 0%, 2.6%, and 5.7%, respectively. Bone measurements showed significantly shorter bones in the peripheral digits of hindpaws of *Nos3<sup>-/-</sup>* newborns. We conclude mice deficient for eNOS show characteristically abnormal prenatal and postnatal development including fetal growth restriction, reduced survival, and an increased rate of limb abnormalities. This characteristic phenotype of eNOS deficient mice dates back to the late third trimester of pregnancy.

**Inherited Non-syndromic Cleft Palate in Mice: Phenotypic and Molecular Studies.** *R.E. Blau<sup>1</sup>, E.T. Everett<sup>2</sup>, W. Harrison<sup>3</sup>, P.A. Overbeek<sup>3</sup>*. 1) DDS Program, Indiana Univ Sch of Dent, Indianapolis, IN; 2) Oral Facial Genetics, Indiana Univ Sch of Dent; 3) Dept of Cell Biology, Baylor Coll of Med, Houston, TX.

The secondary palate in mammals forms through a complex process and when perturbed can lead to cleft palate (CP). Clefts of the secondary palate are consistently included among the more common congenital anomalies occurring in humans, account for approximately one-third of all clefting cases, and carry an incidence of 3 to 9 per 10,000 livebirths / year. CP can be associated with more than 370 characterized disorders, yet more than 50% of CP cases occur as isolated and free of other anomalies (non-syndromic). Our long-term objectives focus on identifying and characterizing genetic determinants that contribute directly and/or indirectly to the occurrence of CP in humans. The identification of genes responsible for CP in mice will facilitate investigation of any putative roles played by their human homologs in familial and sporadic forms of CP. Four separate lines of transgenic mice resulting from recessive insertional mutations that cause non-syndromic CP have been identified. Chromosomal localization of the sites of transgene integration for three of these mutations has been performed. The mutant loci in the lines OVE270 and OVE1226B map to mouse chromosome 3 at bands B-C and F3, respectively. The transgene complex in the third transgenic line, OVE1328, maps to chromosome 4 at band A2. These regions share conservation of linkage with human chromosomes 1q21-q23, 1p13, 3q21-q26, 4q25-q31, and 8q11. Phenotypic studies of embryos from all four lines show cleft palate to be highly penetrant in homozygotes (tg/tg) with no additional overt dysmorphology or malformations present. In one line (OVE427) approximately 6% tg/+ embryos develop CP. Craniometric and radiographic studies of another line (OVE270) reveal mild craniofacial asymmetry and disturbances involving cranial base development. These disturbances of craniofacial growth and development in OVE270 tg/+ and OVE427 tg/+ mice may reflect effects of a haploinsufficient state. Finally, these mice will be invaluable tools for furthering our understanding of genetic factors associated with CP.

**The Opitz syndrome gene product, MID1, interacts with the gene product of an X-chromosomal gene mapping to the linkage interval of FG syndrome.** *S. Schweiger*<sup>1</sup>, *A. Trockenbacher*<sup>2</sup>, *V. Suckow*<sup>1</sup>, *S. Krau*<sup>1</sup>, *H.H. Ropers*<sup>1</sup>, *R. Schneider*<sup>2</sup>. 1) MPI for Molekulare Genetik, Berlin, Germany; 2) Institute for Biochemistry, University Innsbruck, Austria.

Opitz syndrome is a genetically heterogeneous disorder characterized by defects of the ventral midline, including hypertelorism, cleft lip and palate, heart defects and mental retardation. We recently identified the gene responsible for X-linked Opitz syndrome (OS). The ubiquitously expressed gene product, MID1, is a member of the RING finger protein family characterized by an N-terminal tripartite protein-protein interaction domain. We could show that MID1 associates with microtubules through the proteins C-terminus and that mutant proteins found in OS patients abolish microtubules association and form cytoplasmic clots instead. In order to shed more light into the physiological function of MID1, we performed a yeast two hybrid screen. Using MID1 as the bait, we identified a novel binding partner of the MID1 protein, called MIDIA1. Two-hybrid results were confirmed by immunofluorescent experiments and co-immunoprecipitation of MID1 and MIDIA1 overexpressed in both COS7- and HeLa cells. Similar experiments using mutant MID1 proteins found in OS patients revealed that MIDIA1 is present in the cytoplasmic clots formed in the patients. These data implicate the loss or gain of MIDIA1 function as a potential factor in the molecular pathogenesis of OS. Chromosomal mapping assigned the MIDIA1 gene to the linkage interval of the FG syndrome on Xq13. FG syndrome is an X-linked recessive disorder characterized by agenesis of the corpus callosum, imperforate anus, facial abnormalities and similar symptoms that are related to the ventral midline. Proteins interacting with the MID1 protein are obvious candidates for other malformation syndromes involving the ventral midline, and mutation screening should soon clarify the role of MIDIA1 in the molecular pathogenesis of FG syndrome.

**Gene expression changes in kidney stone disease.** *E.G Tzortzaki<sup>1</sup>, A.P Evan<sup>2</sup>, S. Bledsoe<sup>2</sup>, L. Deng<sup>1</sup>, M. Yang<sup>1</sup>, D. Glass<sup>1</sup>, P.J Stambrook<sup>3</sup>, A. Sahota<sup>1</sup>, J.A Tischfield<sup>1</sup>.* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Anatomy, Indiana University, School of Medicine, Indianapolis, IN; 3) Department of Cell Biology, Neurobiology and Anatomy, University of Cincinnati, College of Medicine, Cincinnati, OH.

A prominent feature of adenine phosphoribosyltransferase (APRT) deficiency is 2,8-dihydroxyadenine (DHA) nephrolithiasis. Using mRNA differential display, cDNA microarrays, and RT-PCR, we have recently identified changes in the expression of a subset of genes associated with chemotaxis, fibrosis, calcification, cell adhesion, and growth factors in a knockout mouse model for DHA lithiasis. As a first step in understanding the functional roles of these genes in the initiation and/or progression of kidney stone disease, we have used in situ hybridization (ISH) to identify their cellular locations in one- and three-month-old APRT-deficient mice. Digoxigenin-labeled oligonucleotide probes were hybridized to paraffin-embedded kidney sections. The sensitivity of ISH was demonstrated by detecting messages of low (APRT), medium (1,25-dihydroxyvitamin D3-24-hydroxylase gene), and high (kidney androgen-regulated protein, KAP) abundance. APRT and the selectable marker neo were used to demonstrate the specificity of expression. We also confirmed the proximal tubular localization of KAP and 24-hydroxylase. The expression of KAP was significantly reduced in APRT-deficient male mice, consistent with extensive tubular damage seen in these mice. The expression of imprinted multi-membrane spanning polyspecific transporter-like gene 1 (IMPT-1) was also decreased in proximal tubules, suggesting that impaired renal transport adversely affects renal function. The expression of matrix Gla protein (MGP), a developmentally regulated protein involved in tissue calcification, was significantly elevated in the cortex and inner medulla, suggesting a role for this protein in DHA-induced renal injury. Further characterization of these genes at different stages of disease progression will lead to a better understanding of the pathological basis of kidney stone disease. Supported by NIH grants DK38185, ES05652, and ES06096.

**TBX5 is a cellular arrest signal during vertebrate cardiogenesis.** *C.J. Hatcher<sup>1</sup>, M.-S. Kim<sup>1</sup>, B. Wong<sup>1</sup>, M.M. Goldstein<sup>2</sup>, T. Mikawa<sup>1</sup>, C.T. Basson<sup>1</sup>.* 1) Cardiology Division, Weill Medical College of Cornell University, New York, NY; 2) Division of Anatomic Pathology, Quest Diagnostics, Inc., Teterboro, NJ.

Mutations in human *TBX5*, a T-box transcription factor gene, are responsible for Holt-Oram syndrome, an autosomal dominant condition characterized by congenital cardiac septation and isomerism defects in the setting of limb deformity. We have used retroviral vectors to overexpress wildtype and mutant human *TBX5* isoforms *in vitro* and *in vivo* in order to determine the cellular function of *TBX5* in cardiac development. We observed that wildtype *TBX5* overexpression inhibits cell proliferation *in vitro*, and T-box binding to target DNA's major groove but not minor groove is necessary for this activity. Because human heterozygous *TBX5* mutations that impair T-box binding to target DNA's major groove most severely affect the heart, we hypothesized that *TBX5* participates in cardiogenesis by regulation of cell proliferation. Therefore, we overexpressed wildtype and mutant human *TBX5* isoforms in embryonic (E3) chick hearts *in vivo*. Despite mosaic *TBX5* overexpression, chick hearts infected with wildtype *TBX5* retrovirus were significantly smaller than control hearts; by E15, they exhibited decreased mass, thinned atrial walls and decreased ventricular trabeculation. In contrast, hearts infected with Gly80Arg-*TBX5*, a mutant isoform with disruption of the target DNA major groove binding site, exhibited no morphologic alterations. Immunostaining of genetically engineered chick hearts for PCNA, a nuclear proliferation antigen, revealed that *TBX5* overexpression suppresses myocyte proliferation *in vivo* via a major groove binding mechanism just as it does *in vitro*. *TBX5* inhibition of myocyte proliferation is not cell autonomous; we observed that wildtype *TBX5* overexpression inhibited proliferation of both infected and uninfected chick cardiomyocytes. Further immunohistochemical studies of human embryonic tissues also demonstrated that *TBX5* expression patterns are inversely related to cellular proliferation during human organogenesis. We, therefore, propose that *TBX5* acts as a cellular arrest signal during vertebrate cardiogenesis and thereby modulates growth and development of the human heart.

**Asymmetric lateral plate and midline nodal expression in the proper development of laterality in the mouse**

**embryo.** *M.R. Kuehn*<sup>1</sup>, *L.A. Lowe*<sup>1</sup>, *S. Yamada*<sup>1,2</sup>, *T. Yamaguchi*<sup>1</sup>. 1) Div. of Basic Sciences, NCI, NIH, Bethesda, MD; 2) Osaka University Faculty of Dentistry, 1-8 Yamadaoka, Suita, Osaka 565-0871, JAPAN.

The visceral organs of vertebrates develop along the left-right (L-R) body axis with handed asymmetry. For example, the heart and stomach are positioned on the left. During early somite stages the mouse nodal gene is expressed asymmetrically in the left lateral plate mesoderm (LPM). In addition midline expression of nodal around the node becomes asymmetric at these same stages. In mouse mutants with laterality defects, these asymmetric expression patterns are disrupted. Additional evidence implicates nodal in L-R development: ectopic right sided expression in chick or frog embryos leads to randomization of organ asymmetry. However, formal genetic proof and complete elucidation of nodal function in L-R development has been lacking because the null mutation causes early gastrulation stage defects. We have used a Cre/loxP strategy to generate a conditional mutant (floxed) allele of nodal. This floxed allele is also hypomorphic. Embryos heterozygous for the hypomorphic allele and a nodal null allele undergo gastrulation but display abnormal phenotypes at later stages. These defects fall into three distinct classes. One class of mutants specifically lacks left LPM expression of nodal, although expression around the node is seen. These embryos lack normal asymmetric expression of Pitx2, lefty-1 and lefty-2. At later stages, these mutants exhibit random L-R asymmetry of the heart, transpositions of the great vessels, right isomerism of the lungs, and midline or reversed stomachs. These results provide conclusive evidence that nodal is essential for proper organ laterality, and give the first detailed insight into nodal's actual function. In further studies we have generated a transgenic strain that expresses Cre recombinase in the embryonic node, notochord and floorplate of the neural tube at stages overlapping nodal expression around the node. Crossing the Cre transgenic and floxed nodal lines will lead to deletion of the nodal locus only in cells in the node. This approach will allow us to assess the specific involvement of midline nodal expression in laterality determination.

**Isn't one "zipper" enough to explain neural tube closure? Additional evidence to support the classic theory.** *R.A. Saul<sup>1</sup>, L.H. Seaver<sup>1</sup>, J. Brown<sup>2</sup>, R.E. Stevenson<sup>1</sup>*. 1) Greenwood Genetic Ctr, Greenwood, SC; 2) Shriners Hospital for Children, Greenville, SC.

The classic view of human embryologic neural tube closure notes that closure starts just caudal to the rhombencephalon/cervical spinal cord junction (day 21) and proceeds rostrally to the anterior neuropore (day 26) and caudally to the posterior neuropore (day 28). Evidence from experimentally-induced neural tube defects (NTDs) in mice led to the multi-site closure model; that is, neural tube closure starts or occurs at five different sites (I,II,III,IV, and V). We have elected to study the caudal end of the neural tube by radiographic analysis of affected patients to investigate mechanisms of neural tube closure. We examined radiographs of the vertebral columns in 210 randomly selected patients seen at the Myelodysplasia Clinic at the Shriners Hospital in Greenville, SC from 1978 to 2000. We chose radiographs as a more direct measure of spinal dysraphism since external examinations might be biased by skin closure. Adequate analysis could be performed on 197 patients. All 197 patient radiographs demonstrated spinal dysraphism from the rostral end of the defect all the way to and through the sacrum. No discontinuous spinal dysraphism was observed. Our study calls into question closure site V. We see no radiographic evidence of caudal "closure" even when skin defects stop above the sacrum. Review of recent human embryos corroborates the classic view of neural tube closure (K. Sulik, 1999 and personal communication). While the multi-site closure model might explain externally identified varieties of NTDs (anencephaly [merocrania, holoacrania], encephalocele, faciocranioschisis, faciocraniorachischisis, craniorachischisis, and anencephaly with spina bifida), it is our suspicion that more thoroughly delineated cases (by thorough dissection and radiographic evaluations) will call into question the specificity of these closure sites. More thorough evaluations might blur the margins of these sites, leading to a re-evaluation of the processes and mechanisms involved in neural tube closure.

**Mutation Screening of the Follicle Stimulating Hormone (FSH) Receptor Gene in Korean Infertile Men with Spermatogenic Defects and Hypergonadotropic Hypogonadism.** *G.J. Song<sup>1, 5</sup>, H.S. LEE<sup>1</sup>, Y.S. Park<sup>1</sup>, C.C. Lee<sup>5</sup>, Y.S. Lee<sup>2,4</sup>, I.S. Kang<sup>3,4</sup>.* 1) Laboratory of Reproductive Biology and Infertility, Samsung Cheil Hospital & Women's Healthcare Center, Seoul, Korea; 2) Department of Urology, Samsung Cheil Hospital & Women's Healthcare Center, Seoul, Korea; 3) Department of Obstetrics and Gynecology, Samsung Cheil Hospital & Women's Healthcare Center, Seoul, Korea; 4) Sungkyunkwan University School of Medicine, Seoul, Korea; 5) Department of Biology, Seoul National University, Seoul, Korea.

Follicle stimulating hormone (FSH) is considered to be important for spermatogenesis. Most infertile men with spermatogenic defects have elevated serum FSH concentration. Recently, an inactivating point mutation of the FSH receptor gene has been reported in men with elevated serum FSH concentrations and abnormal sperm parameters. In this study, we screened the point mutation of the FSH receptor gene using exon-specific PCR and SSCP analysis in 98 infertile men with severe hypospermatogenesis or azoospermia and high FSH concentration (>12 IU/l). From the results of SSCP analysis, abnormally shifted bands were detected in exon 10. Sequence analysis showed that either nucleotide A or G is frequently present at position 994 predicting the presence of a threonine or an alanine (AA genotype, 32%; AG genotype, 45%; GG genotype, 23%). However, this polymorphism was also found in the control group with a similar frequency (AA genotype, 35%; AG genotype, 48%; GG genotype, 17%). The FSH receptor genotype was not associated with serum FSH concentration and testicular volume. In conclusion, pathological mutation of the FSH receptor gene was not found in these Korean infertile men. It is suggested that mutation in the FSH receptor gene is not a common cause of male infertility.

**New associations between prenatal exposure to drugs and malformations.** *I.M. Orioli<sup>1</sup>, E.E. Castilla<sup>2</sup>*. 1) Genetics, Fed. Univ. Rio de Janeiro, Rio de Janeiro, Brazil; 2) Genetics, FIOCRUZ, Rio de Janeiro, Brazil and CONICET, Argentina.

The aim of this work is to check known drug/malformation associations and search for new ones taking advantage of the database of the Latin American Collaborative Study of Congenital Malformations (ECLAMC) on drug exposure during the first trimester of pregnancy. In the ECLAMC the next non-malformed baby of the same sex born in the same hospital was selected as the healthy control subject for each malformed case. From the healthy newborn sample 15,378 infants whose mothers had taken one or more drugs during pregnancy were selected for this study. Likewise, 6,316 malformed infants having being exposed to drugs in utero were selected from 27 major, isolated congenital anomaly types. 19 specific drugs (i.e.: aspirine) or pharmacological groups (i.e.: antibiotics), according to sample size, were considered for analysis. Multiple logistic regression analyses were used with the characteristic of being or not affected by a certain anomaly as the dependent variable, while the 19 drug types were the independent ones. Maternal age, year of birth, and country of birth were considered as confounding factors. Several known and new associations were found. Abortives in general concentrated the higher number of positive associations with odds ratios higher than 3. Piperidolate was the drug more used by pregnant women in South America and showed an association with Poland complex. Other non described associations were: antialergics with intestinal, anal, and esophageal atresias; antiepileptics with cephalocele, micrognathia, ambiguous genitalia, equinovarus feet, and Poland complex ; aspirin with limb reduction; tuberculostatics with spina bifida, oral clefts, omphalocele, and intestinal atresias; thyroid hormones with limb reduction; anorexigens with spina bifida, cleft lip, and Adams complex; insulin/hypoglycemics with microcephaly, hypospadias, and intestinal atresias; sexual hormones with esophageal atresia and Adam complex; and corticoids with microcephaly and limb reduction.

**Developmental Expression of Cytochrome P4501B1 (*Cyp1b1*).** B.A. Bejjani<sup>1</sup>, L. Xu<sup>2</sup>, D. Armstrong<sup>1</sup>, J.R. Lupski<sup>1</sup>, L. Reneker<sup>2</sup>. 1) Baylor Col Medicine, Houston, TX; 2) Univ of Missouri, Columbia, MO.

Homozygous and compound heterozygous mutations in *CYP1B1* have been shown to result in Primary Congenital Glaucoma (PCG). The purpose of this study is to analyze the expression patterns of *Cyp1b1* in the developing mouse ocular and brain tissues. Mouse tissues at different developmental stages were isolated for *in situ* hybridization. To make a riboprobe vector, a 646 base pair fragment from the 3'untranslated region (3'UTR) of *Cyp1b1* was amplified from mouse genomic DNA and inserted into the polylinker site of plasmid Bluescript. <sup>35</sup>S-labeled sense and antisense riboprobes were generated using an *in vitro* transcription kit. *Cyp1b1* is expressed in both anterior and posterior segments of the eye. Importantly, the expression in the anterior segment is confined to the ciliary body, most likely in the pigment ciliary epithelial cells. The earliest expression in the ciliary body is detected at postnatal day 4 (P4) and the expression continues into adulthood. Surprisingly, no detectable levels of *Cyp1b1* mRNA were found at or around the trabecular meshwork. In the posterior segments of the eye, *Cyp1b1* is expressed in the retina as early as embryonic day 12 and the expression becomes more specific to the inner nuclear layer by P7. Expression was also detected in the fat tissue around the optic nerve, but not in the optic nerve itself. We also found *Cyp1b1* mRNA in the meninges of the embryonic heads and in the hair follicles of the whiskers. It is hypothesized that developmental anomalies of the trabecular meshwork prevent appropriate drainage of the aqueous humor and cause PCG in human patients. Our results indicated that *Cyp1b1* expression is absent in this tissue in mouse eyes. Instead *Cyp1b1* is highly expressed in the developing and mature ciliary body. Our study suggests that ciliary body is involved in regulating the intraocular pressure either directly or indirectly by influencing the proper differentiation of trabecular meshwork.

**Molecular bases of the phenotypic variability of lysinuric protein intolerance.** *G. Sebastio<sup>1</sup>, M.P. Sperandeo<sup>1</sup>, V. Dall'Asta<sup>2</sup>, O. Bussolati<sup>2</sup>, G.C. Gazzola<sup>2</sup>, M. Pineda<sup>3</sup>, M. Palacin<sup>3</sup>, V. Fiorito<sup>1</sup>, A. Pietrosanto<sup>1</sup>, M.T. Bassi<sup>4</sup>, G. Borsani<sup>4</sup>, A. Ballabio<sup>4</sup>, G. Andria<sup>1</sup>.* 1) Dip. Pediatria, Federico II Univ, Naples, Italy; 2) Dip. Medicina Sperimentale, University of Parma, Italy; 3) Dep. Bioquímica y Biología Molecular, University of Barcelona, Spain; 4) TIGEM-HSR, Milan, Italy.

Lysinuric protein intolerance (LPI, MIM 222700), an autosomal recessive disorder of the  $y^+L$  transport of cationic amino acids, is caused by mutations of the SLC7A7 gene, which we recently identified.  $y^+L$  transport is exerted by the heterodimeric complex 4F2hc/SLC7A7, as seen by its expression in *Xenopus* l. oocytes. This activity is absent if the wild sequence of SLC7A7 is replaced by any of the 3 mutant alleles (M50K, S386R, W242X), found in Italian LPI patients. These data, though confirming the pathogenetic role of SLC7A7 in LPI, do not help to explain the extreme variability of the LPI phenotype. We also performed functional studies of  $y^+L$  in erythrocytes, fibroblasts and lymphoblasts from LPI patients and concluded that these cells normally express the  $y^+L$  transport activity. This suggests a genetic heterogeneity of  $y^+L$  transport. Being  $y^+L$  transport exerted by the heterodimeric complex 4F2hc/SLC7A7, we searched for the co-existence of mutations of 4F2hc in LPI patients as observed in compound heterozygotes for rBAT/SLC7A9 in non type-1 cystinuria, a disease with a molecular pathogenesis similar to LPI. However, we did not find any mutation of 4F2hc in Italian LPI patients, thus ruling out any role of 4F2hc in the determination of the LPI phenotype. Recently another gene, SLC7A6, has been shown to complex with 4F2hc and to yield a  $y^+L$  transport activity. We have elucidated the genomic structure of this gene which consists of 11 exons, spanning a region of some 60kb on chromosome 16q13. We are currently investigating a putative role of this gene in the pathogenesis of the variability of LPI phenotypes. Financial supports of MURST-PRIN 1998 (G.S and V.D.A.) and Telethon E.652 (G.S.) are gratefully acknowledged. M.P.S. is supported by Telethon- Italy (grant n.29cp) and is an Assistant Telethon Scientist.

**Identification and characterization of a novel cochlear gene, *OTOR*, and localization of its encoded protein, otoraplin.** *N.G. Robertson*<sup>1</sup>, *J.S. Lin*<sup>1</sup>, *S. Heller*<sup>3</sup>, *B.L. Resendes*<sup>1,2</sup>, *S. Weremowicz*<sup>1,2</sup>, *C.S. Denis*<sup>3</sup>, *A.M. Bell*<sup>3</sup>, *J.C. Adams*<sup>2,4</sup>, *A.J. Hudspeth*<sup>3</sup>, *C.C. Morton*<sup>1,2</sup>. 1) Brigham & Women's Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Laboratory of Sensory Neuroscience and HHMI, The Rockefeller University, New York, NY; 4) Dept of Otolaryngology, Massachusetts Eye and Ear Infirmary, Boston, MA.

We identified a novel cochlear gene, designated *OTOR*, from a comparative sequence analysis of over 4,000 clones from a human fetal cochlear cDNA library. Northern blots of human and chicken organs show strong *OTOR* expression only in the cochlea; very low levels are detected in the chicken eye and spinal cord. *OTOR* localizes to chromosome 20 in bands p11.23-p12.1, and more precisely to STS marker WI-16380. cDNAs orthologous to *OTOR* were isolated from mouse, chicken, and bullfrog tissues. The encoded protein, designated otoraplin, has a predicted secretion signal peptide sequence and shows a high degree of cross-species conservation. Otoraplin is homologous to the protein encoded by *CDRAP/MIA* (cartilage-derived retinoic acid sensitive protein/melanoma inhibitory activity), which is expressed predominantly by chondrocytes, functions in cartilage development and maintenance, and has growth-inhibitory activity in melanoma cell lines.

We developed a polyclonal antibody against human otoraplin using a KLH-conjugated 16 amino acid-residue peptide from otoraplin's C-terminus as the immunogen. On western blots, the antibody specifically recognizes full-length otoraplin protein (~16 kDa). Preimmune sera and IgYs (from egg yolks of immunized chickens) do not show reactivity to otoraplin. Immunohistochemistry in human fetal inner ear shows presence of otoraplin in the organ of Corti, the spiral and vestibular ganglia, and in the macular epithelium. Immunostaining for otoraplin is also detected in the region of osteocytes in the surrounding temporal bone and in the modiolus, but not in chondrocytes in the same areas on fetal sections from earlier developmental ages.

**Identification of a human melanoma inhibitory activity (MIA)-like gene which is specifically expressed in the human inner ear and exhibits a frequent polymorphism that abolishes protein expression.** *N.D. Rendtorff<sup>1</sup>, M. Frödin<sup>2</sup>, T. Attié-Bitach<sup>3</sup>, J. Augé<sup>3</sup>, M. Vekemans<sup>3</sup>, N. Tommerup<sup>1</sup>*. 1) Department of Medical Genetics, Institute of Medical Biochemistry and Genetics, the Panum Institute, University of Copenhagen, Copenhagen N, Denmark; 2) Department of Clinical Biochemistry, Glostrup Hospital, Glostrup, Denmark; 3) Department of Genetics and INSERM U-393, Hospital Necker, Paris, France.

Genes specifically expressed in the cochlea of the inner ear are candidate genes for non-syndromic hearing impairment. In order to discover new cochlea-specific genes, we searched in the TIGR database for clusters of ESTs, that have been isolated from the cochlea only. This led to the cloning and characterization of a human gene named MIA-like (MIAL) as it encodes a protein related to Melanoma inhibitory activity (MIA) protein, which is expressed and secreted by chondrocytes. The cDNA of the mouse homologue (Mial) was also cloned and mapped to mouse chromosome 2. By semi-quantitative RT-PCR, MIAL mRNA showed a very restricted distribution in humans as it was detected only in fetal inner ear and brain. In the mouse, Mial was expressed in the inner ear as well as in the brain, eye, limb and ovary. Using laser capture microdissection and in situ hybridization we show that MIAL is highly and specifically expressed in the sensory structures in inner ear of human conceptuses ranging from 24 days to 9,5 weeks. The MIAL cDNA predicts a protein of 128 amino acids including a signal peptide. In transiently transfected COS7 cells, the MIAL cDNA expressed a ~15 kDa polypeptide that was modified by sulfation and exists as a covalently linked homo-dimer of ~26 kDa. MIAL protein localized to the Golgi apparatus and was secreted into the culture medium. A frequent polymorphism was discovered in human MIAL. Of 505 individuals, 48 (9.5%) were heterozygous and 1 (0.2%) was homozygous. In COS7 cells, no protein synthesis was detected from cDNA of the variant allele, suggesting that human homozygotes do not express MIAL protein and that the variant MIAL allele may contribute to inner ear defects.

**Genomic Structure, Chromosomal Localization and Functional Study of the Human Glycine N-methyltransferase Gene.** *Y.A. Chen<sup>1</sup>, L. Chen<sup>1</sup>, J.V. Lin<sup>1</sup>, T. Liu<sup>2</sup>, T.L. Yang-Feng<sup>3</sup>*. 1) Prevention Medicine, Institute of Public Health, Taipei, Taiwan; 2) Department of Medical Research, Taipei Veterans General Hospital, Taipei, Taiwan; 3) Department of Genetics, Yale University, School of Medicine, New Haven, C.T. U.S.A.

Previously, we reported that the expression level of GNMT was diminished in human hepatocellular carcinoma (HCC). In this study, the human GNMT gene cloned and characterized. It contains six exons and spans about 10 kb (Accession No. AF101475). Instead of a TATA box, it has a transcriptional initiator located 801-bp upstream from the translation start codon. The gene was localized to chromosome 6p12 using FISH. The GNMT cDNA was cloned and placed under the control of the CMV promoter and the resultant plasmid was used to transfect HCC cell lines. The GNMT was found to be expressed in the cytoplasm of the HCC cells using IFA and it was translocated into the nuclei when the cells were treated with B(a)P. P-32 post-labeling and thin-layer chromatography were used to measure the B(a)P-DNA adducts. In comparison with HCC cells transfected with the vector plasmid, the B(a)P-DNA adducts formed in the cells transfected with pGNMT decreased at least 40% and the activation of cytochrome CYP1A1 enzyme activity by B(a)P was almost down regulated to the baseline level. Therefore, the expression of GNMT may protect the liver cells to against the insult of B(a)P.

**Pyrin, the FMF Protein, Colocalizes with Microtubules in vivo and in vitro.** *E.A. Mansfield<sup>1</sup>, J.J Chae<sup>1</sup>, H. Komarow<sup>1</sup>, T. Brotz<sup>2</sup>, M. Centola<sup>1</sup>, D.L. Kastner<sup>1</sup>.* 1) ARB/NIAMS, NIH, Bethesda, MD; 2) EIB/NCI, NIH, Bethesda, MD 20892.

Familial Mediterranean fever (FMF) is an autoinflammatory syndrome caused by recessively inherited mutations in MEFV; the microtubule inhibitor colchicine is highly effective in preventing FMF attacks. The product of MEFV, pyrin, is a protein of unknown function with a C-terminal RFP (B30.2) domain. Computational analysis of the sequence had suggested a possible role as a transcription factor. We examined the subcellular localization of pyrin in order to gain insight into its function. GFP and myc-tagged fusions of pyrin were expressed in Cos-7 and HeLa cells and the subcellular localization of the protein was examined by fluorescence microscopy. Transfected cells were double-stained with antibodies to various organelles and cytoskeletal proteins to determine if pyrin colocalizes with any cellular structure. These experiments demonstrated that pyrin does not occupy the nucleus, although in transfected cells, staining can be detected in the perinuclear region. All transfected cells show at least some staining throughout the cytoplasm. Cells with bright juxtannuclear staining were examined for colocalization of pyrin with the golgi apparatus. We did not observe colocalization of pyrin and golgi, although in some cells golgi and pyrin signals were adjacent. Treatment of transfected cells with brefeldin A disrupted the staining pattern of golgi but not pyrin. In contrast, treatment with the microtubule stabilizing drug paclitaxel dramatically altered the predominant staining pattern of pyrin, so that it colocalized prominently with bundled microtubules. Colchicine and nocodazole dispersed the pyrin signal in transfected cells into a diffuse or punctate pattern. We assayed the ability of pyrin to bind stabilized microtubules in vitro using both lysates of transfected cells and purified full-length recombinant pyrin. In both cases, pyrin was efficiently sedimented with the microtubule pellet. Deletion analysis showed that the N-terminal portion of pyrin is necessary and sufficient for microtubule binding. The function of the C-terminal RFP domain remains unknown at this time, although biochemical assays are underway to discover interacting proteins of pyrin.

**Identification of six putative anion transporter genes in human and characterization of PAT1, a candidate gene for pancreatic anion exchanger.** *H. Lohi*<sup>1</sup>, *M. Kujala*<sup>1</sup>, *E. Kerkela*<sup>2</sup>, *U. Saarialho-Kere*<sup>2</sup>, *M. Kestila*<sup>1</sup>, *J. Kere*<sup>3</sup>. 1) Dept Medical Genetics, Haartman Inst, Helsinki, Finland; 2) Department of Dermatology, University Central Hospital, Helsinki, Finland; 3) Finnish Genome Center, University of Helsinki, Helsinki, Finland.

Members of the structurally well-conserved family of sulfate transporters have recently been identified as the second gene family of anion exchangers. The three known human members of this gene family, DTDST, CLD and PDS transport in different combinations, at least the chloride, iodine, bicarbonate, oxalate and hydroxyl anions. These genes are expressed in a highly tissue-specific manner and have all been linked to a different recessive disorder. We report the expansion of this gene family to include at least six physically mapped new members. We have characterized one of them, named PAT1 (for putative anion transporter 1), in more detail. It maps to chromosome 3p21.3, encodes a predicted 738 amino acid transmembrane protein, and is highly homologous to the known members of the family, suggesting its function as an anion transporter. PAT1 is most abundantly expressed in the kidney and pancreas. Pancreatic ductal cell lines Capan-1 and Capan-2 express PAT1 and immunohistochemistry localizes PAT1 protein to the apical surface of pancreatic ductal cells, suggesting it as a candidate for a luminal anion exchanger. The mapping and characterization of the novel members of this tissue-specific gene family may provide new insights to anion transport physiology in different parts of the body.

**Approaches to study the genomic impact of human endogenous retroviruses.** *D.L. Mager, J.R. Landry, L.N. van de Lagemaat, P. Medstrand.* Terry Fox Laboratory, BC Cancer Agency, and Dept. of Medical Genetics, Univ. of British Columbia, Vancouver, BC.

A remarkably high fraction of the human genome consists of retroelements that have become fixed in the species during the course of primate evolution. One class of retroelements is made up of the endogenous retroviruses (HERVs) and related solitary long terminal repeats (LTRs) which together comprise over 5% of human DNA. Because LTRs naturally contain transcriptional regulatory elements, we have been interested in determining how such elements can affect the expression of adjacent genes. Here we report on two genes, the apolipoprotein CI gene and the endothelin B receptor gene, for which a HERV-E LTR acts as an alternative promoter via splicing events. Fusion LTR-gene transcripts were initially detected through screens of the Expressed Sequence Tag database and promotion from within the LTR was confirmed by RT-PCR, RACE and/or primer extension. Interestingly, in the case of the endothelin B receptor, LTR-driven transcripts are detected only in placenta where they are comparable in level to the transcripts driven from the native promoter. Transient transfection experiments in the placental cell line JEG-3 using a reporter gene have shown that the HERV-E LTR at the endothelin B receptor locus is a strong promoter and can also enhance the activity of the native endothelin B receptor gene promoter and the SV40 promoter. This LTR has no significant activity in other cell types. As a complementary approach to examining the genomic effects of LTRs, we have developed computational tools for the analysis of integration patterns of many distinct LTR families and have applied these tools using the complete sequences of human chromosomes 21 and 22. Results suggest that LTR integration patterns are non-random with respect to distance along the chromosome and with respect to gene coding regions. These results support the hypothesis that endogenous retroviruses have contributed to the evolution of genes and genomes.

**In silicon cloning of human myelin protein zero-like genes by bioinformatics strategy.** *D. Tang<sup>1,2</sup>, K. Yu<sup>2</sup>, X. Tang<sup>2</sup>, H. Zhang<sup>2</sup>, Q. Pan<sup>2</sup>, H. Dai<sup>2</sup>, J. Xia<sup>2</sup>.* 1) Department of Animal Science, Foshan University, Foshan, Guangdong, P R China; 2) National Lab Of Medical Genetics, Hunan Medical University, Changsha, Hunan, P R China.

To clone novel myelin protein related genes, two human ESTs, which shared significant similarity with the human myelin protein zero gene, were found by the comparison of homologue between the cDNA coding region sequences of MPZ gene and the EST database of NCBI. An 801 bp EST contig was assembled, which was 100% identical with a 128 kb genomic sequence, mapped to 1q24. A 435 bp open reading frame (ORF) within the 801 bp contig was shown by computer analysis. Two primers designed according to the sequence of the contig, were coupled with the primers (lgt10-5 and gt10-) on the sequences flanking cloning site of the cDNA library vector to amplify the cDNA library sequences by nested PCR. New primers, designed based on novel cDNA sequences, were used for the PCR amplification with lgt10-5 and gt10-5 in the same way as above. Finally, the human myelin protein zero like gene isoform I and II (MPZL1a, MPZL1b; GenBank: AF095727, AF092424) were cloned. Comparison of gene and protein structures between MPZL1 and MPZ revealed that MPZL1 is the second member of MPZ family. Mutation analysis of MPZL1 gene was performed in 24 Charcot-Marie-Tooth disease(CMT) families and 26 nonsyndromic deafness families, but no mutation was found.

**Gene identification on chromosome 15q21-23 in a 200 Kb region spanning the CLN6 disease locus.** *R.B. Wheeler<sup>1</sup>, J.D. Sharp<sup>1</sup>, R.A. Schultz<sup>2</sup>, J.M. Joslin<sup>2</sup>, B.D. Lake<sup>3</sup>, S.E. Mole<sup>1</sup>, R.E. Williams<sup>1</sup>, R.M. Gardiner<sup>1</sup>.* 1) Department of Paediatrics, Royal Free and University College Medical School, UCL, London UK; 2) Eugene McDermott Centre for Human Growth and Development, University Texas South Western Medical Centre, Dallas, USA; 3) Department of Histopathology, Great Ormond Street Hospital for Sick Children, London, UK.

The neuronal ceroid lipofuscinoses (NCLs) are a group of autosomal recessive neurodegenerative diseases of childhood. CLN6 is the gene for a variant form of LINCL which we previously mapped to chromosome 15q21-23. The critical region was narrowed to approximately 200 Kb and two overlapping PACs from the region were sequenced at UTSWMC. This sequence, consisting of five contigs, together with additional sequence from the high throughput genome sequence databases (htgs) has been analysed using the NIX and Ensembl packages at HGMP (<http://www.hgmp.mrc.ac.uk>). Putative transcripts were identified by integrating the results of exon and gene prediction programmes eg. MZEF, GRAIL, GENSCAN and sequence similarity searches. Complete coding sequences were obtained by traditional methods. To date, two known genes, MEK5 and hnRNP core protein A1 and three novel genes have been identified. Candidate genes within the critical region have been analysed at the genomic and cDNA level in both human and the *nclf* mouse model but no mutations have been detected. However, several additional predicted genes and EST clusters are currently being analysed as candidates. Completion of the Human Genome Sequencing Project should lead to improvements in gene prediction programmes and facilitate future gene identification.

**DAX1/SHP Family of the Nuclear Hormone Receptor Superfamily Appears Predisposed to Sequence Variability.**

*M.V. Patel*<sup>1</sup>, *G.B. Golding*<sup>2</sup>, *Y.-H. Zhang*<sup>3</sup>, *B.-L. Huang*<sup>3</sup>, *A.P. Arnold*<sup>1</sup>, *J.S. Sinsheimer*<sup>4</sup>, *E.R.B. McCabe*<sup>3</sup>. 1) Dept Physiological Science, UCLA, LA, CA; 2) Dept Biology, McMaster University, Hamilton, ON; 3) Dept Pediatrics; 4) Dept Biomathematics and Human Genetics, UCLA, LA, CA.

We have previously shown that DAX1 is predisposed to amino acid-changing substitutions similarly to SRY and greater than SOX9. The purpose of the current investigations was to compare DAX1 sequence changes during evolution with related genes: SHP, an autosomal encoded member, along with DAX1, of a family within the nuclear hormone receptor superfamily; SF1, a protein that interacts with DAX1; SOX3, a SOX member encoded on the X chromosome; SOX9, an autosomal SOX member involved in sex determination; and GK, a DAX1 neighbor in Xp21.3. We determined the genomic sequence of DAX1, SHP, SF1, SOX3, SOX9, and GK in the rhesus macaque, and compared these with genomic sequences in human and mouse. The number of non-synonymous substitutions per non-synonymous site ( $K_a \times 100$ ) was calculated for rhesus/human pairwise comparisons.  $K_a$  values are DAX1=1.1±0.32; SHP=0.970±0.34, SF1=0.57±0.23, SOX3=0.30±0.18, SOX9=0.00 and GK=0.00. For rhesus/mouse comparisons, codon positions 1 and 2 of DAX1 show a high percentage of transversions (0.096 and 0.090) and transitions (0.12 and 0.081), supporting the high  $K_a$  value for DAX1. In contrast, changes in the 3rd position are not significantly different than the other genes. DAX1 also shows differential codon preferences. Rhesus/mouse DAX1s show differences in four amino acids: Ala (GCG vs. GCC), Arg (CGG vs. AGA), Asp (GAC vs. GAU), and Thr (ACG vs. ACC). SHP and GK have differences in two amino acids, and SF1, SOX3 and SOX9 show identical codon preferences for all amino acids. We then examined the percentage of nonsynonymous codons differing in two out of three or all three positions in rhesus/mouse comparisons: 13.4% of the amino acid changing codons in DAX1 and 11.2% in SHP change in more than one position, compared with 2.6%, 2.44%, 1.38% and 0.76% for SF1, SOX3, SOX9, and GK, respectively. We conclude that, according to several measures, DAX1 is quite variable at the protein level, and SHP, a family member of DAX1, appears to share this predisposition for variability.+++.

**Loss-of-function mutations in DAP12 in PLOSL patients provide a new link between the immune system and**

**dementias.** *J. Paloneva*<sup>1,2</sup>, *M. Kestilä*<sup>3</sup>, *J. Wu*<sup>4</sup>, *A. Salminen*<sup>3</sup>, *T. Böbling*<sup>3</sup>, *V. Ruotsalainen*<sup>5</sup>, *P. Hakola*<sup>3</sup>, *A.B.H. Bakker*<sup>4</sup>, *J.H. Phillips*<sup>4</sup>, *P. Pekkarinen*<sup>2</sup>, *L.L. Lanier*<sup>4</sup>, *T. Timonen*<sup>3</sup>, *L. Peltonen*<sup>1</sup>. 1) UCLA Dept. of Human Genetics, Gonda Center, UCLA, Los Angeles, CA; 2) Dept. of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland; 3) Dept. of Medical Genetics and Pathology, Haartman Institute, University of Helsinki, Helsinki, Finland; 4) Dept. of Microbiology and Immunology and the Cancer Research Center, UCSF, California; 5) Dept. of Biochemistry and Biocenter Oulu, Oulu, Finland.

PLOSL (Polycystic Lipomembranous Osteodysplasia with Sclerosing Leukoencephalopathy; MIM 221770), also known as Nasu-Hakola disease, is a recessively inherited disease characterized by a unique combination of psychotic symptoms rapidly progressing to presenile dementia and bone cysts restricted to wrists and ankles. The first symptoms appear around age 20 and the disease results in death by the age 50. PLOSL has a global distribution, although most of the patients have been diagnosed in Finland and Japan, with an estimated population prevalence of  $2 \times 10^{-6}$  in the Finns. We have mapped the PLOSL-locus to 19q13.1 and identified a shared 153-kb ancestor haplotype in all Finnish disease alleles. Here we report the molecular defect in PLOSL by identifying one large deletion in all Finnish PLOSL alleles and another mutation in a Japanese patient, both representing loss-of-function mutations, in the gene encoding DAP12 (TYROBP). DAP12 is a transmembrane protein that has been recognized as a key activating signal transduction element in natural killer (NK) cells. On the plasma membrane of NK cells, DAP12 associates with several activating receptors recognizing major histocompatibility complex (MHC) class I molecules. Interestingly, no abnormalities were detected in the number or function of the NK cells in PLOSL patients, homozygous for a null allele of DAP12. Instead, they display pathology in the central nervous system (CNS) and bone. This finding not only provides new clues to the pathogenic mechanisms of dementias, but should also stimulate a search for novel biological functions of the DAP12 molecule.

**Hfb1 brainspecific sequence is the 3'-UTR of the complexin 2 mRNA.** *L.V. Dergunova<sup>1</sup>, N.M. Raevskaya<sup>1</sup>, I.P. Vladychenskaya<sup>1</sup>, A.B. Poltarau<sup>2</sup>, S.A. Limborska<sup>1</sup>.* 1) Dept Human Molecular Genetics, Inst Molecular Genetics, Moscow, Russia; 2) Institute of Molecular Biology, Moscow, Russia.

Brain-specific Hfb1 sequence was obtained from human forebrain cortex cDNA library and its primary structure was determined (Acc. No Y15167). By Northern blot hybridization analysis the size of the full length transcriptional product corresponding to Hfb1 was estimated to be about 5,0 kb. Hfb1 was mapped to the human chromosome 5. Human chromosome 5 cosmid library was screened and Hfb1- positive clone with the insert more than 20 kb was selected. 4,5 kb genomic fragment gHfb1 corresponding to Hfb1 was sequenced. Comparison to the sequences of the GenEMBL database using the BLAST program has revealed the 56 nucleotides overlapping region between gHfb1 5'-end and human complexin 2 mRNA 3'-end. The overlapping is supported by two additional ESTs AL119131 and AW896858 highly homologous both to gHfb1 and complexin2 mRNA. These results suggest gHfb1 to be complexin 2 3'-untranslated region. The complexin 2 protein is known to take part in the synaptic vesicle transport processes and is encoded by 940 nucleotide mRNA (Acc. No NM 006650) with the reading frame between 346 and 750 nucleotides. We estimate the size of complexin 2 mRNA 3'-UTR to be about 4 kb . The computer comparison has also shown a large number of short unknown ESTs highly homologous to gHfb1 with their 3'-ends coincident to Hfb1 3'-end and the absence of any homologous ESTs with 3'-ends extending Hfb1 last nucleotides thus confirming gHfb1 to be the part of the last exon of the complexin 2 gene.

**Mice trisomic for a BAC with the single minded 2 gene (Sim2) show phenotypes similar to some of those present in the partial trisomy 16 mouse models of Down syndrome.** *R. Chrast<sup>1</sup>, H.S. Scott<sup>1</sup>, R. Madani<sup>2</sup>, L. Huber<sup>2</sup>, D.P. Wolfer<sup>2</sup>, M. Prinz<sup>3</sup>, A. Aguzzi<sup>3</sup>, H.P. Lipp<sup>3</sup>, S.E. Antonarakis<sup>1</sup>.* 1) Division of Medical Genetics, Geneva University Medical School and University Hospital, Geneva, Switzerland; 2) Institute of Anatomy, University of Zurich, Switzerland; 3) Institute of Neuropathology, University Hospital of Zurich, Switzerland.

The *Drosophila* single minded (*sim*) transcription factor, is a master regulator of fruitfly neurogenesis. Recently, we have cloned and mapped a human homologue of *sim*, SIM2, to chromosome 21 in the so called "Down syndrome critical region". Three copies of SIM2 may contribute to some Down syndrome (DS) phenotypes because of the mapping position, function as transcriptional repressor, temporal and spatial expression pattern of mouse *Sim2*, and the potentially analogous role of human SIM2 to that of *Drosophila sim* during neurogenesis. In order to validate this hypothesis *in vivo*, we have created the first BAC transgenic mice overexpressing a gene possibly involved in DS with only one or two additional copies of mouse *Sim2*. The transgene was shown to be expressed in the same spatial pattern as the endogenous gene. The mice develop normally, are fertile and do not show readily detectable histopathological abnormalities. However, detailed analysis of their behavior revealed changes in their exploratory behavior, and sensitivity to pain, phenotypes which are also present in other partial trisomy 16 mouse models of DS. Our data therefore suggest that overexpression of SIM2 contributes to some of the complex DS phenotypes.

**Evolutionary conservation and differential expression of *EPM2A* gene.** *S. Ganesh*<sup>1</sup>, *K. Shoda*<sup>1</sup>, *A.V. Delgado-Escueta*<sup>2</sup>, *K. Yamakawa*<sup>1</sup>. 1) Laboratory for Neurogenetics, RIKEN Brain Science Institute, Wako-shi, Saitama, Japan; 2) Comprehensive Epilepsy Program, UCLA , Los Angeles, California.

The progressive myoclonus epilepsy of Lafora type is an autosomal recessive disorder caused by mutations in the *EPM2A* gene encoding a putative tyrosine phosphatase. We isolated full-length transcripts of human, mouse and rat orthologues and compared their expression profile. Sequence comparison reveals a highly conserved laforin, the predicted protein product of *EPM2A*. Rat orthologue shows 94 and 95% similarity to human and mouse laforin respectively and in all the three species, the estimated molecular size of laforin is approximately 38 kDa. Interestingly, all the missense mutations identified in Lafora disease families so far were substitutions for highly conserved residues suggesting that laforin's function may have been altered in those patients. *EPM2A* is ubiquitously expressed in various adult tissues of human, rat, and mouse but in human brain, its expression level was notably lower. In mouse, transcripts were detected from 7-dpc embryonic stage onwards and the expression level was higher in adults. We identified differentially spliced transcripts for human *EPM2A* and one of them encodes a truncated laforin. Our results suggest the presence more than one promoter for *EPM2A* in human and that the multiple isoforms may be unique to human. To understand the function of laforin and its isoforms, antibodies were generated for specific regions and studies are underway to characterize the protein using in vivo and in vitro model systems.

Program Nr: 941 from the 2000 ASHG Annual Meeting

**Mapping of alpha6 nicotinic cholinergic receptor subunit (CHRNA6) gene on chromosome 8p11 and analysis of the gene structure.** *M. Ebihara, H. Ohba, S. Ohno, T. Yoshikawa.* Laboratory of Molecular Psychiatry, Brain Science Institute, Riken, Saitama, Japan.

There are eight alpha subunits (alpha2-alpha9) and three beta subunits (beta2-beta4) in the nicotinic cholinergic receptor gene family. The nicotinic cholinergic receptors are multimeric ligand-gated ion channels and involved in neuronal functions. Recently it has been reported that autosomal dominant nocturnal frontal lobe epilepsy is caused by mutations in the alpha4 subunits of the nicotinic cholinergic receptor gene, although the mice lacking nicotinic cholinergic receptor (i.e. CHRNA4, CHRNA7, CHRNB2) did not show any neurological defects. In 1999, postnatal growth deficiency, megasystis and mydrisis have been reported in mice lacking the alpha3 nicotinic cholinergic receptor gene. Thus it is important to study the function of the nicotinic cholinergic receptors in order to understand various phenotypes linked to the receptors, especially epileptic disorders. In this study, we analyzed the gene structure and function of the alpha6 nicotinic cholinergic receptor including the promoter region. CHRNA6 consists of six exons, spanning approximately 10kb. The alpha6 nicotinic cholinergic receptor gene is mapped on chromosome 8p11 by FISH.

**Characterisation of the human homologue of a candidate gene for Slow Wallerian Degeneration.** *S. Fernando*<sup>1</sup>, *S. Tosi*<sup>2</sup>, *L. Conforti*<sup>1</sup>, *A. Tarlton*<sup>1</sup>, *E.A. Buckmaster*<sup>1</sup>, *V.H. Perry*<sup>1</sup>, *A.D. Smith*<sup>1</sup>, *M.P. Coleman*<sup>1</sup>. 1) Pharmacology, University of Oxford, Oxford, UK; 2) Institute of Molecular Medicine, Oxford, UK.

Wallerian degeneration is the process by which the distal part of a nerve axon degenerates following injury. Slow Wallerian degeneration in which this process is delayed has been observed in a mutant strain of mouse, C57BL/Wlds, and in this mouse candidate genes were identified within an 85Kb tandem triplication unit on distal mouse chromosome 4. The proximal and distal boundaries of this triplication unit are spanned by the gene encoding ubiquitin fusion degradation protein 2 (Ufd2) and a previously undescribed gene, D4Cole1e respectively. A third gene within the triplication unit, Rbp7, is not a good candidate for Wlds. Ufd2 and D4Cole1e produce a chimeric mRNA in the Wlds mouse which encodes an in-frame fusion protein. The protein consists of 70 amino acids from the N-terminal region of Ufd2 and 302 amino acids from the C-terminal region of D4Cole1e and is abundantly expressed in the nervous system. As Wallerian degeneration is the end-point of many forms of axonal pathology in the central and peripheral nervous systems the human homologues of these genes could influence susceptibility to neurological disorders. We have identified the human homologue of D4Cole1e, which we have mapped to chromosome 1p36.2 by fluorescent in-situ hybridisation. Northern blot analysis has shown that it is abundantly expressed in the human brain. The exons corresponding to D4Cole1e gene have been cloned and sequenced. A search is on-going for Single Nucleotide Polymorphisms within these exons in order to investigate whether this gene influences the phenotype of neurodegenerative diseases in humans.

**ApoE and APP are alternative ligands for the calcium-sensing receptor.** *Y.P. Conley*<sup>1,2</sup>, *D.N. Finegold*<sup>2</sup>, *R.E. Ferrell*<sup>2</sup>. 1) Department of Health Promotion & Development, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, PA.

The calcium-sensing receptor (CaSR) is a G-protein coupled receptor primarily involved in systemic calcium homeostasis. The CaSR is expressed in tissues involved with calcium homeostasis such as the parathyroid and kidney, however, the CaSR is also expressed in tissues where its function is not readily apparent, for example the brain. We hypothesized that the brain CaSR might have a function other than mineral ion metabolism that could be explained by alternative ligands for the receptor. We conducted sensitive luciferase reporter gene assays to determine if the CaSR is activated by Apolipoprotein E (ApoE) isoforms and amyloid precursor protein (APP), substances implicated in neurodegeneration. We demonstrated that the CaSR is significantly activated by these ligands when compared to a control reaction where no ligand is added to the cultures. APP activated the receptor 36% over the control ( $p < 0.001$ ). ApoE3 activated the receptor 49% over the control ( $p < 0.01$ ). ApoE4 activated the receptor 39% over the control ( $p < 0.001$ ). ApoE2 activated the receptor 19% over the control; however the results did not reach significance. ApoE and APP have been implicated in alterations of intracellular calcium concentration via a mechanism that is currently unknown. ApoE is known to increase cytoplasmic calcium via the phospholipase C pathway and APP is involved with oscillations in intracellular calcium concentration in functional synapse formation. ApoE and APP activation of the CaSR could explain the mechanisms that ApoE and APP utilize to alter intracellular calcium levels and support the calcium hypothesis in neurodegeneration.

**The modulation of HIP1 function through its interaction with its family member HIP12: implications for the pathogenesis of Huntington disease.** *V. Chopra<sup>1</sup>, M. Metzler<sup>1</sup>, D. Rasper<sup>2</sup>, R. Singaraja<sup>1</sup>, L. Gan<sup>1</sup>, D. Nicholson<sup>2</sup>, M. Hayden<sup>1</sup>.* 1) Department of Medical Genetics, and Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada, V5Z 4H4; 2) Department of Biochemistry and Molecular Biology, Merck Frosst Centre for Therapeutic Research, Montreal, Canada, H9R 4P8.

Huntingtin-interacting protein 1 (HIP1) was identified through its interaction with huntingtin, the polyglutamine-containing protein altered in Huntington Disease. Although the function of HIP1 is unknown, it shows homology to Sla2p in *Saccharomyces cerevisiae*. Sla2p is essential for endocytosis and the assembly and function of the cytoskeleton in yeast. Recent evidence suggests that huntingtin may play a potential role in vesicle transport. These findings suggest that the interaction between HIP1 and huntingtin is necessary for vesicle trafficking and maintenance of the membrane cytoskeleton. As such, the altered interaction of HIP1 with huntingtin could result in a disruption of intracellular transport leading to neuronal cell death. Interestingly, it has recently been demonstrated that HIP1 contains a death effector domain (DED). Furthermore, HIP1 has been shown to be toxic when overexpressed in human embryonic kidney (HEK) 293T cells. We have identified a novel protein termed HIP12 that shows profound sequence and biochemical similarities to HIP1 and also shows high sequence similarity to Sla2p, indicating that HIP1 is a member of a family of cytoskeletal-associated proteins. HIP1 and HIP12 show similar subcellular distribution in both neuronal and non-neuronal cell types and are both found within the striatum, the brain region affected in HD. Using the yeast 2-hybrid system and co-immunoprecipitation studies we have demonstrated that HIP12 does not interact with huntingtin but can bind directly with HIP1. Furthermore, HIP12 does not confer toxicity when overexpressed in HEK 293T cells but can reduce the toxicity of HIP1 when co-expressed in the same cells. These findings suggest that the potential interaction of HIP12 and HIP1 *in vivo* may influence the function of each respective protein and this may have important implications in HD.

**Down Syndrome Cell Adhesion Molecule: An endogenous promoter element drives the expression of a candidate gene for DS Congenital Heart Disease in the developing mouse embryo.** *G.M. Barlow<sup>1</sup>, X.-N. Chen<sup>1</sup>, G.E. Lyons<sup>2</sup>, J.R. Korenberg<sup>1</sup>*. 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) University of Wisconsin Medical School, Madison, WI.

Down Syndrome (DS) is a major cause of congenital heart disease (CHD), and is normally caused by trisomy for chromosome 21. Through the study of rare individuals with partial trisomy 21 and DS-CHD, we have narrowed the candidate region for DS-CHD to D21S3 through the PFKL. DSCAM (Down Syndrome Cell Adhesion Molecule) spans more than 840 kb of this narrowed DS-CHD region and encodes a highly conserved member of the immunoglobulin superfamily. The cardiac features of DS implicate disturbances in cell adhesion as responsible for DS-CHD. Further, using the collagen gel system as a model, we have shown that disruption of DSCAM expression using antisense oligonucleotides inhibits the transformation and/or migration of mesenchymal cells derived from the AV cushions. We now report the identification of a 1.8 kb region with DSCAM promoter activity. A reporter construct with this putative promoter region driving lac Z gene expression was generated and introduced into fertilized mouse eggs by pronuclear injection. The resulting mouse embryos were harvested at E12.5 and analyzed for the expression of the lac Z transgene by staining with X-gal. Several embryos showed strong lac Z expression in the ventral diencephalon, in the choroid plexus of the fourth ventricle and in the floor of the rhombencephalon. Specific staining was also observed in subsets of cells of Rathkes pouch and in the Gasserian, superior cervical and dorsal root ganglia. One embryo also showed transgene expression in the skeletal condensations of the developing fore- and hind-limbs. These results represent a subset of the DSCAM expression previously observed by tissue in situ hybridization (TISH) and are consistent with a role for DSCAM in the developing nervous system and limb bud.

**Laforin in Lafora's progressive myoclonus epilepsy: Function and subcellular localization.** *B.A. Minassian<sup>1,2</sup>, L. Ianzano<sup>1</sup>, D. Molinari de Andrade<sup>1</sup>, E.J. Young<sup>1</sup>, E. Chan<sup>1</sup>, C.A. Ackerley<sup>3</sup>, S.W. Scherer<sup>1</sup>.* 1) Dept of Genetics, Hosp Sick Children, Toronto, Canada; 2) Div of Neurology, Hosp Sick Children, Toronto, Canada; 3) Dept of Pathology, Hosp Sick Children, Toronto, Canada.

Lafora's disease (LD) is an autosomal recessive neurodegenerative condition with onset in teenage years and death within 10 years of onset. Two striking features characterize LD: A severe increasingly intractable epilepsy dominates the clinical course, and pathognomonic perikaryal polyglucosan inclusions are seen in neurons and other tissues.

We recently identified the LD gene, *EPM2A* (protein product named laforin). Transcript and mutation analysis revealed 4 essential exons comprising the consensus gene, but several alternative transcripts were also identified. Laforin's C-terminus (coded by exon 4) demonstrates high sequence identity with the catalytic domains of dual-specificity phosphatases. Laforin also appears to contain putative carbohydrate binding and glucohydrolase domains.

In order to study potential phosphatase activity, several bacterially expressed GST-laforin fusion proteins were assayed using the phosphatase substrate pNPP. Whereas wild-type laforin readily dephosphorylated pNPP, mutants including exon 4 alone, exons 2-4, or a single amino acid change (C271S) at the putative catalytic cysteine exhibited no phosphatase activity.

In order to determine the subcellular localization of laforin, COS cells were transfected with Myc epitope-tagged laforin. In-situ hybridization and electron microscopic analyses revealed two sites of localization, at the internal aspect of the plasma membrane and in a perikaryal distribution colocalizing with the endoplasmic reticulum (ER). Results with the Myc tag placed at the N or C terminus were identical.

Further studies are underway to unravel laforin's functions including its potential to bind and hydrolyze the perikaryal polyglucosans and its role at the neuronal plasma membrane.

Program Nr: 947 from the 2000 ASHG Annual Meeting

**Circadian output pathway genes from mouse liver.** *K. Kaasik, C.C Lee.* Molecular and Human Genetics, BCM, Houston, TX.

Circadian clocks control behavior and physiological processes in mammals and in many other organism. The suprachiasmatic nucleus is the central clock structure in mammals. However recent findings indicate that clock elements have found in many of the peripheral tissues in mammals. To better understand the significant of that peripheral clock mechanism we undertook a study to identify genes under the control of peripheral clocks. To find candidate genes we make used of the observation that expression of circadian clock control genes cycle in a daily fashion and the detection of these expression changes by cDNA microarray analysis. To date by analyzing 1000 UniGene library cDNAs using cDNA probes generated from mouse liver mRNA from different circadian time points we have identified several clones that display apparent differential diurnal expression. The differences in expression level between CT 0 and CT 12 were at least 5 times using cDNA microarray analysis. To confirm the microarray analysis, Northern blot using mRNA from wild type and different clock mutant mice is currently in progress.

**Expression analysis of gene from human chromosome 21.** *D. Slavov*<sup>1</sup>, *M. Davisson*<sup>2</sup>, *L. Bechtel*<sup>2</sup>, *K. Gardiner*<sup>1</sup>. 1) Eleanor Roosevelt Inst, Denver, CO; 2) The Jackson Laboratory, Bar Harbor, ME.

Analysis of the recently completed sequence of human chromosome 21 identified 225 genes and gene models. Analysis of the predicted protein sequences shows that ~100 genes/models so far have no similarity to known proteins and no identifiable functional domains or motifs. Furthermore, of the ~125 genes with some functional association, none has been linked to a clear role in the Down syndrome phenotype. Because functional data are limited, expression data may be the most efficient basis for selecting genes for further study of relevance to Down syndrome. Because these data are inadequate or completely lacking for the majority of chromosome 21 genes, we are focussing on the following approaches: i) Based on ESTs and exon prediction and using RT-PCR and RACE, we have generated complete or near complete coding regions for a ~20 novel gene models. ii) dbEST analyses and semi-quantitative RT-PCR have been used to determine expression and alternative processing in ~30 tissues and cell lines for >40 known and novel genes/models; iii) quantitative Northern and RT-PCR analysis using normal and Down syndrome derived cell lines and tissues from normal mice and the Down syndrome mouse model, Ts65Dn, are being used to determine trisomy-associated changes in expression levels; iv) RNA tissue in situ is being carried out on mouse neonatal brain for a subset of known and novel genes. Interesting results include very low levels of expression of many novel genes, a high frequency of potentially functionally relevant alternative processing, gene and tissue specific increases in expression level that range from 0 to 3-5 fold in trisomies, and a set of candidate genes with hippocampal expression.

**Molecular genetics of the human very-low dopamine b-hydroxylase (DBH) trait.** *C.P. Zabetian<sup>1,3</sup>, G.M. Anderson<sup>2</sup>, J. Gelernter<sup>1,3</sup>, H. Ichinose<sup>4</sup>, T. Nagatsu<sup>4</sup>, R.T. Malison<sup>1</sup>, J.F. Cubells<sup>1,3</sup>.* 1) Dept of Psychiatry, Yale Univ, New Haven, CT; 2) Child Study Ctr, Yale Univ, New Haven, CT; 3) Dept of Psychiatry, VACHS, West Haven, CT; 4) Inst Comp Med Sci, Fujita Health Univ, Toyoake, Japan.

Dopamine b-Hydroxylase (DBH) catalyzes the final step in the biosynthesis of norepinephrine, a neurotransmitter involved in many diseases with significant heritability including psychiatric and substance use disorders, Parkinson's disease, and hypertension. DBH enzyme activity is readily assayed in blood, highly heritable, and strongly linked to the DBH gene. Activity values are bimodally distributed; 3-4% of the European-American (EA) population exhibits very low DBH levels (DBH-L), apparently transmitted as a recessive Mendelian trait. The goal of this study was to identify a functional polymorphism(s) responsible for DBH-L. DNA was collected, and DBH activity measured, in EA and Japanese (JP) subjects. DBH-L, average-, and high-DBH individuals were screened by sequencing the proximal 1kb of the promoter, all 12 exons, and all intron/exon boundaries of the DBH gene. Novel single nucleotide polymorphisms (SNPs), and all previously described nonsynonymous SNPs were then genotyped in a larger group of samples. No amino acid sequence-altering SNPs were associated with DBH-L. No new exonic or promoter polymorphisms were found, but a number of unreported intronic SNPs were identified. One such SNP was highly correlated with the very-low DBH trait. All EA and JP DBH-L individuals were homozygous for the same allele. Whether this SNP is itself functional, altering splicing efficiency for example, or simply in linkage disequilibrium with an as yet unidentified functional polymorphism is unknown. Supported by: USDVA, NIDA, NIAAA, NARSAD.

**Mutants in two DNA polymerases, *REV3(z)* and *RAD30(h)* differ in cross-link repair.** *K.F. Grossmann, A.M. Ward, M.E. Matkovic, J.A. Hejna, R.E. Moses.* Molec & Med Genetics, Oregon Hlth Sci Univ, Portland, OR.

The human autosomal recessive disease Fanconi Anemia (FA) displays a cellular phenotype of specific hypersensitivity to DNA cross-linking agents and a prolonged arrest in G2 after cross-linking damage. *S. cerevisiae* cells with a deletion in the catalytic subunit of a translesion DNA polymerase, *REV3*, are also sensitive to cross-link damage, while not significantly sensitive to UV light or Angelicins, much like FA cells (Grossmann, *et al*, Mutation Research, in press). Additionally, *rev3* mutants display a terminal arrest in G2 after CDDP damage, unlike wild-type cells, suggesting that the Rev3 DNA polymerase might play a role in the post-replication repair of DNA cross-links. Rad30, the yeast homolog to human xeroderma pigmentosum variant (XP-V), is a DNA polymerase representative of a new class of DNA polymerases with translesion synthesis function. We find that *rad30* mutants, while sensitive to UV, are not sensitive to CDDP and have no prolongation of G2 arrest after CDDP treatment compared to wild-type cells, suggesting that, unlike Rev3, this bypass polymerase does not play a significant role in post-replication cross-link repair. Our results indicate that DNA polymerases demonstrated to have bypass properties have different specific roles in DNA repair and that the XP-V homolog does not appear to be required for cross-link repair in yeast.

**Inhibition of cell proliferation by the TSC1 and TSC2 tumor suppressor genes.** *L. Khare, A. Astrinidis, P.D. Adams, E.P. Henske.* Dept Medical Oncology, Fox Chase Cancer Center, Philadelphia, PA.

Tuberous sclerosis complex (TSC), a tumor suppressor gene disorder, is characterized by tumors of the brain, heart, and kidney. TSC is caused by mutations in two genes, TSC1 and TSC2. Unlike TSC2 which has been studied more extensively, there have been no studies to investigate the relationship between TSC1 and the cell cycle. We have overexpressed TSC1 in various cell lines to observe its effect on growth and cell cycle kinetics. Hamartin, the TSC1 product, has been found to have a direct interaction with the TSC2 product, tuberin, suggesting that tuberin and hamartin function in the same molecular pathway. TSC2 has been shown to suppress growth of Rat1 fibroblast cells and cells lacking TSC2 derived from the Eker rat, a model of TSC2-linked disease. TSC2 has also been shown to cause an elongated G1 phase in Eker rat embryonic cells, Rat1 fibroblast cells and human neuroblastoma cells. We studied the effect of overexpression of TSC1 and TSC2 in several cell lines. We found that overexpression of TSC1 and/or TSC2 resulted in a suppression in the colony forming ability of MCF-7 and HeLa cells, indicating that both genes have a growth suppressing effect. We then used flow cytometry to analyze the cell cycle profile of 293 kidney cells and HeLa cervical adenocarcinoma cells overexpressing TSC1 and/or TSC2. Overexpression of TSC2 in 293 kidney cells resulted in increased proportion of cells in G1 fraction of the cell cycle. Overexpression of TSC1 did not lead to an arrest of the cell cycle in the G1 phase. This is the first report showing that TSC1, like TSC2, has a cell growth suppressing activity as observed in the colony formation assay, but this effect may not be mediated by a G1 arrest in the cell cycle.

Program Nr: 952 from the 2000 ASHG Annual Meeting

**Promoter Analysis of TBX5.** *S.J. Cross, A.J. Bonser, T.K. Ghosh, J.D. Brook.* Institute of Genetics, University of Nottingham, Queens Medical Centre, Nottingham, United Kingdom.

T-box genes are a family of developmentally-important transcription factors related to mouse Brachyury. Mutations in one member of the family, TBX5, have previously been shown to cause Holt-Oram syndrome, a disorder of the development of the heart and skeleton. Holt-Oram patients typically present with septal and conduction defects of the heart, and with shoulder and radial malformations. The promoter region of TBX5 has yet to be described, and the precise length of the transcript is not known. Also, little is known about the regulation of this gene in the developmental pathways within which it acts. In an attempt to fill these gaps in current understanding, we have sequenced extensively from a genomic clone of this region and have used a variety of sequence analysis programs to predict the location of the transcriptional start and promoter of TBX5. We have also identified sites for the binding of transcription factors involved in heart and limb development in the upstream region of TBX5. Reporter assays in tissue culture have been used in order to dissect the functional elements of the promoter of this gene. We present here a map of a total of approximately 13kb of the upstream region of TBX5, showing the relative positions of important promoter elements, along with an details of a new gene with exons located within the promoter of TBX5.

**Functional analysis of human thymosin b4 promoter in aortic valve interstitial cells.** *Q.Y. Li, R.P. Lafferty, R.J. Levy.* Cardiology Res/Abramson Bldg, Children's Hosp Philadelphia, Philadelphia, PA.

Calcific aortic valve stenosis is the most common cardiac valvular disorder. Studies have showed that abnormal extracellular matrix (ECM) remodeling, for example, the deposition of bone related proteins, is associated with the progression of aortic valve calcification. Recently, we observed that an ECM protein involved in bone development, tenascin C (TN-C), is co-localized with metalloproteinase-2 (MMP-2) in the perimeter of calcified nodules in human aortic valve. In order to understand the disease-associated ECM remodeling, we established sheep aortic valve interstitial cell culture. We found that TN-C can induce MMP-2 expression in these cells. Using cDNA subtraction and competitive RT-PCR, we identified thymosin b4 (Tb4) as a downstream gene upregulated by TN-C. Furthermore, we observed that Tb4 upregulates MMP-2 expression in sheep and human aortic valve interstitial cells. Thus, we decided to study the promoter function of Tb4 in aortic valve interstitial cells in order to understand how Tb4 gene is regulated by TN-C. Human Tb4 belongs to a multiple gene family. By PCR screening a human PAC genomic library, we identified five PAC clones carrying Tb4 conserved sequences. We also cloned the Tb4 cDNA expressed in human aortic valve interstitial cells. In comparisons of the cDNA sequence and the sequences derived from PCR products of the PAC clones, we identified two PAC clones that share 96-97% identity with the Tb4 cDNA. We isolated the restriction fragments with Tb4 by Southern blot and subcloned them into pBluescript vector. The 5' untranscribed regions of Tb4 genes from these PAC are cloned into pGL-Basic (promoterless luciferase gene). The promoter activities of these promoter-reporter constructs are being examined in both sheep aortic valve interstitial cells cultivated on type I collagen with or without TN-C. The promoter showing induction activity for TN-C will be truncated for further functional analysis in order to identify the minimal TN-C responsive element.

**Gene expression studies of the cardiac *hH1* sodium channel (*SCN5A*) in human saphenous vein endothelium.** A. Scoumanne, J.T. Powell, M. Gosling, N. Carey. Department of Vascular Surgery, Imperial College School of Medicine, Charing Cross Hospital Campus, Fulham Palace Road, London W6 8RF, UK.

Human saphenous vein is the most commonly used conduit for bypass of occlusive arterial disease such as atherosclerosis. However, a third of bypasses fail within the first year due to stenosis and/or thrombosis. Saphenous vein endothelial cell responses to the arterial environment may be an important contributor to these pathological processes. Recently, we described the unexpected presence of a voltage-dependent sodium current in human saphenous vein endothelial cells (HSVECs) (Gosling *et al.*, 1998) resulting from the expression of the cardiac sodium channel *hH1*. Although, we previously showed that *hH1* expression can be regulated by serum, nothing is currently known about the factors regulating its expression and the physiological importance of its presence in the endothelium. We have established real-time quantitative RT-PCR experiments using Taqman to investigate the effects of potential regulatory proteins e.g. smoking metabolites, selected drugs and shear stress on levels of the *hH1* transcript. In addition, we have identified promoter elements for *SCN5A*, which we are assessing for activity in cell lines and *in vivo*, to identify critical promoter elements for expression in vascular endothelium. Primary HSVECs have a limited life span *in vitro*. To obtain a permanent source of HSVECs, cell lines were generated by transfection with simian virus 40 large T-antigen or papillomavirus type 16 E6 and E7 genes. The cell lines were characterised by the presence of the endothelial marker CD31, the ability to bind *Ulex europaeus* lectin I as well as the functional expression of intercellular adhesion molecule-1. Furthermore, HSVEC lines were characterised by the presence of *hH1* transcripts using RT-PCR and functional *hH1* sodium channel by patch-clamp electrophysiology. These constitute a useful resource for the analysis *hH1* regulation in human vascular endothelium. Gosling M, Harley SL, Turner RJ, Carey N, Powell JT. Human saphenous vein endothelial cells express a tetrodotoxin-resistant, voltage-gated sodium channel current. *J. Biol. Chem.* 1998;273:21084-21090.

***DGSI*, a gene deleted in DGS/VCFS, encodes a nuclear phosphoprotein associated with the nuclear matrix.** W. Gong<sup>1</sup>, M.L. Budarf<sup>1,2</sup>. 1) Division of Human Genetics and Molecular Biology, The Children's Hospital, Philadelphia, PA; 2) Dept Pediatrics, Univ Pennsylvania School of Medicine, Philadelphia, PA.

*DGSI* is a gene that maps to human chromosome region 22q11.2 and is deleted in the vast majority of patients with DGS/VCFS. Although *DGSI* is highly conserved in eukaryotic species and is expressed very early in development, computational analysis of the predicted amino acid sequence does not reveal any similarity to known proteins, suggesting that *DGSI* is a member of a novel family of proteins with unknown function. Thus, the characterization of *DGSI* will provide fundamental data that will aide in understanding the function of this protein. In this study, we observed a punctate staining pattern for *DGSI* in nucleoplasm with exclusion from nucleoli by immunofluorescence. The punctate signal was retained in nuclei of cells after *in situ* nuclear matrix preparation, suggesting that *DGSI* is associated with the nuclear matrix. Confocal microscopy was used to produce a series of optical sections through cells at interphase and mitosis. The data show that *DGSI* is excluded from condensed chromosomes during mitosis. In addition, a shift in gel mobility was observed after phosphatase treatment, suggesting that *DGSI* is a phosphoprotein. This result was confirmed by cellular phosphorylation studies. Using the yeast two-hybrid system, we identified a protein, topoisomerase II binding protein (TopBp1), that interacts with *DGSI*. Take together, our studies show that *DGSI* encodes a phosphoprotein associated with the nuclear matrix. Additional experiments are needed to confirm the *DGSI*-TopBp1 interaction and to further characterize the role of *DGSI* in the cell.

**Regulatory features of the *Cas-1* genomic organization and evolution associated with oxygen radical metabolism, health and disease.** A.K. Black, P.A. Laansoo, N.J. Schisler, B.C. Murphy, S.M. Singh. Zoology, University of Western Ontario, London, Ontario, Canada.

The *Cas-1* gene, encoding the antioxidant enzyme murine catalase, implicated in diverse aspects of aging, cancer, development and alcohol response. In conjunction with SOD and Gpx, this enzyme is responsible for detoxification of  $O_2^-$ , and the adverse biological effects associated with it. We have established that this gene is under complex and poorly understood transcriptional and post-transcriptional regulation. Toward a better understanding of its regulatory features, we have assessed the organization, evolution, and associated regulatory features of *Cas-1*. It includes 12 introns, ranging in size from 256bp to 7.5kb. The exon/intron boundaries correspond to the rat and human sequence with species-specific consensus, and the introns contain no apparent regulatory sequences. Two repeats common to more than one *Cas-1* intron appear to be repeated in the introns of a variety of other mouse genes. Such repeats are hypothesized to represent mammalian-specific intronic elements of unknown origin and effect. Further, using sodium bisulphide modifications, the 5' TATA-less promoter was established to be unmethylated in most tissues. These results are compatible with the ubiquitous expression of this gene. Also, the 3' UTR with two specific repeats that actively interact with a set of redox-responsive proteins provides the basis for its post-transcriptional regulation. Finally, we have isolated a 16kb *SalI* 5' 129/SvJ genomic fragment toward generation of *Cas-1* knockouts that are required to fully understand the role of individual genes of the oxygen radical metabolic pathway in health and disease. The observed regulatory features of *Cas-1* argue that this gene could serve as a model for multilevel regulation in response to external challenges.

**The Ubiquitin-activating enzyme UBE1 gene produces multiple transcripts in mouse and human.** *N. Levy, G. Longepied, M. Mitchell.* Inserm U491, Genetique medicale et Developpement, Faculte de Medecine, Marseille, France.

The ubiquitin-activating enzyme E1 activates ubiquitin and ligation of the activated ubiquitin polypeptide to various proteins targets them for degradation. Ubiquitination is a process whose first step involves the binding of inactive ubiquitin to the ubiquitin-activating enzyme E1. The activated ubiquitin is then transferred to a ubiquitin-conjugating enzyme E2 which transfers the ubiquitin to the protein target, with or without the participation of a ubiquitin ligase E3. There are many different genes for E2 and E3 proteins but only one E1 gene is known and maps to the X chromosome. This suggests that the specificity of ubiquitination is determined largely by the E2 and E3 proteins. We previously identified a testis-specific UBE1 homologue on the mouse Y chromosome, *Ube1y*. *Ube1y* is not present on the human Y chromosome, having been lost during primate evolution. UBE1 may be performing the testis-specific functions of *Ube1y*. To investigate if this role in spermatogenesis is reflected in the transcription of UBE1 and *Ube1x*, we investigated the structure of the transcripts produced by these two genes. One mouse and one human ubiquitous transcripts coding for UBE1 were already known. We investigated the existence of other UBE1 and *Ube1x* transcripts by screening a testis cDNA library and the genbank database and identified multiple mouse and human transcripts, all varying only in their 5'UTR. We have sequenced the genomic region containing these 5'UTR exons in the mouse. We have identified four transcripts in the mouse whose 5'UTR have more than 80% nucleotide identity to four human transcripts. We show that one of these transcripts is expressed predominantly in the testis in human and mouse and may play a role in the degradation of histones during spermiogenesis. The definition of the stage at which this transcript is up-regulated should help elucidate its function. Our results indicate that the selectivity of ubiquitination is controlled in part through the translation of a variety of distinct ubiquitin-activating enzyme E1 transcripts.

**Identification of a domain of the FANCD2 protein that is toxic to cells when overexpressed.** *D.A. Bruun, J.A. Hejna, R.E. Moses.* Dept Molecular & Medical Gen, Oregon Health Sci Univ, Portland, OR.

The Fanconi anemia complementation group D gene on chromosome 3p25-26 gene has been positionally cloned and identified as FANCD2 (Timmers et al., submitted). The full-length cDNA contains a 4413 bp open reading frame. Like other Fanconi anemia genes, the sequence reveals few identifiable features; however, the FANCD2 cDNA, like FANCA, encodes a functional nuclear localization signal (NLS). This was demonstrated by cloning a 147 bp fragment encoding amino acid residues 1-49 in-frame with enhanced green fluorescence protein (EGFP) in the expression vector pEGFP-N1 (Clontech), resulting in expression of the EGFP fusion protein exclusively in the nucleus. Attempts to demonstrate functional complementation of FA group D cells with full-length FANCD2 cDNA in various expression vectors have been unsuccessful because overexpression of FANCD2 is toxic to cells, as manifested by a failure to obtain stable expressing transfectants. In order to determine which part of the protein was responsible for cellular toxicity, we subcloned fragments of the FANCD2 cDNA in-frame into pEGFP-N1. A 3 kb subclone lacking the C-terminal 471 aa residues was toxic to GM639 fibroblasts within 24 hours after electroporation. Nested exonuclease III deletions of this subclone produced fusion constructs which expressed the respective EGFP fusion proteins in the nucleus without affecting cellular viability. The "toxic" domain of FANCD2 has been localized on subclones which express the respective EGFP fusion proteins in the nucleus. Cell death appears to depend on a region of 300 bp or less. *FANCD2FANCD2FANCAFANCD2*.

**Identification and characterization of proteins that interact with midin, the Opitz syndrome gene product.** *G. Meroni, S. Cainarca, C. Berti, S. Messali, A. Ballabio.* Telethon Inst Genetics & Med, Milan, Italy.

Opitz syndrome (OS) is a multiple congenital anomaly manifested by abnormal closure of midline structures. The gene responsible for the X-linked form of this disease, MID1, encodes a protein (midin) that contains a RING, two B-boxes, a coiled-coil (the so-called tripartite motif) and an RFP like domain. We found that midin is associated with microtubules throughout the cell cycle. Consistent with the evidence obtained by gel filtration analysis, immunoprecipitation experiments demonstrated the ability of the tripartite motif, and in particular of the coiled-coil domain, to mediate midin homo-interaction. Functional characterization of altered forms of midin, resulting from mutations found in OS patients, revealed that association with microtubules is compromised, while the ability to homodimerize and form multiprotein complexes is retained. We have therefore undertaken experiments aimed at the identification of cellular partners of midin to comprehend the pathways and the molecular mechanisms underlying the OS phenotype. Using both a candidate and a two-hybrid screening approach we have selected a number of clones that we are testing as interactors of midin. The interactions mediated by the N-ter of midin should be maintained in the mutants, while the interactions through the C-ter should be altered in OS patients. Based on this idea we performed two-hybrid screenings using two different baits: the tripartite motif and the C-terminal domain. We are characterizing an N-terminus interactor belonging to a class of proteins known to bind cytoskeletal structures and a C-terminus interactor sharing homologies with a gene involved in development. Moreover, we are characterizing another member of the B-box family of proteins showing a cytoskeleton distribution and that interact with the N-terminal portion of midin. The assessment of these interactions will render possible to draw a hypothesis on the physiological role of midin and its altered function in OS mutant cells.

**A mutation in the Cys-loop region of the acetylcholine receptor (AChR)  $\alpha$  subunit reduces affinity for acetylcholine (ACh) and compromises gating efficiency.** K. Ohno<sup>1</sup>, X.-M. Shen<sup>1</sup>, A. Tsujino<sup>1</sup>, J.M. Brengman<sup>1</sup>, M. Gingold<sup>2</sup>, A.G. Engel<sup>1</sup>. 1) Neurology, Mayo Clinic, Rochester, MN; 2) Morgantown, WV.

**Background:** The fast-channel myasthenic syndromes are characterized by fast decaying endplate (EP) currents and abnormally brief channel opening events. We previously reported a fast-channel mutation, eP121L, in the extracellular domain of the AChR  $\epsilon$  subunit, which decreases affinity for ACh (*Neuron* 1996, 17:157), and another mutation,  $\alpha$ V285I, in the M3 transmembrane domain of the AChR  $\alpha$  subunit, which affects the channel gating mechanism (*Nat Neurosci* 1999, 2:226). Here we describe a fast-channel mutation in the Cys-loop of the AChR  $\alpha$  subunit. **Patient:** A 5-year-old girl with life-threatening myasthenic symptoms since birth has no anti-AChR antibodies and responds partially to anticholinesterase drugs. The number of AChRs per EP, EP ultrastructure, and quantal releases by nerve impulse are normal. The miniature EP potential amplitude is 10% of normal. Patch clamp recordings from EP AChRs reveal normal channel conductance but the opening events are 6-fold briefer than normal. **Mutation analysis:** The patient carries two heteroallelic mutations in the extracellular domain of the AChR  $\alpha$  subunit: a missense  $\alpha$ V132L in the Cys-loop between Cys128 and Cys142, and a frameshifting null mutation,  $\alpha$ 381delC. **Expression studies in HEK cells:** The level of expression of  $\alpha$ V132L-AChR is normal, but its open probability and apparent affinity for ACh are markedly reduced. The channel opening episodes of  $\alpha$ V132L-AChR are much shorter than of wild-type. Interval-based maximum likelihood analysis of clusters of channel openings elicited by desensitizing concentrations of ACh is consistent with a model in which the diliganded receptor opens in two sequential steps. This model predicts a 14-fold increase in the equilibrium dissociation constant ( $K_2$ ) of ACh from the diliganded receptor, and an 8-fold decrease in the gating equilibrium constant ( $q_2$ ). **Conclusions:** The Cys-loop region plays an important role in AChR subunit assembly (*Neuron* 1995, 15:1231). We here show that the Cys-loop region also plays an important role in governing affinity for ACh and efficiency of gating.

**The localization of FRG1P in the nucleolus, Cajal bodies and speckles implies a fundamental role in RNA processing.** *S. van Koningsbruggen<sup>1</sup>, G. Deidda<sup>2</sup>, R.W. Dirks<sup>3</sup>, A.M. Mommaas<sup>4</sup>, J. Onderwater<sup>4</sup>, G.W. Padberg<sup>5</sup>, R.R. Frants<sup>1</sup>, S.M. van der Maarel<sup>1</sup>.* 1) Human and clinical genetics, LUMC, Leiden, The Netherlands; 2) Institute of Cell Biology, CNR, Rome, Italy; 3) Department of Molecular Cell Biology, LUMC, Leiden, The Netherlands; 4) Laboratory for Electron Microscopy, LUMC, Leiden, The Netherlands; 5) Department of Neurology, University Hospital Nijmegen, The Netherlands.

The FSHD region gene 1 (FRG1) was cloned as candidate gene for facioscapulohumeral muscular dystrophy (FSHD). Although the sequence is highly conserved between vertebrates and non-vertebrates, the function of the FRG1 protein (FRG1P) is still unknown. To obtain more insight in the biological role of FRG1P, we studied its cellular localization after transient transfections. Colocalization studies demonstrate that FRG1P is localized in the nucleoli, speckles and Cajal bodies after transient transfection. This localization is suggestive for a dynamic interplay between these three components in the nucleus as already suggested by several studies involving snRNP maturation. Immunoelectron microscopy showed that FRG1P is localized in the dense structures of the nucleolus. The functionality of two predicted nuclear localization signals (NLS and BP) in FRG1P was confirmed by studying several deletion constructs. The construct missing the NLS signal showed a diffuse cellular staining, while the construct missing the BP signal, was detected in speckles. Its high evolutionary conservation and its potential role in a fundamental process like RNA processing make FRG1P an attractive target for the position effect variegation mechanism that is hypothesized to underlie FSHD pathogenesis.

**Towards understanding the tissue-specific functions of dyskerin, the protein responsible for causing the telomere maintenance disorder (dyskeratosis congenita).** *N.S. Heiss<sup>1</sup>, A. Kolb<sup>1</sup>, R. Salowsky<sup>1</sup>, D. Bächner<sup>2</sup>, A. Poustka<sup>1</sup>.* 1) Department of Molecular Genome Analysis, German Cancer Research Center (DKFZ), Heidelberg, Germany; 2) Universitätsklinikum Eppendorf, Cell Biochemistry and Clinical Neurobiology, Hamburg, Germany.

X-linked dyskeratosis congenita (DKC) is a progressive multisystem disorder most severely affecting tissues with a high cellular turnover such as skin and blood. Most patients die of bone marrow failure, although the chances of developing various types of cancer are also high. Predominantly missense mutations in the *DKC1* gene are responsible for causing DKC, as well as a more severe allelic variant of the disease, Hoyeraal-Hreidarsson syndrome (HHS). The protein dyskerin is a highly conserved nucleolar protein that functions in rRNA biogenesis and possibly also in the processing of the RNA component (hTR) of the telomerase complex. To unravel the functions of dyskerin together with disease progression, we determined the in situ tissue- and developmental-specific expression pattern of the mouse *Dkc1* transcript. A ubiquitous expression was detected at all stages of development with a notably higher expression confined not only to the rapidly dividing epithelia, but also to specific quiescent neurons of the adult brain. These results indicate that some of the pertinent functions of dyskerin may be more tissue-specific than previously thought and are not limited to rapidly dividing cells. It has been proposed that DKC could be a telomere maintenance disorder, although it remains a challenge to understand the underlying disease mechanism. To generate mouse models of the disease we determined the entire mouse genomic sequence. Further, we are functionally characterizing the promoter regions of both the human and mouse genes. By transfecting a series of *DKC1* promoter constructs expressing a secreted form of alkaline phosphatase, preliminary data indicate that the core promoter activity lies within the first 550 bp 5' of the ATG start codon. To understand the tissue-specific functions of dyskerin we aim to identify the corresponding tissue-specific transcription factors.

**The study of a cat eye syndrome candidate gene using model organisms.** S.A. Maier<sup>1</sup>, D. Bushey<sup>1</sup>, L. Podemski<sup>1</sup>, P. Dickie<sup>2</sup>, J. Locke<sup>1</sup>, H.E. McDermid<sup>1</sup>. 1) Biological Sciences, University of Alberta, Edmonton, AB, Canada; 2) HSLAS, University of Alberta, Edmonton, AB, Canada.

Cat eye syndrome (CES) is a human genetic abnormality associated with the duplication of a segment of 22q11.2. It is characterized by defects of the eyes, anus, heart, kidney and face, as well as mental retardation. The CES critical region, which has been sequenced, is thought to contain dose-sensitive genes responsible for the CES phenotype. One promising candidate gene is *CECR1* (Riazi *et al*, 2000). *CECR1* shows significant amino acid identity to several invertebrate growth factors, and is expressed in the outflow tract and atrium of the embryonic human heart, the VII/VIII cranial nerve ganglion, and the notocord, making *CECR1* an excellent candidate gene for CES.

In order to study the function of this gene, we are utilizing two model organisms. Using the genomic sequence of *Drosophila melanogaster*, we have identified six genes with sequence similarity to *CECR1*. These uncharacterized gene products show 38 to 40% amino acid identity over the entire human protein. Each gene has significantly diverged from the others, and preliminary evidence shows expression pattern differences. Although there may be functional redundancy, the amount of divergence may allow subtle phenotypes to emerge upon overexpression or disruption. The completion of the human genome sequence will allow us to determine if *CECR1* paralogues also exist in humans.

We are also producing transgenic mice that overexpress human *CECR1*. Initial low yield of founders suggested that *CECR1* may be detrimental *in utero*. Subsequent lower concentrations of the injected clones have produced three transgenic founders, which are currently being bred. We are also in the process of isolating the mouse homologue for expression studies.

By studying this novel gene family in *Drosophila* and mouse, we hope to shed light on gene function. Overexpression of these genes may elucidate roles in the development of symptoms involved in CES.

**Development and analysis of a murine BAC contig syntenic to the Smith-Magenis syndrome common deletion.** *J. Yan, C.F. Boerkoel, S.S. Park, J.R. Lupski.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Smith-Magenis syndrome (SMS) is a multiple congenital anomaly syndrome associated with deletion of human 17p11.2. The complex phenotype is thought to result from haploinsufficiency effects of contiguous genes that map within the critical interval. This region is syntenic to the murine chromosome 11 32-34cM region. Using 21 overgo probes made from genes and genetic markers mapped in the murine syntenic region, we constructed a BAC contig of this region by screening the murine RPCI-23 BAC library. Ten BACs (479J7, 82E8, 326M22, 181C17, 345K4, 52O1, 77B23, 40J4, 201K2, 77I12) define the minimal tiling distance across this region. After fingerprinting analysis, these BACs have been submitted to the Baylor Genome Sequencing Center for sequencing. Based on the draft sequences of six BACs, we have confirmed the presence of 7 out of 12 genes formerly mapped in the murine syntenic region and mapped 33 additional ESTs. In addition to formerly mapped genes and these 33 ESTs, we also found four more genes in this region (*Eppb9*, *Pemt2*, *Epsin2*, and *Mapk7*). The latter three have also been found in the human SMS region. The expression pattern of these four genes and some ESTs have been examined by both RT-PCR and Northern blot analysis. We are now extending our contig centromeric and telomeric to the SMS deletion to precisely map the boundaries of the region syntenic to the SMS common deletion. This work will identify all genes in the murine chromosome 11 region that maintains conserved synteny with human 17p11.2; several of which may contribute to phenotypic feature of the SMS.

**Variable expressivity, androgen insensitivity and androgen receptor gene mutations.** *B. Gottlieb, L. Pinsky, LK. Beitel, M. Trifiro.* Dept Cell Genetics, Lady Davis Inst for Medical Research, Montreal, Quebec, H3T 1E2 Canada.

Variable expressivity is a genetic concept whose mechanism of action is poorly understood. We report on an example of variable expressivity in two families with Androgen Insensitivity Syndrome (AIS). An identical mutation in the Androgen Receptor (AR) gene, Ser 814 Asn, has been identified in two unrelated families. Affected members of one family have a partial AIS (PAIS) phenotype with ambiguous female genitalia while those from the second have a mild AIS (MAIS) phenotype with normal male genitalia. This is one of 25 examples of variable expressivity that have been reported in the Androgen Receptor Gene Mutations Database. Phenotypic variation in most AIS cases has usually been reflected in differences in the kinetic properties of ARs, which has allowed for the correlation of functional properties of ARs with phenotypic expression. However, in this study all ARs exhibited an identical and unique set of kinetic properties. Their ARs were ligand specific, with abnormal kinetics only observed with DHT (high Kd) and with MB (high k). This lack of correlation with their phenotypes could not be explained by the CAG polymorphism in exon 1 of the AR, as they shared the same length (20 CAGs) polyGln tract. Further analysis of the kinetics of the ARs from the MAIS family revealed that while the overall value of Kd with DHT was elevated; there was a wide degree of variability in individual experiments, with the Kd sometimes appearing normal. This suggests a heterogeneous AR population of both mutant and WT ARs, and the possibility that in this family there exists a degree of mosaicism that would account for their virilized phenotype. Similar mosaicism has been observed in 6 other cases of AIS and was found to be somatic in nature, with mutant AR genes undergoing a back mutation to produce WT receptors in some cells. An understanding of the relationship of somatic mutations to variable expressivity, is however, likely to require gene mutation databases that distinguish between germline and somatic mutations. Ultimately, it seems reasonable to expect that somatic mutations and somatic mosaicism is likely to have considerable impact on phenotype expression.

**Functional Analysis of the Primary Congenital Glaucoma (PCG) Gene - CYP1B1.** *I. Stoilov<sup>1</sup>, I. Jansson<sup>2</sup>, J.B. Schenkman<sup>2</sup>, M. Sarfarazi<sup>1</sup>.* 1) Molecular Ophthalmic Genetics Laboratory, Department of Surgery, University of Connecticut Health Center, Farmington, CT; 2) Department of Pharmacology, University of Connecticut Health Center, Farmington, CT.

CYP1B1 cDNA was amplified from a retinal cDNA library and 5' modifications were introduced to enhance expression. Plasmids were constructed using pCWori<sup>+</sup> expression vector. The expression proved to be highly dependent upon the heme precursor d-aminolevulinic acid (ALA), with levels of CYP1B1 increasing about 20-fold, to 920 nmol/l in the presence of up to 2.5 mM ALA. The expressed human Cytochrome P4501B1 (CYP1B1) has been purified and antibodies to the protein were raised in chickens. Two PCG mutations G61E (hinge region) and R469W (hem-binding region) were introduced in the expression construct. Difference spectroscopy analysis of bacterial homogenates indicated that the absorption peak at 450nm characteristic for the formation of stable hemoprotein complex is absent or substantially diminished in the mutants compared to the wild-type CYP1B1. Western blot detected the presence of CYP1B1 protein indicating that the mutations most probably do not prevent expression of intact hemoproteins, but alters their stability. Metabolism of progesterone and testosterone by a reconstituted system containing the human CYP1B1 and CYP1A2. Metabolism of progesterone and testosterone by a reconstituted system containing the human CYP1B1 or CYP1A2 was studied. The enzymes are reconstituted by adding NADPH-cytochrome P450 reductase and phospholipid vesicles. NADPH is added to start the monooxygenase reaction. Product identification was done by thin-layer chromatography. Comparative analysis found differences in the metabolic activities of CYP1B1 and CYP1A2. For example 15 $\alpha$ -hydroxylation of testosterone was demonstrated only by CYP1B1. This indicates that although the members of family CYP1 may share some substrates their substrate specificities are not completely overlapping and CYP1B1 deficiency may not be fully compensated by other members of this family. Supported By National Eye Institute (EY-11095); The Mary Jane & Peter DaPuzzo Research Fund of the Glaucoma Foundation and the UCHC-GCRC (M01RR-06192).

**Expression of *Macaca fascicularis* Liver Arginase in Erythrocytes.** P.S. Kim<sup>1,2</sup>, R.K. Iyer<sup>1,2</sup>, K.V. Lu<sup>1</sup>, H. Yu<sup>2</sup>, A. Karemi<sup>2</sup>, R.M. Kern<sup>2</sup>, D. Tai<sup>1</sup>, J. Miller<sup>4</sup>, S.D. Cederbaum<sup>2,3</sup>, W.W. Grody<sup>1,2</sup>. 1) Dept Pathology & Lab Med, UCLA School of Medicine, Los Angeles, CA; 2) Division of Genetics and the Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA; 3) Department of Psychiatry and Pediatrics, UCLA, Los Angeles, CA; 4) Laboratory of Chemical Biology, National Institute of Diabetes and Digestive and Kidney Disease, National Institutes of Health, Bethesda, MD.

Arginase I (AI) has a critical function in mammalian liver as an enzyme responsible for the disposal of nitrogenous wastes from protein catabolism. AI is also expressed in various extrahepatic tissues, and may play a role in providing ornithine for biosynthetic reactions that generate various regulatory molecules such as glutamate, glutamine, GABA, agmatine, polyamines, creatine, proline and nitric oxide. Among these, AI is expressed in red blood cells (RBCs) in humans and certain higher primates. *Macaca fascicularis* was identified as an evolutionary transition species for RBC-AI expression. The *M. fascicularis* AI gene was analyzed to study AI expression in erythrocytes. We found globin enhancer-like elements in the 5' upstream of the AI gene, which provided tantalizing clues for its expression in erythrocytes. Since available erythroleukemia cell lines have no apparent AI activity, erythroid progenitor cells (nRBCs) isolated from cord blood were cultured and used to demonstrate AI expression by immunocytochemical staining using anti-AI antibody. Introduction of EGFP reporter vectors into nRBCs showed that the proximal 1.2 kbp upstream of the AI gene are sufficient for AI expression. Expression of a second arginase isoform, AII, in nRBCs was discovered by cDNA profiling, and this was confirmed by immunoprecipitation with anti-AII antibody. An alternatively spliced AI (AI') variant was observed from erythroid cDNA analysis. The alternative splice acceptor site was found to be located within intron 2, resulting in the insertion of 8 additional amino acids without losing its enzymatic activity. Understanding AI gene regulation in erythrocytes may provide alternative treatment options for arginase deficient patients.

**Differential expression and distribution of Dp71 isoforms during PC12 cells differentiation.** *C. Montanez<sup>1</sup>, B. Cisneros<sup>1</sup>, F. Garcia<sup>2</sup>, V. Ceja<sup>1</sup>, H. Rosas<sup>1</sup>, M. Mustre<sup>1</sup>, A. Rendon<sup>3</sup>, D. Mornet<sup>4</sup>, F. Marquez<sup>1</sup>.* 1) Dept. Genetics and Molecular Biol., Cinvestav IPN, Mexico; 2) Dept. Physiology and Neurosciences, Cinvestav IPN, Mexico; 3) Lab. Physiopatol. Retinienne, Strasbourg, France; 4) INSERM UI28, Montpellier, France.

Dystrophin gene product Dp71 is transcribed from a promoter localized between exons 62 and 63 of the gene, the function of this protein is unknown. With the aim of establishing a cell model for studying Dp71 function in nervous system, we adopted PC12 cell line, which has been widely used to investigate the mechanisms underlying neuronal differentiation. In the current study we show by RT-PCR assays that PC12 cells express at least two different Dp71 transcripts generated by alternative splicing of exons 71 and 78. Two Dp71 protein isoforms are observed in PC12 cells by Western blot analysis, Dp71f and Dp71d. The level of Dp71f protein displays an increase along differentiation process while Dp71d remains constant over fifteen days of differentiation. Using immunofluorescence we have examined the localization of Dp71 protein isoforms in PC12 cells. Our results show a localization of Dp71 isoforms to different regions. Dp71f is at cytoplasm being most of it at the cell periphery. During differentiation, PC12 cells showed a similar immunoreactivity to undifferentiated stage. Additionally, neuritic process showed a discontinuous labeling being strong at varicosities and growth cone. Dp71d appears at cytoplasm and at nucleus except nucleolus of undifferentiated cells. At nine days of differentiation, most of the cells show a strong immunoreactivity at nucleus, as well as at cytoplasm and neuritic processes. Our results suggest that Dp71d and Dp71f are functionally distinct in PC12 cells.

**Biochemical and genetic analysis of myozenin, a novel human Z line protein of skeletal muscle.** *F. Takada, H-Q. Tong, T.G. Thompson, L.M. Kunkel, A.H. Beggs.* Genetics Division, Children's Hospital, Harvard Medical School, Boston, MA.

Myozenin (*MYZN*) is a Z line-specific,  $\alpha$ -actinin-binding protein of human skeletal muscle. The *MYZN* gene encodes a unique 32 kDa protein with unknown domain structure and no similarities to proteins in any current databases. Specific interaction of this protein with  $\alpha$ -actinin was demonstrated *in vivo* using the yeast two-hybrid system and *in vitro* by co-immunoprecipitation and blot overlay experiments. A yeast two-hybrid screen, using muscle gamma filamin (*FLNC*) as bait, pulled out multiple myozenin clones, suggesting that myozenin may serve as a linker to anchor filamin to  $\alpha$ -actinin at the Z lines. Double label indirect immunofluorescence microscopy using anti-myozenin and other sarcomeric protein-specific antisera showed that prior to differentiation, myozenin is diffusely distributed in the peri-nuclear cytoplasm and not associated with sarcomeric  $\alpha$ -actinin which is localized to stress fibers and adhesion plaques at the periphery of the myoblasts. During premyofibrillar differentiation, myozenin is segregated away from subcellular compartments containing myosin, however, mature myofibrils contained myozenin localized exclusively at Z lines. Immunofluorescence analysis of muscle from a patient with nemaline myopathy reveals myozenin localized to the nemaline rods. The *MYZN* gene is composed of 6 exons spanning 10 kb on human chromosome 10q22. To determine if mutations of myozenin are responsible for any human congenital myopathies, we have screened the *MYZN* gene in over 75 unrelated patients, including 67 with nemaline myopathy. To date, no convincing pathogenic changes have been identified and we are now expanding the range of phenotypes tested to include patients with limb girdle muscular dystrophy and other neuromuscular disorders.

**A unique substitution mutation in the human androgen receptor confers ligand specificity.** *S.A. Ghali<sup>2</sup>, L.K. Beitel<sup>5</sup>, R. Lumbroso<sup>5</sup>, L. Pinsky<sup>1,2,3,4,5</sup>, M.A. Trifiro<sup>2,3,5</sup>.* 1) Biology; 2) Human Genetics; 3) Medicine; 4) Pediatrics; 5) LDI, SMBD-Jewish General Hosp.; McGill Univ., Montreal, Quebec, Canada.

The human androgen receptor (hAR), a member of the large superfamily of nuclear receptors, functions as a transcription factor mediating androgen action and is responsible for normal male sexual development. The hAR is comprised of a C-terminal ligand binding domain (LBD), a central DNA-binding domain (DBD), and a polymorphic N-terminal domain. There is strong evidence to suggest that hAR N/C terminal interactions are crucial to the normal transactivation of androgen-responsive genes. Ligand-dependent transcriptional activation is partially mediated by the intra-LBD activation function 2 (AF-2) domain. This domain is essential in recruiting transcription intermediate factors (TIFs), such as coactivators, which associate directly with steroid receptors, forming a "transcriptionally-ready" pre-initiation complex. Mutations in the hAR LBD can hinder recruitment of these coactivators, disturb normal N/C terminal interactions, and ultimately reduce the transactivational competence of the hAR. We report on a ligand-selective mutant AR containing a single Ser814Asn substitution mutation identified in an individual with partial androgen insensitivity. Using the mammalian two-hybrid system, this mutation was tested for its effect on hAR N/C terminal interactions in the presence and absence of the coactivator TIF2. In the presence of mibolerone, methyltrieneolone and testosterone, N/C terminal interactions for the S814N mutant were ~50% that of the normal hAR, with or without the addition of TIF2. In the presence of 5 $\alpha$ -dihydrotestosterone, N/C terminal interactions further decreased compared to the normal hAR; markedly so in the presence of TIF2. The ligand-specificity of N/C terminal interactions, which is observed even upon addition of TIF2, complements previous reports on the ligand-specific kinetic abnormalities of this mutation. Further analysis of the ligand-specific nature of this mutation will enable us to decipher the intricate molecular events associated with hAR function.

**Identification of pancreatitis-associated missense mutations in the cationic trypsinogen gene providing insights into the molecular evolution of the human trypsinogen gene family.** *J.M. Chen<sup>1</sup>, C. Ferec<sup>1,2</sup>*. 1) Etablissement Francais du Sang-Bretagne, Brest, France; 2) Centre de Biogenetique, Universite de Bretagne Occidentale and Centre Hospitalier Universitaire, Brest, France.

All of the mammalian trypsinogens in one species (paralogs) are more closely related to each other than to trypsinogens of other species (orthologs), and it has long been suggested that **gene conversion** must have contributed to this process of **concerted evolution**. However, such events, if present, have been largely obliterated by subsequent mutations. Interestingly, the presence of such events has been revealed by the identification of pancreatitis-associated missense mutations in the cationic trypsinogen (T4) gene. To date, two missense mutations, an R122H (R117H) in exon 3 and a N29I (N21I) in exon 2 in the T4 gene, have been identified as causing hereditary pancreatitis, and another variant A16V in exon 2 also reported as a possible predisposing factor to pancreatitis. Of note, we identified a CGC to CAT 2 bp nucleotide substitution resulting in the R122H. The theory that it arose as a **gene conversion** event was strongly supported by the presence of AT at corresponding positions of the highly homologous T6 and T7 genes and a *Chi*-like sequence located 27 nucleotides downstream from the mutation. Similarly, the N29I and A16V in exon 2 could also be explained by such an event: the presence of a possible donor sequence in the functional T8 gene for the N29I mutation and the presence of several possible donor sequences for the A16V mutation among the family members; and the presence of a *Chi*-like sequence and a seven nucleotide inverted repeat split by an asymmetric 21 bp sequence in the 5' and 3' proximity of the A16V and N29I mutations, respectively. The constellation of these observations argues strongly that **gene conversion** is a likely cause of these mutations in the T4 gene and more importantly, by inference, provides concrete evidence for the contribution of **gene conversion** to the molecular evolution of the human trypsinogen family. Additionally, this genetic finding also aids in understanding the pathologic effects of these cationic trypsinogen missense mutations in causing pancreatitis.

**On the Fate of Plant or other Foreign Genes upon the Uptake in Food or after Intramuscular Injection. U.**

*Hohlweg, W. Doerfler.* Inst Genetics, Univ Cologne, Cologne, Germany.

Food is the most abundant source of foreign DNA intake by all organisms. We have investigated uptake and distribution of food-ingested foreign DNA in model experiments with mice. The DNA of bacteriophage M13 and the cloned gene for green fluorescent protein (GFP) as test genes have been traced from the intestinal contents, via the gut wall, Peyer patches and peripheral white blood cells to spleen and liver. There is evidence that in spleen the re-cloned test DNA can become covalently linked to mouse pseudogenes. Foreign DNA orally administered to pregnant mice can be transmitted via the placenta to fetuses and newborn animals.

We have now chosen a natural scenario and fed soybean leaves to mice. The distribution of the plant-specific gene for the ribulose-1.5-bisphosphate-carboxylase (rubisco) gene has then been studied in the mouse organism. Starting at 2 h after feeding, the rubisco gene can be recovered almost intact from the contents of the gut. Rubisco gene fragments remain detectable up to 49 h after feeding in the intestine, up to 121 h in the cecum. Thus, plant-associated, naturally fed DNA is more stable in the intestinal tract than naked DNA which had disappeared from the intestinal tract by 18 h after feeding. Rubisco gene-specific PCR products of 337 nucleotides in length have been amplified from spleen and liver DNA. After feeding the cloned GFP gene, GFP-expressing, green fluorescing cells have never been detected in any organ system of the mouse. Hence, there is no evidence for the detectable expression of orally administered genes. Moreover, mice have been fed daily with GFP DNA for eight generations and have been examined for the transgenic state by PCR. The results have been uniformly negative and argue against the germline transfer of orally administered DNA. Upon the intramuscular injection of GFP DNA, GFP gene-specific fragments have been amplified by PCR up to 4 months post injection in DNA from injected muscle, up to 24 h post injection in DNA from liver and blood. GFP fragments can also be retrieved from the intestinal contents. Apparently, the organism eliminates injected foreign DNA via the liver-bile-intestinal route.

**Evolution of the human immunoglobulin Vk gene locus.** *K. Kawasaki*<sup>1</sup>, *S. Minoshima*<sup>2</sup>, *K. Shibuya*<sup>2</sup>, *A. Shintani*<sup>1</sup>, *S. Asakawa*<sup>1</sup>, *H.G. Klobeck*<sup>3</sup>, *G. Combriato*<sup>3</sup>, *H.G. Zachau*<sup>3</sup>, *N. Shimizu*<sup>1,2</sup>. 1) Dept. of Mol. Biol., Keio Univ. Sch. of Med., Kawasaki, Kanagawa, Japan; 2) Dept. of Mol. Biol., Keio Univ. Sch. of Med., Shinjuku, Tokyo, Japan; 3) Adolf-Butenandt-Inst. fur Chem., Physikal. Biochem. und Zellbiol., Ludwig-Maximilians Univ., Munich, Germany.

The complete nucleotide sequence of the entire human immunoglobulin k gene locus of 1,010,706-nt was determined and 131 Vk genes, including 55 newly identified Vk genes were localized. Among these Vk genes, 45 possessed open reading frames (ORFs), while the remaining 86 had obvious defects in the coding regions. The Vk gene locus was composed of inverted duplication of 350-kb DNA segment with an average of 99.1% sequence homology. This duplication has been observed only in humans and not in apes. Among the 118 Vk genes located within two duplication units, 40 possessed ORFs; 17 each reside in both duplication units, while 4 became pseudogenes and 2 were deleted from one of the duplication units. Comparison of the nucleotide sequences of these duplication units of 350 kb revealed that it was divided into 14 distinct homology blocks, each of which has significantly different sequence homology ranging 98.1-99.9%. A homology plot along the duplication units revealed that the sequence homology abruptly changes at the borders of adjacent blocks, suggesting these homology blocks might have been generated by rearrangements rather than different rate of mutation. A homologous recombination between inverted duplication units results in an inversion of the locus. Subsequent meiotic recombination between the original allele and the newly created inversion allele can generate a block with high sequence homology. If this is the mechanism by which the homology blocks of the Vk gene locus were generated, the block with the lowest homology will provide a basis for the accurate estimation of the time of duplication. Based on the sequence difference in the b-globin locus between human and chimpanzee, the inverted duplication took place ~4.85 million years ago, which is immediately after the coalescent time of human and chimpanzee.

**The evolutionary origins of the pseudogenes for glucocerebrosidase and metaxin on human chromosome 1q21.**

*J.K. Park, N. Tayebi, M. Callahan, R. Samimi, E. Sidransky.* Clinical Neuroscience Branch, NIMH, Bethesda, MD.

Gaucher disease, the most common of the lysosomal storage disorders, results from mutations within the gene encoding for the enzyme glucocerebrosidase (GC). The gene for human GC has an nearby pseudogene located 16kb downstream on chromosome 1q21 that shares 96% sequence homology with the functional gene. Metaxin, a convergently transcribed gene located adjacent to the GC pseudogene, also has a highly homologous pseudogene located downstream from the GC gene. Many mutations identified in patients with Gaucher disease are found in the pseudogene sequence, suggesting that the pseudogene contributes to the introduction of mutations within the GC gene through reciprocal crossover or gene conversion. These recombination events have been previously documented to occur between both the GC gene and pseudogene as well as between the metaxin gene and pseudogene. The murine GC and metaxin genes are also located within close proximity on the mouse chromosome 3E3-F1. Sequencing of this region failed to identify nearby murine pseudogenes. Two strategies were used to determine the presence or absence of pseudogenes in other species. After comparing the human and murine GC and metaxin sequences and the human pseudogene sequences, PCR primers were designed to correspond to conserved regions and were used to amplify gene and pseudogene fragments whose size differs. These primers were used to screen DNA from nine different species. Nucleotide sequence alignments demonstrated that the GC protein sequence in all the species shared homology with human glucocerebrosidase. Sequencing analysis also indicated that the GC pseudogene was present in the human and rhesus monkey, but absent from the other species. This was confirmed by Southern analysis using genomic DNA from different species digested with SspI and HindIII. Further investigations using DNA sequencing and Southern blots are being performed to establish the presence or absence of the metaxin gene and its pseudogene in each of the species. Studying the evolutionary origin of the glucocerebrosidase and metaxin pseudogenes may help to elucidate their role in Gaucher disease.

**Clinical and molecular correlations in individuals with a Fragile X full mutation.** *F. Tassone*<sup>1</sup>, *R.J. Hagerman*<sup>2,3</sup>, *A.K. Taylor*<sup>4</sup>, *P.J. Hagerman*<sup>1</sup>. 1) Dept Biochem & Molecular Gen, Univ Colorado Health Sci Ctr, Denver, CO; 2) Child Development Unit and Fragile X Treatment and Research Center, The Children's Hospital, Denver, CO; 3) Department of Pediatrics and JFK Partners, University of Colorado Health Sciences Center, Denver, CO; 4) Kimball Genetics.

Fragile X syndrome is caused by a large expansion of a CGG trinucleotides repeat (>200) in the 5' untranslated region of the FMR1 gene, which is often associated with hypermethylation and downregulation of transcription. FMR1 DNA methylation, transcriptional silencing and the consequent absence of the gene product FMRP result in fragile X syndrome. Although methylation is correlated with the transcriptional silencing of genes, the mechanism by which DNA methylation influences transcription has not been determined.

In a previous study we have reported that unmethylated alleles in the full mutation range are transcriptionally active and in some cases show higher levels of FMR1 messenger RNA relative to normals. In line with this finding, we have measured the FMR1 mRNA expression levels in 50 individuals with a full mutation fully methylated by QF RT-PCR. Surprisingly, we have found that the majority of individuals express FMR1 mRNA, with some subjects having FMR1 mRNA levels in the normal range, despite the presence of complete methylation of the FMR1 promoter region. All individuals show reduced FMRP expression by immunocytochemistry. Methylation pattern studies by sodium bisulfite conversion of genomic DNA are under way in the attempt to identify the nature of the observed variability in FMR1 transcription.

Preliminary analysis demonstrates no significant correlations between molecular measures (mRNA or FMRP) and IQ or Behavioral or Physical Index score. The fact that >50% of males with a fully methylated full mutation have significant levels of FMR1 mRNA suggests that therapy which will enhance translation, and therefore, FMRP levels, would be of great benefit in these individuals.

**Characterization of PDZ1, a gene in Xq13.1 encoding a protein with a single PDZ domain expressed in human bone marrow stromal cells.** *L.M. King, C.A. Francomano.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

A human bone marrow stromal cell (BMSC) cDNA library was constructed as a resource to identify genes expressed in the development of bone. BMSCs are a population of pluripotent cells capable of differentiating into at least four tissue types: bone, cartilage, hematopoiesis-supportive stroma, and adipocytes. We describe a gene we call PDZ1 isolated from this library. The gene localizes to Xq13.1 at SHGC118320 between DXS983 and DXS995 by radiation hybrid (RH) mapping (Stanford G3 panel, LOD score 12.38) and to Xq13 by fluorescence in situ hybridization (FISH) using a human BAC clone containing the gene. This chromosomal localization makes PDZ1 a candidate gene for the Mendelian disorder, FG Syndrome. The genomic sequence was determined by sequencing the BAC clone. The gene comprises 8 exons and 7 introns that span approximately 3.4 kb. Searches of nucleotide databases suggest that this gene is a member of a multigene family. The 1054 bp cDNA sequence was completed by assembling ESTs from the database, by 5' RACE and was confirmed by RT-PCR. The second exon in the mRNA transcript is alternatively spliced and based on RT-PCR, transcripts containing exon 2 are in low abundance. The 420 bp open reading frame encodes a 140 amino acid protein with a theoretical pI/Mw of 6.65/16 kD. We call the protein PDZ1 because it has a single PDZ domain, which is a domain found in diverse signaling proteins. A 967 bp mouse cDNA sequence was assembled from ESTs in the database. No alternatively spliced transcripts were found based on this assembly technique. The human and mouse cDNA sequences have 83% nucleotide identity and the encoded proteins have 99% amino acid similarity. RH mapping also places the mouse Pdz1 gene on chromosome X (LOD score 12.5) between DXMit229 proximal and DXMit230 distal. Northern analyses using human and mouse multiple tissue blots and species specific cDNA probes shows mRNA expression in various tissues. Further analysis of human and mouse PDZ1/Pdz1 gene expression will help to elucidate the role of this gene in bone biology.

**Definition of a "functional R domain" of the cystic fibrosis transmembrane conductance regulator (CFTR).** C.

*Ferec*<sup>1,2</sup>, *J.M. Chen*<sup>2</sup>. 1) Centre de Biogenetique, Universite de Bretagne Occidentale and Centre Hospitalier Universitaire, Brest, France; 2) Etablissement Francais du Sang-Bretagne, Brest, France.

The R domain of CFTR was originally defined by Riordan et al. (1989) as 241 amino acids from C590 to K830, encoded by exon 13. Such exon/intron boundaries provide a convenient way to define the R domain, but do not necessarily reflect the corresponding functional domain within CFTR. Based upon a comparison of the R domain sequences from 10 species, Dulhanty and Riordan (1994) proposed a two-domain model. RD1, the N-terminal third of the R domain (F587 to E672) is highly conserved; RD2, the large central region of the R domain (W679 to P798) has less rigid structural requirements. This two-domain model was given strong support by the striking observation that mutations clustered in RD1 largely caused a processing defect, while those scattered throughout RD2 showed a normal maturation pattern. And two models of the nucleotide-binding domain (NBD) 1 of CFTR have extended the C-terminus of NBD1 to include part of the N-terminus of the R domain, albeit disagreeing with the length of amino acids included. However, the simple observation that two (S660 and S813) out of the four main phosphorylation sites (S660, S737, S795 and S813) are excluded from RD2 clearly indicates that RD2 still does not satisfy the requirements of a "functional R domain". Nevertheless, knowledge of the CFTR structure and function accumulated over the past decade and re-evaluated in the context of a comprehensive sequence comparison of 14 CFTR homologues enabled us to define such a "functional R domain (**Rf**)", i.e., amino acids C647 to D836. We believe **Rf** is a more realistic representation of the "functional R domain" primarily because it contains all of the important potential consensus phosphorylation sequences. In addition, **Rf** also includes the highly charged motif from E822 to D836, which may be important in keeping the channel closed in a basal or unstimulated state through electrostatic interactions with other CFTR domains. Finally, it includes all of the deletions/insertions in this region. This definition also aids in understanding the effects of missense mutations in this extremely divergent region.

**X-linked RING zinc finger, ZNF127-Xp is active during mouse embryonic development.** *A.J. Kim, M. Ko, D. Schlessinger.* Laboratory of Genetics, NIH/NIA-IRP, Baltimore, MD.

ZNF127, an autosomal gene that may be associated with Prader-Willi syndrome phenotypes, and is one of a family that encode proteins with both a RING(C3HC4) zinc finger and multiple C3H-zinc finger motifs. The Ring zinc fingers have been implicated both in transcription and in protein-protein interactions. An X-linked human homologue of ZNF17, ZNF127-Xp, had been partially recovered in cDNA form and shown to escape X-inactivation. We have found that the mouse orthologue of ZNF127-Xp is expressed in preimplantation mouse embryos, and isolated a full-length cDNA for the mouse gene from a testis full length-enriched cDNA library, using PCR-based techniques with primer pairs inferred from fragmentary ESTs. Sequencing of the full-length cDNA revealed an insert of 1738 bp, encoding an open reading frame of 515 amino acids. The putative protein contained 4 C3H motifs, 1 C2H2CH motif, and near the carboxy terminus, a RING-finger motif (C3HC4). We have made 3 types of recombinant GST-RING protein in Sf9 cells from constructs with the N-terminal, C-terminal, or complete coding sequences. In cell fractionation experiments the expressed N-terminal peptide was soluble, but the C-terminal and complete RING proteins appeared in the insoluble fraction, and could only be solubilized in complex detergent solutions, suggesting that they may be associated with cytoskeletal or nuclear matrix. In initial studies of expression, Northern blot analysis of mouse and human tissue detected three species of approximately 3.4, 1.9 and 0.8kb. Expression increased during mouse embryonic development and expression patterns different with adult mouse tissues. The highest mRNA expression in adult mouse tissues is in testis, with high levels also present in heart, spleen, brain, and kidney. But particularly in the human, the expression of the 3.4kb mRNA is detected in testis.

**Functional Genomics of Single-minded 2 (SIM2) Gene Located on Human Chromosome 21q22.2.** *Y. Shimizu*<sup>1</sup>, *A. Yamaki*<sup>1</sup>, *J. Kudoh*<sup>2</sup>, *S. Minoshima*<sup>2</sup>, *N. Shimizu*<sup>2</sup>. 1) Department of Medical Genetics, Kyorin University School of Health Sciences, Hachioji, Tokyo; 2) Department of Molecular Biology, Keio University School of Medicine, Shinjuku-ku, Tokyo.

Human SIM2 protein has been postulated to function as an important transcription factor in the development of the central nervous system. To understand the molecular mechanism of SIM2 gene expression, we have analyzed the promoter region of SIM2 gene using SIM2 expressing glioblastoma cell line, T98G. By 5'-RACE method, we found that the major transcription initiation site was at about 1.2kb upstream of the initiation codon. Two series of deletion constructs of the presumed promoter region (between nt-2449 and nt-184) fused with luciferase reporter gene. The results revealed that most significant promoter activity was located in the 60-bp sequence between nt-1385 and nt-1325. Computer analysis predicted the presence of three cis-elements, those for c-myb, E47 and E2F, in this region. A point mutation at the consensus sequence for c-myb reduced substantially the promoter activity, whereas a point mutation at the consensus sequence for E2F increased the promoter activity. The gel shift assay using oligo DNA of various cis-element sequences revealed the presence of protein factor(s) which bind to the cis-element for c-myb. To assess intracellular localization of SIM2 protein, we generated fusion genes of full-length of SIM2 cDNA and its deletion mutants with the green fluorescent protein (GFP). Transient expression study in glioblastoma and HeLa cells revealed that the intact SIM2 protein was accumulated in the nuclei, and that the bHLH-PAS and HST domains were not sufficient for the nuclear translocation of SIM2 protein. These data suggest the translocation signal exists in the carboxy terminal region which is rich in basic amino acids.

**The severity of experimental colitis in mice is dependent on the presence of the  $\alpha 5$  neuronal nicotinic acetylcholine receptor (nAChR) subunit.** *A. Orr-Urtreger<sup>1,2</sup>, M. Kedmi<sup>1</sup>, F. Karmeli<sup>1</sup>, Y. Yaron<sup>1,2</sup>, D.*

*Rachmilewitz<sup>1,2</sup>.* 1) Genetics Inst, Tel-Aviv Sourasky Medical Ctr, Tel Aviv, Israel; 2) Sackler Medical School, Tel-Aviv University, Tel Aviv, Israel.

Cigarette smoking has diverse effects on IBD (Inflammatory Bowel Diseases). It is beneficial in Ulcerative Colitis and deleterious in Crohn's disease. The ingredients and mechanisms involved in the relationship between smoking and IBD remain to be defined. In order to study the possible involvement of the nicotinic receptors in the pathogenesis of IBD we compared the severity of experimental colitis in mice with  $\alpha 5$  nAChR subunit deficiency to wild type control mice. Colitis was induced in  $\alpha 5$  deficient ( $\alpha 5^{-/-}$ ) and control mice by the addition of 2.5% dextran sodium sulfate (DSS) to the drinking water. Control groups received tap water. Disease activity index was determined by scoring changes in body weight and the presence of gross bleeding in stool. On day seven mice were sacrificed, the colon was dissected and weighted, and sections were obtained for histology and to determine the mucosal MPO activity and PGE<sub>2</sub> generation. Expression analysis, using RT-PCR, demonstrated that the  $\alpha 5$  neuronal nAChR subunit is expressed in normal adult mouse colon. DSS induced colitis in the  $\alpha 5^{-/-}$  mice was significantly more severe as expressed by the percentage change in body weight, and by disease activity and histological score. Mucosal MPO activity and PGE<sub>2</sub> generation were also higher in DSS treated  $\alpha 5^{-/-}$  mice as compared to the respective levels in DSS treated control mice. The augmented severity of DSS induced colitis in  $\alpha 5$  deficient mice suggests that this subunit may have an important role in the pathogenesis of experimental colitis. It may further suggest that the role of nicotine in IBD may be mediated via neuronal nicotinic acetylcholine receptors that include the  $\alpha 5$  subunit.

**Molecular characterization of PRY and TTY2 genes on the human Y chromosome.** *L. Stuppia*<sup>1,2</sup>, *V. Gatta*<sup>1</sup>, *A. Gaspari*<sup>1</sup>, *R. Grande*<sup>1</sup>, *E. Morizio*<sup>1,3</sup>, *D. Fantasia*<sup>1,3</sup>, *R. Mingarelli*<sup>4</sup>, *G. Calabrese*<sup>1,3</sup>, *G. Palka*<sup>1,3</sup>. 1) Dept di Science Biomediche, Univ G D Annunzio, Chieti, Italy; 2) Istituto di Citomorfologia Umana Normale e Patologica CNR, Chieti, Italy; 3) Servizio di Genetica Medica, Ospedale Civile, Pescara, Italy; 4) CSS-IRCCS Mendel, Roma, Italy.

About 10% of infertile males have Yq microdeletions involving the three loci AZFa, AZFb and AZFc. Several genes have been isolated in these loci, but so far the role played by most of them in male infertility has not been clarified, due to the lack of information about their genomic organization and localization within the Y chromosome. In this study we report the molecular characterization of PRY (PTA-BL related Y) and TTY2 (Testis Transcript Y 2) genes, present with multiple copies within AZFb and on Yp. The cDNA sequences of these genes were used for a database screening and aligned with genomic sequences with high homology to identify exon-intron junctions. It was found that PRY spans 25 kb and is composed by 5 exons, while TTY2 spans 17.8 kb and is composed by 7 exons. Specific primers were derived from the intronic sequences, and PCR analysis was performed on normal controls, 9 infertile patients with different Yq deletions and one female patient with a 45,X,i(Yq) karyotype. Patients with Yq deletions involving entire interval 6 showed loss of exons 3-5 of PRY, while all exons were present in patients with deletions involving AZFc alone. On the other hand, TTY2 exons were present in all infertile patients. In the patient with an i(Yq), PCR showed amplification of all PRY exons, but only of exons 1, 3 and 7 of TTY2. These results suggest that copies in Yp and Yq of these genes are not identical. In fact, patients with large Yq deletions retain only exons 1 and 2 of PRY, suggesting that copies in Yp are partial and likely non functional, while the active copies are mapped in AZFb. Thus, PRY could represent another candidate for male infertility. As to TTY2, it is likely that full-length copies are present only in Yp, since the patient with i(Yq) retained only exons 1, 3 and 7. Thus, this gene would not be involved in male infertility, but could be a candidate for the gonadoblastoma locus on Yp.

**Novel gene family encoding putative Ca<sup>2+</sup>-binding proteins with EGF-like modules and a CUB domain. A.**

*Winterpacht<sup>1</sup>, N. Pfarr<sup>1,2</sup>, A. Cichutek<sup>2</sup>, A. Bahr<sup>3</sup>, E.R. Schmidt<sup>3</sup>, T. Hankeln<sup>3</sup>, B. Zabel<sup>2</sup>.* 1) Institute of Human Genetics, University of Hamburg, Hamburg, Germany; 2) Childrens Hospital, University of Mainz, Mainz, Germany; 3) Institute of Molecular Genetics, University of Mainz, Mainz, Germany.

The epidermal growth factor (EGF)-like domain is one of the most widely distributed protein modules commonly found in cell membrane-bound and extracellular proteins usually involved in extracellular signaling and cell guidance. The common occurrence of the EGF-like domain and its potential involvement in human disease has led to intense study of this module. By comparative sequencing of human chromosome region 11p15.3 and the corresponding region on mouse chromosome 7, we determine the coding sequence and the complete genomic structure of a novel gene which we designated CEGP1 (CUB and EGF-like domain containing protein-1). CEGP1 represents a member of a novel gene family and encodes a protein with 11 EGF-like domains (8 of them with Ca<sup>2+</sup>-binding capability) and a single CUB domain, a widespread module in developmentally regulated proteins. BLASTN homology searches revealed two related genes localized on chromosome 22q (CEGP2) and chromosome 6p (CEGP3). We cloned and sequenced the complete coding sequence of the human and parts of the murine genes. The deduced protein structures of CEGP2 and 3 are quite similar to CEGP1 although the number of EGF-like domains vary. Transcription of the three CEGP family members is very complex due to alternative splicing. Northern blot analysis showed a strong ubiquitous expression of CEGP1 in all fetal and adult human tissues examined. In contrast, CEGP2 showed a very slight expression in adult tissues and expression of CEGP3 could not be detected by Northern blot analysis. Interestingly, expression studies during mouse development revealed a strong expression of CEGP2 in an early stage of mouse embryogenesis (7 dpc) with a sharp decrease in later stages. We are currently investigating the detailed expression pattern of CEGP2 in early mouse development. Functional investigation of the CEGP gene family members and there potential involvement in disease is in progress.

**The epsilon-subunit gene of F1FO-ATP synthase on HSA 20q13 shows splice variants in 3' UTR.** *C. Gross<sup>1</sup>, S. Kussmann<sup>1</sup>, A. Hehr<sup>1</sup>, K. Koerber<sup>1</sup>, H. Miller<sup>2</sup>, J. Peters<sup>2</sup>, I. Hansmann<sup>1</sup>, D. Schlote<sup>1</sup>.* 1) Institut f. Humangenetik und Medizinische Biologie, Univeritaet Halle, Halle, FRG; 2) Medical Research Council, Harwell, GB.

In order to identify genes on human chromosome region 20q13 with a conserved synteny to the imprinting region 1 (IR1) on mouse chromosome 2, predicting the presence of imprinted genes, a lot of ESTs were mapped into a BAC contig of this region. To isolate full length cDNA we screened Gene Finder pools of different human tissues (RZPD, Berlin) and obtained several cDNA clones for sequencing analysis after rescreening high density filters. So far we could characterize several human cDNA sequences, one of them the human gene of ATP5e with an open reading frame of 51 AS corresponding to a transcript of about 400 bp in Northern blot analysis using a human multiple tissue blot (Clontech) and an exon 3 specific probe. This sequence could be mapped proximal to D20S171 based on our BAC contig spanning about 800 kb around the anchor marker GNAS and EDN3. Analysing several PCR-products amplified out of a marathon ready cDNA library (Clontech) as well as MTP-cDNA clones, sequencing revealed three alternative splice products differing in 3' UTR without affecting protein structure. Furtheron Northern blot analysis as well as in situ hybridisation will give insight into the expression pattern of this new splice variants of the epsilon-subunit gene on human chromosome 20q13. Sequencing of already isolated homologous mouse cDNA clones is in progress and might be relevant for identification of splice variations in mouse as well as to get insight into the possible role of the epsilon-subunit in the mitochondrial F1FO-ATP synthase. This work was supported by grant of the DHGP.

**Human Pantothenate Kinase 1 (*PANK1*) Gene: Characterization of the cDNAs, Structural Organization and Mapping of the Locus to Chromosome 10q23.2-23.31.** *M.A. Karim*<sup>1</sup>, *V.A. Valentine*<sup>2</sup>, *S. Jackowski*<sup>1,3</sup>. 1) Dept. of Biochemistry, St Jude Children's Res Hosp, Memphis, TN; 2) Dept. of Tumor Cell Biology, St Jude Children's Res Hosp, Memphis, TN; 3) Dept. of Biochemistry, University of Tennessee Medical Center, Memphis, TN.

Pantothenate Kinase (PanK) is the regulatory enzyme in the coenzyme A (CoA) biosynthetic pathway. CoA is the major acyl group carrier in intermediary metabolism and is required for fatty acid mobilization and degradation. We cloned and sequenced three human cDNAs that encode the a, b and g isoforms of PanK1, which have distinct amino termini and are predicted to arise from alternative splicing of transcripts of the same gene. These three protein isoforms share a common carboxy terminus of 40 kDa. Northern blot analysis of human multiple tissues with a common PanK1 cDNA probe shows that PanK1 is abundant in liver and kidney. Human PanK1 a, b and g isoform-specific RT-PCR shows that hPanK1a expression is relatively low in all the tissues except kidney and liver; hPanK1b is abundant in all tissues with the highest level found in the liver followed by kidney; and hPanK1g is also expressed in all tissues. Human PanK1a, PanK1b and PanK1g encode 598, 373 and 400 amino acids, respectively. The hPanK1g transcript includes an Alu exonic sequence which translates into an in-frame insertion of 31 amino acids within the hPanK1b protein. The significance of the insertion on PanK1 biochemical function is unclear. We mapped the novel gene encoding human PanK1, named *PANK1*, by fluorescence in situ hybridization (FISH) to human chromosome 10q23.3-23.31 using a BAC containing human PanK1 genomic DNA as a probe. We also mapped the mouse PanK1 gene by FISH to the conserved syntenic locus of mouse chromosome 19C2-3 using a BAC containing mouse PanK1 genomic DNA as a probe. Determination of the gene structure reveals that the *PANK1* gene spans about 62 kb with 9 exons and 8 introns. Defective PanK gene expression is implicated in metabolic disorders such as diabetes. This research was supported by NIH grant GM45737, Cancer Center (CORE) Support Grant CA 21765, and ALSAC.

**Mapping and genomic structure of the gene encoding the p22 light chain of dynactin (DCTN-22).** *D.R. Mills<sup>1</sup>, S.J. Humphray<sup>2</sup>, C.L. Jackson<sup>1</sup>*. 1) Pathology, Rhode Island Hospital, Brown University, Providence, RI; 2) The Sanger Centre, Wellcome Trust Genome Campus, Hinxton, CB10 1SA, Cambridge, UK.

Cytoplasmic dynein is a minus end-directed microtubule-based motor that requires the multiprotein complex dynactin for much of its functional activity. The smallest protein component of the dynactin complex, the p22 light chain (DCTN-22), was recently purified and characterized by other investigators. Immunocytochemistry demonstrated localization of the p22 subunit to the centrosome during interphase, the kinetochores and spindle poles during mitosis, and to the cleavage furrow during cytokinesis. We identified an EST for DCTN-22 and initial YAC-based physical mapping localized this gene to human chromosome region 9p13 between the genes APAH1 and CNTFR. As confirmation, we also mapped this gene to 9p13 by screening the human GeneBridge 3 radiation hybrid panel by PCR. DCTN-22 was most tightly linked to SHGC-33703 with a lod of 16.86. Novel PCR primers were designed from the 3' untranslated region of the human gene and optimized to amplify rat genomic DNA. These primers were used to map DCTN-22 to the telomere of rat chromosome 1p13 (lod>10) by PCR screening of a rat radiation hybrid panel suggesting evidence for conserved homology between these regions of the human and rat genomes. We are currently in the process of mapping additional genes from human 9p13 in the rat to investigate the extent of linkage within this syntenic group. We have initiated single strand conformation polymorphism (SSCP) analysis of human DCTN-22 using a series of nested PCR primers designed from cDNA sequence. The SSCP analysis has identified a silent (C/T) single nucleotide polymorphism (SNP) at nucleotide position 18 of the cDNA coding region. This SNP was confirmed by DNA sequencing of amplified cDNAs. Three of the nested cDNA primer pairs were used to amplify across introns to begin examination of exon/intron boundaries. Two regions of the cDNA appear to have introns too large to amplify by PCR-based methods. We are in the process of sequencing a BAC clone that contains DCTN-22 in order to complete our investigation of the genomic organization of this gene.

**Isolation and characterization of a novel gene encoding a protein with UBA and SH3 domains on Human Chromosome 21q22.3; its exclusion for the autosomal recessive deafness locus, DFNB10** . *M. Wattenhofer*<sup>1</sup>, *J. Kudoh*<sup>2</sup>, *K. Shibuya*<sup>2</sup>, *S. Minoshima*<sup>2</sup>, *N. Shimizu*<sup>2</sup>, *A. Berry*<sup>3</sup>, *I. Talior*<sup>3</sup>, *B. Bonne-Tamir*<sup>3</sup>, *R. Lyle*<sup>1</sup>, *J. Michaud*<sup>1</sup>, *C. Rossier*<sup>1</sup>, *S.E. Antonarakis*<sup>1</sup>, *H.S. Scott*<sup>1,4</sup>. 1) Medical Genetics, Geneva University, CMU, Geneva, Switzerland; 2) Department of Molecular Biology, Keio, University School of Medicine, Japan; 3) Department of Human Genetics, Sackler School of Medicine, Tel Aviv university, Israel; 4) Genetics and Bioinformatics Group, Walter and Eliza Hall Institute, Royal Parade, Parkville, P.O. Royal Melbourne Hospital, Victoria 3050, Australia.

We have recently refined the critical region for the autosomal recessive deafness locus, DFNB10, to ~1Mb, just telomeric to D21S212, using additional markers (precisely mapped on BAC contigs). In order to identify (i) candidate genes for DFNB10, or (ii) genes that may contribute to some of the Down syndrome phenotypes, we analysed a 74 kb genomic sequence from the DFNB10 critical region and isolated a novel cDNA that maps between TFF1 and D21S49. This gene encodes a putative protein of 661 amino acids and was termed UBASH3A. Alternative splicing results in an isoform of 623 amino acids. UBASH3A is composed of 15 exons distributed over 40-kb. It is expressed in kidney, spleen, lung, PBLs and bone marrow. Both putative proteins contain, in order, an UBA domain (ubiquitin associated, first described in proteins involved in ubiquitination) a SH3 domain, and a previously undefined domain at the C-terminus end. UBA and SH3 domains are thought to be involved in protein-protein interactions. UBASH3A is homologous with a predicted protein (CG13604) in *Drosophila* of unknown function (about 35 % identity at the protein level). Sequence analyses in DFNB10 patients failed to identify pathogenic mutations and therefore this gene was excluded as the cause of DFNB10. By its position, UBASH3A is a candidate for other genetic disorders mapped to 21q22.3, such as one form of bipolar affective disorder.

**Epididymal Expression of SPAM1 in the Mouse and Evidence for a New Category of Spermatogenic Expressed Genes.** P.A. de Leon, Y. He, X. Deng. Dept Biological Sci, Univ Delaware, Newark, DE.

**Introduction:** The Gene for the Sperm Adhesion Molecule 1 (PH-20), *SPAM1*, which maps to human 7q31 encodes a GPI-linked protein with hyaluronidase activity and multiple roles in mammalian fertilization. *SPAM1* has been shown to be testis-specific and exclusively haploid expressed. However, a 4-fold increase in the protein (SPAM1) quantity in caudal epididymal sperm compared to caput ones has been observed in mice. **Purpose:** The goal of the study was to determine if SPAM1 is also expressed in the epididymis. **Methods:** Protein extracts from the epididymides of wild-type and germ cell-deficient mice were used for Western blot analysis and hyaluronic acid substrate gel electrophoresis to determine hyaluronidase activity. Steady-state *Spam1* mRNA was analyzed by RT-PCR and by *in situ* hybridization, while confocal microscopy was used in Spam1 immunolocalization. **Results:** The two common isoforms of Spam1 seen in sperm were shown to be also present in the caput, corpus, and cauda and were enzymatically active. Qualitative and quantitative variations of expression of Spam1 were seen, with the highest expression in the corpus. Steady-state *Spam1* mRNA was shown to be localized to the principal cells of the epididymal epithelium where the protein was similarly immunolocalized, predominantly in the apical vesicles. **Conclusions :** The results suggest a mechanism for transport of Spam1 from the epididymal epithelium to sperm during their maturation in transit and their storage in the cauda. None of the current categories of spermatogenic expressed genes show this dual expression (haploid testicular/diploid epididymal).

**Sox transcription factors and the development of the intestine.** *W.A. Takash, P. Jay, P. Berta.* Dept Human Molecular Genetics, Inst de Genetique Humaine, Montpellier, Cdx5, Montpellier, France.

Sox genes are members of an evolutionary conserved family encoding transcription factors having homology to the HMG box DNA-binding domain of SRY, the Y-linked testis determining gene. Sox genes show highly restricted spatial and temporal expression profile at different developmental stages. To date, human mutations in SRY, SOX9 and SOX10 cause XY sex reversal, Compomelic Dysplasia and Hirschsprung Waardenburg syndrome respectively. Our laboratory had participated in the cloning and mapping of several Sox genes. In the present study, we have been interested in understanding the function of Sox genes in the physiopathology of the intestine, in both man and mouse. The intestinal epithelium, which is in constant and rapid renewal, provides an attractive system for studying the mechanisms involved in the cell fate determination and differentiation, primarily because of the well-defined architecture of its crypt-villus axis renewal unit. Using different molecular approaches (RT-PCR, Northern, in situ, and whole mounts...), we have detected the expression of several Sox genes in the intestine, including Sox4, Sox5, Sox7, Sox9, sox13, Sox17 and Sox18. Current investigations involve : 1) FISH analysis, in order to find possible correlations with human diseases, 2) Analysis of alterations of Sox expression patterns in tumorigenesis / carcinogenesis, 3) In vitro experiments towards a functional analysis of these Sox genes in the regulation of intestinal cell functions, namely proliferation and differentiation.

**Detailed Analysis of the Pericentromeric 7.1-Mb Region of Human Chromosome 22 Based on the Genomic Sequence.** *S. Minoshima, T. Sasaki, K. Kawasaki, S. Asakawa, J. Kudoh, A. Shintani, K. Shibuya, Y. Matsushita, N. Aoki, S. Mitsuyama, K. Hosono, N. Shimizu.* Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan.

We have finished genomic sequencing of chromosome 22q in collaboration with The Sanger Centre, Oklahoma Univ and Washington Univ as the first human chromosome (*Nature* **402**:489-495, 1999). The complete sequence covers 33.4 Mb and at least 545 genes were found using homology search against sequence database, which include 247 "known-genes", 150 "related-genes" and 148 "predicted-genes". The gene prediction softwares and the analysis of CpG islands predicted additional 200 or more genes. To further evaluate these various classes of genes, we have extensively analyzed 4 separate regions (total 7.13 Mb) : (1) the CES (cat eye syndrome) region (proximal 1.03 Mb), (2) the DGS (DiGeorge syndrome) region (2.5 Mb), (3) BCRL2-IGL-GNAZ region (1.97 Mb), and (4) BCR-IGLL region (1.63 Mb). For the CES region, most genes including NF1-like and ALD-like were considered as pseudogenes except CESK1 (T-complex protein-1 q-like) which is active and the most centromeric gene on 22q. For the BCRL2 region, 16 (pseudo)genes were found including GGT, GGT-related (GGTR), BCRL2 and POM121. For the IGL locus, 36 potentially functional Ig V genes, 83 V pseudogenes, 7 J genes, 7 C genes and 13 non-Ig (pseudo)genes including VPREB and TOP3B were identified. For the IGLL region, 42 genes were identified, including known-genes such as rhabdoid tumor gene (hSNF5/INI1), 2 IGLL genes, BCR, GGT, GGTR, glutathione S-transferase q (GSTT) and 4 D-dopachrome tautomerase (DDCT). GSTT and DDCT were found as a large cluster consisting of 9 GSTT and 4 DDCT (pseudo)genes. Six related-genes and 3 predicted-genes in this region were proven to be active because isolation of cDNAs were successful. Similarly, in the DGS region, cDNAs were isolated for 3 related-genes. In the 22q11.2, LCR22s (Low Copy Repeat on 22q) were found at 7 sites. LCR22s consist of various sequence elements including BCR and GGT, and are strongly associated with the chromosomal breakpoints of various syndromic diseases such as CES, DGS and VCFS.

**Analysis and complete genomic sequence of the refined 178 kb Familial Dysautonomia candidate region on**

**chromosome 9q31.** *M. Leyne*<sup>1</sup>, *J. Mull*<sup>1</sup>, *S.P. Gill*<sup>1</sup>, *M.P. Cuajungco*<sup>1</sup>, *C. Karbott*<sup>1</sup>, *B. Johnson*<sup>1</sup>, *C.M. Familial Dysautonomia (FD) is an autosomal recessive disorder that affects the development and survival of sensory, sympathetic and some parasympathetic neurons. To date, the disease has only been described in the Ashkenazi Jewish population where the carrier frequency is 1:30. The FD gene maps to human chromosome 9q31, and haplotype analysis of 441 disease chromosomes initially defined a 471 kb candidate region contained within 58 cosmids and 3 overlapping BAC clones. This region contains 11 candidate genes and the coding sequence of each has been screened using RT-PCR and direct sequencing. This screening did not identify any pathogenic mutations. Because our mutational screening did not identify the FD mutation in the coding sequence of the candidate genes, we set out to sequence the entire 471 kb candidate region using the 3 overlapping BACs spanning the interval. This genomic sequence confirmed that there were no additional genes in the candidate region. In addition, an FD cosmid library was constructed using a patient homozygous for the major haplotype. Sequencing of the FD cosmids allowed us to directly compare the sequence of the candidate interval between affected and control individuals. This sequence comparison identified 2 critical polymorphisms that have narrowed the candidate region from 471 kb to 178 kb. The contiguous 178 kb uninterrupted genomic sequence of this refined candidate interval was determined. To date, 184 DNA sequence differences between the control and FD sequence have been identified. We are currently assessing these DNA changes in FD and control individuals to determine which of these may be the pathogenic FD mutation.

**Determination of the genomic sequence of the dystrophin gene.** *M. Maheshwari, P.E. Tabor, S. Scherer, R.A. Gibbs.* Department of Molecular & Human Genetics, Baylor college of Medicine, Human Genome sequencing Center, Houston, TX.

Duchenne muscular dystrophy (DMD) is one of the most common X-linked genetic disorders characterized by progressive muscle weakness. It affects about one in 3500 males. The gene responsible for the disease is dystrophin, located at Xp21. It is one of the largest genes with a coding sequence of 14 kb spread over 2,400 kb of genomic DNA and contains 79 exons. DMD is caused primarily by deletion mutations in 60-65% of subjects, while 30-40% of mutations remain uncharacterized. Knowledge of the genomic sequence of the DMD gene will facilitate the search for development of additional methods to detect uncharacterized mutations and carrier detection in females. It may also lead to a mechanistic understanding of DMD mutations and potential insight into understanding the high mutation rate at this locus. Although the exon structure of the DMD gene has been studied, its genomic sequence has not yet been fully characterized. The Human genome project aims to determine the complete nucleotide sequence of the estimated 50000-100000 genes within the human genome. A working draft sequence of 90% of the approximately three billion total bases has been completed, of which the Human Genome Sequencing Center at Baylor College of Medicine has contributed 8.09%. The aim of this study is to determine the sequence extending from exon 44 to 79 of DMD gene. Other regions of DMD are being sequenced by the other centers. To initiate the study, 34 candidate BAC clones were chosen by BLAST searching using sequences of exons and the FPC database produced at Washington University. Candidate BAC clones were screened by exon primer pairs, and primers generated from the BAC end sequences of BAC clones from this region. Positive BACs identified were aligned to determine the extent of overlap between clones and a tiling path of clones were selected for sequencing.

**The Integration of Foreign DNA into Mammalian Genomes Can Lead to Alterations in Methylation and Transcription Patterns Remote from the Insertion Site.** *K. Mueller, W. Doerfler.* Inst. Genetics, Univ Cologne, Cologne, NRW, Germany.

In earlier work from this laboratory, evidence was presented that in hamster cells transgenic for the DNA of adenovirus type 12 (Ad12) or for the DNA of bacteriophage lambda the patterns of DNA methylation in specific cellular genes or DNA segments had been altered. These alterations were located remote from the site of transgene insertion and were documented by methylation-sensitive restriction endonucleases or by the genomic sequencing technique. We now aimed at selecting a wider scope of cellular DNA segments and genes whose methylation and/or transcription patterns had been altered in transgenic cells as compared to normal cells. The technique of methylation-sensitive representational difference analysis (MS-RDA) was used to isolate differentially methylated DNA fragments. The thus selected DNA segments were then used to verify changes in DNA methylation in the transgenic cells by Southern blot hybridization or by the genomic sequencing technique. The MS-RDA protocol led to the isolation of several cellular DNA segments that were indeed hypermethylated in lambda DNA-transgenic hamster cell lines. In one mouse line transgenic for the DNA of bacteriophage lambda, hypermethylation was observed in the imprinted gene *Igf2r* in a tissue-specific manner. Two mouse lines transgenic for an adenovirus promoter-indicator gene construct showed hypomethylation in the *IL10* and *Igf2r* loci. By applying the suppressive subtractive hybridization technique to cDNA libraries from non-transgenic, Ad12-transformed and lambda DNA-transgenic hamster cells, we were able to clone several cellular genes that showed altered transcription patterns in transformed or in lambda DNA-transgenic hamster cells. In control experiments, no differences in gene expression or DNA methylation patterns were detectable among individual non-transgenic BHK21 cell clones. Many of the DNA segments with altered methylation and/or transcription patterns were identified by their nucleotide sequences. The data presented support the interpretation that the insertion of foreign DNA into an established mammalian genome can lead to marked alterations in cellular DNA methylation and transcription patterns.

**Structure of IL-12Rb1 gene and identification of a new polymorphic tetranucleotide repeat.** *S. Abdelhak, H. Elloumi, M.R. Barbouche, M. BenFadhel, N. Labben, K. Dellagi.* Immunology Department, Pasteur Institute, Tunis, Tunisia.

The heterodimeric cytokine IL-12 is a powerful inducer of IFN- $\gamma$  by T and NK cells, thus playing an important role in the control of mycobacteria infection in humans. The IL-12 receptor is composed of two chains b1 and b2 encoded by different genes mapped respectively to chromosomes 19p13.1 and 1p31.3-p31.2. IL-12Rb1 deficiency has been shown to be responsible for severe mycobacterial infections in humans. We have determined the gene structure of IL-12Rb1 by long range PCR amplifications of overlapping fragments and direct sequencing of exon/intron junctions using primers from the cDNA sequence. The gene of IL12Rb1 spans over 26 kilobases of DNA and is organized in at least 16 exons ranging in size from 31 to 238 pb. All splice acceptor and donor sites conform to the AG/GT rule. A tetranucleotide repeat CCAT flanking an ALU element was found in the intron 3 of the gene. Investigation of normal individuals from Tunisian population revealed at least 3 alleles and a heterozygosity frequency of 57% . The intrafamilial genotyping showed a segregation compatible with a mendelian inheritance. This new polymorphism as well as the definition of the genomic structure will facilitate the study of IL-12Rb1 gene mutations and its involvement in the susceptibility to intramacrophagic pathogens.

**Variation in the clinical manifestations in Ellis van Creveld may result from differential expression of the EVC gene.** *M. Galdzicka<sup>1</sup>, P. Damschroder-Williams<sup>1</sup>, G. Hirshman<sup>1</sup>, R. Long<sup>1</sup>, A. Kashani<sup>1</sup>, S. Winfield<sup>1</sup>, B.M. Martin<sup>1</sup>, W.J. Kleijer<sup>2</sup>, E.I. Ginns<sup>1</sup>.* 1) Clinical Neuroscience Branch, NIMH/NIH, Bethesda, MD; 2) Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Ellis van Creveld syndrome (EvC) is an autosomal recessive disorder with clinical manifestations of dwarfism, polydactyly, ectodermal dysplasia, often congenital heart disease, and occasionally renal failure. We have investigated the molecular basis of EvC in the Old Order Amish in Lancaster County, Pennsylvania, as well as in sporadic cases in other populations. The gene for EvC syndrome has been mapped to human chromosome 4p16.1 and the gene, EVC, has recently been identified. However, the single splice site mutation reported in this gene in the Amish does not readily explain the wide range of observed phenotypes. We have sequenced all 20 exons of the gene in 18 Amish and 7 non-Amish individuals having EvC. One of the Amish EvC individuals does not have the published spliced mutation. Among the non-Amish population, we have identified a heterozygotic novel mutation, 873-874insT in exon 7. We have also used RTPCR to characterize the alternative transcripts of this gene which differ in fibroblasts, lymphoblasts, heart and kidney. We have identified several normal transcripts, among which: one contains 115 bp longer exon 13; one is missing exon 13; and another, only expressed in heart, contains an additional exon, 27 bases long, between exons 2 and 3. In addition to the expression of a variety of transcript isoforms, the EVC mRNA may also undergo RNA editing, providing yet another level by which the EVC gene expression may be regulated and protein diversity elaborated. Our results suggest that the regulation of the EVC gene may be more complex than previously described, and that this may contribute to phenotypic variability of the syndrome.

**Genomic organization of ACF7, a candidate for deafness gene DFNA2.** T.L. Gong, C.G. Besirli, R.S. Winnicki, M.I. Lomax. Kresge Hearing Research Institute, Department of Otolaryngology/Head-Neck Surgery, University of Michigan, Ann Arbor, MI.

Mammalian ACF7 (actin cross-linking protein family 7) belongs to the plakin subfamily of structural proteins that cross-link actin cytoskeleton to other structures within the cell. We report here cDNA cloning of a new isoform of human actin cross-linking protein ACF7. In a study on regeneration of auditory hair cells in the chick (Gong et al., Hearing Res. 96, 20-32, 1996), we isolated a partial chick cDNA (KH124). The human orthologue of KH124 maps to chromosome 1p32, in the *DFNA2* region. Although mutations in gene for Connexin31 and potassium channel KCNQ4 in this region have been shown recently to be responsible for deafness in some families, neither of these genes is mutated in an Indonesian family that maps to the *DFNA2* region (Van Hauwe et al., Nat Gen 21, 263, 1999). Thus, our newly identified gene remains a candidate for this Indonesian *DFNA2* family. We cloned a 18-kb human cDNA by screening pituitary and heart cDNA libraries. The C-terminal half of the deduced protein sequence was virtually identical to that of the recently cloned full length ACF7 (named macrophin, trabeculin-a) (Okuda et al., Biochem Biophys Res Comm 264, 568, 1999; Sun et al., J Bio Chem 274, 33522, 1999), containing spectrin repeats, two EF-hands, and a GAS2 domain. In contrast to the three previously cloned isoforms of ACF7 in human and mouse, our newly identified sequence did not contain the sequence for an actin-binding domain (ABD). To determine whether this new sequence is derived from the *ACF7* gene, we isolated and sequenced several human genomic BAC/PAC clones spanning the *ACF7* gene. The human *ACF7* gene consists of at least 104 exons, spans over 200 kb, and gives rise to at least 4 proteins with different N-termini by alternative splicing at the 5' end. The unique N-terminus of our new sequence is encoded by exons internal to the exons for the ABD. The functional significance of these different ACF7 isoforms remains to be determined. (Supported by NIH grants RO1 DC02492, PO1 DC02982).

**Gene Structure, Expression and Organization at the *GABRG3* Locus in the Human 15q11-q13 Autism Candidate Region.** *M.K. Han, Y.-h. Chen, E.L. Nurmi, J.S. Sutcliffe.* Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

A candidate region for an autism susceptibility locus is localized to an interval on human chromosome 15q11-q13, based on chromosomal duplications, linkage and association studies in families with autistic disorder and broader phenotypes. A cluster of three GABA<sub>A</sub> receptor subunit genes (*GABRB3*, *GABRA5* and *GABRG3*) map to this interval and are considered positional and functional candidate genes for involvement in autism. Here we describe the gene structure, organization and expression profile for the g3 subunit gene (*GABRG3*), which is the most distal of the three genes. The *GABRG3* gene is encoded in 10 exons, which span ~400 kb across this region. The gene is expressed at low abundance in adult brain tissues as 4.2-kb or 10.5-kb transcripts, with highest abundance in cerebellum and cortex. *GABRG3* is associated with a CpG island, which is not subject to differential methylation in lymphoblastoid cells. A BAC contig representing the *GABRG3* transcriptional unit was developed and related to emerging phase I human genome sequence and corresponding BAC clones. Analysis of this phase I sequence from the *GABRG3* gene locus indicates the existence of several ESTs representing potential internal genes.

**Characterization of the Human NMO-1 gene at 1q43 and genomic organisation of the region. *NMO-1*. S.**

*Halford*<sup>1</sup>, *J. Bellingham*<sup>2</sup>, *M.S. Freedman*<sup>1</sup>, *S.L. Inglis*<sup>1</sup>, *S. Poopalasundaram*<sup>1</sup>, *R. Foster*<sup>2</sup>, *D.M. Hunt*<sup>1</sup>. 1) Department of Molecular Genetics, Institute of Ophthalmology, University College London, London, UK; 2) Department of Integrative & Molecular Neuroscience, Imperial College School of Medicine, Charing Cross Hospital, London, UK.

Light is a potent regulator of many physiological processes in vertebrates. For example, the synchronisation of circadian rhythms to the 24 hr solar cycle and the proper seasonal timing of reproduction are greatly influenced by environmental light cues. In contrast to non-mammalian vertebrates, the photoreceptors mediating non-visual photic processes are ocular in mammals. However, the rod and cone photoreceptors of the retina are not required for the regulation of circadian rhythms or acute suppression of pineal melatonin levels. Therefore, the ocular photoreceptors mediating these non-visual tasks in mammals remain unknown, but it can be reasoned that novel opsin proteins may mediate these responses. As part of an ongoing search to identify novel mammalian photopigments that may be involved in non-visual tasks, recently cloned novel opsin sequences were used to search dbEST. Novel mammalian opsin-1 (*NMO-1*) was one of the clones identified using this approach. The full-length sequence was compiled from overlapping ESTs and 5' RACE products derived from human retinal cDNA. The predicted protein is 403 amino acids. The gene has two predicted polyadenylation signals that result in transcripts which differ in size by 400bp. Northern blot analysis detects two transcripts of approximately 2.1 and 2.5kb, which are expressed in a wide range of tissues. FISH analysis using a PAC clone and PCR on a monochromosomal somatic cell hybrid panel localised the gene to chromosome 1q43, a region also encompassing the kynurenine monooxygenase (*KMO*) and choroideremia-like Rab escort protein 2 (*CHML*) genes. *KMO* and *NMO-1* are transcribed in opposite directions but overlap at the 3' end. *CHML*, an intronless gene, lies in intron 1 of *NMO-1*. The intron/exon boundaries of both *NMO-1* and *KMO* have also been deduced. *NMO-1*.

**Characterisation of murine CDP-diacylglycerol synthase (CDS1 & CDS2) genes.** *S.L Inglis, S. Halford, D.M. Hunt.* Department of Molecular Genetics, Institute of Ophthalmology, University College London, London, UK.

The phototransduction pathway in *Drosophila* is a phosphoinositide-phospholipase C mediated signalling process which results in the signalling molecule phosphatidylinositol-4-5-bisphosphate (PIP<sub>2</sub>) being hydrolysed into two second messengers. The regeneration of PIP<sub>2</sub> for subsequent signalling is tightly regulated and involves a number of enzymes. Mutations in many of these genes involved in this pathway give rise to retinal degeneration in flies. As part of an ongoing study to identify mammalian homologues of these genes, two human CDP-diacylglycerol synthase (CDS) genes were identified and clones from retinal cDNA libraries. In *Drosophila*, a retinal specific form of this enzyme is encoded by *eye-cds* and catalyses the formation of diacylglycerol from phosphatidic acid, the rate limiting step in the regeneration of PIP<sub>2</sub> for signalling. Mutations in this gene cause light-induced retinal degeneration in flies. Mammals have been shown to possess two homologues of this gene that are expressed in the retina. In order to determine the full coding sequence and genomic structure of both genes, a full length CDS2 and a partial CDS1 clone were identified in the mouse EST databases. The CDS1 sequence was subsequently completed by 5' RACE. Mouse and human CDS1 and CDS2 sequences show 96% and 93% identity at the amino acid level. Cosmid and PAC genomic clones were obtained by screening the 129 and PAC libraries using fragments from the cDNA clones. From these, we have been able to determine the genomic structure of each gene and to correlate this with the different protein domains of the protein. Finally, a construct for the targeted knockout of CDS2 by homologous recombination has been generated and is presently in use in the production of knockout mice. *Drosophila*<sub>2</sub>*eye-cdsl*.

Program Nr: 999 from the 2000 ASHG Annual Meeting

**The human *UBE3B* gene encodes a novel E3 ubiquitin ligase with a partial HECT domain.** *M.I. Lomax, L. Huang.*  
Dept. of Otolaryngology, University of Michigan, Ann Arbor, MI.

Our long term goal is to identify and understand molecular processes involved in the repair and regeneration of the auditory epithelium and in restoration of auditory function after acoustic trauma. We have identified and partially cloned several chick genes whose expression is altered after noise overstimulation. Chicks were exposed to octave band noise (center frequency 1.5 kHz, 118 dB SPL for 6 hr). RNA was isolated from the inner ears of control chicks and from chicks immediately after noise exposure. We identified differentially regulated genes by both differential display and subtractive hybridization, then confirmed differential expression by Northern blot analysis. One differentially regulated gene contained a HECT domain, the signature domain for E3 ubiquitin ligases. This novel E3 ubiquitin ligase, *UBE3B*, is the second member of this family. The human *UBE3A* gene encodes the first member of this family and is known to be mutated in Angelman Syndrome. In this study, we compared predicted *UBE3B* HECT domains from chick, human, mouse, and *C. elegans* proteins. The human *UBE3B* protein deduced from a full length human *UBE3B* cDNA contains a truncated HECT domain, in contrast to the chick, mouse and worm *UBE3B* proteins, which have complete HECT domains. Analysis of the intron-exon structure of the human *UBE3B* gene on Chromosome 12q23-25 revealed that the human cDNA arose through alternative splicing of an exon not observed in the *UBE3B* cDNA sequences from other organisms. Inclusion of this alternatively spliced exon generates a frame shift that leads to premature termination of the *UBE3B* protein near the beginning of the HECT domain. Since the HECT domain encodes the active site of these E3 ubiquitin ligases, the functional significance of a protein lacking the active site is not clear. Further analysis of human *UBE3B* transcripts to determine whether or not there are human cDNAs that encode a complete HECT domain are in progress. We are also cloning the mouse *Ube3b* gene to determine the comparative gene structure. (Supported by NIH grants RO1 DC02492 and PO1 DC02982).

**Human transthyretin intronic open reading frames are not independently expressed *in vivo* or part of functional transcripts.** *M.L. Soares*<sup>1,2</sup>, *M. Centola*<sup>1</sup>, *J. Chae*<sup>1</sup>, *M.J. Saraiva*<sup>2</sup>, *D.L. Kastner*<sup>1</sup>. 1) Arthritis and Rheumatism Branch, National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 2) Instituto de Biologia Molecular e Celular, Amyloid Unit, Porto, Portugal.

The human transthyretin (TTR) gene encodes a protein composed of four identical subunits with an important role in the plasma transport of thyroid hormone T4 and retinol. TTR spans about 7.0 kilobases and consists of four exons. Two independent open reading frames (ORFs) with putative regulatory sequences have been described in the first and third introns, but their function - if any - is unknown. We have screened human cDNA libraries to determine if these sequences are transcribed. Transcripts of both ORFs were found in liver, pancreas and brain. Hybridization of the two sequences with multiple tissue northern blots further confirmed these results and revealed transcript sizes of ~1.5 and 2.2 kb for ORF 1, and ~5.2 and ~7.8 kb for ORF 2. Rapid Amplification of cDNA Ends (RACE) was performed to characterize the full-length cDNAs containing each sequence. All products containing the ORFs were continuous in the genomic sequence corresponding to unspliced or partially spliced TTR. No evidence was found for novel transcripts containing productively spliced products of either ORF, or for shorter transcripts using the promoter and polyadenylation signals associated with them. ORF 1 RACE products identified in the liver, pancreas and brain correspond to TTR transcripts in which intron 1 had not been removed; the transcripts containing ORF 2 may represent TTR HN-RNA. Neither ORF is productively expressed as part of a larger transcript, or as an independent polypeptide.

**Promoters of the the Human neuronal apoptosis inhibitory protein (NAIP) Gene and the isoform NAIP gene (psi-naip).** *M. Xu*<sup>1</sup>, *T. Okada*<sup>2</sup>, *N. Miyamoto*<sup>1</sup>, *H. Sakai*<sup>1</sup>, *S. Hadano*<sup>2</sup>, *R. Korneluk*<sup>3</sup>, *A. MacKenzie*<sup>3</sup>, *J.-E. Ikeda*<sup>1,2</sup>. 1) NeuroGenes (ICORP), Inst Med Sci, NeuroGenes project, ICORP, JST, Kanagawa, Japan; 2) Tokai Univ, Isehara, Kanagawa, Japan; 3) Mol.Genet.Res.Lab.,Univ.of Ottaw,Canada.

The neuronal apoptosis inhibitory protein (NAIP) gene has been identified as a candidate gene for spinal muscular atrophy (SMA). The deletion of NAIP is correlated with the clinical severity of the disease. NAIP is duplicated, and one is the deletion isoform gene (psi-naip), which is unknown whether it is transcribable sequence. In this study, we analyzed the 5'-flanking region of the NAIP gene and psi-naip. The 5'-flanking region of 350 bp nucleotides (-765 to -416) was inserted into a luciferase reporter vector, and it revealed apparent promoter activity in monocytic leukemia THP-1 cells but weak activity in neuroblastoma SH-SY5Y and cervical carcinoma C-33A cells. This promoter activity in these human cell lines was appeared by deletion of both of nucleotides from -2218 to -766 and -415 to +294, whereas it was decreased by further deletion from -765 to -483. A 56 bp nucleotides (-483 to -415) in the promoter is essential to promote transcription of NAIP gene. In this region, TATA-like box, an initiator-like sequence, and putative binding sites for GATA-1 and Brn-2 were found. It is noteworthy that the psi-naip promoter region is identical to that of the NAIP gene suggesting that psi-naip is a transcribable unit. Therefore, the identification of transcription factors playing role in the regulation of both gene expression may perceive a molecule pathogenesis of NAIP and psi-naip in SMA.

**Genomic organization and expression of the MTHFS gene.** *M. Rubini, S. Carturan, I. Bononi, E. Calzolari.*

Dept.Exp.Diag.Med. Sect. Medical Genetics, University of Ferrara, Ferrara, Italy.

The 5-formyl-tetrahydrofolate (5-formyl-THF) is an inhibitor of several folate-dependent enzymes and plays a role in folic acid-dependent one-carbon metabolism. It is synthesized *in vivo* by the Serine-Hydroxymethyl-Transferase (SHMT), an enzyme expressed at steady level, which activity is inhibited by 5-formyl-THF itself. The 5,10-methenyl-tetrahydrofolate-synthetase (MTHFS) is the only enzyme that metabolize the 5-formyl-THF, catalyzing the ATP-dependent conversion to 5,10-methenyl-THF. The combined activities of MTHFS and SHMT constitute a futile cycle that may buffer the 5-formyl-THF concentration. The MTHFS is a 28 kDa polypeptide. Its transcripts are detectable in all tissues, but so far no evidence of modulation of its expression has been reported. The MTHFS gene is located in 15q24.3. It is organized in three exons. The two introns are > 7Kb in length. The gene has no TATA-box, and transcription is initiated at multiple sites at 14-23 nt upstream the translation start codon. Two distinct poly(A) sites have been identified downstream the coding sequence. The expression kinetics of MTHFS enzyme and transcript has been studied in phytohaemagglutinin (PHA)-activated human lymphocytes. Quiescent cells have low transcription while the enzyme level is relatively high. Upon PHA stimulation the 28 kDa protein level drops down, whereas a 20 kDa isoform is expressed. This smaller isoform is due to the use of an alternative transcription initiation site located 12 nt downstream the major translation start codon, within an initiator element consensus sequence. The role and function of this 20 kDa protein is not known. As the activated lymphocytes enter the cell cycle, the 20 kDa isoform is replaced by the 28 kDa MTHFS enzyme. This evidence indicates that the MTHFS expression is modulated during the proliferation process, and this may in turn determine changes in the intracellular 5-formyl-THF level. Regulating the intracellular level of 5-formyl-THF, the MTHFS activity may influence the methyl-THF concentration and the homocysteine remethylation.

Program Nr: 1003 from the 2000 ASHG Annual Meeting

***Drosophila* DHFR: Gene expression and methotrexate resistance.** *K.M Al-Batayneh, M. Kuiper, K. Neumann, V.K Walker.* Department of Biology, Queen's University, Kingston, Ontario, Canada.

Dihydrofolate reductase (DHFR) (EC 1.5.1.3) catalyzes the NADPH-dependent reduction of 7,8-dihydrofolate to 5,6,7,8-tetrahydrofolate. DHFR is responsible for maintaining intracellular levels of tetrahydrofolate and its derivatives, which are essential cofactors in the biosynthesis of purines, thymidylate, and several amino acids. Thus, DHFR is a target enzyme for a number of antifolate drugs including the anticancer agent methotrexate (MTX) and is potentially a useful target for novel insecticides.

A computer model of *Drosophila melanogaster* DHFR was constructed by homology modeling to human DHFR. Based on the model, several MTX resistant mutant DHFRs were generated by site-directed mutagenesis. The mutant genes were expressed in *E. coli* to determine the kinetic properties of the recombinant enzymes. Some of these DHFR mutants showed high resistance to MTX, as well as lower affinity to the natural substrate.

Moreover, these mutants as well as a mutant found after selection of *Drosophila* cells on  $10^{-4}$ M MTX have been transfected into *Dhfr*<sup>-</sup> CHO cell line to assess the ability of these insect genes to confer resistance to MTX in a system that usually depends on gene amplification for the drug resistance phenotype.

**Identification of a dominant negative Rieger syndrome mutation in *PITX2*.** *I. Saadi*<sup>1</sup>, *E.V. Semina*<sup>2</sup>, *D.J. Harris*<sup>5</sup>, *K.P. Murphy*<sup>3</sup>, *J.C. Murray*<sup>1,2</sup>, *A.F. Russo*<sup>1,4</sup>. 1) Genetics Program; 2) Department of Pediatrics; 3) Department of Biochemistry; 4) Department of Physiology and Biophysics, University of Iowa, Iowa City, IA; 5) Children's Mercy Hospital, Kansas City, MO.

Mutations in the *PITX2* bicoid-like homeobox gene cause Rieger syndrome. Rieger syndrome is an autosomal-dominant human disorder characterized by ocular anterior chamber anomalies causing glaucoma in more than 50% of affected individuals, as well as dental hypoplasia, mild craniofacial dysmorphism and umbilical stump abnormalities. *PITX2* has also been implicated in the development of multiple organs and left-right asymmetry in the body plan. The *PITX2* homeodomain has a lysine at position 50, which has been shown to impart the bicoid-type (TAATCC) DNA-binding specificity of other homeodomain proteins through interactions with the last 2 bases of the hexanucleotide element. In a Rieger syndrome patient this lysine is mutated to glutamic acid (K88E). We were intrigued by the marked phenotypic consequences of this mutation. In this study we have examined the functional properties of the mutant *PITX2* K88E protein. The mutant protein had essentially no DNA binding and transactivation activities and, unlike the wildtype protein, the mutant was unable to synergize with another transcription factor, Pit-1. However, when the K88E mutant was coexpressed with wildtype *PITX2*, analogous to the patient genotype, the K88E mutant suppressed the synergism of wildtype *PITX2* with Pit-1 suggesting the formation of nonfunctional complexes between wildtype *PITX2*, K88E mutant, and Pit-1. These results describe the first dominant negative missense mutation in a homeodomain protein and support a model that may partially explain the phenotypic variation within Rieger syndrome and other transcription factor disorders.

**A duplication of the glucocerebrosidase pseudogene and a metaxin fusion gene found in patients with Gaucher disease and in normal controls.** *N. Tayebi, J.K. Park, V. Madike, E. Sidransky.* Clinical Neuroscience Branch, NIH/NIMH, Bethesda, MD.

The genes for glucocerebrosidase and metaxin, both located on chromosome 1q21, each have a highly homologous pseudogene sequence nearby. We describe a novel recombinant allele consisting of a duplication of the glucocerebrosidase pseudogene and a fusion between the metaxin gene and its pseudogene, resulting from a crossover between metaxin and pseudometaxin in the region downstream of the glucocerebrosidase gene. We also show that certain individuals have a metaxin-pseudometaxin fusion gene without a duplication resulting from the same crossover. DNA from patients with Gaucher disease and normal controls were screened for recombinant alleles by Southern blot analyses prepared with the restriction enzymes *SspI* and *HincII* and by direct sequencing. Downstream alterations were identified in eight of the 398 patient alleles studied and in seven of the 200 normal control alleles examined, and were encountered more frequently among patients and controls of African American ancestry. This is the first recognition of a duplicated allele in the glucocerebrosidase gene region and its presence may contribute to genotype-phenotype studies in Gaucher disease.

**Tissue and in vitro expression studies of normal human and murine DNAS1L3.** *A. Wilber<sup>1</sup>, S.A. Abdullah<sup>1</sup>, M. Lu<sup>1</sup>, M.C. Schneider<sup>2</sup>.* 1) Department of Pediatrics, SIU School of Medicine, Springfield, IL; 2) Division of Research Urology, Brigham and Womens Hospital, Harvard Medical School, Boston, MA.

DNAS1L3 or deoxyribonuclease (DNase) 1 like 3 is one of at least four DNASE 1-like loci in humans. Abnormalities in enzymes of this nuclease family are associated with the predisposition to systemic lupus erythematosus (SLE), an autoimmune disease characterized by a humoral response to nucleosomal antigens. Mutation and dysregulation of this enzyme have been described in polygenic models of SLE. Complete loss of function of DNASE 1 has been found to be associated with a murine lupus phenotype. In a project that aims to understand the role of these nucleases in the predisposition to SLE, we have studied the expression of the DNAS1L3 enzyme in normal human and murine tissues. Previous groups have identified this secreted protein in either macrophages or the nuclei of lymphocytes. Using peptide-specific antisera, we find expression of the murine protein is restricted to liver, spleen, thymus, and bone marrow macrophages. In normal splenocytes, expression of the protein is not inducible by phorbol myristate acetate (PMA), concavalin A, lipopolysaccharide, or activating anti-Fas antibodies. However, in the human Jurkat T-cell line and normal murine macrophages, the expression is highly inducible by PMA. We detect the enzyme in the non-adherent population of human peripheral blood leukocytes. Transfection into COS cells of C-terminal GFP fusions of the enzyme show the enzyme localizes to cell-surface granules and is secreted into the media. N-terminal fusions (lacking a signal peptide) are associated with rapid cell death. We propose potential roles of this enzyme in lymphocyte chromatin fragmentation during apoptosis and macrophage scavenging functions of apoptotic debris.

**Imprinting of *PEG3*, the Human Homolog of a Gene Involved in Nurturing Behavior.** *S.K. Murphy*<sup>1</sup>, *A.A. Wylie*<sup>1,2</sup>, *R.L. Jirtle*<sup>1</sup>. 1) Radiation Oncology and Pathology, Duke University Medical Center, Durham, NC; 2) AstraZeneca Pharmaceuticals, Ltd. Alderley Edge, Cheshire, UK.

The imprinted *Peg3* gene in mice encodes an unusual Krüppel-type zinc finger protein implicated in critical cellular and behavioral functions including growth, apoptosis, and maternal nurturing behavior. We conducted methylation and expression analyses to determine if the human homolog, *PEG3*, on chromosome 19q13.4, is imprinted in humans. The *PEG3* promoter is encompassed within a CpG-rich region that is differentially methylated in human fetal brain, kidney, liver, and pancreas, suggesting regulation of expression in an allele-specific manner. Expression studies using a single nucleotide polymorphism (SNP) within exon 9 revealed that *PEG3* is monoallelically expressed during fetal development. Monoallelic *PEG3* expression was also found postnatally in normal adult brain and ovarian tissues. Using a second SNP, allele-specific expression was demonstrated for two additional isoforms of *PEG3* including a novel isoform. Genotyping of maternal decidua matched to fetal tissues showed that all *PEG3* isoforms are paternally expressed. These results are the first to demonstrate that human *PEG3* is imprinted and that chromosome 19q13.4 contains an imprinted region. The ubiquitous imprinting of *PEG3* coupled with putative roles in regulating cell survival suggest that *PEG3* might function as a cancer susceptibility locus. This study was supported by NIH grants CA25951 and ES08823, DOD grant DAMD17-98-1-8305, Sumitomo Chemical Company, Ltd., and AstraZeneca Pharmaceuticals, Ltd.

**Human GRB10 is imprinted and expressed from the paternal and maternal allele in a highly isoform- and tissue-specific fashion.** *V.M. Kalscheuer<sup>1</sup>, N. Blagitko<sup>1</sup>, S. Mergenthaler<sup>2</sup>, U. Schulz<sup>1</sup>, H.A. Wollmann<sup>3</sup>, W. Craigen<sup>4</sup>, T. Eggermann<sup>2</sup>, H.H. Ropers<sup>1,5</sup>.* 1) Max-Planck-Institute, for Molecular Genetics, Ihnestrasse 73, D-14195 Berlin, Germany; 2) Department of Human Genetics, RWTH Aachen, Germany; 3) Universitaets-Kinderklinik Tuebingen, Germany; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 5) Department of Human Genetics, University Hospital Nijmegen, The Netherlands.

As part of a systematic screen for novel imprinted genes of human chromosome 7 we have investigated GRB10 which maps to 7p11.2-12. The protein belongs to a small family of adapter proteins, known to interact with a number of receptor tyrosine kinases and signaling molecules. The mouse counterpart was found to be imprinted with expression from the maternal allele only. In mice, maternal duplication of the chromosomal region containing *Grb10* results in prenatal growth retardation, whereas paternal duplication causes growth enhancement. Human GRB10 is a candidate for Silver-Russell syndrome, a heterogeneous disorder characterized by intrauterine and postnatal growth retardation, with or without additional dysmorphic features. A subset of patients exhibit maternal uniparental disomy for chromosome 7 (mUPD7) strongly suggesting that genomic imprinting plays a role in the aetiology of the disease. Upon allele-specific transcription analysis involving multiple distinct splice variants in various fetal tissues, we found that human GRB10 in a highly isoform- and tissue-specific manner. In fetal brains, most variants are exclusively transcribed from the paternal allele. Imprinted expression in this tissue is not accompanied by allele-specific methylation of the most 5 CpG island. In skeletal muscle, one GRB10 isoform, gamma 1, is expressed from the maternal allele alone, whereas in numerous other fetal tissues, all GRB10 splice variants are transcribed from both parental alleles. A remarkable finding is paternal-specific expression of GRB10 in the human fetal brain since in the mouse, this gene is exclusively transcribed from the maternal allele. To our knowledge, this is the first example of a gene that is oppositely imprinted in mouse and human.

**Expression and methylation studies in mice harbouring a *Snrpn* transgene.** *M.J. Smith, D.A. Carter.* School of Biosciences, Cardiff University, Cardiff, Wales, UK.

Imprinted genes are characterised by their differential expression according parent of origin, and are associated with chromosomal regions bearing epigenetic marks that enable discrimination between the maternal and paternal allele. As imprinted genes pass through the germ line, an epigenotype appropriate to the bearers sex has to be established in the gametes. Disruption of the paternally expressed genes in the imprinted domain on human chromosome 15q11-q13 causes Prader-Willi syndrome (PWS). Most cases occur sporadically by *de novo* deletions on the paternally inherited chromosome, or by uniparental disomy of the maternal chromosome 15. Less than 5% of PWS cases are caused by the inheritance of microdeletions that affect the promoter region and exons of the small ribonucleoprotein N gene (*Snrpn*). These deletions delineate an imprinting centre (IC) that influences gene expression and methylation patterns within the entire imprinted domain; they are passed silently through the female germ line, but in the male germ line the female epigenotype is retained. Expression of all the paternal transcripts is consequently silenced in the offspring of male carriers, causing PWS. Mouse chromosome 7C is syntenic to human 15q11-q13 and orthologous genes retain their physical order and imprinted pattern of expression. It is therefore likely that the generation and analysis of mouse models of imprinting will yield important information pertaining to human imprinting disease processes. To this end we have generated lines of mice transgenic for a DNA construct which contains 8 kb of promoter region, exon 1 and the first intron of *Snrpn* linked to a green fluorescent protein reporter. This transgene spans the region equivalent to the human IC, and contains a differentially methylated region that discriminates between maternal and paternal alleles in its native context. Studies of methylation and reporter expression will reveal if sufficient information is present in the transgene to confer imprinting.

**Construction of an imprinted status transcript map flanking *MEST/PEG1* at 7q32.** K. Yamasaki, S. Hayashida, Y. Tachibana, T. Kishino, N. Niikawa. Human Genetics, Nagasaki Univ., Nagasaki, Japan.

*MEST/PEG1*, a gene expressed paternally in mesodermal derivatives in early embryonic stages is the first imprinted gene mapped to chromosome 7. Since imprinted genes are clustered in general at a chromosomal region, we speculated that a similar imprinted-gene cluster may exist at 7q32 and that the functions of some such genes may contribute to the phenotype of Silver-Russell syndrome (SRS) including maternal UPD7. Recent linkage analysis revealed that 7q31-q35 region, especially a region near D7S530 and D7S684, is one of the putative autistic disorder (AD) susceptibility loci. In addition, paternal effect in an AD locus on 7q was reported (Ashley-Koch et al., 1999). These findings promoted us to isolate an imprinted gene(s) that implicates SRS or AD. As an initial step toward isolation of imprinted genes at 7q32, we constructed a complete contig of PAC and BAC clones and transcript map spanning the entire ~1-Mb region between D7S530 and D7S649 (Hayashida et al., 2000). Based on the Human Transcript Map, we precisely mapped 47 genes/ESTs and analyzed the imprinting status of several genes/ESTs adjacent to *MEST*. One of them is *COPG2*, coatamer protein complex subunit gamma 2, which overlaps *MEST*'s 3'UTR. *COPG2* was first reported to be expressed from paternal allele (Blagitko et al., 1999), however, our results revealed biallelic expression in all fetal tissues examined. On the other hand, *CITI*, coatamer protein complex subunit gamma 2 intron transcript 1, showed paternal expression in fetal tissues. *CPAI*, carboxypeptidase A1, 100 kb centromeric to *MEST* is biparentally expressed. KIAA0265, a cDNA clone with little similarity to any known genes, was mapped several hundred kb centromeric to *MEST* and it also showed biparental expression. So far, we identified only one novel non-coding imprinted transcript, *CITI*, 30 kb telomeric to *MEST*. These data suggest that 7q32 region is regionally imprinted, but may not make a large imprinted-gene cluster as seen at 11p15.5 and 15q11-q13.

**Identification of a novel imprinted domain at human chromosome 14q32.** *A.A Wylie*<sup>1,2</sup>, *S.K Murphy*<sup>1</sup>, *T.C Orton*<sup>2</sup>, *R.L Jirtle*<sup>1</sup>. 1) Radiation Oncology, Duke University, Durham, NC; 2) Safety Assessment, AstraZeneca, Alderley Edge, Cheshire, UK.

Using a genomics based approach, we have identified two imprinted genes on human chromosome 14q32, which together define a novel imprinting cluster. The first gene, DLK1, belongs to the epidermal growth factor (EGF)-like homeotic family and was named due to its homology with the Drosophila neurogenic proteins Delta and Notch. Delta/Notch signaling is an essential intercellular communication mechanism involved in cell fate decisions. The second gene, GTL2, encodes a non-translated RNA transcript with unknown function. Gene expression analysis in human fetal tissues demonstrated parent of origin dependent, monoallelic expression with DLK1 and GTL2 being expressed exclusively from the paternal and maternal alleles, respectively. Further characterization of the genomic structure of this domain, including methylation analysis, indicated that the spatial organization, differential methylation and reciprocal imprinting of the DLK1/GTL2 domain is very similar to that of the IGF2/H19 domain on chromosome 11. Analysis of GTL2 upstream sequences indicated differential methylation of a putative CTCF binding site. The enhancer-blocking protein, CTCF, has recently been shown to function as a crucial chromatin boundary element involved in directing appropriate expression of IGF2 and H19. These results provide the first characterization of a novel imprinted domain on human chromosome 14 and show imprinting of a human EGF-like homeotic protein with close homology to the Drosophila homeotic protein, Delta.

**Identification of potential cis-acting elements regulating expression of the imprinted *SNRPN* gene.** *S. Rodriguez-Jato*<sup>1</sup>, *D.J. Driscoll*<sup>2</sup>, *T.P. Yang*<sup>1</sup>. 1) Department of Biochemistry and Molecular Biology, Center for Mammalian Genetics, University of Florida College of Medicine, Gainesville, FL; 2) Department of Pediatrics, Center for Mammalian Genetics, University of Florida College of Medicine, Gainesville, FL.

The imprinted human *SNRPN* gene is located in the Prader-Willi /Angelman syndrome (PWS/AS) region of human chromosome 15 and is expressed exclusively from the paternally-inherited chromosome. PWS patients with imprinting mutations share a common deleted region located in the 5' region of the *SNRPN* gene that defines the PWS imprinting center (IC) and includes the *SNRPN* promoter region and exon 1. The proximal promoter of *SNRPN* contains a differentially methylated CpG island and displays differential histone acetylation between the paternal and maternal alleles. To identify potential cis-acting regulatory elements that may be involved in imprinted *SNRPN* gene expression and/or IC function, we performed *in vivo* footprint analysis of this region on the paternally and maternally-inherited chromosomes. Lymphoblasts from PWS and AS patients with maternal and paternal uniparental disomy, respectively, were treated with dimethyl sulfate *in vivo* and purified DNA was subjected to ligation-mediated PCR *in vivo* footprinting. To date, we have identified four footprints, all specific to the transcriptionally active paternally-inherited allele, and all clustered within 200 bp spanning the translation initiation site and the immediate 5' flanking region. Only one of the four footprints falls within a series of six boxes in the promoter region that are conserved between the human and mouse genes. These *in vivo* footprinted sites are candidate cis-acting elements that regulate imprinted expression of the *SNRPN* gene and/or participate in PWS-IC function.

**Characterization of murine phosphatidylserine-specific phospholipase A1 (*Ps-pla1*): its sequences and chromosomal location.** X. Wen<sup>1</sup>, K. Stewart<sup>1</sup>, J. Skaug<sup>2</sup>, E. Wei<sup>1</sup>, L. Tsui<sup>2</sup>. 1) Dept Experimental Therapeutics, Toronto General Hospital, Toronto, Ontario, Canada; 2) Dept Genetics, The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada.

We have previously generated a mouse transgenic line with an insertional mutation designated *lpd* that demonstrates a phenotype of hypertriglyceridemia and fatty liver. Since the recently identified phosphatidylserine-specific phospholipase A1 (PS-PLA1) demonstrates significant homology to triglyceride lipases, we reasoned that the mouse *Ps-pla1* gene could be the gene disrupted in the *lpd* locus. Using a rat PS-PLA1 cDNA sequence to search EST database, we identified a mouse EST homologue AA839424. Sequencing analysis of AA839424 revealed a putative *Ps-pla1* protein of 456 amino acids with extensive overall structural conservation with human and rat PS-PLA1 and with triglyceride lipases, including a lipase consensus sequences GxSxG, a catalytic triad and eight of the ten conserved cysteine residues that are required for tertiary structure. Mouse *Ps-pla1* carries a phosphatidylserine-binding motif that is absent in all triglyceride lipases. Using a mouse whole genome radiation hybrid (WG-RH) mapping panel (T31), we mapped mouse *Ps-pla1* to chromosome 16 between genetic markers D16Mit194 and D16Mit38 which is 17.1 cM centromeric to the *lpd* locus. Based on chromosome location, we conclude that *Ps-pla1* and *lpd* are distinct genes in lipid metabolism.

**A new method for generating modifications in Bacterial artificial chromosomes by homologous recombination in E. coli.** *M.D. Lalioti, J.K. Heath.* Molecular Cell Biology Group, School of Biosciences, University of Birmingham, UK.

There is a growing need for high throughput techniques to determine gene function and spatial/temporal patterns of expression, as more human genes are predicted or identified. There is also a requirement for the generation of animal models of dominant and gene dosage-dependant genetic diseases. In order to recapitulate the endogenous pattern of expression, it is necessary that the transcriptional and post transcriptional regulatory elements of each gene are preserved. The use of large DNA molecules containing the entire genomic sequence and regulatory elements of a gene is, therefore, the method of choice.

Several methods have been developed in order to modify large clones (BACs/PACs) by homologous recombination in *E. coli*, all of which aimed to introduce insertions or deletions. We developed a new, efficient, and rapid method for introducing point mutations in BACs, in order to study a dominant human disease. We have used the framework of the shuttle vector pKOV, constructed by Link and Church in order to modify *E.coli* genes (J. Bact. 1997). We created a new generation of vectors for mutation of any sequence encoded by BACs in a two step procedure. The new pKOV-Kan contains a temperature-sensitive origin of replication, the chloramphenicol and kanamycin resistance genes for positive and the *sacB* gene for negative selection. A fragment of the gene of interest containing a single point mutation is cloned into the new shuttle vector. This vector and a *recA* expressing plasmid are co-transformed in the BAC cells. In a first recombination event, the "cointegration", the shuttle vector integrates in the BAC. This is followed by a second recombination, the "resolution", which results in BAC which contain either the mutant or the wild type nucleotide. Both steps are selected using resistance or sensitivity conferred by the shuttle vector, and easily confirmed by PCR or southern blot. We have also used this method to engineer an in-frame fusion of our gene of interest and *lacZ*. This allows us to analyse the BAC gene expression in transgenic mice. BACs modified in this manner yield transgenic mice with high efficiency.

**Variable X inactivation of human TIMP1: Effect on levels of RNA and role of DNA methylation.** *C.L. Anderson, C.J. Brown.* Dept Medical Genetics, Univ British Columbia, Vancouver, Canada.

We have previously demonstrated that the human tissue inhibitor of metalloproteinases-1 (TIMP1) gene shows variable X inactivation being expressed from the inactive X (Xi) in some females but subject to inactivation in other women. As TIMP1 and its target metalloproteinases are involved in many biological processes, women with altered TIMP1 levels may be predisposed to some diseases and metastases. We have used quantitative RPA to establish TIMP1 RNA levels, and observed considerable variation among active X (Xa) chromosomes. Multiple assays have demonstrated 3 origins for this variability: 8% experimental variance; a further 30% reflects cell cycle variation; and lastly a 2x range of TIMP1 expression between different Xas. Diverse expression levels from the Xa precluded analyzing the contribution of the Xi to total TIMP1 RNA in females, so we examined expression in Xi-containing hybrids expressing TIMP1. The Xi levels varied even more widely, with some of the Xi hybrids expressing 5x less TIMP1 than the highest Xa level, which may reflect the presence of residual features associated with X inactivation. To investigate the contribution of methylation, we examined 4 sites at the 5' end of TIMP1 using PCR after methylation-sensitive digestion. TIMP1 is generally unmethylated when expressed, but remained methylated in the lower-expressing Xi hybrids. Since decreased expression in the presence of methylation may reflect a heterogeneous cell population, we analyzed expression in over 100 single cell clones. Although we did detect ongoing instability, with some populations yielding both expressing and non-expressing clones, methylation and low expression (0.2x Xa) were still mutually present in some clones. We conclude that once TIMP1 becomes unmethylated, it behaves like an active copy and therefore could contribute significantly to expression in females. However, the 3 females studied with expression from the Xi have shown methylation of TIMP1. Future studies will analyze more women to establish if TIMP1 becomes unmethylated on the Xi in humans, perhaps preferentially in diseases associated with increased TIMP1.

**Cytochrome c oxidase subunit Vb co-localizes with polyglutamine-expanded human androgen receptor. A.**

*Beauchemin*<sup>1</sup>, *L.K. Beitel*<sup>5</sup>, *L. Pinsky*<sup>1,2,3,4,5</sup>, *M. Trifiro*<sup>2,3,5</sup>. 1) Biology; 2) Medicine; 3) Human Genetics; 4) Pediatrics; 5) Lady Davis Institute, SMBD-Jewish General Hospital, Mtl, Que, Canada.

Spinobulbar muscular atrophy (SBMA) is a late onset motor neuronal disorder caused by the expansion of the polyglutamine (polyGln) tract in exon 1 of the androgen receptor (AR). One way polyGln-expanded proteins are believed to cause neurotoxicity is through abnormal interaction and possible sequestration of critical cellular proteins. Using polyGln-containing fragments of the normal (20Q) and expanded (50Q) hAR as baits, yeast two-hybrid screening of a motor neuron NSC-34 cDNA library led to the identification of COXVb as a new AR-interacting protein. COXVb is a 98 aa nuclear-encoded protein containing a 31 aa signal sequence responsible for mitochondria-targeting. Its interaction with hAR was further substantiated in GST pulldown assays. Mammalian two-hybrid experiments in CV-1 cells showed COXVb to bind to hAR20Q and hAR50Q to the same extent in a hormone-free environment. Addition of androgens increased COXVb-hAR20Q and COXVb-hAR50Q by 4- and 2-fold respectively. Increasing hormone concentrations (up to 10 nM) augmented COXVb-hAR20Q interaction in a dose-dependent fashion, whereas having no effect on COXVb-hAR50Q interaction. Aggregation of COXVb-hAR50Q leading to sequestration of complexes may account for less two-hybrid activity. Co-expression of Hsp70 led to enhanced COXVb-hAR20Q interaction but not of COXVb-hAR50Q. To further document in vivo interactions between COXVb and hAR, COS-1 cells were transfected with either GFP-hAR20Q or GFP-hAR50Q and BFP-COXVb constructs. In several instances, BFP-COXVb was found to co-localize with aggregates of GFP-hAR50Q. This co-localization was restricted to hormone exposure, unique to GFP-hAR50Q co-expression, and only documented within cytoplasmic aggregates. **CONCLUSION:** Mitochondrial dysfunction may precede classical neuropathological findings and may thus represent an early event in neuronal toxicity. Interaction of COXVb and hAR may provide a mechanism for putative mitochondrial dysfunction in SBMA.

**Mapping genes for human mitochondrial ribosomal proteins.** *T.W. O'Brien<sup>1</sup>, H.-R. Graack<sup>2</sup>, N. Fischel-Ghodsian<sup>3</sup>, E.B. Mougey<sup>4</sup>, B.A. Maguire<sup>4</sup>, B. Wittmann-Liebold<sup>5</sup>, D.P. Nierlich<sup>3</sup>, J.E. Sylvester<sup>4</sup>.* 1) Biochemistry and Mol Biol, University of Florida, Gainesville, FL; 2) Institute for Genetics, AG Kress, Free University of Berlin, Germany; 3) UCLA and Cedars-Sinai Medical Center, Los Angeles, CA; 4) Nemours Children's Clinic, Jacksonville, FL; 5) Max-Delbruck-Center for Molecular Medicine, Berlin, Germany.

Mitochondrial DNA encodes tRNAs and rRNAs, but the other genes for the mitochondrial translation system are found in nuclear DNA. Upward of 85 mammalian mitochondrial ribosomal proteins (MRPs) are imported into mitochondria where they assemble into ribosomes that are responsible for translating the 13 mRNAs for essential proteins of the oxidative phosphorylation system. Since mutations in mitochondrial tRNA and rRNA can cause various pathological states, we hypothesize that mutations in MRP genes are also candidates for human disorders. Our approach is to use N-terminal and internal amino acid sequence data obtained from purified bovine MRPs (O'Brien, et al. *J Biol Chem.* 2000 Apr 5 [epub ahead of print]) to search EST databases. A representative I.M.A.G.E. clone (ATTC) is purchased and used to screen a human lambda genomic library. Chromosome map positions for the MRP genes are ascertained by in situ hybridization (FISH) with genomic sequences and/or by using in silico methods to search Genbank and GeneMap through NCBI. At present, we have over 30 different human MRPs at various stages of characterization. We are currently investigating one MRP as a potential candidate for Russell-Silver Syndrome (RSS), a dwarfism characterized by low birth weight and lateral asymmetry, characteristics that are consistent with reduced mitochondrial function. DNA from RSS patients is being analyzed for possible mutations in MRPs. In addition to studying their clinical relevance, long term characterization of MRP genes should lead to important insights into mammalian evolution, coordinate regulation of nuclear and mitochondrial gene expression, and ribosome function. This work is being done as part of the Mammalian Mitochondrial Ribosomal Consortium and is supported by NIH/NIDCD grant RO1DC04092 and the Nemours Research Program.

**Heart-specific splice-variant of human mitochondrial ribosomal protein L5 (MRP-L5).** *O. Spirina*<sup>1</sup>, *Y. Bykhovskaya*<sup>1</sup>, *A.V. Kajava*<sup>2</sup>, *T.W. O'Brien*<sup>3</sup>, *D.P. Nierlich*<sup>1</sup>, *E.B. Mougey*<sup>4</sup>, *J.E. Sylvester*<sup>4</sup>, *H.-R. Graack*<sup>5</sup>, *B. Wittmann-Liebold*<sup>5</sup>, *N. Fischel-Ghodsian*<sup>1</sup>. 1) Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA; 2) Center for Molecular Modeling, NIH, Bethesda, MD; 3) University of Florida, Gainesville, FL; 4) Nemours Children's Clinic, Jacksonville, FL; 5) Free University, Max-Delbrück Center, Berlin, Germany.

It has been proposed that splice variants of proteins involved in mitochondrial RNA processing and translation may be involved in the tissue specificity of mitochondrial DNA disease mutations (*Mol Genet Metab* 65:97, 1998). To identify and characterize the structural components of mitochondrial RNA processing and translation, the Mammalian Mitochondrial Ribosomal Consortium has been formed. The 338 a.a. long MRP-L5 was identified (*J Biol Chem* 274:36043, 1999), and its cDNA was used to search for tissue specific splice variants. Cyberscreening of the EST databases revealed a single putative splice variant, due to the insertion of an exon consisting of 89 nucleotides prior to the last exon. Screening of multiple cDNA libraries revealed this inserted exon to be present only in heart tissue, in addition to the more abundant MRP-L5 transcript. Sequencing of this region confirmed the EST sequence, and revealed the introduction of a termination codon at the beginning of the last exon. Thus the inserted exon replaces the regular last exon, and creates a new 353 a.a. long protein (MRP-L5V1) with a different C-terminus. Sequence analysis and 3-D modeling reveal similarity between MRP-L5 and threonyl-t-RNA synthetases, and a likely RNA binding site within MRP-L5, with the C-terminus in proximity to the RNA binding site. Sequence analysis of MRP-L5V1 also suggests a likely transmembrane domain at the C-terminus. Thus it is possible that the MRP-L5V1 C-terminus could interfere with RNA binding and may have gained a transmembrane domain. Further studies will be required to elucidate the functional significance of MRP-L5V1.

This work was done as part of the Mammalian Mitochondrial Ribosomal Consortium and is supported by NIH/NIDCD grant RO1DC04092.

**Radiation-induced changes in the expression of stress response and DNA repair genes in human and mouse cells.**

*M.A. Coleman<sup>1</sup>, E. Yin<sup>1</sup>, K. Sorensen<sup>1</sup>, B.J. Marsh<sup>1</sup>, S. Mabery<sup>1</sup>, L. Tomascik-Cheeseman<sup>1</sup>, S. Liu<sup>2</sup>, J.P. Gregg<sup>2</sup>, L. Mascio-Kegelmeyer<sup>1</sup>, T. Attix<sup>1</sup>, J. Tucker<sup>1</sup>, A.J. Wyrobek<sup>1</sup>.* 1) Biol. & Biotech. Res. Prog., Lawrence Livermore National Laboratory, Livermore, CA. 94551; 2) Dept. Path., University of California, Davis, School of Medicine, Sacramento, CA 95817.

Exposure to DNA damaging agents can result in tissue toxicity and lead to diseases, including cancer. We hypothesize that genes exhibiting altered expression within the first few hours after low-dose ionizing radiation (IR) exposure are pivotal in determining cellular responses. We designed custom cDNA microarrays containing genes involved in stress/damage response and DNA repair-related functions. Our microarray system was validated to detect transcript ratio differences of less than 2-fold with strong signal specificity and sensitivity. For these initial studies, we characterized the response of two model systems (human lymphoblastoid cells and whole mouse brain tissue) for relative changes of known genes and to identify novel radiation responsive genes within 7 hrs after 2 Gy IR. Two Coriell Cell Repository human lymphoblastoid cell lines were evaluated using both a brain-specific array and a custom cDNA array. From 57 genes expressed in both cell lines, we found 7 novel and 15 known genes with differential responses between the two cell lines. DNA repair genes showed a slight increase over control samples. The in vivo model used B6C3F1 mouse brain tissue that was collected after whole animal irradiation. Genes important for recombination and repair such as RAD51, ERCC1, MRE11 and RAD52 showed changes in expression patterns that were consistent with the in vitro studies. Several unique gene expression patterns were identified, in addition to those that have been previously described in the literature. These studies have identified genes and pathways that are modulated by IR that will be used to understand the early cellular responses for low-dose irradiation and oxidative stress. [This work was conducted under the auspices of DOE and LLNL under contract W-7405-ENG-48 with support from NIH (ES09117-02) and DOE (KP110202).].

**Functional analysis of presenilin 1 in *Drosophila*.** M. Lecourtois, O. Blard, C. Dumanchin, D. Champion, T. Frébourg. INSERM EMI 9906, IFRMP, Faculté de Médecine et de Pharmacie, 22 Boulevard Gambetta, 76183 Rouen, France.

Alzheimer's disease (AD) is the major neurodegenerative dementia and is characterized by the extracellular deposition of Ab peptide and the presence of intracellular neurofibrillary tangles. Missense mutations of the *PSEN1* gene, located on chromosome 14, account for the majority of autosomal dominant early-onset Alzheimer's disease (ADEOAD) cases. *PSEN1* mutations lead to an increase production of the amyloidogenic Ab 42 peptide, but the mechanisms of this increased production are unknown. To characterize the pathogenic effects of *PSEN1* mutations and the PSEN1 biological pathway *in vivo*, we developed functional analysis of PSEN1 in *Drosophila*. Wild-type or ADEOAD mutant forms of human PSEN1 or its drosophila homolog (DPS) were expressed under the transcriptional control of the endogenous DPS regulatory region. The heterozygote transgenic flies harboring a wild-type and a mutant allele, which mimic the genetic status of ADEOAD patients, exhibited a wing phenotype which was not observed in flies (Wt/-) harboring only one wild-type allele. This phenotype was also observed when we overexpressed truncated forms of PSEN1 binding proteins. These results suggest a dominant negative effect of the PSEN1 mutations which could explain the gain of function of these mutations.

**Functional analysis of the gene products of the homologs of the human XNP/ATR-X gene product in**

***Caenorhabditis elegans* and *Drosophila melanogaster*.** F. Usseglio<sup>1</sup>, N. Pujol<sup>2</sup>, U. Rothbacher<sup>1</sup>, C. Cardoso<sup>3</sup>, J. Ewbank<sup>2</sup>, J. Pradel<sup>1</sup>, M. Fontès<sup>3</sup>, L. Villard<sup>3</sup>. 1) Laboratoire de Génétique et Physiologie du Développement, Faculté des Sciences Luminy, MARSEILLE, FRANCE; 2) Centre d'Immunologie de Marseille Luminy, Marseille, France; 3) Inserm Unité 491, Faculté de Médecine La Timone, Marseille, France.

We have identified single genes highly homologous to the XNP/ATR-X in the genomes of the nematode *Caenorhabditis elegans* and the fly *Drosophila melanogaster*. We have called these new genes *xnp-1* and *dxnp*, respectively. The putative proteins encoded by these two genes are the closest relatives of the human XNP and mouse Xnp proteins known to date. These invertebrate proteins, however, do not possess N-terminal zinc fingers present in the human protein. We are currently undertaking an analysis of the cellular mechanisms in which the two newly identified proteins are involved. In the nematode, we have performed RNAi and *xnp-1* promoter driven eGFP-expression experiments. In *Drosophila*, we have established the *dxnp* transcription pattern during the embryonic development and raised antibodies against the *dxnp* protein to analyse its cytological distribution. We have also taken advantage of the existence of a *Drosophila* line containing a P element in the promoter of *dxnp*. We have induced the excision of the P element and several mutant lines were obtained in which part of the *dxnp* locus is deleted. Lastly, we have undertaken the rescue of the mutant phenotypes with the human XNP/ATR-X protein. These experiments will test the extent to which these two proteins have shared functions at the cellular level.

**Towards a mouse model for Smith Magenis Syndrome.** *K. Walz, S. Carattini-Rivera, J. Wesley, G. Schuster, J. Yan, C.F. Boerkoel, A. Bradley, J.R. Lupski.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Smith-Magenis syndrome (SMS), caused by del(17)p11.2, represents one of the most frequently observed human microdeletion syndromes. Clinical features include mental retardation, short stature, minor craniofacial anomalies, short fingers, microcornea, developmental defects of the heart and kidneys, and neurobehavioral abnormalities. The majority of patients (>50%) have a common genomic region deleted resulting from an homologous recombination between flanking repeat gene clusters. The complex phenotype features of SMS and the size of the deletion (5-6 Mb) suggests the deletion of several contiguous genes and it is likely that haploinsufficiency of one or more genes in the commonly deleted region underlies this disorder. Although several genes have been identified in the SMS deletion interval, their contribution to this complex phenotype remains speculative. Chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. Our goal is to produce a mouse model using chromosome engineering to construct a deletion of murine chromosome 11 spanning the syntenic region for the human deletion interval in order to define which gene or group of genes is responsible for SMS. COPS3 and ZNF179 are the flanking genes of the human deletion. We targeted both of these genes in mouse ES cells with 2 different vectors carrying the loxP sequence, a coat color marker and two different halves of the Hprt gene for selection of the rearranged chromosomes. The rearrangements were achieved by electroporation with Cre recombinase. Southern blot and FISH were used to analyze the products of the recombination. One ES cell clone gives the deletion and the reciprocal duplication of SMS syntenic region. This clone was injected and the chimeric mice were born. The analysis of the F1 is underway.

**The Induced Mutant Resource at The Jackson Laboratory.** *S.F. Rockwood, J.J. Sharp, L.E. Mobraaten, M.T. Davisson.* Induced Mutant Resource, The Jackson Laboratory, Bar Harbor, ME.

Transgenic and targeted mutant mice have emerged as the preeminent tool used to undertake the challenge of determining gene function in both normal and disease states. To ensure the greatest possible access to these tools, the Induced Mutant Resource (IMR) at The Jackson Laboratory was created in 1992 to serve as a centralized facility to collect and distribute induced mutant mice to the scientific community. Since its inception, the IMR has accepted over 700 different induced mutant mouse strains, distributing over 100,000 mice a year to the scientific community. Current growth in the IMR collection is approximately 80-100 new strains each year, offering new mouse models in many areas including cancer, diabetes, neurobiology, development and immunology. Each strain accepted into the IMR is vigorously reviewed for biomedical significance and subjected to rederivation procedures that rid them of any pathogens they might carry. Cryopreservation of embryos and sperm derived from these stocks is performed to protect them against accidental loss and genetic contamination. Often, these mutations are placed on defined genetic backgrounds by backcrossing to an inbred strain. An on-line resource is available allowing researchers to retrieve information related to the mutant strains maintained in the IMR. Mutant strain records retrieved from the IMR database include brief phenotype descriptions, strain construction and husbandry information, and a listing of related references. Where appropriate, mutant strain information is linked to entries in other online databases such as the Mouse Genome Database (MGD) and the human Genome Database (GDB). Researchers wishing to have mutant strains considered for inclusion in the IMR collection may submit their strains using the form available at the IMR web site. The IMR database can be accessed at URL: <http://www.jax.org/resources/documents/imr/>. The Induced Mutant Resource is supported by the National Center for Research Resources (RR09781 and RR11081), The National Institute for Arthritis and Inflammatory Disease and The Howard Hughes Medical Institute.

**The use of microarrays in the analysis of human skeletal muscle.** *J.N. Haslett, D. Sanoudou, H.G.W. Lidov, I.S. Kohane, A.H. Beggs, L.M. Kunkel.* Genetics Division, Children's Hospital, Harvard Medical School, Boston, MA.

The development of cDNA and oligonucleotide arrays has enabled the simultaneous analysis of very large numbers ( $>10^3$ ) genes. Rather than studying single candidate genes for a disease phenotype, expression profiles can be created which represent total gene expression in normal and diseased tissue and specific changes identified. In order to obtain a global expression profile for human skeletal muscle we used Affymetrix oligonucleotide arrays, assaying approximately 7130 genes. This study reports the baseline variation in normal skeletal muscle.

Multiple control experiments were performed using normal human skeletal muscle. Initially identical RNA samples were hybridized to identical chips and compared. 0.3% of genes showed a greater than three-fold difference at their expression level. Two different RNA samples from the same tissue were hybridized on identical chips and compared. 5.2% of genes had an expression level difference higher than three-fold. There was a strong non-linear correlation between expression level and the degree of variation between identical genes. Finally, RNA samples from the skeletal muscle of two different normal individuals were hybridized as before and analyzed. Only 5.7% of genes showed greater than three-fold differences. The differences seen between the samples used for the three paired comparisons are indicative of experimental (i.e. intensity of hybridization signal), inter-microarray, intra-tissue and inter-tissue variation. Data analysis by the Affymetrix GeneChip® software judged approximately 3100 of the 7130 genes studied on each chip to be expressed in the normal human skeletal muscle samples.

In addition to continuing to establish this baseline we are examining muscle specific gene expression profiles in Duchenne muscular dystrophy and Nemaline myopathy patients. We will apply both conventional fold-difference comparisons, as well as automated classification and clustering techniques to identify the genes that are most tightly coupled to those involved in these myopathies. We will also define those genes that most reliably distinguish and characterize these two myopathies.

**Identification of a PDZ domain-containing protein scaffold in skeletal and cardiac muscle.** *J.L. Siders, C.K. Colton, T.A. Hainsey, J.A. Rafael.* Department of Molecular and Cellular Biochemistry, The Ohio State University College of Medicine Columbus, OH.

The genetic cause for over one hundred described neuromuscular diseases remains unknown. We have identified a family of synapse-associated proteins in skeletal muscle that represent excellent candidates for involvement in this class of disorders. These membrane-associated quanylate kinase proteins have previously been characterized in the brain and have been shown to cluster channels and receptors via their PDZ protein domains. We now show the expression of the three PDZ domain-containing proteins, Dlg, Dlg-3, and CASK in skeletal muscle and heart. CASK and Dlg are expressed at the membrane in cardiac and skeletal muscle. CASK also co-localizes with nuclei in cardiac tissue, providing further evidence for its previously suggested role in modulating gene expression. These results suggest that Dlg, Dlg-3, and CASK may be components of a PDZ domain-containing scaffold similar to the one at central nervous system synapses. Overexpression studies using full-length and PDZ domain-deleted versions of Dlg, Dlg-3, and CASK will delineate the role of these proteins in normal skeletal muscle and heart. Analysis of PDZ domain-containing protein localization in animal models of muscular dystrophy and cardiomyopathy will elucidate the role of these proteins in neuromuscular diseases and heart failure.

**Analysis of the transcriptional control of utrophin promoters as a therapeutic strategy for Duchenne muscular dystrophy (DMD).** *K.J Perkins, E.A Burton, A.C Potter, K.E Davies.* Human Anatomy and Genetics, University of Oxford, Oxford, UK.

Duchenne muscular dystrophy (DMD) is an X-linked muscle wasting disease caused by the lack of the protein dystrophin. There is no effective treatment for the disorder and patients usually die of cardiac arrest or respiratory failure in their late teens to early twenties. Utrophin is a protein that is closely related in amino acid sequence to dystrophin and its ability to replace dystrophin without toxic side effects is seen to be a major advancement in development of an utrophin-based therapy for DMD individuals. It may be possible to up-regulate endogenous utrophin production in skeletal muscle by a 2 to 3 fold increase in the steady state protein level necessary to prevent dystrophic pathology. One way of achieving this might be through transcriptional up-regulation of the endogenous utrophin gene, analogous to the transcriptional re-activation of  $\gamma$ -globin in  $\beta$ -globinopathies. We have therefore commenced a systematic investigation of the factors responsible for expression of utrophin in order to identify methods of affecting its up-regulation for a promoter-based therapy. Promoter A lies within the CpG island at the 5' end of the gene and contains several transcription start sites, giving rise to the synaptically expressed isoform, whereas promoter B appears to be widely regulated in vitro. EMSA (electrophoretic mobility shift assay) and DNaseI footprinting methods were utilized to delineate functionally important regions of both promoters. Our data demonstrate that the mutagenesis of binding sites of  $\text{ap}2$  and  $\text{sp}1$  transcription factors within the A promoter results in a significant decrease in promoter activity, supporting the hypothesis that the binding of general transcription factors to this housekeeping promoter is essential for optimal activity. A similar approach has been used to delineate regions of interest in the B promoter and is currently under investigation.

**Mutational modelling of missense mutations in Hemophilia A.** *P.S. Lai<sup>1</sup>, J.H.M. Tan<sup>1</sup>, N.O. Cho<sup>1</sup>, B. Cheng<sup>2</sup>.* 1) Dept Pediatrics, National Univ Singapore, Singapore; 2) Bioinformatics Centre, National Univ Singapore, Singapore.

Hemophilia A is a common X-linked inherited bleeding disorder caused by molecular defects in the factor VIII (FVIII) gene which codes for coagulation factor VIII protein. Molecular characterisation of FVIII gene has uncovered a wide spectrum of mutations such as nucleotide substitutions, insertions, deletions, splicing errors and gross gene rearrangements. While most of the deleterious mutations result in absence or dysfunctional protein, the effect of missense mutations is unclear. We report the identification of four missense mutations in our patients, G73S, R282C, R2307C and M1934R, the last being novel. Direct sequencing of all exons and flanking introns of FVIII gene did not reveal the presence of a second mutation in all four patients. The missense mutations were analysed for their involvement with common functional motifs using the MOTIFS sequence analysis program. It was found that the mutations in G73S, R282C and M1934R involved the A domains homologous to the copper-binding protein, ceruloplasmin. Homology modelling for secondary structure prediction using Insight II showed that changes in electrostatic interactions in the mutant molecules were likely to result in conformational instability. It is predicted that the metal-ion binding activity of the A domain was adversely affected resulting in severe hemophilia phenotype in G73S while not completely abolishing the functional activity of the protein in R282C and M1934R. The R2307L mutation occurs in the C2 domain of FVIII protein which is homologous to the lipid-binding domain of galactose oxidase. The normal arginine residue in wildtype molecule is highly conserved in both FVIII and FV proteins. This residue may represent an important functional site as molecular modelling shows it being directed towards membrane surface and possibly involved in binding to phosphatidylserine. The change in charges in the mutant molecule is likely to result in structural instability affecting membrane binding, or chemical peptide properties such that the mature protein becomes relatively unstable or rapidly degraded.

**Mutational analysis of the skeletal and cardiac muscle specific filamin gene, filamin C (FLNC), in LGMD 1E patients.** *T.G. Thompson<sup>1</sup>, M.C. Speer<sup>2</sup>, H. Webber<sup>1</sup>, C. Feener<sup>1</sup>, J.M. Vance<sup>2</sup>, L.M. Kunkel<sup>1</sup>.* 1) Howard Hughes Medical Institute and Division of Genetics, Children's Hospital, Boston, MA; 2) Department of Medicine, Duke University, Durham, NC.

Gamma filamin, the protein product of the filamin C gene, interacts with members of the sarcoglycan complex, specifically gamma and delta sarcoglycans. There are four sarcoglycan proteins found in skeletal muscle (alpha, beta, gamma and delta) and mutations in any one sarcoglycan gene causes a recessive form of limb-girdle muscular (LGMD 2C-2F). Interestingly, patients and mice with mutations in gamma sarcoglycan, delta sarcoglycan or dystrophin show an increase of gamma filamin at the sarcolemmal membrane indicating a disruption of filamin distribution within skeletal muscle. In addition, families with a dominant form of muscular dystrophy, LGMD 1E, were previously linked to a region on chromosome 7 that may include the FLNC gene. To investigate the possibility of FLNC mutations in these families, we determined the intron/exon borders for FLNC, amplified and sequenced all 48 exons in two affected patients and three control individuals. To date, no apparent disease causing mutations have been found in the LGMD 1E patients, although several single nucleotide polymorphisms (SNP) were found. To eliminate the possibility of undetected mutations or gene deletions, segregation of the newly identified SNPs will be followed through the LGMD 1E families. If recombinational events are found between SNPs in affected individuals, FLNC can be ruled out as a candidate gene for LGMD 1E.

**Mammalian operons.** *R.D. Nicholls, T.A. Gray.* Dept Genetics, Case Western Reserve Univ, Cleveland, OH.

The accelerating identification of mammalian genes and gene structures from genome projects, and the subsequent characterization of their regulation and functional relationships can be expected to open new avenues of understanding in genome regulation. Here, we have examined evidence leading to the unexpected conclusion that some mammalian loci have features reminiscent of prokaryotic operons. This challenges the decades-old dogma that operons are restricted to prokaryotes, but also reveals additional superimposed levels of regulation more typical of mammalian systems. As defined here, an operon is a single locus that produces transcripts encoding more than one protein and in which the encoded proteins function in a common biological pathway (in contrast, synexpression groups [Niehrs & Pollet, *Nature* **402**:483-487, 1999] have no structural component and are not equivalent to operons). For example, functional L1 repeat elements, the *UOG-GDF1* locus, and the *SNURF-SNRPN* (Prader-Willi syndrome) locus emulate the classical prokaryotic polycistronic mRNA structure, in which the cognate proteins are separately translated from each cistron *in vivo*. Other mammalian operons variously combine alternative splicing, promotion, or translation, or antisense or bidirectional transcription, to diversify and modulate the encoded protein products. Examples include three proteins produced at *GNAS1* (at least two co-localized in secretory granules, and associated with two hormonal disorders), two at *INK4A* (cell cycle regulation, mutated in melanoma), and complex regulation at *MOCS1* and *MOCS2* (both involved in molybdenum cofactor biosynthesis). The evolutionary benefit of an operon is likely the transcriptional and/or translational co-regulation of factors in a common biochemical or physiological pathway. With the completion of human and other vertebrate genome sequences, additional loci will likely be predicted with potential polycistronic or operon structures. Rigorous phylogenetic and *in vivo* mRNA and protein studies of potential mammalian operons will help form a consensus about their evolution, regulation, and physiologic roles in mammalian development.

**BIPs and BIPf, newly identified Battenin/Battenim-interactive proteins, may play central roles in the pathogenesis of Batten disease.** *N. Zhong<sup>1,3</sup>, W. Ju<sup>1</sup>, D. Moroziewicz<sup>1</sup>, A. Jurkewicz<sup>1</sup>, K. Wisniewski<sup>2,3</sup>, W.T. Brown<sup>1</sup>.*  
1) Dept. Human Genetics, NYS Institute for Basic Research, Staten Island, NY; 2) Dept. Neuropathology, NYS Institute for Basic Research, Staten Island, NY; 3) Dept. Neurology, SUNY-HSCB, Brooklyn, NY.

Batten disease (BD), the juvenile form of neuronal ceroid lipofuscinoses (NCLs), is one of the most common pediatric neuronal degenerative disorders in the United States. A gene underlying BD is designated CLN3, which encodes a protein, Battenin, with unknown function. The pathogenic mechanism whereby Battenim, the mutant form of Battenin, results in lipofuscinosis and consequently causes neuronal degeneration is unknown. We hypothesize that there is a common metabolic pathway shared by all NCLs including BD, leading to lipofuscinosis and resulting in pathological neuronal degeneration. Unidentified proteins in this pathway may be functional downstream from, or be regulated by, or along with, Battenin to compose of a protein complex involving in BD as the secondary deficit. We have recently identified two novel Battenin-interactive proteins, BIPs and BIPf, with a yeast two-hybrid system. Our preliminary data revealed that (1) there is an increased interaction of the mutant Battenim with BIPf indicating a genetic deficit of "gain-of-function", (2) BIPs and BIPf interact with each other in addition to Battenin/Battenim, (3) BIPf interacts with mitochondrial ATPase subunit C which has been demonstrated to accumulate in NCLs, including BD, and (4) BIPf interacts strongly with CLN8-encoded protein CLN8p. Our results provided strong evidence supporting our hypothesis, may lead to better understanding of the molecular mechanism underlying BD and shed light on the pathogenesis of NCLs.

**Identification of new genes as candidate for imprinting on human chromosome 20q13 segment.** *S. Kussmann<sup>1</sup>, A. Hehr<sup>1</sup>, K. Koerber<sup>1</sup>, H. Miller<sup>2</sup>, J. Peters<sup>2</sup>, I. Hansmann<sup>1</sup>, D. Schlote<sup>1</sup>.* 1) Institut f. Humangenetik und Medizinische Biologie, Univeritaet Halle, Halle, FRG; 2) Medical Research Council, Harwell, GB.

Two mouse models have been generated carrying reciprocal translocations (T1Goe and T30H) which served to define chromosomal segments of parental source effect (Imprinting) on mouse chromosome 2 (MMU2) and shows conserved synteny of gene loci to a human chromosome 20q13 segment. Uniparental disomies for these segments on MMU2 results in different neonatal lethalties with opposite anomalous phenotypes. Using a mouse YAC contig representing one of these imprinting regions (IR1; T(2;8)2Wa and T(2;16)28H), we have assigned several human ESTs, by means of Southern hybridization to PFGE blots of mouse YACs. Based on these results we screened a BAC-library by PCR and isolated a set of 24 BAC clones, covering the syntenic region on human chromosome 20 (HSA20) suspected to carry imprinted genes. Altogether these BACs have been arranged into a preliminary map of approximately 800 kb in length. Sequencing the ends of the BAC inserts results in defining novel STS sites in this segment. Furthermore a total of 13 human ESTs were assigned to the contig and full length cDNA of these ESTs were constructed as well as corresponding mouse cDNA identified. Based on this results we could assign the novel human genes for ATP5e and Hb1 to this segment together with 4 other genes of so far unknown function. Genomic structure and expression analysis will be presented in parallel. These genes are candidates for investigation of monoallelic gene expression and imprinting in mouse and man and will be analysed for their potential association with a given human disease. This work was supported by a grant of the DHGP.

Program Nr: 1032 from the 2000 ASHG Annual Meeting

**Functional analysis of promoter region polymorphisms.** *S.L. Coleman, B. Hoogendoorn, C.A. Guy, S.K. Smith, T. Bowen, A. Halsall, J. Austin, M.C. O'Donovan, P.R. Buckland.* Psychological Medicine, UWCM, CARDIFF, S.GLAM, UK.

The aim of this ongoing project is to identify functional promoter polymorphisms using a screening set of 8 individuals. Denaturing high performance liquid chromatography was used to screen the first 500bp of the 5' flanking region of promoters. To permit T/A cloning an EcoRV site was added to the luciferase reporter gene vector pGL3 to form a T-vector. Insert orientation in the vectors was checked by PCR of E.coli XL1B colonies following transformation. Positive PCR products were mixed in pairs and reanalysed by dHPLC to identify different alleles. Those colonies containing each of the 2 alleles were used for plasmid preparation. The ability of each allele to promote transcription of the luciferase gene is tested transiently in human cell lines HEK293, TE671 and JEG-3. To compensate for number, viability and transfection efficiency of cells a control plasmid SEAP-SV40 was co-transfected. The quantity and ratio of both pGL3 : SEAP DNA and transfection reagent : DNA were optimised for each cell line. Preliminary data shows some promoters have a significant difference in transcription between alleles suggesting that promoter polymorphisms can have functional effects, and, consequently, such polymorphisms should be regarded as a high priority for candidate gene analysis.

**Strong association of novel tau promoter polymorphisms with progressive supranuclear palsy.** M. Weiler<sup>1</sup>, H.A.R. de Silva<sup>1,2</sup>, H. Morris<sup>2</sup>, N.W. Wood<sup>2</sup>, A.J. Lees<sup>1</sup>. 1) Reta Lila Weston Institute of Neurological Studies, Royal Free & University College Med. Sch., London W1P 6DB, UK; 2) University Dept. of Clinical Neurology, Institute of Neurology, London, WC1N 3BG, UK.

**Purpose:** The H1 variant of an extended haplotype spread over 100kb of the *tau* gene is strongly associated with progressive supranuclear palsy (PSP). The functional relevance of this is unclear. In frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP17), splice donor site mutations in *tau* exon 10 cause increased inclusion of exon 10. This results in a pathological increase in four microtubule binding repeat isoforms of tau. Similarities in tau protein deposition between PSP and FTDP17 suggest a similar mechanism in PSP. Since exon 10 mutations are absent in PSP, we analysed the *tau* gene promoter for polymorphisms that could affect tau expression levels. **Methods:** We sequenced a 772bp region that includes 361bp of promoter sequence upstream to the untranslated exon -1 of *tau* in samples homozygous for the *tau* H1 and H2 haplotypes. We identified three single nucleotide polymorphisms (SNP) within the *tau* promoter region that affect *Bsm*AI, *Spe*I and *Alu*I restriction sites, respectively. Analysis of these SNPs in 42 PSP cases (13 pathologically confirmed) and 71 age-matched controls was carried out by PCR amplification of the flanking regions followed by restriction digests. **Results:** We confirmed a previously described SNP, a C®G at position -221 (relative to 5'-end of exon -1) [Ezquerra *et al.* (1999) *Neurosci Lett*], and identified two novel SNPs; an A®G at -44 and G®A at +309 that are in linkage disequilibrium with each other. Restriction analysis of the SNPs in PSP confirm strong association of the allele combination [C(-221)/A(-44)/G(+309)] (PSP=98.8% Contr=78.9% ) and homozygotes of this combination (PSP=97.6% Contr=62.0%). Variation at position -221 affects a predicted c-myb binding site whereas the SNP at -44 affects potential AP2 and USF sites. The combination of these two allelic variants could affect *tau* promoter activity and therefore, the expression levels of tau protein, providing a potential functional basis of the well-established haplotype association in PSP.

**Hierarchical control of Ectodysplasin-A expression: Involvement of the *Wnt* and EGFR pathways. M.C.**

*Durmowicz*<sup>1, 2</sup>, *C.-Y. Cui*<sup>1</sup>, *D. Schlessinger*<sup>1</sup>. 1) NIGMS, NIH, Bethesda, MD; 2) NIA, NIH, Baltimore, MD.

X-linked anhidrotic ectodermal dysplasia is a human recessive genetic disorder caused by lesions in the EDA gene and characterized by rudimentary teeth, sparse hair, and absent sweat glands. Ectodysplasin-A, the protein encoded by the EDA gene, is a Type II transmembrane protein that forms a collagen triple helix, and may function in cell-cell or cell-matrix interactions at an early point in the development of ectodermal appendages. The EDA gene exhibits a complex hierarchical pattern of regulation, with at least three regions of the promoter responsible for successively more specific levels of control. A first level includes two Sp1 sites near the start site of the gene that drive basal transcription. Upstream regulatory elements of the second and third levels are described here. Level 2, centered at nt-369, contains a binding site for the Lef-1 transcription factor. In co-transfection studies Lef-1 and b-catenin expression plasmids stimulate transcription from the EDA promoter 9-fold in HeLa cells and 7-fold in HaCaT keratinocytes. Mutations in the Lef-1 binding site, gel shift, and supershift experiments confirm that Lef-1 binds specifically to the EDA promoter and is required for full activation of EDA gene expression. Level 3 is a complex enhancer region between nt-673 and nt-550 containing three potential transcription factor-binding sequences within two areas crucial for enhancer activity. Two of the sequences are consensus binding sites for the GATA and Nkx-2 families of transcription factors, which are key regulators of developmental gene expression. The third potential site is a sequence found in the downstream enhancer region of the EGF Receptor gene, to which no known class of proteins binds. Gel shift crosslinking studies implicate four enhancer-binding proteins, each of which has been partially purified by ion exchange and is now being isolated by DNA affinity chromatography. The results indicate that in addition to auxiliary transcription factors, both major pathways classically implicated in epidermal formation (*Wnt* and EGFR) participate in the integration of the EDA gene in skin development.

**Identification of a Pea3 responsive element in the *wt1* tumour suppressor gene promoter.** *M.T. Discenza<sup>1</sup>, J. Pelletier<sup>1,2</sup>*. 1) Biochemistry, McGill University, Montreal, Quebec, Canada; 2) McGill Cancer Center, McGill University, Montreal, Quebec, Canada.

*Wilms' tumour 1 (wt1)* is a tumour suppressor gene and transcription factor shown to be important for kidney development. Members of the Ets (E26 transformation specific) family of transcription factors are believed to be involved in the regulation of epithelial-mesenchymal interactions during organogenesis, such as during branching morphogenesis in the kidney. The Ets family member polyomavirus enhancer activator 3 (Pea3) and Wt1 have overlapping expression profiles in the mesenchymal compartment of the developing kidney. Analysis of the *wt1* promoter for consensus Pea3 recognition sequences revealed potential binding sites at positions -1019, -864, -696, -425 and +78 with respect to the major start site of transcription. Transfection assays were done using a CAT reporter vector containing the *wt1* promoter together with a Pea3 expression vector. Results from transient transfections in Chinese hamster ovary (CHO) cells revealed that Pea3 is able to transactivate the *wt1* promoter. Progressive 5'-end deletions of the *wt1* promoter were constructed extending to positions -910, -733 and -449. These *wt1* promoter-reporter gene constructs were unresponsive to Pea3 transactivation. Similar experiments were performed with 293 human embryonic kidney cells and comparable results were obtained. This data indicates that the Pea3 responsive element in the *wt1* promoter is located in the vicinity of the consensus Pea3 binding site at position -1019. *In vitro* translation of Pea3 in rabbit reticulocyte lysate yielded a protein of 66 kDa. In an electrophoretic mobility shift assay (EMSA), this Pea3 protein bound to an oligonucleotide containing the Pea3 consensus binding site located at position -1019 of the *wt1* promoter. These preliminary results suggest that Pea3 may be a regulator of *wt1* gene expression during kidney development.

**Interaction between SOX10, PAX3 and MITF, three genes altered in Waardenburg syndrome.** N. Bondurand<sup>1</sup>, V. Pingault<sup>1</sup>, D.E. Goerich<sup>2</sup>, N. Lemort<sup>1</sup>, E. Sock<sup>2</sup>, C. Le Caignec<sup>1</sup>, M. Wegner<sup>2</sup>, M. Goossens<sup>1</sup>. 1) Genetique Moleculaire et Physiopathologie, INSERM U468, et Laboratoire de Biochimie et Genetique Moleculaire, AP-HP, Hopital Henri Mondor, 94010 Creteil Cedex, France; 2) Zentrum fur Molekulare Neurobiologie, Universitat Hamburg, Martinistr. 52, 20246 Hamburg, Germany.

Waardenburg syndrome (WS) is an autosomal dominant disorder with an incidence of 1 in 40 000 that manifests with sensorineural deafness and pigmentation defects. It is classified into four types depending on the presence or absence of additional symptoms. WS1 as well as WS3 are due to mutations in the *PAX3* gene whereas some WS2 cases are associated with mutations in the *MITF* gene. The WS4 phenotype can result from mutations in the endothelin-B receptor gene (*EDNRB*), in the gene for its ligand, endothelin-3 (*EDN3*), or in the *SOX10* gene. *PAX3* has been shown to regulate *MITF* gene expression. The recent implication of *SOX10* in WS4 prompted us to test whether this transcription factor, known to cooperate *in vitro* with *PAX3*, is also able to regulate expression from the *MITF* promoter. Here we show that *SOX10*, in synergy with *PAX3*, indeed strongly activates *MITF* expression in transfection assays. Detailed analyses revealed that *PAX3* and *SOX10* interact directly by binding to a proximal region of the *MITF* promoter containing binding sites for both factors. Moreover, *SOX10* or *PAX3* mutant proteins fail to transactivate this promoter, providing further evidence that the two genes act in concert to directly regulate expression of *MITF*. Finally, *in situ* hybridization experiments carried out in the *Dom* mouse, confirmed that *SOX10* dysfunction impairs *Mitf* expression as well as melanocytic development and survival. These experiments, which demonstrate an interaction between three of the genes that are altered in Waardenburg syndrome, could explain the auditory-pigmentary symptoms of this disease.

**Transcriptional regulation of the *GPC3* gene in embryonal tumors.** G. Boily<sup>1</sup>, Z. Saikali<sup>1</sup>, S. Ouellet<sup>2</sup>, R. Drouin<sup>2</sup>, D. Sinnett<sup>1</sup>. 1) Service d'Héματο-Oncologie, Centre de Recherche, Hôpital Sainte-Justine, Université de Montréal, Montréal, Canada; 2) Unité de Recherche en Génétique Humaine et Moléculaire, Pavillon Saint-François-d'Assise, Université Laval, Québec, Canada.

We have previously shown that the *Glypican 3* (*GPC3*) gene was expressed in embryonal tumors, including neuroblastoma (NB), Wilms' tumor (WT), but not medulloblastoma. *GPC3* is an X-linked gene that is almost exclusively expressed in embryonal tissues. We propose that *GPC3* could play a role in the etiology of embryonal tumors. To understand the mechanisms regulating the expression of this gene, we performed DNA methylation studies and *in vivo* footprinting analysis in the promoter region. Southern Blot and PCR-derived methylation assays were used to assess the methylation status of the *GPC3* promoter in genomic DNA from both normal and tumoral cells. In normal cells, we found that the methylation patterns did not correlate with the expression but rather with the gender (absence of methylation in male, partial methylation in female). Except for a few cases, similar methylation patterns were observed in tumor cells. These results suggest that DNA methylation of the promoter region plays little or no role in the transcriptional repression of the *GPC3* gene and that the partial methylation observed in females is probably linked to the inactive X chromosome. To determine whether transcription factors (TF) could be involved in the control of the expression of *GPC3*, we performed *in vivo* footprinting analysis in order to map putative TF binding sites in the promoter region. Two NB cell lines, SJNB-7 (expressing *GPC3*) and SK-N-FI (not expressing *GPC3*), both derived from males, were treated with dimethyl sulfate (DMS) and UV light (UVC). The presence of protected or hypersensitive regions was then revealed by ligation-mediated PCR (LM-PCR). Several footprints were found and many of them were shared by both cell lines. However, some footprints were specific to the expressing cell line (SJNB-7), but not the opposite. These results suggest that the transcriptional activity of *GPC3* requires the presence of a number of specific TFs at the promoter level.

**Transcriptional regulation of the LDL receptor-related protein (LRP).** *P. Greiser<sup>1</sup>, S. Schulz<sup>1,3</sup>, G. Birkenmeier<sup>2</sup>, U. Schagdarsurengin<sup>1</sup>, E. Archoukieh<sup>1</sup>, U. Mueller-Werdan<sup>3</sup>, K. Werdan<sup>3</sup>, I. Hansmann<sup>1</sup>, C. Glaeser<sup>1</sup>.* 1) Inst. of Human Genetics, Univ. Halle, Halle, Germany; 2) Inst. of Biochemistry, Univ. Leipzig, Leipzig, Germany; 3) Dep. of Internal Med., Univ. Halle, Halle, Germany.

LRP, a multifunctional cell receptor is one of the most interesting candidate genes for degenerative cellular processes like Morbus Alzheimer, Parkinson and atherosclerosis. Methods: We investigated the human intraindividual (10 subjects, withdrawal once a week over a period of 4 weeks) and the circadian variation of LRP-mRNA-level (5 subjects, withdrawal at 8 am, 12 am and 4 pm) in native monocytes from healthy volunteers, respectively, by competitive RT-PCR and tested the influence of a novel promoter polymorphism (89 male subjects), and the effect of the adipocyte-derived hormone leptin (100 ng/ml for 24 hours) and the cytokine TGF- $\beta$ 1 (5 ng/ml for 24 hours) on mRNA-expression (cell lines). Results: The measured intraindividual LRP-mRNA-level remained relatively constant regardless age or gender (SD: 0.12). The circadian rhythm of LRP-transcription showed gender specific differences: the increase during the day in female probands may be due to a sex hormone specific regulation. The males did not show such a remarkable circadian variation. The promoter mutation P C-25G (creation of a new binding site for the universal transcription factor SP1) led to a significant increase of the individual message expression: 149 vs. 110 ag/cell ( $p < 0.048$ ). In all cell lines leptin had an upregulating influence on LRP-mRNA expression: endothelial cells - 11.8 to 24.8 ag/cell, monocytes (Mono-Mac-6) - 283.2 to 449.5 ag/cell, fibroblasts from skin - 1825 to 2898 ag/cell, fibroblasts from chorion - 1348 to 1544 ag/cell and keratinocytes (HaCat) - 438.7 to 481.6 ag/cell. Different effects on mRNA-level were measured after administration of TGF- $\beta$ 1: carcinoma cell lines (downregulation: AsPc-1- 131 to 107 ag/cell, upregulation: LNCAP - 51 to 137 ag/cell, PC-3 - 181 to 652 ag/cell, DU-145 - 381 to 472 ag/cell) and skin fibroblasts (upregulation: 2754 to 8423 ag/cell). Our results suggest a complex transcriptional regulation of this multifunctional cell receptor in man.

**The tissue-specific LMX1B gene is associated with a CpG island and is transcribed from a TATA-less promoter.**

*J.A. Dunston, J.D. Hamlington, I. McIntosh.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

The LIM-homeodomain transcription factor, LMX1B, is required for the development of the limbs, eyes, kidneys and portions of the CNS. Patients with heterozygous loss-of function mutations in the LMX1B gene develop Nail Patella Syndrome (NPS), which is typically characterized by nail dysplasia, patellar hypoplasia and elbow dysplasia. The severity of the phenotype varies greatly and can include nephropathy and Open Angle Glaucoma. It is hypothesized that the variation in severity reflects the level of LMX1B transcript/protein at critical points in development; therefore, we are interested in identifying cis-acting elements that control the spatio-temporal expression of LMX1B. Two regions of the human LMX1B gene were cloned for further study: 1) the 5' end of the gene including 5'flanking sequence and 2) the 3'UTR. 3.5 kb of sequence containing the putative transcription start site of the human LMX1B gene was subcloned from BAC 265A2. The insert was sequenced and tested for promoter activity in fibroblast cells. The TATA-less promoter directed transcription of a luciferase reporter gene at a level 10-fold greater than the empty vector. Additional sequence was obtained by searching the NCBI-htgs database. 15.5 kb of 5' sequence was analyzed for the presence of CpG islands with the GRAIL v1.3 program. In a GC-rich region spanning approximately 4 kb, multiple CpG islands were identified. The longest island (1.4 kb) spans exon 1 of the LMX1B gene. ESTs mapped to this region suggest that the CpG island is interrupted by a gene transcribed from the opposite strand relative to LMX1B. The CpG islands and EST sequence were conserved in mouse sequence obtained from the NCBI-htgs database. The terminal exon of the LMX1B gene was cloned from BAC 265A2 and sequenced. From this sequence, primers were designed for 3'RACE. RACE products indicate a 3'UTR of 4.57 kb. The 3'UTR sequence was searched for the presence of known motifs using the UTRscan program. No known motifs were detected. Identification of both human and mouse sequence containing the LMX1B promoter and 3'UTR will allow for comparative and functional analysis of cis-regulatory elements.

**Analysis of the human alpha-synuclein promoter.** *O. Chiba-Falek*<sup>1</sup>, *B.M. Orrison*<sup>1</sup>, *J.W. Touchman*<sup>2</sup>, *A. Dehejia*<sup>3</sup>, *M.H. Polymeropoulos*<sup>3</sup>, *R.L. Nussbaum*<sup>1</sup>. 1) GDRB, NHGRI, NIH, Bethesda, MD; 2) NISC, NIH, Gaithersburg, MD; 3) Novartis Pharmaceuticals, Gaithersburg, MD.

Mutations in the alpha-synuclein gene have been implicated in familial Parkinson's Disease (PD). In order to study the structure and regulation of the human alpha-synuclein gene, we sequenced the entire mouse and human genes, including ~20 kb upstream of the gene. A comparison between the human and the mouse sequence revealed several regions of sequence similarity over 11 kb upstream of the gene. We cloned from human PAC 27M7 a 10.7 kb fragment upstream of the translational start site, including the first two untranslated exons and the first intron, and used restriction sites to construct 7 additional constructs extending varying distances upstream of the gene; all 8 constructs were inserted in a luciferase expression vector and transfected into 293T and the neuroblastoma cell line SH-SY5Y. The shortest fragment, 400bp upstream of the transcriptional start site, was found to be sufficient for transcription in both cell lines. The other constructs led to variable expression levels, with some showing maximum expression and others showing nearly complete extinction of expression. There were also differences in relative expression level for each construct between the cell lines. These results illustrate that the different regions of the promoter might contribute to tissue specific up/down regulation of alpha-synuclein. Next, we constructed an alpha-synuclein "minigene" expression vector in which expression of the alpha-synuclein cDNA was driven by the full length 10.7 kb upstream region. Upon transient transfection into 293T cells, the minigene was transcribed and translated with high efficiency into the alpha-synuclein protein. This minigene provides an opportunity to study the regulation of alpha-synuclein expression both in cultured cells and in whole animals.

**Nucleosomes in the *HPRT* promoter region are translationally phased on the active X chromosome and rotationally phased on the inactive X chromosome.** *C. Chen*<sup>1,2</sup>, *T.P. Yang*<sup>1,2,3</sup>. 1) Dept Biochemistry & Molecular Biology; 2) Center for Mammalian Genetics; 3) Department of Pediatric Genetics, University of Florida, College of Medicine, Gainesville, FL.

Differential chromatin structure is one of the hallmarks distinguishing active and inactive genes. For the X-linked human hypoxanthine phosphoribosyl transferase gene (*HPRT*) this difference between alleles on the active and inactive X chromosomes is evident in both the general DNase I sensitivity and hypersensitivity of the promoter. Here we show that the differential chromatin structure of the active and inactive *HPRT* promoters involves alterations in nucleosomal positioning. Translationally positioned nucleosomes occupy the same DNA sequence in all cells, whereas rotationally positioned nucleosomes contact the same positions on the DNA helix in all cells. Using micrococcal nuclease digestion, we find translationally positioned nucleosomes on the active promoter except over a 350 bp region that includes all of the known transcription factor binding sites as well as the transcription initiation sites. Over this region, nucleosomes are either altered or absent based on increased sensitivity to both micrococcal nuclease and DNase I. In contrast, no translational positioning is evident on the inactive promoter and both DNase I and micrococcal nuclease hypersensitivity are absent. We also examined rotational positioning of nucleosomes in the *HPRT* promoter by high resolution DNase I *in vivo* cleavage analysis. This analysis reveals a strong 10 bp-laddering pattern consistent with rotationally positioned nucleosomes on the inactive minimal promoter but not on the active minimal promoter. In summary, we show differential nucleosomal positioning between the active and inactive alleles of the *HPRT* promoter, with the active promoter exhibiting translational positioning and the inactive promoter exhibiting rotational positioning.

**Role of Human Chromosome Associated Protein-H (hCAP-H) in Chromatin Condensation.** *W. He<sup>1</sup>, S. Colicos<sup>1</sup>, I.I. Ouspenski<sup>2</sup>, J.W. Belmont<sup>1</sup>, O.A. Cabello<sup>2</sup>.* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Department of Molecular and Cellular Biology, Baylor College of Medicine.

In the normal progression of the cell cycle, compaction of DNA from nucleosomes to high order loop structures is necessary for congression of condensed chromosomes in metaphase and for segregation of chromosomes in anaphase. Chromosome condensation requires the activity of a multimeric protein complex called 13S Condensin. Condensin is comprised of CAP-C and CAP-E ATPases that directly bind DNA and catalyze bending and supercoiling, and three other components of unknown function, CAP-D2, CAP-G, and CAP-H. When mutated, the *Drosophila* homolog of CAP-H, barren, gives a cellular phenotype suggesting failure of chromatid decatenation. The purpose of this project is to investigate the functional role of human CAP-H in mitosis and its more general roles in chromatin remodeling. One ongoing strategy for the analysis of mammalian CAP-H function consists of its targeted inactivation in mouse embryonic stem cells. A second approach is the elucidation of the functional domains of hCAP-H. Deconvolution microscopy indicates that in mitosis EGFP-tagged hCAP-H localizes in subchromosomal domains identical to those detected by immunofluorescence using anti-hCAP-H antibodies. Moreover, EGFP-hCAP-H (as well as CAP-E and CAP-C) localizes to the interphase nucleolus. Interspecies comparisons of CAP-H homologs highlight four conserved peptide motifs. Eight EGFP-tagged mutant forms of hCAP-H were prepared that selectively delete these conserved domains. These mutants have been studied for subcellular localization and effect on cell cycle progression. The N terminal domain of hCAP-H contains signals for nuclear localization not detected by motif analysis. The C terminal domain is required for localization to the nucleolus. Overexpression of full length hCAP-H leads to mitotic arrest, failure of progression to G2/M, and increased apoptosis in HeLa cells. Overexpression of C terminal domain mutants has a similar effect. Continuing characterization of these mutants and their relevant protein interactions should allow identification of the critical interaction domains required for Condensin function.

**Molecular cloning and expression analysis of PAQ1/2, a transcriptional cofactor gene deleted in DiGeorge and velocardiofacial syndromes.** E. CONTI<sup>1,4</sup>, G. MITTLER<sup>2</sup>, F. AMATI<sup>1</sup>, L. BERTI<sup>2</sup>, M. BENGALA<sup>1</sup>, A. BOTTA<sup>1</sup>, B. DALLAPICCOLA<sup>3,4</sup>, G. NOVELLI<sup>1</sup>, M. MEISTERERNST<sup>2</sup>. 1) Dept. of Biopathology, University of Rome Tor Vergata, 00133 Rome, Italy; 2) Immunology of the GSF, Dept. for Proteinbiochemistry, D-81377, Muenchen; 3) Dept. of Exp. Med. and Pathology, La Sapienza University of Rome, I-00141 Italy; 4) CSS Mendel, Rome, Italy.

PAQ1/2 (PC2 associated Q-rich protein 1/2) is a component of a large multiprotein complex named PC2, highly related to the coactivator complexes TRAP/SMCC and DRIP/ARC. PAQ1/2 was identified during PC2 characterization by using a monoclonal antibody (IF8) directed against a polyglutamine stretch. PAQ1/2 protein is encoded by a gene of 79 Kb organized in 17 exons expressing a cDNA of 2241 bp. PAQ1/2 gene maps within the deletion interval 4 of the DiGeorge/Velocardiofacial (DGS/VCFS) critical region on chromosome 22q11.2. PAQ1/2 protein is constituted by 746 aminoacids and displays proline-rich domains, its calculated MW is 82,3 kDa while the apparent MW on SDS-PAGE is 105-107 kDa. The gene is deleted in the majority of patients with hemizigosity of the region resulting in haploinsufficiency of the product. PAQ1/2 is ubiquitously expressed in all investigated human tissues (RNA Master blot, Clontech). RT-PCR analysis revealed the presence of two different mRNA isoforms both in fetal and adult tissues. TRANSFAC and TFD analysis revealed that the 5' portion of the gene containing multiple transcription factor binding sites including, AP-2, Sp1, TFIID, GATA-1, GATA-2 and the absence of a TATA box. PAQ1/2 is a bridging factor for a variety of human regulatory proteins and could have an architectural role in the PC2-mediator complex; therefore, it is an excellent candidate for concentration-dependent perturbations of gene expression during development. Work supported by Telethon grants (E.723 and 364/bi).

**Analysis of the transcriptional regulation of the human *HFE* gene.** C. Mura, G. Le Gac, C. Ferec. Lab Biogenetique, INSERM, CHU, UBO, Brest, France.

Hereditary hemochromatosis (HHC) is the most common iron metabolism disorder in man. *HFE* gene, clearly involved in HHC, encodes a protein which interacts with the transferrin receptor (TfR) and should play a role in the regulation of iron uptake. *HFE* is widely expressed but the mechanism of the transcriptional regulation of the human *HFE* gene still remains to be clarified. The goal of the present study was to identify the *cis*-acting elements and the *trans*-acting factors involved in transcriptional regulation of the *HFE* gene expression. Transient transfection experiments were performed using a series of luciferase reporter pGL3 plasmid constructs containing various *HFE* 5'-flanking sequence. The *HFE* promoter-driven luciferase reporter gene activity was determined in three different human cell lines: hepatoma HepG2 cells, colon adenocarcinoma HT29-19A cells and epithelial HeLa cells. The *HFE*-promoter constructs displayed the greatest activity in HepG2 cells, followed by a significant activity in HT29-19A cells. The analysis of *HFE*-driven luciferase reporter gene activity indicated that the region extending from -253 to -6 relative to the first coding nucleotide contains a basal promoter region, and the -555/-6 segment showed the maximum activity. Cotransfection studies with *HFE*-promoter deletion constructs and vectors expressing transcription factors showed that the ubiquitous Sp1 and the liver-enriched protein GATA-1 can transactivate *HFE*-directed gene transcription with a maximum of 7.1-fold and 8.7-fold increase, respectively. This stimulating effect can be ascribed to their functional interaction with the presence of consensus binding sites in the *HFE* gene promoter; thus its expression appears to be regulated in a tissue-specific manner.

**Direct transactivation of type X collagen by CBFA1 contributes to abnormal endochondral ossification in cleidocranial dysplasia.** Q. Zheng, G. Zhou, Y. Chen, B. Lee. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Mutations in the transcription factor *CBFA1* (core binding factor), a nonredundant determinant of osteoblast cell fate, cause the dominantly inherited cleidocranial dysplasia (CCD). CCD is characterized by hypoplastic clavicles, delayed closure of fontanelles, dental anomalies, and delayed skeletal development. It also involves long bones, especially in the hands and feet. Interestingly, *Cbfa1*<sup>-/-</sup> mice have been shown to exhibit a defect in chondrocyte maturation. Based on these observations, we hypothesized that *Cbfa1* participates in chondrogenesis by activating type X collagen gene expression. The type X collagen gene (*Col10a1*) is specifically expressed in hypertrophic chondrocytes and mutations in *Col10a1* cause Schmid-type metaphyseal dysplasia. It was previously shown that 1.6 kb of the chicken *Col10a1* promoter in combination with the first intron contained elements sufficient to confer tissue specificity in transgenic mice. However, the corresponding sequence of murine type X collagen gene promoter failed to confer tissue-specific expression. We characterized a larger 4 kb promoter sequence in *Col10a1* both in cells and in transgenic mice. This 4 kb promoter drove expression of a *LacZ* reporter weakly, but specifically to the hypertrophic chondrocytes in E15.5 and E18.5 transgenic mouse embryos. Sequence analysis of this promoter showed three potential CBFA1 binding sites at -3.5 kb (A), -2.4 kb (B) and -1.5 kb (C) prior to the transcription start site. Gel shift assays confirmed that they all bind to full length CBFA1 and its DNA binding runt domain. Furthermore, in transient transfection in COS-7 cells, CBFA1 transactivates a reporter gene which contained eight copies of the "A" enhancer element and a 50bp *Col10a1* minimal promoter upstream of the luciferase gene. Taken together, our *in vitro* and *in vivo* studies of mouse type X collagen suggest that its 4 kb promoter can confer tissue specificity and CBFA1 directly transactivates type X collagen gene. Hence, *CBFA1* mutations result in decreased *Col10a1* expression explaining the long bone dysplasia in CCD.

**The Dp71 promoter activity is down-regulated during muscle cell differentiation.** *M. Bermudez<sup>1</sup>, C. Montanez<sup>1</sup>, P. Gomez<sup>1</sup>, D. Yaffe<sup>2</sup>, B. Cisneros<sup>1</sup>.* 1) Department of Genetics and Molecular Biology, CINVESTAV-IPN, Mexico city 07360, Mexico; 2) Department of Cell Biology, The Weizmann Institute of Science, Rehovot 76100, Israel.

The Dp71 protein is a product of the Duchenne muscular dystrophy gene, which is present in many cell types and tissues. Detectable levels of Dp71 are found in non-differentiated muscle cells, but not in mature muscle cells. The Dp71 promoter is considered a "housekeeping" promoter because it lacks TATA and CAAT boxes, but contains several Sp1 binding sites and a putative initiator element that overlaps with the transcription start site. To study the regulation of the Dp71 promoter along muscular differentiation, a series of plasmids, carrying the wild type or different deleted promoter sequences driving the chloramphenicol acetyl transferase gene (CAT) were transiently transfected into C2C12 cells. Cells were differentiated by changing then to differentiation medium. Interestingly, the activity of the Dp71 promoter decreases 70% during muscle cell differentiation. The promoter region responsible for such regulation was mapped to 244 base pair fragment, which maintains the three Sp1 binding sites. Gel shift experiments prove that indeed Sp1 transcription factor binds to the Dp71 promoter. Since Sp1 transcription factor is developmentally down-regulated during muscle differentiation, it is possible that its diminish causes the drop of the Dp71 promoter activity. To test this hypothesis, transfection assays with a plasmid overexpressing Sp1 factor are currently in progress.

**Up regulation of the RET gene expression by histone deacetylase inhibitor sodium butyrate: hints to the gene physiologic regulation and applications for mutations screening.** *G. Patrone<sup>1</sup>, F. Puppo<sup>1</sup>, P. Griseri<sup>1</sup>, G. Romeo<sup>2</sup>, I. Ceccherini<sup>1</sup>, R. Ravazzolo<sup>1</sup>.* 1) Molecular Genetics Lab., G.Gaslini,Genova,Italy; 2) IARC, Lyon, France.

Histone acetylation is emerging as a major mechanism thought to modulate gene expression by altering the accessibility of transcription factors to DNA. Drugs inhibiting histone deacetylases have been shown to relieve repression of specific genes. In a previous study on the regulation of the RET gene expression, we showed that this gene transcription is cell-line specific, characterised the functional domains of its minimal promoter, and collected evidence that Sp1 is the main activator of RET promoter. This sequence did not exhibit cell-line specific activity. The apparent paradox of regulated levels of mRNA in the context of a housekeeping type promoter might be explained by the peculiar position of RET on chromosome 10, close to the third pericentromeric satellite. Under the assumption that chromatin conformation of this region might play a role in regulating RET transcription, we have started addressing the question of chromatin structure and histone modification within the RET locus. In this report we show that histone deacetylase inhibitor sodium butyrate can upregulate RET mRNA levels in both expressing and non-expressing cells. Reporter constructs containing the RET promoter display a 20 - 40 fold activation upon sodium butyrate treatment. We envisage promoter accessibility can be modulated by histone acetylation, and ubiquitous Sp1 might be subjected to tissue specific activity modulation. RET germline mutations account for 10-40% of patients affected with Hirschsprung disease (HSCR), a complex genetic disorder affecting intestinal innervation. Analysis of RET mRNA from HSCR patients has been hampered by the lack of this gene expression in blood cells. Sodium butyrate treatment has enabled us to analyse cDNA derived from blood cells: we report examples of detection of anomalous transcripts, defective gene expression in HSCR patients, as well as nucleotide substitutions in the coding region. Thus we have improved our potential to investigate the molecular basis of the disease.

**Identification of a silencer element of the human acid maltase gene in normal human fibroblast cells and Glycogenesis type II fibroblast cells.** *B. Yan, P. Plotz.* ARB, NIAMS/NIH, Bethesda, MD.

Acid maltase (acid alpha-glucosidase, GAA) is a lysosomal enzyme, deficiency of which results in a recessively inherited disorder-Glycogenesis type II. In our previous work, a 25bp silencer element and its binding transcriptional factors (Hes-1 and YY1) were identified in Hep G2 cells. We have now performed transient transfection experiments in normal human fibroblast cells (CRL1513) and fibroblast cells from an adult patient carrying a point mutation of the GAA gene at position -13 (t-g) relative to the intron1/exon2 boundary in intron 1. A series of intron 1 fragments were cloned in both orientations upstream of a reporter gene, CAT, under the control of a thymidine kinase (TK) gene promoter. Deletion analysis identified a silencer in a 25bp element which is located between 1711bp and 1735bp relative to the exon 1/intron 1 boundary. The significant repressive effect on TK promoter activity was 35-50% in both orientations in both normal and mutant fibroblast cells. The element is upstream of the previous silencer found in Hep G2 cells, and it is inactive in Hep G2 cells. Electrophoresis mobility shift assay (EMSA) showed that three proteins specifically bound to the element. Site-directed mutagenesis and functional analysis indicated that a 5bp motif (GGTAC) was essential to the silencer function. Mutation of the motif abolished the repressive effect entirely in both normal and mutant fibroblast cells. The precise identification of the responsible proteins binding to the element is under investigation. The data may be helpful for designing a therapy to overcome the most common genetic defect in adult patients with the disease: reduced production of structurally normal enzyme caused by the mutation (-13 t-g) that reduces the efficiency of normal splicing.

**Analysis of the role of the branchpoint A of CFTR intron 8 upon alternative splicing.** *T. Hefferon, E. Niemitz, M. Egan, G. Cutting.* Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD.

Mis-splicing of CFTR transcripts, which results in reduced levels of full-length mRNAs, has been associated with cystic fibrosis, atypical CF, and congenital bilateral absence of the vas deferens (CBAVD). The 5T allele at the splice acceptor of intron 8 of the CFTR gene is found in 10% of the general population and has been shown to contribute to the aberrant splicing of exon 9. The 5T allele displays variable penetrance which has been hypothesized to be due to the distance of the branchpoint A from the 5T mutation; the intervening sequence consists solely of a TG dinucleotide repeat. To investigate the role of the branchpoint A in alternative splicing at this locus, we created a minigene construct containing parts of exons 8 and 10 and all of exon 9, including flanking intronic sequences, fused in-frame to an ornithine-amino-transferase (OAT) cDNA, and transfected it into mammalian cells. Splicing efficiency was evaluated using RT-PCR and capillary electrophoresis; we controlled for overamplification of shorter products by use of a correction factor determined by the amplification of a control plasmid containing one copy each of exon 9- and exon 9+ targets. HEK293 cells transfected with the minigene construct carrying the 9T allele spliced approximately 99% of minigene transcripts fully (n=3), whereas one carrying a shorter polypyrimidine tract, the 5T allele, spliced with only 70% efficiency (n=3). These results replicate observations of transcripts derived from 9T and 5T alleles in vivo and support the use of this system as a model for studying splicing at this locus. Then, to evaluate the role of the branch A in alternative splicing, we mutated the putative branch A to a G (on a 9T background) in the minigene construct, and found that splicing of transcripts derived from this plasmid was unperturbed (97% efficiency, n=2). We suggest three possible explanations for these observations: 1) use of an alternative branchpoint A nearby when the primary branchpoint has been eliminated; 2) use of the substituted G as a novel branchpoint target, or 3) the putative branchpoint A is not involved in splicing of exon 9.

**An RBMX-like gene selectively expressed in testis and located at 9p24.** *P.A. Lingenfelter<sup>1</sup>, H.E Hoekstra<sup>2</sup>, D.L. Delbridge<sup>3</sup>, J.A. Marshall Graves<sup>3</sup>, C.M. Disteche<sup>1</sup>.* 1) Dept Pathology, Univ Washington, Seattle, WA; 2) Dept of Zoology, University of Washington, Seattle, WA; 3) Dept of Biochemistry and Genetics, La Trobe Univ., Melbourne, Australia.

RBMY is an X-linked gene homologous to RBMY, a Y-borne gene implicated in male fertility. Both genes encode for proteins involved in RNA splicing. We previously reported that several RBMX-like sequences existed in the human genome. These copies are all processed retroposons. Some of the copies are expressed in different tissues. We report here that one RBMX copy is located at band 9p24 and is selectively expressed in testis and to a lesser extent in brain. This copy of RBMX is conserved in primates. Interestingly the region of chromosome 9p24 where this gene is located is deleted in patients with 46,XY sex reversal. Although DMRT1 has been proposed as a candidate for this type of sex reversal, the testis-specific RBMX-like sequence we describe may also play a role in normal sexual development, specially in view of its potential role in tissue-specific splicing. Alternative splicing has been shown to play a critical role in sex determination of model organisms such as *Drosophila*. Another role for the RBMX-like gene at 9p24 would be to provide RBMX-like expression in the testis when RBMX is inactivated on the X chromosome. This would be analogous to other X-linked genes which have processed copies on autosomes which are selectively expressed in testis.

**Nramp2 ANALYSIS IN HEMOCHROMATOSIS PROBANDS.** *G. LE GAC*<sup>1</sup>, *C. MURA*<sup>2</sup>, *A.Y. MERCIER*<sup>1</sup>, *O. RAGUENES*<sup>3</sup>, *C. FEREC*<sup>1</sup>. 1) EFS-Bretagne, Brest, France; 2) UBO, Brest, France; 3) CHU, Brest, France.

The mechanism that leads to iron overload in hereditary hemochromatosis (HHC) is not yet fully understood and other genes than HFE may be involved. Nramp2 is an intestinal iron transporter, upregulated by dietary iron deficiency, and which also co-localizes with transferrin in recycling endosomes. The purpose of the present study was to analyse the coding region of the Nramp2 gene in hemochromatosis probands (HC) without any HFE mutation on both chromosomes. RT-PCR was designed to encompass the entire coding region of the Nramp2 gene and amplification was achieved from peripheral blood leukocytes of fourteen HC probands and eighteen control subjects. Then, sequencing analysis of the RT-PCR products allowed us to detect one single nucleotide polymorphism (a TC change at nucleotide 1254 in the cDNA) presumably not associated with HHC, but no mutation. On the other hand, we identified seventeen splicing forms of the Nramp2 mRNA: five of them corresponded to exons skipping and the twelve others to utilisation of cryptic splicing sites. Systematic genomic DNA sequencing of the corresponding exon-intron borders and the sequences surrounding the cryptic splicing sites did not reveal any mutation liable to result in aberrant splicing. Thus, these seventeen splice variants are likely alternative splicings. Eight of them were especially detected in most HC probands and control subjects. They corresponded to activation of cryptic splicing sites, which match consensus splicing sequences, between exons 3 and 4. This indicates existence of an important splicing instability in this region. In conclusion, our study did not give evidence for the involvement of the Nramp2 gene in hereditary hemochromatosis. However, the biological significance of the splicing instability revealed between exons 3 and 4 is unclear and require thorough investigations to be understood.

**An IVS32+1G®A mutation in a type I collagen gene, *COL1A2*, results in use of a rare AT/AC splice system and may ameliorate the osteogenesis imperfecta phenotype caused by exon-skipping.** C.D. Kuslich, P.H. Byers. Dept Pathology, Univ Washington, Seattle, WA.

The type I collagen gene *COL1A2*, like most human genes, uses the U2 spliceosome and 5' GT / 3' AG splice junctions in each intron. A mutation of any of these four nucleotides leads to aberrant splicing. We identified a substitution that creates a 5' AT donor site and leads to use of a cryptic 3' AC acceptor site in IVS32 of the *COL1A2* gene, in an individual with moderately severe osteogenesis imperfecta (OI type III/IV). Total cellular and nuclear RNA were isolated separately from cultured dermal fibroblasts cultures, DNase I treated, and cDNA was synthesized. The *COL1A2* transcript was amplified in four overlapping fragments by RT-PCR using total cellular RNA. In a fragment spanning exons 31-44, the expected 1038 bp fragment and a 930 bp product, which lacked exon 32, were seen. Genomic DNA was heterozygous for an IVS32+1G®A mutation. When nuclear derived cDNA was amplified with primers in exons 28 and 33 an additional heteroduplex was seen that contained both the normal sequence and one with the last 6nts of IVS32 inserted (TTTCAG). This insertion was created by use of the new 5' splice site, ATACGT, and a cryptic 3' splice site TAC, adjacent to the 6 bp insertion. AT-AC intron termini are used in a minor U12 splicesomal pathway, which has stringent intron sequence requirements not met by the *COL1A2* mutant allele. Two human genes, *SCN4A* and *SCN5A*, use U2-dependent AT-AC intron termini. The 5' splice site sequence for *SCN5A* (AG/ATACGTAG) differs by one nucleotide from the new *COL1A2* sequence (AG/ATACGTGT). These findings imply that a rare AT-AC spliceosome pathway removes all but 6nts of IVS32 from some transcripts diminishing the amount of the exon 32-skipped product, which may ameliorate the expected severe outcome of this mutation. Use of the AT-AC splice sites in this intron in addition to exon 32 skipping may indicate IVS32 is quickly removed promoting exon 32 skipping for many transcripts while for others IVS32 is spliced slower permitting the use of the of the AT-AC mechanism. Similar mutations in other genes may be more common than expected. (NIH AR21557, AR41223).

**Alternative splicing of DNA Polymerase  $\beta$  mRNA in normal tissues and bladder cancer.** *T.E. Thompson<sup>1</sup>, P.K. Rogan<sup>2</sup>, J.I. Risinger<sup>1</sup>, J.A. Taylor<sup>1</sup>.* 1) Lab Mol Carcinogenesis, NIEHS, Research Triangle Park, NC; 2) Sect Med Genet & Mol Medicine, Children's Mercy Hosp, Univ Missouri-Kansas City School of Medicine.

Large intragenic somatic deletions of DNA Polymerase  $\beta$  (POL $\beta$ ) have previously been inferred from analysis of tumor cDNAs. We noticed that the breakpoints of these presumed rearrangements were delineated by exon-exon junctions, which could instead be consistent with alternative splicing. Genomic DNA of bladder tumors and bladder cancer cell lines was screened for mutations. Deletions and somatic mutations were not seen, although 2 polymorphisms were detected. We then analyzed cDNA from the cell lines and a subset of tumors with matched normal tissue. A diverse array of alternative splice variants was found, even within the same samples. Alternative splicing is somewhat more common and variable in bladder cancer cell lines and tumor tissues than in normal bladder. In alternative splicing, the upstream acceptor that is skipped generally exhibits weaker splicing signals than the downstream acceptor site which is selected. Since the sequences of acceptor sites in POL $\beta$  were unaltered, we explored the possibility that differences in splice site strength, ie. information content ( $R_i$ ), could account for the alternative splicing variants. The  $R_i$  values of alternatively spliced and skipped acceptor sites were compared with those of the corresponding constitutively spliced acceptors. In most alternative splicing events (41 of 49 cDNAs; exons 2, 4, 4-6, 9, 2-13, 7-9 or 4-13 skipped), the  $R_i$  value of the acceptor site that was selected exceeded that of the upstream acceptor had splicing been constitutive. Differences between the strengths of these pairs of sites ranged from  $>1.3$  to 36 fold, with the most common variant (lacking exon 2) exhibiting  $> 22.6$  fold difference. By contrast,  $R_i$  values of downstream acceptor sites did not exceed those of the corresponding upstream sites in alternative splicing events where either exons 2-6, 4-5, 5-6, 7-8 or 11 were skipped. Interestingly, 6 of 8 cDNAs derived from these splice forms occurred in tumor cell lines. There appears to be loss of specificity in tumors for alternative splice forms in which splice site strength dictates splice site use.

**Molecular dissection of the Schwann cell specific promotor of the PMP22 gene.** *M. Fontes, D. Saberan-Djoneidi, V. Sanguedolce, N. Levy, E. Passage.* INSERM U491, Medical Genetics and developmentl, Fac de Medecinede la Timone, Marseille Cedex 5, France.

PMP22, one of the major components of myelin, is overexpressed in Charcot-Marie-Tooth type 1A (CMT1A) patients. In an attempt to determine the mechanisms of regulation of the expression of this gene (and potentially to lower its expression in CMT1A patients), we subcloned genomic fragments from the promotor, up to 6 kb, in an expression vector containing the b-galactosidase gene as reporter, and used it in a transfection assay. We determined that only 300 bp upstream of the transcriptional start are sufficient to promote the Schwann cell specific expression of the reporter gene. This minimal promotor seems to be under the control of a silencer element sensitive to cAMP, located between -0.3 kb and -3.5 kb from the start of transcription. We sequenced and analyzed 2 kb of the promotor using computer programs, which have predicted the existence of potential binding sites for transcription factors binding sites, such as CREB (which is probably involved in the response of PMP22 expression to cAMP stimulation) and steroid receptors. Using constructions containing or not the CREB sites, we were able to demonstrate that these sites are involved in the silencing process of the PMP22 promoting activity. Finally, we found a region containing blocks of polymorphic CA repeat, located close to the CREB binding site, which can potentially influence the transcriptional activity of this gene.

**Function of *Distal-less* subfamily isoforms, BP1 and DLX7, in the repression of human b-globin gene.** *S. Fu*<sup>1</sup>, *J.W. Strovel*<sup>2</sup>, *S.B. Haga*<sup>2</sup>, *J. Stamberg*<sup>2</sup>, *P.E. Berg*<sup>1</sup>. 1) Dept. of Biochemistry & Molecular Biology, George Washington Univ Med Ctr, Washington, DC; 2) Div. of Human Genetics, University of Maryland, Baltimore, MD.

Beta Protein 1 (BP1), a new homeobox (HOX) cDNA encoding a transcription factor, appears to be involved in repression of the human b-globin gene. Sequence comparison revealed that BP1 is a HOX gene, which shares the same HOX domain with human *Distal-less* gene DLX7 and DLX4. DLX7 and DLX4 have been mapped to chromosome 17q21-22. In order to explore the possible relationship of BP1, DLX7 and DLX4, we mapped BP1 using fluorescence in situ hybridization (FISH) and PCR. One positive clone was obtained by screening a human bacterial artificial chromosome (BAC) genomic library using a 360bp BP1 unique region cDNA probe. The total BAC genomic DNA was direct-labeled and FISH analysis was performed. The BP1 gene was localized to chromosome 17q by dual hybridization with this probe and a labeled whole chromosome 17 library. To precisely define the map location of BP1, we successfully amplified DLX7 from this BAC clone using PCR. These results indicate that BP1 and DLX7, DLX4 are isoforms since they map to the same locus and exhibit extensive regions of sequence homology. Gel shift analysis of BP1 and DLX7 proteins after *in vitro* transcription and translation shows that they both bind to Silencers I and II located upstream of the b-globin gene. To compare the functions of BP1 and DLX7, we cloned both BP1 and DLX7 open reading frames into eukaryotic expression vectors. Subsequent transfection of BP1 and DLX7 respectively into the human erythroleukemia cell line K562 was carried out to determine the role of DLX7 in b-globin gene expression. Interestingly, contrary to BP1, overexpression of DLX7 does not repress b-globin gene expression. Nevertheless, both BP1 and DLX7 proteins bind to Silencer I and II *in vitro*, but only BP1 shows functional activity *in vivo*. Therefore, further characterization of these isoforms is of significance to the understanding of the control and balance of b-globin gene during early development.

**Spastin, a new AAA protein, binds to a and b tubulins.** *A.C. Azim, A. Hentati, M.F.U. Haque, M. Hirano, K. Ouachi, T. Siddique.* Neurology, Northwestern Medical School, Chicago, IL.

Autosomal dominant hereditary spastic paraplegia (AD-HSP) is a heterogeneous neurodegenerative disorder. This involves progressive and bilateral spasticity of lower limbs. Four genes responsible for this condition have been localized on chromosomes 14q, 2p, 15q and 8q. The SPG4 locus on 2p22 accounts for 40-50 % of AD-HSP families and is caused by mutations in spastin gene. We have identified five novel mutations in spastin gene. Spastin is a 616 amino acid long protein and has homology to AAA family proteins. Spastin also has homology to a known microtubule severing protein, Katanin. In order to address the function of spastin protein we made three spastin-GST-fusion proteins of different lengths and developed a GST-spastin pull down assay using total human platelet protein as the source for a and b tubulin. Bound tubulin was visualized using anti tubulin monoclonal antibodies. The first construct corresponding to amino acid (1-264) binds to tubulin more specifically. The c terminus GST-spastin clone also showed binding to a and b tubulin, suggesting that there are two microtubule binding site in spastin, each located in the two halves of the protein. Glutathione S-transferase was used as a control and showed no binding at all to a and b tubulin. Experiments are underway to explore the specificity and affinity of this interaction. We are also developing reagents to test direct interaction of spastin and tubulin. Spastin also has a consensus nucleotide binding P-loop. Experiments are underway to explore expected nucleotide binding, ATP-ase activity, microtubule severing, and the effect of spastin human mutations on its interaction with tubulin.

**JAG1 missense mutations in Alagille syndrome.** *J.J. Dowhanick-Morrisette, R.P. Colliton, K.A. Lantz, N.B. Spinner.*  
Dept Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

Alagille syndrome (AGS) is a developmental disorder caused by mutations in Jagged1 (JAG1), a cell surface ligand in the Notch signaling pathway. JAG1 interacts with the Notch transmembrane receptor to release an intracellular form of Notch that stimulates transcription. JAG1 mutations are found in 60-70% of AGS patients. The majority of these mutations are protein truncating and 14% are missense mutations, however, no genotype-phenotype correlation has been observed. Over 30 missense mutations have been identified. Twenty are at the N-terminus of the protein, 9 are in the EGF-repeats and 1 is in the cysteine-rich domain. The precise mechanism by which Jagged1 and the Notch receptors interact is unknown. We are studying missense mutations in AGS patients to determine whether they are disease causing and how these single amino changes effect protein function. Four missense mutations (L37S, P163L, R184H, and P871R) were introduced into JAG1 by site-directed mutagenesis, cloned into a retroviral expression vector and expressed in NIH 3T3 cells. In order to test mutant JAG1 function, we used an assay to measure JAG1 induced activation of transcription via release of a Notch sensitive repression complex. In the presence of JAG1 signaling, transcription from the sensitive promoter can be measured. Both JAG1-L37S and JAG1-R184H were unable to activate the Notch signaling system, while P163L and P871R were comparable to wild-type JAG1. Intracellular localization studies demonstrated that L37S and R184H were not present on the cell surface. Furthermore, R184H is abnormally glycosylated which may result in improper trafficking through the ER and Golgi, preventing expression on the cell surface. JAG1-P163L and P871R and wild-type JAG1 were correctly localized. This is consistent with these latter two mutations being normal variants of JAG1. Missense mutations clustered at the N-terminus of Jagged1 may lead to defects in proper targeting of the protein to the cell surface. Studies involving missense mutations located in the EGF-repeats and cysteine-rich domain are in progress and may provide insight into other mechanisms for inactivation of Jagged-Notch signaling.

**Transfer of the complete 2.4 Mb human DMD-gene to mice; expression analysis and crossing with *mdx* mice.** *J.T. Den Dunnen, R.G. Maatman, E.J. De Meijer, B.M. Van Rijn, A.J. Verkerk, G.J.B. Van Ommen.* Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland.

Starting from overlapping YACs, we have reconstructed the full 2.4Mb human DMD gene in yeast. For transfer of the gene to murine LA9 and ES cells we tried two approaches, direct transfer and as a mammalian artificial chromosome (MAC). Assuming that for a functional MAC the DMD gene itself would provide length and replication origins, we have re-modelled the original YAC by adding 150 kb of Y-centromeric DNA, human telomeric sequences and mammalian selectable markers. After yeast spheroplast/mammalian cell fusion clones were obtained of which four LA9 and two ES clones contained all DMD exons. FISH analysis showed that MAC-derived clones often contained extra-chromosomal structures, however, these were present in variable copy numbers and upon non-selective culturing were either gradually lost or integrated. To assess integrity and proper transcription, the full-size DMD clones were analysed by RT-PCR and subjected to MyoD-induced myo-differentiation. Subsequently, transgenic mice were generated and subjected to detailed phenotypic and expression analysis. RT-PCR, Western blot analysis and immuno-histochemical studies showed that the human DMD gene had the proper expression of muscle-specific and ubiquitous dystrophin isoforms. To study whether the human DMD gene was able to functionally complement a murine DMD mutation, the mice were crossed with *mdx* mice. Currently, we are analysing these mice and their offspring using several techniques, including expression profiling using cDNA chip and micro-array technology. The results of these studies will be reported. In combination with a DMD-gene deficient mouse which we are generating, we aim to breed a "dystrophin-humanized" mouse which should facilitate human-specific functional and therapeutic studies.

**Structure-Function Analysis of Alternate Substitution Mutations at Codon 892 of the Human Androgen Receptor Associated with Complete Androgen Insensitivity.** *Y.A. Elhaji*<sup>1,4</sup>, *R. Lumbroso*<sup>4</sup>, *D.R. Foerster*<sup>5</sup>, *C.R. Greenberg*<sup>5</sup>, *K. Wrogemann*<sup>5</sup>, *L. Pinsky*<sup>1,2,3,4</sup>, *L.K. Beitel*<sup>4</sup>, *M.A. Trifiro*<sup>1,2,3,4</sup>. 1) Human Genetics; 2) Medicine; 3) Pediatrics, McGill University; 4) Lady Davis Institute, JGH, Montreal, PQ, Canada; 5) Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, Canada.

The human androgen receptor (AR), a member of the nuclear receptor superfamily, acts as a ligand-dependent transcription factor. AR mutations may result in varying degrees (ranging from mild to complete) of androgen insensitivity syndrome (AIS). The AR contains a polymorphic N-terminal region that modulates transcriptional responses, a DNA-binding domain, and a C-terminal ligand-binding domain (LBD). Here we describe two novel mutations in the LBD of the AR, in unrelated patients with complete AIS, that result in substitution of two different amino acids (A and L) for a proline at an identical location: position 892. Kinetic analysis of the mutant receptors in cultured GSF and in transfected COS-1 cells revealed reduced total binding ( $B_{\max}$ ) and increased dissociation ( $k_{\text{diss}}$ ) and equilibrium affinity constants ( $K_d$ ) for mibolerone (MB). However, with methyltrienolone (MT; R1881),  $K_d$  values were elevated for P892A and normal for P892L. The proline at position 892 is immediately adjacent to the N-terminus of helix 12 (H12) of the LBD. H12 contains the transcriptional activation function-2 (AF-2) core and is important for the recruitment of and interaction with transcription intermediate factors. H12 is also involved in AR N/C terminal interactions. Upon binding androgen, H12 is thought to undergo a distinct repositioning, forming a lid over the ligand-binding pocket and exposing a coactivator recruitment surface. We postulate that substitutions at position 892 alter the precise repositioning of H12, allowing for faster ligand dissociation. This hypothesis may explain the kinetics of both mutant ARs. Investigation of different substitutions at a single position of the AR provides a fine tool for detailed AR structure-function analysis and understanding of the mechanisms by which normal and mutant ARs regulate androgen-responsive genes.

**Binding of L1 ORF1 protein to RNA using in vitro studies.** *V. Kolosha, S. Martin.* Department of Cellular & Structural Biology, University of Colorado School Medicine, Denver, CO.

LINES are long interspersed nuclear elements that are abundantly present in the mammalian genome. They belong to the non-long terminal repeat (non-LTR) class of retrotransposons, which contain a 3' poly(A) tail. Full-length mouse and human LINE-1 elements contain two open reading frames that encode proteins essential for retrotransposition. ORF1 protein is implicated in both protein-protein and protein-single stranded nucleic acid interaction. These functions of the ORF1 protein are likely to be important for ribonucleoprotein complex (RNP) assembly. Using both baculo- and bacterially- expressed ORF1 protein we reproducibly co-immunoprecipitated the largest T1 nuclease fragment (38nt) from mouse L1 RNA which is positioned just 3' of the initiation codon for the ORF2 region. However, further studies revealed that short transcripts containing this region, either in sense or in complement orientation, are efficiently co-immunoprecipitated. There is an apparent length-dependence for the co-immunoprecipitation of RNA fragments. Studies using nitrocellulose filter binding assay also did not detect any sequence specificity of the ORF1 protein binding to RNA. ORF1 protein binds long transcripts containing the 38 nucleotide region and its antisense with an apparent dissociation constant of approximately 75nM in 100mM NaCl. Based on UV-crosslinking studies the C-terminal 1/3 of ORF1 protein is the region involved in RNA binding. The affinity for the C-terminal portion of the protein under similar conditions is more than 10-fold less than for the full-length protein. This is likely to be closer to the real association constant for the RNA-protein interaction, since the C-terminal protein does not have the protein-protein interaction domain, that contributes to the cooperativity of binding. The binding of the protein to RNA is likely explained by electrostatic interaction of its highly positively charged C-terminal portion with the negatively charged phosphodiester backbone of RNA. Consistent with this, there is a strong salt dependence of RNA binding by the ORF1 protein.

**Comparative sequencing of RP1 to identify evolutionarily conserved regions of the protein. The RP1**

**Consortium.** *K.A Malone*<sup>1</sup>, *J. Zuo*<sup>2</sup>, *D.B. Farber*<sup>3</sup>, *J.R. Heckenlively*<sup>3</sup>, *E.A. Pierce*<sup>4</sup>, *C.F. Inglehearn*<sup>5</sup>, *S.P. Daiger*<sup>1</sup>, *L.S. Sullivan*<sup>1</sup>. 1) Human Genetics, University of Texas-Houston, Houston, TX; 2) St.Jude Children's Research Hospital, Memphis TN; 3) Jules Stein Eye Inst. UCLA; 4) Scheie Eye Inst., Univ of Penn; 5) Molecular Medicine Unit., Leeds Univ. UK.

Retinitis pigmentosa (RP) is a group of inherited retinopathies that is a leading cause of inherited blindness worldwide. Mutations in the RP1 gene may account for approximately 10% of all autosomal dominant retinitis pigmentosa (adRP), yet to date, there is limited structural or functional knowledge about the RP1 protein. Database searches have revealed significant sequence similarities with members of the doublecortin family of proteins, as well as a retina-specific EST, EYE2931, but the similarity extends only throughout the first 300 amino acids of RP1. The remaining 70% of the protein has no significant similarity to any known protein. In order to identify evolutionarily conserved regions of the protein, which are likely to be functionally important, we have sequenced the coding region of the RP1 protein in several different species of mammal. We used comparative sequencing as a way to predict which regions of the gene may be important for normal function or stable protein structure, and for examining the potential effects of missense mutations, polymorphisms, and benign variants. Several of the possible functional domains identified in human RP1 such as transmembrane domains, cell attachment signals, a leucine zipper, and an NDP kinase active site are not conserved in other mammals. Two of the three nuclear localization signals are conserved in baboon, squirrel monkey and mouse. The leucine zipper is not conserved in mouse or squirrel monkey, and the NDP kinase active site is not conserved in squirrel monkey. The exceptional amount of sequence divergence in RP1 is unusual for a seemingly critical retinal protein, and may explain why only large disruptions in the protein sequence appear to cause retinal disease.

**The Sonic Hedgehog signaling pathway: analysis of the *Hedgehog Interacting Protein* and *HNF-3b* genes as potential causes of holoprosencephaly.** *L. Huo*<sup>1</sup>, *E. Roessler*<sup>1</sup>, *P.T. Chuang*<sup>2</sup>, *A.P. McMahon*<sup>2</sup>, *M. Muenke*<sup>1</sup>. 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Department of Molecular and Cellular Biology, The Biolabs, Harvard University.

The Hedgehog-Interacting Protein (HIP) is a novel component of the Sonic Hedgehog (SHH) signaling pathway. Recently, defects in the cell signaling pathway involving SHH have been shown to cause HPE, which is the most common birth defect of the brain and face in humans. In animal models, knockout mice with homozygous null mutations for *Shh* displayed abnormalities consistent with HPE. Hip has been shown to attenuate Hedgehog signaling by cell-surface binding of the hedgehog protein and to act in a negative regulatory feedback loop. Although Hip has been considered an important factor in the Shh signaling pathway, its potential role in HPE had not been examined in humans. Here we report for the first time the complete gene structure of the human *HIP* gene and present its mutational analysis in HPE patients. No mutations were found in the entire coding region or 1 kb upstream 5' of transcription start site (determined by 5'-RACE and primer extension analysis) suggesting a limited role for this gene in HPE pathogenesis. We are currently working on HNF-3b which is a transcription factor which acts as regulator of floor plate development whose induction depends on Sonic Hedgehog signaling. Preliminary mutational analysis of the *HNF-3b* gene in HPE patients is presented.

**The role of PDZ-binding motif in polarized distribution of CFTR and other apical or basolateral membrane proteins.** *M.I. Milewski<sup>1</sup>, J.K. Forrest<sup>1</sup>, J.E. Mickle<sup>1</sup>, B. Stanton<sup>2</sup>, G.R. Cutting<sup>1</sup>.* 1) Inst Genetic Medicine, JHU Sch Med, Baltimore, MD; 2) Dept Physiology, Dartmouth Med Sch, Hanover, NH.

C-terminal PDZ-binding motifs are required for polarized apical/basolateral localization of many membrane proteins. However, apparent sequence similarities observed between PDZ-binding motifs of some apical and basolateral membrane proteins suggest that the specific subcellular localization of these proteins cannot depend solely on the PDZ domain-based interactions. We have previously shown that the PDZ-binding motif of cystic fibrosis transmembrane conductance regulator (CFTR), a protein mutated in cystic fibrosis (CF), is a part of a multi-component C-terminal localization signal responsible for apical protein distribution in epithelial cells. To further explore the function of this PDZ-binding motif we utilized the green fluorescent protein (GFP) fused to the CFTR C-terminal region containing all signals required for apical membrane localization in polarized MDCK cells. Substitution of the PDZ-binding motif of CFTR (D-T-R-L>) with E-T-H-F>, a motif from the apically located protein GAT3 did not alter apical distribution of the fusion protein. Interestingly, substitutions with PDZ-binding motifs from basolateral proteins BGT1 (E-T-H-L>) or LET23 (E-T-C-L>) did not affect the apical localization of the fusion protein. The fusion proteins containing PDZ-binding motifs of two other basolateral proteins GLUT1 (D-S-Q-V>) or SYN2 (A-F-Y-A>) showed diffuse cytoplasmic distribution and no specific basolateral or apical localization. These results strongly suggest that PDZ-binding motifs are auxiliary components of apical/basolateral localization signals that might be required for stabilization of protein at given location but do not determine its specific subcellular distribution.

**Characterization of the Promoter of Human LST1: A Small Gene with a Complex Pattern of Alternative Transcripts.** *X.F. Yu, S.M. Weissman.* Dept Genetics, Yale Sch Medicine, New Haven, CT 06519.

The gene for the human leukocyte-specific transcript 1(LST1) encodes a small protein that modulates immune responses and cellular morphogenesis. LST1 transcripts are expressed at high levels in dendritic cells. Because of its complex splicing pattern, use of alternative 5'-UT exons, and biologically interesting pattern of expression, we studied the human LST1 gene promoter and regulatory elements. We identified an additional upstream 5'-UT exon and found that each of the five alternative first exons was expressed from the endogenous in U937 monocytic cells. Transient transfection studies demonstrated that the combination of regions from -1363 to -621 with -112 to -54, relative to the translation start codon, produced the highest level of transcripts from among the various constructs tested, but the pattern of transcripts produced was only a subset of those produced from the endogenous gene. DNase I footprinting analysis and electrophoretic mobility shift assays (EMSA) showed that oligonucleotide probes corresponding to three regions, -1171 to -1142 (BI), -1136 to -1111 (BII), and -783 to -751 (BIV), bound proteins in U937 nuclear extracts. Competition and super-shift EMSA did not identify any known transcription factors responsible for BII probe binding. These studies suggest that a novel DNA binding site and interaction of multiple regulatory elements may be involved in mediating the expression of the various forms of LST1 mRNA.

**A new paramyotonia congenita mutation in a novel Na<sup>+</sup> channel region involved in inactivation.** *F. Wu<sup>1,5</sup>, M. Takahashi<sup>2</sup>, E. Pegoraro<sup>3</sup>, C. Angelini<sup>3</sup>, P. Colleselli<sup>4</sup>, S. Cannon<sup>2</sup>, E. Hoffman<sup>5</sup>.* 1) University of Pittsburgh, Department of Human Genetics, Pittsburgh, PA; 2) Harvard University, Department of Neurology, Boston, MA; 3) University of Padova, Department of Neurological and Psychiatric Sciences, Padova, Italy; 4) Divisone di Pediatria, ULSS n.1 Belluno Agordo Cadore, O.C. di Belluno, Belluno, Italy; 5) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC.

Paramyotonia Congenita (PC) is an autosomal dominant non-progressive disorder showing cold-induced myotonia and transient muscle weakness, and is caused by gain-of-function missense mutations in the skeletal muscle sodium channel gene (SCN4A). Most PC mutations cluster in a voltage sensing region of the channel, and result in fast inactivation defects. Single-strand conformation polymorphism (SSCP) was used to screen all 24 exons of SCN4A and conformers were sequenced to confirm the presence of mutations. A new SCN4A mutation was introduced into a mammalian expression construct using site-directed mutagenesis method. Whole-cell recording from transiently transfected human embryonic kidney (HEK) cells was performed to determine electrophysiological characteristics of mutant channels. A new three generation Italian family segregating PC is presented, in which we identify a novel SCN4A mutation (L266V). This change removes only a single methylene group from the 1,836 amino acid protein, and is present in a region of the protein previously not known to be critical for channel function (domain I transmembrane segment 5). Electrophysiological studies of the L266V mutation showed defects in fast inactivation, consistent with other disease-causing SCN4A mutations studied to date. This change showed no significant abnormalities in slow inactivation. This novel mutation of the sodium channel indicates that a single carbon change in a transmembrane alpha-helix of domain I can lead to dramatic changes in channel inactivation and cause paramyotonia congenita.

**Alternative splicing regulates the nuclear or cytoplasmic localization of dystrophin Dp71.** *E. Gonzalez-Rodriguez<sup>1</sup>, C. Montanez-Ojeda<sup>1</sup>, P. N. Ray<sup>2</sup>, P. L. Howard<sup>2</sup>, F. Garcia-Sierra<sup>3</sup>.* 1) Genetic and Molecular Biology, CINVESTAV, Mexico, Mexico DF; 2) Department of Molecular and Medical Genetics University of Toronto, Canada; 3) Department of Cell and Molecular Biology. Northwestern University Medical School.

To get insight into the functional role of Dp71 alternative splicing, we determined the pattern of subcellular distribution of Dp71 isoforms alternatively spliced for exon 71 and/or 78. The cDNA sequence of each Dp71 variant was fused to the C-terminus of the green fluorescent protein (GFP). GFP-Dp71 gene fusion plasmids were transfected transiently in three different cell lines (HeLa, C2C12, and N1E-115) and the subcellular distribution of the fused proteins was determined by confocal microscope analysis. The Dp71 variant lacking amino acids encoded by exon 71 and conserving those encoded by exon 78 completely localizes to the nucleus whereas the variant lacking the amino acids encoded by both exons 71 and 78 was found exclusively in the cytoplasm. The remaining two isoforms generated from constructs containing exon 71 and exon 78 or preserving exon 71 but not exon 78 show a predominant nuclear localization. These results indicate that alternative splicing of Dp71 modulates its subcellular localization and that the presence of amino acids encoded by either exon 71 or exon 78 enables Dp71 to migrate into the nucleus. The nuclear localization of Dp71 provides a new clue towards the establishment of its cellular function.

**Cell Cycle dependent phosphorylation of the murine homologue of the Treacher Collins Syndrome gene product, treacle.** *S. Rujirabanjerd*<sup>1</sup>, *S.T. Winokur*<sup>2</sup>, *R. Shiang*<sup>1</sup>. 1) Dept Human Genetics, MCV, Virginia Commonwealth Univ., Richmond, VA; 2) University of California, Irvine, CA.

Treacher Collins Syndrome (TCOF1) is an autosomal dominant disorder of craniofacial development. Although the gene has been cloned, the functional and biochemical properties of the protein, treacle, are still unknown. Treacle is thought to be a member of a class of nucleolar phosphoproteins from its predicted protein sequence. The murine homologue of the TCOF1 gene has also been identified. The murine treacle is 1320 amino acids in length and contains several potential sites for CKII (casein kinaseII) phosphorylation. Both the human and mouse proteins have been previously shown to localize to the nucleolus. The murine protein has also been shown to be highly phosphorylated. To determine whether phosphorylation of treacle is cell cycle dependent, which is one characteristic of nucleolar phosphoproteins, cell synchronization of mouse P19, an embryonic carcinoma cell line, was performed. Using a protocol involving a rapid change in growth in MEMa media, cells were synchronized in G1 phase. A mitotic inhibitor, nocodazole, and mitotic shake off were used to collect cells in mitosis. Synchronization was monitored by flow cytometry. Immunoprecipitation was performed using lysates from synchronized cells. The results were visualized using anti-treacle antibodies after electroblotting on SDS-PAGE and isoelectric focusing gels. The result shows that treacle is hyperphosphorylated in mitosis compared to the protein in G1 phase. Thus treacle has two different forms depending on the degree of phosphorylation. This work confirms that treacle is a member of nucleolar phosphoprotein family and shows that the function of treacle may be regulated by the cell cycle.

**Human L1s retrotransposition: cis-preference vs. trans-complementation.** *J.V. Moran<sup>1</sup>, N. Gilbert<sup>1</sup>, J. Boeke<sup>2</sup>, H. Kazazian<sup>3</sup>, E. Ostertag<sup>3</sup>, S. Loon<sup>2</sup>, W. Wei<sup>1</sup>.* 1) Department of Human Genetics and Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 2) Department of Molecular Biology and Genetics, Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Genetics, The University of Pennsylvania Medical School, Philadelphia, PA.

Long Interspersed Repetitive DNA Elements (LINEs or L1s) comprise approximately 17% of human DNA; however, only 60 of the ~400,000 L1s are mobile. Using a L1 retrotransposition assay in cultured human cells, we demonstrate that the L1-encoded proteins predominantly mobilize the RNA that encodes them. This profound cis-preference mechanism allows L1 to remain retrotransposition-competent in the presence of an overwhelming number of non-functional L1s. We further demonstrate that the L1-encoded proteins also can act in trans at much lower levels to promote retrotransposition of mutant L1s and other cellular mRNAs, creating processed pseudogenes. Remarkably, some of the resulting pseudogenes are chimeric; their 5' ends are derived from L1 and their 3' ends are derived from cellular mRNA. Thus, akin to vertebrate retroviruses, some L1 retrotransposition intermediates may contain at least two RNA molecules.

**Retroelements in the 5' untranslated region of a human zinc finger gene modulate transcription and translation efficiency.** *J.-R. Landry<sup>1, 2</sup>, P. Medstrand<sup>2</sup>, D.L. Mager<sup>1, 2</sup>*. 1) Medical Genetics, University of British Columbia, Vancouver, B.C., Canada; 2) Terry Fox Laboratory, British Columbia Cancer Agency, Vancouver, B.C., Canada.

A significant proportion of the human genome consists of repetitive sequences. Although long believed to be useless or junk DNA, retroelements, such as Alu sequences, L1s and HERVs (human endogenous retroviruses), have recently been implicated in the regulation of various genes. Our laboratory previously identified a novel, alternatively spliced zinc finger gene, ZNF177, which incorporates Alu, L1 and HERV segments into the 5' untranslated region (UTR) of transcripts. In this study, we investigated the functional significance of those repetitive sequences in the 5' UTR of ZNF177 mRNAs. Using luciferase and GFP reporter constructs, we assessed the effect of the HERV, Alu and L1 sequences on gene expression levels. Our results indicate that the presence of the retroelement sequences, particularly the Alu and L1 segments, in the 5' UTR significantly modifies the expression level of both reporter genes. We present evidence that the Alu and L1 sequences alter both the RNA and protein levels of reporter genes by increasing transcription efficiency while decreasing translation efficiency. Our findings suggest that the Alu and L1 repeats in the 5' UTR of ZNF177 exert a positive transcriptional enhancer effect but repress translation of the zinc finger gene. These results illustrate the complex regulatory effects that retroelements can have on human gene expression.

**Comparison of expression and toxicity of long polyglutamine and polyleucine stretches in mammalian cells.** *J. Dorsman, B. Pepers, M. Bremmer-Bout, M. IJszenga, G.J.B. Van Ommen, J.T. Den Dunnen.* CBG-Dept Human Genetics, LUMC, Leiden, The Netherlands.

Several neurological disorders are caused by the expansion of a trinucleotide repeat. The largest group of these diseases, including Huntington's disease (HD) and many forms of spinocerebellar ataxia's (SCA) are associated with an expansion of a (CAG)<sub>n</sub> repeat in the coding region of the gene. Since the instability of the (CAG)<sub>n</sub> repeat lies at the DNA level there is no a priori reason why the sequence (CAG)<sub>n</sub> or its complement (CTG)<sub>n</sub> would not occasionally be translated as (gln)<sub>n</sub>, (leu)<sub>n</sub>, (ser)<sub>n</sub>, (ala)<sub>n</sub> or (cys)<sub>n</sub>, depending on reading frame and translated strand. Yet, in the neurodegenerative disorders only gln-repeat expansions are found, while the occurrence of repeats encoding (very) long stretches of other amino acids has not been documented in the sequence databases. To address why this might be so and to determine the potential effect of other repeats, we first needed to overcome the pronounced instability of long homogeneous (CAG)<sub>n</sub> repeats in bacterial, yeast and mammalian systems. Therefore, we have constructed a 300-mer of a mixed nonrepetitive DNA oligomer consisting of CAG and CAA triplets. This sequence replicates stably in pro- and eukaryotes and encodes ca 300 glutamines or leucines in two different reading frames. The results obtained in the transfection experiments using cultured mammalian cells indicate that both (gln)<sub>300</sub> and (leu)<sub>300</sub> display a high propensity for aggregation. Immune-histochemistry of the transfected cells suggests however that polyleucine is significantly more toxic than polyglutamine, implying that nature may select against reading frames or polarities for (CAG)<sub>n</sub>:(CTG)<sub>n</sub> repeats other than that coding for polyglutamine. As a follow-up of these studies, we are currently studying the gene expression changes mediated by expression of polyglutamine and polyleucine stretches in mammalian cells using DNA chips and micro-arrays. These studies should provide insight in the cellular changes and the toxic effects of these aggregation-prone proteins.

**Development and characterization of a unique set of anti-FMRP antibodies using a novel strategy.** *S.S. Ceman*<sup>1, 2</sup>, *A. Kenneson*<sup>1,2</sup>, *R. Nelson*<sup>1,2</sup>, *C. Jin*<sup>1</sup>, *L. Lakkis*<sup>1,2</sup>, *V. Brown*<sup>1,2</sup>, *K. Wilkinson*<sup>1</sup>, *S.T. Warren*<sup>1,2</sup>. 1) Departments of Biochemistry, Genetics, and Pediatrics, Emory Univ, Atlanta, GA; 2) Howard Hughes Medical Institute, Atlanta, GA.

Full characterization of the function of the FMR protein (FMRP), deficient in fragile X syndrome, has been hampered by a paucity of useful antibodies. In part, this is due to the highly conserved nature of the FMR1 gene throughout vertebrates, which limits its immunoreactivity in animals, as it would appear as a self antigen. To circumvent this problem, we immunized the *Fmr1* knockout mouse with recombinant murine *Fmrp*, as this protein would now be viewed as foreign by the immune system of the mouse. We successfully obtained a collection of monoclonal antibodies (mAbs) that were determined to recognize murine *Fmrp* by ELISA. By western analysis, we identified mAbs that recognize only mouse *Fmrp* or both mouse and human FMRP. Importantly, we have identified new mAbs with features not found in the available mAb, 1C3. For example, mAb 7G1-1 found in this screen, unlike 1C3, recognizes only *Fmrp* and not related proteins *Fxr1P* and *Fxr2P*. Indeed, epitope mapping of both 1C3 and 7G1-1 revealed that 1C3 recognizes two epitopes of *Fmrp* (VEVR and VVRVR) which are both found in the *Fxr* proteins, while 7G1-1 recognizes the peptide KHLDTKENTHF, which is unique to rodent *Fmrp*, not being found within the *Fxr* proteins. Moreover, 7G1-1 and other mAbs developed here have the ability, which was not previously available, to efficiently immunoprecipitate *Fmrp*. Using these new mAbs we have been able to immunoprecipitate the *Fmrp*-associated mRNP complex containing associated proteins and mRNAs. Further, because of the specificity of 7G1-1 for *Fmrp* and not for related family members, we demonstrate conclusively that the existing *Fmr1* knockout mouse produces no detectable *Fmrp*, a point of contention due to the inability of previous antibodies to recognize solely *Fmrp*.

**Huntingtin Interacting Protein 1 Knock-Out Mice are Viable and Provide Insights into the Developmental Expression of HIP1.** *M.M. Metzler<sup>1</sup>, L. Gan<sup>1</sup>, R. Oh<sup>1</sup>, M. Gertsenstein<sup>2</sup>, A.S. Hackam<sup>1</sup>, A. Borowski<sup>1</sup>, F.R. Jirik<sup>1</sup>, A. Nagy<sup>2</sup>, M.R. Hayden<sup>1</sup>.* 1) Centre for Molecular Medicine and Therapeutics, UBC, Vancouver, Canada; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada.

The neurodegenerative disorder Huntington Disease (HD) is caused by polyglutamine expansion in the ubiquitously expressed protein huntingtin. Altered interaction with brain-predominant proteins, such as huntingtin interacting protein 1 (HIP1), have been proposed as a mechanism for the selective neuronal loss. Decreased interaction between HIP1 and huntingtin following polyglutamine expansion has been observed by yeast two hybrid analyses. This altered interaction may lead to changes in the function of both proteins, thereby contributing to the pathology in HD. Although the function of huntingtin and HIP1, a cytoskeletal-associated protein, is unknown evidence suggests that both proteins are involved in intracellular transport processes. Interestingly, overexpression of HIP1 in 293T and neuronal NT2 cells is toxic and results in caspase 3 activation and subsequent cell death. This observation may be important in understanding the pathologic mechanism in HD since striatal and cortical neurons in HD patients degenerate by apoptosis and high levels of HIP1 protein are expressed in affected brain regions. In order to assess *in vivo* function of HIP1 and its potential role in HD pathogenesis a targeted mutation was introduced into the HIP1 locus by homologous recombination in embryonic stem (ES) cells. A promoter trap targeting vector was used which allows expression of the b-galactosidase gene under control of the endogenous HIP1 promoter. Homozygous HIP1 mutant mice are viable and show no obvious phenotype at 4 weeks of age. Western blot analysis demonstrated that HIP1 expression which is present in frontal cortex and striatum of wild-type mice, has been ablated in HIP1<sup>-/-</sup> mice. Future studies will determine whether more subtle abnormalities in HIP1 mutant mice occur and whether these mice develop a phenotype at later stages of development. Moreover, HIP1 mutant mice represent an excellent tool to determine the developmental expression of HIP1.

**The human *MJD* gene: genomic structure, transcripts, and expression.** *Y. Ichikawa*<sup>1,2</sup>, *J. Goto*<sup>1,2</sup>, *M. Hattori*<sup>3</sup>, *A. Toyoda*<sup>3</sup>, *K. Ishii*<sup>3</sup>, *S.-Y Jeong*<sup>2</sup>, *H. Hashida*<sup>1,2</sup>, *N. Masuda*<sup>1,2</sup>, *K. Ogata*<sup>1,2</sup>, *Y. Suzuki*<sup>1,3</sup>, *S. Sugano*<sup>1</sup>, *F. Kasai*<sup>1</sup>, *M. Hirai*<sup>1</sup>, *P. Maciel*<sup>4,5</sup>, *G.A. Rouleau*<sup>5</sup>, *Y. Sakaki*<sup>1,3</sup>, *I. Kanazawa*<sup>1,2</sup>. 1) Univ of Tokyo, Tokyo, Japan; 2) CREST, Japan Sci and Tech Corp, Saitama Japan; 3) RIKEN Genomic Sci center, Kanagawa, Japan; 4) UnIGENE, IBMC, Porto, Portugal; 5) McGill Univ, Montreal, PQ, Canada.

Machado-Joseph disease (MJD) is an autosomal dominant neurodegenerative disorder characterized by cerebellar ataxia and variable associated symptoms. The disease is caused by an unstable expansion of the CAG repeat in MJD that maps to chromosome 14q32.1. The original cDNA clone, MJD1a, consists of 1776bp. We constructed a contig that spanned approximately 300kb, was composed of 6 cosmid clones and 8 BAC clones: B472N19, B472P19, B445M7, B386D20, B400P9, B531L24, B750O6, and B372P2. We sequenced a BAC clone: B445M7 including the *MJD* gene. We analyzed Northern blots and screened four human cDNA libraries and a CAP site cDNA library. Northern blot analysis showed at least four transcripts of which sizes were approximately 1.4, 1.8, 4.5 and 7.5kb, and were ubiquitously expressed. By screening of the four human cDNA libraries of whole brain, caudate, retina, and testis, we obtained 27 clones, including 21 independent clones. Two alternative splicing sites and 8 polyadenylation signals were identified. We determined the complete sequence (175,330bp) of B445M7. These results indicate that the *MJD* gene spans 48,240bp, composed of 11 exons, and coded, at least 5 transcripts, the sizes of which were approximately 1.4, 1.9, 2.0, 4.8 and 7.0 kb, by alternative splicing and polyadenylation.

**Spinocerebellar ataxia type 12 (SCA12): Additional evidence for a causative role of the CAG repeat expansion in PPP2R2B.** *S.E. Holmes<sup>1</sup>, H. Fujigasaki<sup>3</sup>, E. O'Hearn<sup>1</sup>, S.E. Antonarakis<sup>4</sup>, J.K. Cooper<sup>1</sup>, C. Callahan<sup>1</sup>, J. Hwang<sup>1</sup>, D. Gorelick-Feldman<sup>1</sup>, I.C. Verma<sup>2</sup>, R. Saxena<sup>2</sup>, A. Dürr<sup>3</sup>, A. Brice<sup>3</sup>, C.A. Ross<sup>1</sup>, R.L. Margolis<sup>1</sup>.* 1) Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Dept of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, India; 3) INSERM U289, Hôpital de la Salpêtrière, Paris, France; 4) University of Geneva Medical School, Geneva, Switzerland.

SCA12 is an autosomal dominant neurodegenerative disorder associated with an expansion of a CAG repeat in the 5'UTR of the gene PPP2R2B, which encodes a brain-specific subunit of the phosphatase PP2. In the originally described family of German origin, the expansion mutation ranged from 66 to 78 triplets. The phenotype typically begins with tremor in the 4th decade, progressing to include ataxia and other cerebellar and cortical signs. We have now identified a second family of different ethnic origin, with a similar phenotype and an expansion ranging from 55 to 61 triplets (Fujigasaki et al., submitted). We have examined the genomic structure of PPP2R2B, and have identified 9 exons which contribute to the known transcript. To better understand the effect of the expansion on the expression of PPP2R2B, we have cloned a 1.7kb fragment of the 5' region of PPP2R2B containing the CAG repeat into reporter constructs. Expression was assayed in the neuroblastoma cell line LA-N-1. The results indicate that this region of PPP2R2B functions as a promoter, comparable in activity to an SV40 control promoter, and that the promoter containing an expanded repeat increases reporter gene expression. We postulate that, unlike other known repeat expansions, the CAG expansion in the 5' region of PPP2R2B increases gene expression.

**PHR1, A PH Domain-Containing, Integral Membrane Protein Expressed Predominantly in Primary Sensory Neurons.** *S. Xu*<sup>1,2</sup>, *R. Ladak*<sup>3</sup>, *D.A. Swanson*<sup>4</sup>, *R.R. McInnes*<sup>3</sup>, *D. Valle*<sup>2</sup>. 1) Predoctoral training program, Johns Hopkins Univ, Baltimore, MD; 2) Howard Hughes Medical Institute, Inst Genetic Med, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Programs in Developmental Biology and Genetics, Research Institute, Hospital for Sick Children, Toronto, Ontario, Canada M5G1X8;; 4) Genetics and Molecular Biology Branch National Human Genome Research Institute, Bethesda, MD.

In a differential hybridization screen of an arrayed retinal cDNA library, we cloned a gene, PHR1, expressed at high level in retina. We showed that PHR1 utilizes two promoters and alternative splicing, to produce four isoforms, each with a pleckstrin homology (PH) domain at its N-terminus and a transmembrane domain at its C-terminus. We also showed that PHR1 is an integral membrane protein, abundant in photoreceptor outer segments, pineal body and also in retinal ganglion cells. In *in vitro* binding assays, PHR1, unlike many other PH domain proteins, does not bind any of a series of inositol phosphates, phosphatidylinositides or other phospholipids. PHR1 does, however, bind transducin  $\beta\gamma$  subunits, suggesting a possible interaction with G proteins. To better understand PHR1 function, we made a *Phr1* knockout mouse model inserting *bgal* and *neor* genes into exon 3 and bringing the *bgal* gene under the control of *Phr1* promoters. By X-gal staining, we found that *Phr1* is highly expressed in virtually all primary sensory neurons, including olfactory receptor neurons, taste cells and hair cells in the vestibular and cochlear sensory epithelia of the inner ear. We also found specific expression of *Phr1* in certain interdental cells in the spiral limbus of the cochlea, shown recently to have the potential to develop into hair cells. Despite this widespread and specific expression, the *Phr1* knockout mice have no discernable phenotype at age 6 months: ERGs, ABRs and rotorod tests are normal as is the histology of the retina, olfactory system and inner ear. Nevertheless, the specific expression of *Phr1* in sensory neurons and the potential functions of the PH domain indicates PHR1 may play an important role in the function of sensory neurons.

**Studies of X inactivation and the identification of *XIST* in the insectivore *Scapanus orarius*.** S. Karalic, C.J. Brown.  
Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

X inactivation is the transcriptional silencing of one of two Xs in mammalian females and is thought to be a means of dosage compensation. The molecular mechanisms of this process are not fully understood; but involve the *XIST* functional RNA that is only expressed from the inactive X, histone hypoacetylation, late replication and hypermethylation. While X inactivation seems to exist in all three mammalian subclasses, there are significant differences regarding the parental origin, stability and extent of inactivation. Delayed replication timing and hypoacetylation have been observed in marsupials, but the roles of hypermethylation and *XIST* may be less conserved. We have examined methylation and *XIST* expression in *Scapanus orarius* (Coast mole), a member of the highly diverged and possibly basal eutherian order Insectivora. Methylation is associated with silencing in eutherians, but apparently not in marsupials. We performed methylation-sensitive restriction digests followed by PCR with conserved primers for two X-linked genes, *ZFX* and *FMRI*. Methylation of the inactive X is conserved in insectivores, as *FMRI* appears to be methylated in females but not males. No methylation is observed for *ZFX*, consistent with it escaping inactivation. *XIST* expression is crucial for initiating inactivation in mice, but has not yet been identified in marsupials, possibly due to low sequence conservation of functional RNAs. Full-length *XIST* sequences are available for human and mouse, as well as small fragments for cow, horse, rabbit, cat and rat. We now report that PCR primers designed from conserved sequence were successful in amplifying 245 bp of Coast mole *XIST* that shows significant similarity (59-84%) to other *XIST* sequences. Furthermore, expression has only been detected in females. The presence of *XIST* in an insectivore indicates that its involvement in X inactivation is conserved within the eutheria. The full sequence of Coast mole *XIST* may highlight conserved functional domains, which could facilitate the identification of a potential marsupial *XIST* and provide valuable information on the evolution and mechanisms of mammalian X inactivation.

***In vivo* footprint analysis of intronic *HPRT* MARs on the active and inactive X chromosomes.** S.-H.L. Kang<sup>1,2</sup>, C. Chen<sup>1,2</sup>, T.P. Yang<sup>1,2,3</sup>. 1) Department of Biochemistry & Molecular Biology; 2) Center for Mammalian Genetics; 3) Department of Pediatrics Division of Genetics, University of Florida, College of Medicine, Gainesville, FL.

Matrix associated regions (MARs) are specific DNA sequences with characteristic AT-richness and topoisomerase II consensus binding sites that bind to the nuclear matrix. Although the role of MARs is not well understood, they are thought to be involved in chromosome organization, DNA replication and/or transcriptional regulation. A role for MARs in X-chromosome inactivation is suggested by the recent observation that the *XIST* RNA is localized to the nuclear matrix. Thus, MARs may mediate the silencing activity of the *XIST* RNA for genes on the inactive X chromosome. We have examined 2 intragenic MARs at the X-linked human *HPRT* locus in introns 1 and 3. DNase I *in vivo* footprint analysis of the 2 intronic MARs was performed to examine sequence-specific DNA-protein interactions on the active and inactive alleles. No DNase I footprints were detected over the MAR in intron 1 on either the active or inactive allele. However, 3 footprinted regions were detected over the MAR in intron 3. All 3 of these footprints are found on both the active and inactive alleles indicating that proteins are bound to this MAR regardless of whether the locus is actively transcribed or silenced. This suggests that the MAR in intron 3 may act as an attachment site of the *HPRT* locus to the nuclear matrix irrespective of transcriptional state and thus plays a role in the global gene organization rather than in transcriptional regulation.

**Large-scale gene function discovery in the post-genome era.** *A.T. Sands.* President & CEO, Lexicon Genetics Incorporated, The Woodlands, TX.

The dramatic increase in the accumulation of human genomic DNA sequence information has far outpaced the rate at which current technologies enable the discovery of gene function. This gene function gap has significant implications for the development of new therapeutics and diagnostics from the human genome. We have developed a systematic functional genomics methodology to discover the physiologic functions of genes in mammals on a large-scale. Our novel method of high-throughput gene trapping has broad applicability in eukaryotic genomes for gene function discovery. The ability to create mutations in mouse embryonic stem (ES) cells on a large-scale provides a powerful approach for rapidly determining gene function in a mammalian system. Lexicon's gene trap technology allows for the automated production of sequence tags from the trapped genes with rapid bioinformatics analysis. We have used these techniques to create the world's largest library of mouse ES cells called OmniBank that now contains over one-third of genes in the mammalian genome catalogued using bioinformatics in a relational database ([www.lexgen.com](http://www.lexgen.com)). We have implemented systems and infrastructure for the generation and analysis of mutant mice at an unprecedented rate of more than twenty novel mutant lines per week. Such a capacity obviously raises the challenge of obtaining meaningful phenotypic information from such mutant lines at a concomitant pace. Fortunately, increasingly widespread recognition of the importance of mouse genetics as a tool in functional genomics has led to the development of mouse scale clinical technologies such as CAT scanning, ECG, CBC and DEXA equipment. Effective application of these technologies now permits the accumulation of a wealth of physiological data on numbers of mutants, which would have been inconceivable as recently as two years ago. Data will be presented on the quality and quantity of information which can now be gathered in screening mode for large numbers of mutant mice in short periods of time. The rapid acquisition of meaningful physiological, structural and behavioral information in mutant mice promises to revolutionize mammalian functional genomics and drug target validation as we enter the post-genome era.

**Homozygosity for the connexin 26 167delT mutation in an Ashkenazi Jewish family.** *M.Q. Salvador<sup>1, 2</sup>, M.A. Fox<sup>1</sup>, L.A. Schimmenti<sup>1</sup>, M. Telatar<sup>1</sup>, S. Yazdani<sup>1</sup>, W.W. Grody<sup>1</sup>.* 1) Departments of Pediatrics, Human Genetics and Pathology, UCLA School of Medicine, Los Angeles, CA; 2) Program in Genetic Counseling, California State University at Northridge, CA.

A 31 year old G2P2 Ashkenazi Jewish woman was referred for genetic counseling for a history of profound nonsyndromic sensorineural deafness believed due to prenatal rubella exposure. Her 33 year old husband, also deaf, believed his deafness resulted from prenatal rubella and x-ray exposure. Their sons, ages 24 months and 10 months, also had sensorineural deafness. The couple sought genetic evaluation to determine why both of their sons were deaf. The 24 month old son had been diagnosed at 19 months with a 90 decibel loss in the right ear and a 40-80 decibel loss in the left. He had normal tympanograms and a normal CT scan of the temporal bones. The 10 month old son was diagnosed at 5 months by audiogram to have a 70-90 decibel loss in the right ear and 90 decibel loss in the left ear with normal tympanograms. The family reported that the 10 month old appeared to be hearing in the newborn period, but brainstem auditory evoked response studies were unavailable. Mutation analysis of the connexin 26 GJB2 gene was performed by PCR and allele-specific restriction endonuclease digestion on genomic DNA from the parents and both sons. All four members of the family were shown to be homozygous for the 167delT mutation, which has a reported carrier frequency of 4% in the Ashkenazi Jewish population. The findings in this family illustrate the importance of considering mutations in connexin 26 as a significant cause of heritable deafness even when the typical clinical presentation and autosomal recessive inheritance pattern are not apparent. Given that approximately 50% of nonsyndromic autosomal recessive congenital hearing loss is caused by mutations in the connexin 26 gene, DNA testing will assume a key ancillary role in newborn hearing screening programs. Our experience would suggest that consideration should be given as to whether screening for the common connexin 26 mutations should be incorporated as a first or second tier procedure in early screening for congenital deafness.

**A population-based study of knowledge, risk perception, and screening practices among subjects with familial colorectal cancer in Ontario.** *O. Ginsburg, M. Aronson, M. Cotterchio, H. Sutherland, S. Gallinger.* The Ontario Familial Colon Cancer Registry, Toronto, Canada.

Objectives: To study risk perception, knowledge, and screening practices reported by CRC (colorectal cancer) patients in the Ontario Familial Colon Cancer Registry (OFCCR). Methods: A questionnaire was administered by telephone to subjects with CRC in the OFCCR, a population-based registry of CRC in Ontario. Results: 119 questionnaires were completed, including subjects from 52 high-risk families (history suggestive of HNPCC), 24 intermediate-risk and 36 low-risk families (sporadic cases randomly sampled from the registry). CRC was detected by screening in 9 people. Although there was no difference in screening patterns between risk groups, high-risk subjects who believed they were at increased risk prior to their diagnosis were more likely to have been screened vs. those who did not think they were at increased risk (28.57% vs. 4.35%,  $p = 0.007$ ). Although 95% of subjects knew at least one symptom of CRC, most could only name rectal bleeding. Only 42% named change in bowel habit as a symptom. Few knew of constitutional symptoms: fatigue (16.1%), and weight loss (10.1%). High-risk subjects were no better than low-risk at naming symptoms. Subjects whose families spoke openly about cancer prior to their diagnosis were slightly more likely to be diagnosed by screening vs. subjects who did not (77.8% vs. 55.96%,  $p = 0.20$ ). 80.6% of the patients referred for genetic counseling received counseling by the study completion. Of persons who did not speak openly prior to their diagnosis but received subsequent genetic counseling, all stated they speak openly now vs. only half of those who did not receive counseling (100% vs. 50%,  $p = 0.001$ ). Conclusions: Although much has been published on hereditary CRC, our results indicate that few cases are detected by screening, even in high-risk families. To our knowledge this is the first North American study of attitudes, risk perception, and screening from a population-based registry of CRC. Further studies are needed to address the apparent lack of awareness about familial CRC syndromes among high-risk families and their health care providers.

**Psychosocial issues following a positive genetic test for BRCA1 and BRCA2: Findings from a focus group and a needs assessment survey.** *J. Honeyford<sup>1</sup>, L. Di Prospero<sup>2</sup>, M. Seminsky<sup>2</sup>, B. Doan<sup>2</sup>, E. Franssen<sup>2</sup>, P. Chart<sup>2</sup>, E. Warner<sup>2</sup>, W. Meschino<sup>1,2</sup>.* 1) Genetics, North York General Hospital, Toronto, ON, Canada; 2) Toronto-Sunnybrook Regional Cancer Centre, Toronto, ON, Canada.

Genetic testing for BRCA1 and BRCA2 has been available in Ontario for the past 5 years on a research basis. The purpose of our study was to obtain feedback about how genetic testing had affected our patients and their families, and to explore whether there was interest or need for ongoing support beyond routine follow-up in the Familial Breast Cancer Clinic.

Twenty-seven BRCA1 and BRCA2 mutation carriers who had received genetic test results at either of two Familial Breast Cancer Clinics were invited to participate in a focus group and concurrently complete a questionnaire (participants), with 8 agreeing to attend the group (30%). A slightly revised version of the questionnaire was subsequently mailed to 26 mutation carriers who did not participate in the focus group (respondents). Of these, 16 were completed and returned (62%).

The questionnaire was divided into 9 main areas of interest: 1) demographic information, 2) the effect of genetic testing on cancer risk perception, 3) the effect of genetic testing on worry about cancer, 4) communication with family members since receiving test results, 5) attitudes towards surveillance, 6) attitudes towards preventive options, including prophylactic surgery, chemoprevention, diet and/or lifestyle changes, 7) satisfaction with clinical services, 8) need for additional support, and for non-focus group participants 9) satisfaction with their decision to have undergone genetic testing.

Results suggest that risk perception and cancer worry increase after carriers receive test results. Although all participants and respondents were highly satisfied with clinical services provided to them, a significant proportion of BRCA1 and BRCA2 mutation carriers strongly favoured the availability of support groups. Organization of such support groups should be a priority for clinical cancer genetics programs.

**ATTITUDE TOWARDS PROPHYLACTIC SURGERY AND EFFECTS OF GENETIC COUNSELLING IN FAMILIES WITH BRCA MUTATIONS.** *R. Moeslinger<sup>1</sup>, T. Wagner<sup>1</sup>, G. Langbauer<sup>1</sup>, Austrian Hereditary Breast and Ovarian Cancer Group<sup>1</sup>, E. Fleischmann<sup>1</sup>, A. Autherith<sup>2</sup>, A. Friedmann<sup>3</sup>, T. Helbich<sup>4</sup>, P. Oefner<sup>5</sup>.* 1) Dept OB/GYN, Div Senology, Vienna, Austria; 2) Department of Statistics, University of Vienna; 3) Department of Psychiatry, University of Vienna; 4) Department of Radiology, University of Vienna; 5) Stanford DNA Sequencing and Technology Center.

The intent of this study was to evaluate the effect that awareness of being a BRCA1 or BRCA2 mutation carrier has on the attitude towards prophylactic surgery and on developing depression symptoms. Sixty three families were selected on the basis of previously detected BRCA1 or 2 mutations and 142 family members were given the appropriate questionnaires. Prophylactic mastectomy (PM) was considered by 23% of the Austrian mutation carriers (28% affected and 17% non-affected carriers). The majority of affected and non-affected carriers expected PM to impair the quality of their life. Sixty percent would undergo prophylactic oophorectomy (68% affected and 50% non-affected carriers). The self-rating depression scale indicated that following mutation result disclosure the depression scores of carriers decreased (40 baseline vs. 39 after result disclosure,  $p=0.5$ ), whereas, for non-carriers, scores increased (37 baseline vs. 39 after result disclosure,  $p=0.8$ ). However in affected carriers only 4% have performed PM respectively only 17% PO and in non-affected carriers these percentages were even lower: Only 2% performed PM and 13% PO. We conclude, that information about carrier status is not associated with increased depression symptoms in mutation carriers. In non-carriers depression scores increased slightly, probably reflecting survivor guilt. The option of having PM was associated with a negative impact on the quality of life and was declined by the majority of Austrian mutation carriers.

**Counseling of Parents of the Neonate with Down Syndrome: The Need for Echocardiography.** *E.H. Zackai<sup>1</sup>, M. Straka<sup>1</sup>, E. Goldmuntz<sup>2</sup>*. 1) Division of Human Genetics and Molecular Biology; 2) Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA.

The counseling of the parents of a newborn with Down syndrome is multifaceted and since the incidence of congenital heart disease is high, it is important to determine the minimal screening procedures sufficient to identify the congenital heart defects. We undertook a study to determine whether normal cardiac exam was predictive of normal cardiac anatomy. 118 Down syndrome infants, ages birth-30 days, had a cardiac exam and subsequent echocardiogram regardless of initial findings. Of the 66 who had an abnormal cardiac physical exam, 55 (83%) had significant intracardiac defects (VSD - ventricular septal defect, CAVC - common atrioventricular canal, TOF - tetralogy of Fallot), while 8 (12%) had a PDA (patent ductus arteriosus) only and 3 (5%) had normal anatomy by echocardiogram. 52 patients had a normal cardiac physical exam, of which 19 (36.5%) had intracardiac anomalies (VSD, CAVC, bicuspid aortic valve), 14 (27%) had PDA only, and 19 (36.5%) had normal cardiac anatomy by echocardiogram. None of the 15 patients with a TOF had a normal cardiac exam, however, 10 of 37 patients with CAVC and 8 of 21 patients with VSD had a normal neonatal cardiac exam. Thus, the cardiac exam alone would have been falsely reassuring 19 out of 52 cases (36.5%) and these patients would most likely present later with a murmur or symptoms of congestive heart failure. The sensitivity of the clinical cardiac exam was only 74% (55/74). Thus, performing an echocardiogram on neonates with Down syndrome regardless of normal clinical cardiac exam, would increase the sensitivity of detection of the heart defect to 100%. It is noted that a cohort of patients with normal cardiac exam underwent echocardiogram and were anatomically normal as well (19/52; 36.5%) and that patients diagnosed with a PDA in the neonatal period (possibly representing normal transitional circulation) will require re-evaluation. Ultimately, however, echocardiogram in the neonate with Down syndrome leading to definitive diagnosis, either allays parental concerns or permits parental adjustments and allows for early presymptomatic care.

**Current views on continuing education and employee awareness assessed by a voluntary questionnaire during The 6th Annual New England Regional Genetics Conference: A need assessment for improved educational forums for genetic laboratory personnel.** *J.M. Luszcz, R. Naeem.* Dept. of Pathology, Baystate Medical Center, The Western Campus of Tufts University School of Medicine, Springfield, MA.

Recent advances in the human genome project have given rise to rapid developments in genetics. As a result, the provision of continuing education for those who work in the field is paramount in maintaining and improving both awareness and practical skills. A voluntary questionnaire was employed during The 6th Annual New England Genetics Conference to ascertain the opinion of genetic laboratory personnel regarding job satisfaction, laboratory competence, and their employers focus on continuing education. Forty one questionnaires were completed by attendees and subsequently reviewed. Approximately one third felt they were undereducated for their current duties. Interestingly, 85% had stated they had attended an educational event within the last year. Forty six percent felt they had reached a educational or training plateau at their current position. In response, 95% stated they would attend more educational events if made accessible by the employer. When asked about educational benefits, journals, regional genetics seminars, and local specialist lectures were rated in the fiftieth percentile. Sixty six percent said they had not attended a national genetics conference due to either financial difficulty, lack of support or the inability to receive time off. Fifty seven percent stated they were unsatisfied with their current salary status. In addition, 69% stated they would consider leaving the field of genetics for a better paying opportunity in an alternative career. Furthermore, only 29% felt they would still be working in laboratory genetics within the next five years. Based on this information it appears that an effort to improve continuing education policies in the workplace is warranted. Discrepancies with salaries, responsibilities, and employee support need further investigation in order to maximize productivity and minimize turnover rates in this particular subset of the field. In addition, a national survey is currently underway to determine similar trends across a broad geographical base.

**First, the bad news: What people with Marfan syndrome(MS)find when they search the internet for information.**

*R.W. Marion, A. Mendelson.* Dept Pediatrics, Children's Hospital at Montefiore/Albert Einstein College of Medicine, Bronx, NY.

As physicians feel the impact of managed care, leaving them with less time to spend with patients (pts), the internet is increasingly becoming a primary source of medical information for newly-diagnosed individuals. Because no editorial control exists, there is the potential that pts may encounter false information, raising the potential for harm. To investigate this, we examined information available on "Marfan-list" ([www.widowmaker.com/~jnavia/list.htm](http://www.widowmaker.com/~jnavia/list.htm)), a pt-run website consisting of a list of "subscriber" entries, and compared the clinical manifestations of MS reported by pts to those reported in a large retrospective series (Sun et al., *Am Heart J*, 120:934-948, 1990)

Of the 206 entries listed on "Marfan-list", 115 (56%) were written by pts and described clinical manifestations in enough detail to be analyzed. The website population reported a much higher incidence of serious cardiac manifestations (79% vs 38%), and a much lower incidence of ophthalmologic (42% vs 68%) and skeletal manifestations (50% vs 97%) than was observed in the Sun et al. series, indication that more life-threatening (and more fear-inducing) features are over-represented on the website, while the milder features were underrepresented.

Although more work is needed, this preliminary study confirms that information available from at least one pt-run website is skewed to provide more dire features. Physicians should provide guidance to their pts before they begin to search the internet.

**An Evaluation of the Usability of Pedigrees Produced by Patient-Driven Software for Stratifying Cancer Risk.**

*J.S. Graham<sup>1</sup>, L.M. Prensky<sup>1</sup>, K.L. Danziger<sup>1</sup>, R.W. Weber<sup>2</sup>, M.S. Komaromy<sup>1,3</sup>.* 1) Genetic Health, Inc, San Mateo, CA; 2) St. Mary's Hospital, San Francisco, CA; 3) University of California San Francisco, San Francisco, CA.

The ability to determine the degree of hereditary cancer risk has important implications for medical management of the entire family. The best method of assessment of hereditary risk is through examination of the family medical history or pedigree. The process of collecting the pedigree is time-consuming and often necessitates a separate genetic counseling visit. In order to streamline the process of risk assessment we have developed a web-based pedigree-builder system. In this study we compared the web-based pedigree with a pedigree produced by a genetic counselor for accuracy, completeness, and performance during cancer risk assessment. Pilot data with 12 patients indicates that using the web-based tool is acceptable to patients and can be completed without assistance. We collected pedigrees from forty patients recruited from a community-based oncology office. Participants provided their pedigree both by meeting with a genetic counselor and by recording their pedigree using the web-based software. The study included a crossover design in which half of the patients met first with a genetic counselor, and half used the web-based pedigree-builder system first. Using the counselor pedigree as the gold standard, the web-based pedigree was graded for accuracy and completeness. Then the pedigrees were analyzed using expert reviewed, rule-based computer algorithms designed to stratify their degree of hereditary cancer risk (general population, elevated risk, markedly elevated risk, or meeting established criteria for a hereditary syndrome). Results will be presented comparing the on-line tool with in-person collection methods with regard to: pedigree accuracy and completeness, and concordance for cancer risk stratification.

**The development of algorithms to assess family health history in a web based application - HealthHeritage.** *S.L. Pelletier<sup>1</sup>, B.B. Worrall<sup>2</sup>, M.B. Harrison<sup>2</sup>, S. Miesfeldt<sup>3</sup>, A.L. Tucker<sup>3</sup>, T.E. Kelly<sup>4</sup>, P. Schnatterly<sup>4</sup>, J. Einbinder<sup>1</sup>, M. Reitmeyer<sup>3</sup>, W.F. Cohn<sup>1</sup>, W.A. Knaus<sup>1</sup>.* 1) Department of Health Evaluation Sciences, University of Virginia Health System, Charlottesville, VA; 2) Department of Neurology; 3) Department of Internal Medicine; 4) Department of Pediatrics.

Advances in the understanding of the genetic basis of common diseases, including those that are multifactorial, have the potential to change the practice of clinical medicine. Complete patient care may involve the ability of the primary care physician to assess genetic risk and make individual patient recommendations regarding prevention, screening and treatment. A secure patient-driven web tool has been developed to facilitate the collection and interpretation of family health history information. This tool includes algorithms for assessing individual risk based on family health history in five disease areas: (1) oncology (e.g. breast, ovarian, colon, prostate, kidney, skin, thyroid); (2) cardiology (e.g. cardiomyopathy, arrhythmia, structural heart abnormalities); (3) vascular disease (e.g. hypertension, atherosclerosis, metabolic lipid disorders, stroke); (4) neurology (e.g. neuromuscular disease, movement disorders, epilepsy, dementia); and (5) endocrinology (e.g. diabetes, osteoporosis). Risk algorithms were developed using comprehensive, evidence-based literature reviews and consultation with genetic specialists. Rules were developed to stratify risk for autosomal dominant, recessive, mitochondrial and X-linked conditions. Factors that modify risk were included in development of algorithms for the multifactorial conditions. These algorithms make the process of risk assessment explicit and can be updated if new risk information becomes available. Management recommendations are based on the best available evidence, published guidelines and expert opinion and include screening, treatment, prevention and risk modification. The tool has the potential to increase recognition of the influence of genetics on disease in the primary setting and decrease the burden on primary care physicians. A pilot test of HealthHeritage in the primary care setting is currently underway.

**Views and attitudes toward malformations among nursing college students.** *H. Kawame*<sup>1,3</sup>, *Y. Fukushima*<sup>2</sup>, *Y. Eto*<sup>3</sup>.  
1) Tokyo Metropolitan Kita Med.& Rehabilitation Ctr, Tokyo; 2) Shinshu Univ. School of Med., Matsumoto; 3) Jikei Univ. School of Med., Tokyo, Japan.

In Japan, an increasing percentage of hospitalized children have congenital malformations. Factors contributing to this increase include improved medical management, improved clinical genetics services, and longer length of stay for medical and social reasons. Currently, genetic counseling, as a profession, does not exist in Japan. Therefore nurses provide much of the genetic counseling, which these children's families receive. This pilot study was designed to characterize the attitudes of Japanese nursing students toward visible malformations. Information from this study can be used to develop genetic curricula for these students. A questionnaire was given to 61 3rd year nursing students at a private medical university in Tokyo. Fifty eight percent of the students previously had contact with individuals with physical malformations. All 61 students reported a personal negative attitude toward physical malformations, especially to the Japanese word "ki-kei" (strange shape). They also all felt that current Japanese society would respond negatively to people with physical malformations. The majority (74%) thought of malformations as a "disease" and considered people with malformations as being "disabled" or "handicapped." On the other hand, 75% considered the malformation to be only one aspect of the child's personality. Regarding prenatal diagnosis, 45% felt that they would consider prenatal diagnosis for malformations and 38% would not. Almost half (49%) said that prenatal diagnosis of an abnormality would inevitably lead to a termination. In an open-ended question about what professionals can do for families with malformations, the nursing students suggested providing as much information as possible, referring families to support groups, helping mothers deal with feelings of guilt, and providing a non-discriminatory atmosphere for families. We conclude that genetic training programs for nurses should include early and frequent exposure to various disabilities and more formal education on congenital malformations and genetic disabilities.

**Parental Attitudes Toward Genetic Testing for Pediatric Deafness.** *J.W. Brunger<sup>1</sup>, A.L. Matthews<sup>1</sup>, M. O'Riordan<sup>2</sup>, G.S. Murray<sup>3</sup>, R.J.H. Smith<sup>4</sup>, N.H. Robin<sup>1,2,3</sup>.* 1) Genetics; 2) Pediatrics; 3) Otolaryngology, Case Western Reserve Univ, Cleveland, OH; 4) Otolaryngology, Univ Iowa.

Recent advances in understanding the molecular genetic basis of deafness has resulted in genetic testing becoming an option for deaf individuals and their families. However, there is little information about the level of interest in such testing. To investigate this question, a survey was sent addressing attitudes toward diagnostic, carrier, and prenatal genetic testing for deafness. The target population, parents with normal hearing who have one or more deaf children, represents the vast majority of individuals who will be encountered in clinical practice, as 90-95% of deaf individuals are born to normal hearing persons. Collaborating audiologists, otolaryngologists, and geneticists distributed 328 surveys, and 96 (29%) were completed and returned. Overall, 96% recorded a positive attitude toward genetic testing for deafness, including 70/96 (76%) who were interested in or had had such testing. 61/70 (87%) believed that genetic testing for deafness should be offered prenatally, but only 1/61 stated she would terminate her pregnancy because of profound deafness. The vast majority would not terminate such a pregnancy and did not believe that deafness implied a poor quality of life. In general, however, these parents had a poor understanding of genetics. The vast majority (98%) incorrectly estimated the recurrence risk of deafness, and misunderstood the mode of inheritance in their family. Notably, these findings were similar in both the group who had had genetic testing for their children and those who had not had testing. This similarity suggests that the parents who received genetic testing (n=32) did not receive genetic counseling, or that the counseling was not effective. Based on these results, we conclude that this population is interested in utilizing genetic testing. The testing should not be done without first providing formal genetic counseling. By including appropriate counseling, the risks, benefits, and limitations of genetic testing can be addressed. Each individual then will have the ability to make an informed decision whether to utilize this testing.

**Assessment of knowledge regarding the prevention of alcohol related birth defects (ARBDs) and neural tube defects (NTDs) among postpartum women in Washington (WA) State.** *M.A. Eaglin, T. Bell, R.M. Fineman.* MCH, Washington State DOH, Olympia, WA.

The relationships between the consumption of alcohol and ARBDs, and the consumption of folic acid (FA) and the prevention of NTDs, are well established. An important question that remains is whether all pregnant women are equally informed about these important health care issues. In order to help address this question, we analyzed self-reported, postpartum (PP) data from the WA State Pregnancy Risk Assessment Monitoring System from April 1996 through December 1998. PP, resident women were asked whether a doctor, nurse, or other prenatal care provider (PCP) talked to them about how drinking during pregnancy could affect their baby, and whether they had ever heard or read that taking the vitamin FA could help prevent some birth defects (BDs). Overall, 81.7% of PP women reported that a PCP talked to them about how drinking during pregnancy could affect their baby; while 70.4% reported hearing or reading about how taking FA could prevent some BDs. This means that, overall, PCPs in WA probably missed a significant number of opportunities to educate pregnant women about the prevention of ARBDs and NTDs. In addition, PCPs were: 1) significantly LESS likely to discuss the effects of drinking during pregnancy with women who were: older than 20, had more than 12 years of education, married, White, and not Medicaid recipients; and 2) MORE likely to discuss the effects of drinking with their traditionally under-served patients. Not surprisingly, maternal attributes associated with NOT having heard or read about the beneficial effects of FA included: maternal age less than 20, education less than 12 years, Hispanic, unmarried at the time of birth, used Medicaid to subsidize prenatal care, and had an unintended pregnancy (i.e., traditionally underserved patients). In order to improve birth outcome, PCPs, public health professionals and others should attempt to educate all women of reproductive age (and especially pregnant women) about these important health care issues, instead of targeting certain groups based on certain socio-demographic attributes (see also *Comm Genet* 2:61-68, 1999).

**Four Years of Experience in a High-Risk Cancer Genetics Clinic: Lessons Learned.** *J.P. Evans, C. Skrzynia, E.M. Rholfs, J.K. Booker, L.M. Silverman, Q. Yang, H. O'Lear, M.L. Graham.* Dept Medicine, Univ N Carolina, Chapel Hill, Chapel Hill, NC.

Since 1996 The UNC Cancer Genetics Program has counseled high-risk Breast and Ovarian cancer families and offered BRCA1/2 testing. Over 400 families of diverse ethnicity were counseled. Individuals from 117 families(25%) chose to pursue genetic testing. The UNC Clinical Laboratory performed Protein Truncation analysis (PT) for BRCA1 and 2 and complete sequencing of the BRCA1 coding region. PT variants were confirmed by sequencing. Sixteen different BRCA1 or 2 mutations were found in 17 families, for a mutation incidence of 17%. A total of 50 at-risk relatives were also tested and 45% carried the familial mutation. The presence of phenocopies is a potentially confounding issue in high-risk families. This concern is highlighted by our experience in which 4 individuals who belonged to mutation positive families and had previously developed breast cancer were found to be mutation negative. It has been postulated that African Americans (AA) with a family history of breast cancer are at lower risk of carrying a mutation in BRCA1/2. Of 9 AA families tested, 2 carried a BRCA1 mutation (22%), similar to that of Caucasians. A strong predictor of discovering a familial mutation included the presence of an individual with both breast and ovarian cancer (5/12 or 42% of such pedigrees were mutation positive). Likewise, the presence of breast cancer diagnosed at less than 41yo in a first degree relative indicated a high likelihood of finding a mutation (8/31 or 26%). A variety of statistical models have been developed to predict the chance of finding a BRCA1/2 mutation as a function of family history. The most recent version of BRCAPro (a modeling program) was used to estimate the chance that a mutation would be discovered. For the BRCA1/2 positive individuals, the BRCAPro estimate ranged from 2.9% to 100%, emphasizing the need for clinical judgement in determining appropriate candidates for testing and not exclusive reliance on a statistical modeling program. The above issues should be considered when counseling individuals regarding the decision to undergo genetic testing.

**An analysis of reproductive choices within families affected by Huntington's Disease.** *B.J. Beyer, V.E. Headings.*  
Genetics and Human Genetics, Howard University, Washington, DC.

Huntington's disease (HD) is a late-onset progressive neuropsychiatric disorder. Children of affected parents are at 50% risk to develop the disease. Presymptomatic gene testing is now available to determine if at-risk individuals will develop HD. One common reason individuals undergo predictive testing is to make informed decisions regarding reproduction. Therefore, this study examined how individuals in families affected by HD approach the available reproductive options. There were 45 questionnaires completed, with 69% of the participants at-risk to develop HD, and the remaining 31% spouses of at-risk individuals. The reproductive choice considered most likely was to refrain from having children (47.5%), with sperm donation the least likely (87.5%). Males were more likely than females to choose to have children without assisted reproduction ( $p=.001$ ). Spouses were more likely than at risk-individuals to choose sterilization of the at-risk parent ( $p=.04$ ). Those participants less than the median 45 years of age were more likely to choose preimplantation genetic diagnosis than those who were older ( $p=.03$ ). Individuals who learned of HD in their family at a younger age ( $< 29$  years) were more likely to adopt/foster children than those who learned later in life ( $p=.042$ ). None of the participants had undergone prenatal diagnosis in the past. However, 40% would choose prenatal diagnosis in the future, with 38% stating they would terminate a pregnancy with HD. Only 44.8% of the at-risk individuals met with a genetic counselor, and only 13.8% discussed reproductive options during the encounter. However, 25% stated that the appointment changed their opinions regarding reproduction. Therefore, this study strongly suggests that some individuals within families affected by HD have considered various reproductive options, and may benefit from more discussion with genetic counselors. Hence, we feel that the results from this study indicate the necessity of a pamphlet listing and defining the various reproductive options, in addition to identifying diagnostic and counseling services.

**Initial phone disclosure of BRCA1/2 results is acceptable in high risk women.** *J.R. Klemp, C.J. Fabian.* Breast CA Prev Ctr, Univ Kansas Medical Ctr, Kansas City, KS.

Women at high risk for breast cancer based on family history, precancerous breast disease, and/or prior breast cancer, were eligible to undergo free and confidential BRCA1/2 full sequencing (Myriad Genetic Laboratories, Inc ) as part of a 6-month Phase II chemoprevention trial. Women received pre-test counseling performed by a risk counselor at their 4-month visit and prior to drawing their blood sample at their 6-month study completion visit. Ninety-seven percent (116/119) of the eligible subjects underwent testing. In >90% of the subjects, results were initially discussed by phone with either the physician and/or risk counselor. A subsequent in-person consultation was mandatory for uncertain or deleterious subjects including the patient, physician, cancer risk counselor, and additional family members if desired and optional for negative individuals. Subsequently, subjects were sent a satisfaction survey in the mail, 91% (105/116) responded. Twenty-four of the 26 women with a deleterious (3), uncertain mutation (17 ), or polymorphism (4) responded. One subject with a positive result felt that the information provided needed to be easier to understand and another subject with a deleterious mutation felt that the results should have been disclosed over the phone instead of requiring an in-person visit. Subjects with negative results were satisfied with the testing process. 100% of the respondents felt they made a wise decision in having the testing and 97% (102) would recommend that other woman in a similar situation undergo genetic testing. Access to genetic testing was influential in recruiting eligible women onto the chemoprevention trial: 41% (43) stated access to genetic testing was influential, 43% (45) stated they will be more likely to participate in future trials, and only 3% (3) stated they will be less likely. The vast majority of high risk women participating in a clinical trial will undergo anonymous and free BRCA1/2 genetic testing, were accepting of receiving results initially by phone, and felt they made a wise decision to undergo genetic testing.

**Amniocentesis rates in women of Puerto Rican ethnicity.** *E.L Habecker<sup>1</sup>, J.G Habecker-Green<sup>1</sup>, R. Naeem<sup>2</sup>, G.M Cohn<sup>1</sup>*. 1) Clinical Genetics, Baystate Medical Center, Springfield, MA; 2) Cytogenetics, Baystate Medical Center, Springfield, MA.

Several studies have been published on the selective use of amniocentesis by patients of different socioeconomic status, educational background, and ethnicity. We were unaware of any studies that specifically addressed uptake of amniocentesis by patients of Puerto Rican ethnicity. We hypothesized that, based on religious and cultural values Puerto Rican patients may opt for fewer amniocenteses than patients of other ethnicities. A retrospective chart review was undertaken of a random sample of patients seen by genetics services at Baystate Medical Center. Patients were selected for analysis if they had been counseled about amniocentesis between 1994 and 1997, and if they had been referred for genetic counseling by Baystates resident clinic. Resident clinic patients were selected in an attempt to control for socioeconomic status and educational background. 200 charts were selected and the following data points recorded: consult date, counselor, patient age, patient ethnicity, whether the patient was accompanied to the consult, the indication for offering amniocentesis, the numeric risk quoted for the relevant anomaly, whether amniocentesis was accepted, and the result of amniocentesis if performed.

Of the 200 charts reviewed, 10 were excluded from further analysis as the ethnicity was mixed Puerto Rican and other or because the ethnicity had been recorded as hispanic. Of the remaining charts, 93 patients were Puerto Rican and 97 were of other ethnicities. Each group was equally distributed with respect to consult date, counselor, whether accompanied, indication, and numeric risk for anomaly. The patients of Puerto Rican ethnicity had an average age of 25.7 years, those of other ethnicities of 27.1 years. 3 chromosomal anomalies / variants were seen, all in patients of Puerto Rican ethnicity. 27% of each group accepted amniocentesis no differences based on ethnicity were seen. This finding would indicate our hypothesis that Puerto Rican patients would choose fewer amniocenteses was incorrect.

**The Belief of the Role of Genetics in the Development of Alcoholism.** *P. Manowitz<sup>1</sup>, R.M. Hamer<sup>1</sup>, T.M. Creeden<sup>2</sup>, J. Ballou<sup>3</sup>*. 1) Dept Psychiatry, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 2) Reproductive and Perinatal Genetics, St. Peter's University Hospital, New Brunswick, NJ; 3) Eagleton Institute, Rutgers, The State University of New Jersey, New Brunswick, NJ.

**Objective:** A number of genetic studies have been conducted to identify genes predisposing to alcoholism. The reason for identification of these genes is that this information may be useful in alcoholism prevention and treatment. However, little if anything is known about the receptivity of the general public to the concept that alcoholism has a genetic basis. The purpose of this study was to assess the belief regarding the role genetics plays in the development of alcoholism. **Method:** A general telephone survey was conducted of 953 individuals asking them to assess the effect the following have on a person's likelihood to become an alcoholic: parent's drinking habits when a child is growing up, a bad home situation, genetics - which is a person's genes or biological make-up, or a bad work or job situation. **Results:** Seventy seven percent of the respondents said that genetics has either a lot or some effect on a person's likelihood to become alcoholic. **Conclusions:** For each subgroup examined with regard to a wide variety of variables (age, education, alcohol intake, etc.), the majority stated that genetics has a lot or some effect on alcoholism formation. The data do support the hypothesis that having a parent with an alcohol problem is related to an increased belief in the importance of genetics in alcoholism formation. Even though modifying factors such as age, sex, alcohol intake, and educational level may be operable in determining the extent of the belief, these effects appear to be modest. This information may be helpful in devising future strategies for utilizing genetic information to prevent and treat alcoholism.

**Genetic testing for Alzheimer's disease: Preliminary results of a protocol for presymptomatic APOE genotyping.**

*S.A. LaRusse<sup>1</sup>, L.D. Ravdin<sup>1</sup>, C. Brockman<sup>2</sup>, J. Tsai<sup>2</sup>, J.G. Davis<sup>1</sup>, R.C. Green<sup>3</sup>, T.B. Brown<sup>3</sup>, N.R. Relkin<sup>1</sup>.* 1) Neurology, Cornell Medical Center, New York, NY; 2) New York University, New York, NY; 3) Boston University, Boston, MA.

Consensus statements have advised against clinical use of APOE genotyping for predictive purposes. Future use of genetic tests to identify patients at an increased risk for AD is anticipated and therefore, an AD susceptibility genetic counseling model needs to be developed. We have conducted a pilot study for APOE genetic counseling and testing. The study protocol consisted of an informational session, genetic counseling and testing, results disclosure, and a follow-up interview. Participants were self-referred from the community. Exclusion criteria included significant neurologic or psychiatric history and cognitive deficits on neuropsychological testing. Subjects completed a questionnaire on genetics and AD before and after the informational session, after the second session, and 3 to 6 months after disclosure of genotype. Thirty-four individuals enrolled in the study and attended the informational session. Seventeen of those individuals consented to APOE genotyping. The primary reasons for wanting testing were future planning (71%), potential for early treatment (57%), and reducing anxiety (48%). The most common reasons for declining testing were fear of insurance discrimination (75%) and lack of treatment for AD (75%). The results indicate that the informational session was effective in conveying factual information. Four individuals possessed at least 1 e4 allele, and only one of these subjects reported feeling greater anxiety after learning their genotype. Results from the follow-up survey show that counseling had a positive impact and increased most subjects' knowledge about AD genetics. In addition, our results indicate that sense of personal risk decreased over the course of the study for the majority of participants. This protocol can be used as a prototype for future AD susceptibility testing and is undergoing further development as part of an ELSI sponsored study now underway (The REVEAL Study).

**Knowledge and Attitudes of Obstetricians and Gynaecologists and Patients towards the Maternal Serum Triple**

**Screen.** *T. Stermer*<sup>1, 2</sup>, *P. Craig*<sup>1, 2</sup>, *D. Viljoen*<sup>1, 2</sup>, *A. Krause*<sup>1, 2</sup>. 1) Human Genetics, South African Inst Med Res, Johannesburg, Gauteng, South Africa; 2) University of Witwatersrand, Johannesburg, Gauteng, South Africa.

Genetic counselling experiences in Gauteng, South Africa, of patients who have undergone the maternal serum screen (MSS) have indicated that women may not be given sufficient information about the test, resulting in much anxiety. A study evaluating the knowledge and attitudes of Obstetricians and Gynaecologists (O&Gs) and patients towards the MSS was conducted. A questionnaire exploring these subjects as well as the practices of O&Gs with this test was posted to 275 O&Gs in and around the Gauteng region. In addition, patients who received either a high risk/low risk result in the MSS have also been interviewed to determine their attitudes and experiences with this test. So far, 60 questionnaires have been returned (22% return rate) and more are expected. Thirty-five interviews of the 60 interviews targeted have been conducted. Results suggest that O&Gs' factual knowledge concerning this test is relatively good (scoring over 75%), however, in some cases extremely poor (as low as 36%). A large number of doctors (78%) offer this test to all their pregnant patients, and not only to women under 35 years of age, for whom the test is designed, thus resulting in many false positive results. Most O&Gs felt it is unnecessary to refer a patient to a genetic counsellor (57% of the time). Almost all O&Gs felt this test is inadequate in sensitivity and specificity resulting in much unwarranted anxiety, however, as no definite alternative is available, it is still a useful procedure. Patient interviews suggest that although women are aware of the purpose of the test, they are not made aware of its accuracy and sensitivity, and are often falsely reassured with a low risk result. There seems to be a general consensus that receiving an information pamphlet explaining this test, its short-comings and consequences, in a visit prior to the 16-week visit when the test is performed, would be very helpful in making an informed choice whether to have the test or not, based on their personal and religious beliefs.

**Monsters, Myths, and Eugenics: Public Perception of the Human Genome Project.** *M.Z. Peliás, N.J. Markward.*  
Dept Biometry & Genetics, Louisiana State Univ Health Sciences Ctr, New Orleans, LA.

Recent events in the world of gene therapy have attracted close scrutiny to the activities of professionals in medical genetics and genetics research. While the genetics community has celebrated the successful treatment of children in France for SCIDS and grieved the death of a young American man with OTC deficiency, individual commentators and the media have continued to suggest that professional geneticists are less than ethical in the practice of medical genetics and in biomedical research. One report, now 10 years old, began with a long discussion of the monsters of literary fiction, followed by a lengthy examination of the perils of human genome research and the eugenic overtones of medical genetics and genetic counseling. These themes continue to surface, always without thorough explanation of the perceived connections to genetics, and often without definitions and distinctions among similar words. Further, the media, in search of news items, are necessarily constrained by column space and time clips from presenting thorough, comprehensible reports about current activities in medical genetics and genetics research. These approaches to reporting news about genetics nourish fear and suspicion among the lay public and generate one of two responses within the genetics community. Some geneticists, faced with unfounded allegations and generalizations, retreat from public view and, probably unwittingly, contribute to the shroud of mystery that covers research and practice in genetics. Others, at least in small numbers, are available for comment and clarification, and participate in public programs that seek to make genetics and the benefits of genetics research understandable and attractive to the lay public. A forthright approach in public communication should become the standard of conduct for genetics professionals.

**Genetic knowledge , opinions and practices amongst general practitioners in South Africa.** *K.L.M. Trenton<sup>1,2</sup>, P. Craig<sup>1,2</sup>, D. Viljoen<sup>1,2</sup>, A. Krause<sup>1,2</sup>.* 1) Human Genetics, South African Inst Med Res, Johannesburg, Gauteng, South Africa; 2) University of the Witwatersrand, Johannesburg, Gauteng, South Africa.

The arena of Human Genetics is playing a greater role in healthcare than ever before. The question arises whether these scientific advances are moving swiftly enough from the field of science to the practitioners of medicine. In general, since the onset of genetic services in South Africa (SA) in 1971, knowledge and attitudes regarding the utilization of these services have often been misguided. Medical institutions and practicing doctors are unaware of the important intricacies of genetics that impact on their patients. Genetic counseling (GC) is underutilized and many genetic conditions are neither recognised nor diagnosed. The field of Human Genetics is clearly beneficial but in SA has lagged far behind in areas such as health service and education. This study aimed to obtain and analyze the current genetic knowledge and attitudes that are in place amongst primary care physicians (GPs) in the Gauteng province of SA. It also aimed to obtain a clearer understanding of the opinions that GPs have towards GC. A questionnaire examining these topics was designed and was posted to 1091 GPs selected by choosing 1 in 9 of the GPs registered with the South African Medical Association in the Gauteng area. Less than 7% of this targeted group replied - a possible indication in itself of the general apathy and insecurity that doctors may feel towards the topic of genetics. Fifty face-to-face interviews utilizing the questionnaire were also conducted so that first hand responses could be recorded. The data collected from all these responses indicate that SA GPs have a poor genetic knowledge with a mean overall score of 57% in the genetic knowledge section of the questionnaire. Whilst genetics and GC is held in high regard, and deemed important in the primary care context, it is generally viewed as out of the GPs realm and in general they do not feel informed enough in this area to become involved in genetics. In this study 92% of GPs felt unable to construct a family history and draw pedigrees and 94% felt unable to discuss genetic tests and risks with their patients.

**Prophylactic Surgery to Reduce Cancer Risk: Attitudes Before and After the Availability of Genetic Testing.** C. Skrzynia, E.M. Rohlf, J.K. Booker, H. O'Lear, L.M. Silverman, M.L. Graham, J.P. Evans. University of North Carolina at Chapel Hill; Chapel Hill, NC.

Many women who perceived their risk of breast and ovarian cancer to be elevated underwent prophylactic mastectomy (PM) and/or oophorectomy (PO) in the years preceding the availability of genetic testing. Some of these women subsequently underwent genetic testing for BRCA1/2 mutations once it was available. Little is known about how these women react to learning their mutational status. The Cancer Genetics Clinic at UNC has evaluated over 400 families in the past 4 years regarding their cancer risk. 168 women were tested. There were 32 mutation carriers, for a mutation incidence of 17%. Three of the women who learned they were negative for a familial mutation had previously undergone PM. These three women were interviewed and their reactions to having undergone what might, in retrospect, be considered unnecessary surgery, were assessed. In the current era, genetic testing is sometimes undertaken to guide a woman's decision regarding prophylactic surgery. We were interested in how the results of genetic testing are used when making a decision about the pursuit of PO. In the 19 mutation carriers who still had their ovaries the decision to undergo PO was highly age dependent. Of 11 women who were under 36 years old and were mutation carriers, none underwent PO, while of the 8 women over 35 years of age, 6 (75%) opted for PO. The discovery that one is a BRCA mutation carrier can lead to a change of attitude about prior treatment. For example, one woman in our series had undergone bilateral lumpectomies, chemotherapy, and XRT for previously diagnosed bilateral breast cancer. Upon learning that she carried a mutation in BRCA1, she proceeded with bilateral PM and PO. The decision about prophylactic surgery is highly dependent upon age of the carrier, previous diagnoses and treatment, and may be influenced by new data regarding the efficacy of prophylactic surgery in reducing cancer risk.

**Amniocentesis Utilization in a Diverse Urban Population: A Profile of Patients in the 21st Century.** *V.B. Penchaszadeh, D. Puñales-Morejon, G. Havens, M. Cantwell.* Division of Medical Genetics, Beth Israel Medical Center, New York, NY.

Information about factors that impact on women's decision-making processes regarding prenatal diagnosis is important for genetic counseling. Various studies have examined women's experiences with amniocentesis and have described specific factors as having a role in women's testing decisions. However, most studies were limited by sampling homogenous populations, analyzing small numbers of patients or showing methodological inconsistencies in data collection. This study was conducted to assess utilization of amniocentesis in a diverse urban population and to correlate its use with demographic and medical factors. Variables included: referral reasons, indication for amniocentesis, maternal age, race, ethnicity, education, occupation, marital status, partner attendance, gestational age of current pregnancy, parity, planning of pregnancy and amniocentesis decision. Data was collected on 1227 patients referred for prenatal genetic counseling primarily for age-related risk or abnormal prenatal screening. Seventy-eight percent of the 1063 patients for whom amniocentesis was medically indicated, and 18 percent of the 164 patients for whom it was not indicated elected to have the procedure. Blacks and Latinos were found to be less likely than Whites or Asians to have amniocentesis. In addition, those who were married, were professionals, had medical insurance, came to counseling with their male partners or planned their pregnancies, were more likely to have amniocentesis performed. Furthermore, patients who had amniocentesis tended to be older, have at least a bachelor's degree and be at an earlier gestational age. A multivariate logistic regression indicated that education was the primary factor associated with having amniocentesis performed. Data from this study can be helpful for genetic counselors and geneticists to identify which variables are useful in predicting a woman's decision to use or not use prenatal diagnosis. It is anticipated that the results from this investigation will assist in better understanding the prenatal diagnostic decision-making process.

**Cultural and Linguistic Considerations in Development of Genetic Educational Materials in a Predominately Mexican American Population in South Texas.** *M. Aguilar*<sup>1</sup>, *S. Kolb*<sup>2</sup>, *P. Visio*<sup>3</sup>, *J. Livingston*<sup>3</sup>, *C. Aguirre*<sup>3</sup>, *C.I. Kaye*<sup>3</sup>. 1) CHRISTUS Santa Rosa Health Care; 2) University of the Incarnate Word; 3) University Texas Health Science Center at San Antonio.

Children in South Texas, of whom 76% are Mexican American (MA), fail to comply with recommendations for genetic services. Over 63% of families of children with Spina Bifida (SB) are not compliant with recommendations for urinary care; 65% of children with SB are obese; 53% of children with Metabolic Disorders and 72% of children with Diabetes Mellitus are in poor dietary control. A sample of 27 MA families was selected based on clinic attendance rate of 80% and poor compliance with medical recommendations. Each family was assessed for Spanish/English health literacy, values/attitudes, and preferred learning methods. The Test of Functional Health Literacy in Adults (TOFHLA) was used to assess literacy. A Family Learning Preferences (FLP) tool inquired about previous teaching received by the family, and preferred "ways of learning." Family specific culturally based health factors were assessed using the Health Beliefs Questionnaire - Revised (HBQ-R). The TOFHLA scores indicated that 31 % of the subjects interviewed had an inadequate to marginal functional health literacy level, while 69 % of subjects had an adequate functional health literacy level. The FLP indicated that "best liked way of learning" was in small groups (4-5) and by videotapes and demonstration. The "least liked way of learning" was in large groups (10 or more), by written materials, and teaching done by other parents. Using the HBQ-R Likert Scale, there were statistically significant positive correlations between acculturation and education ( $r = .648$ ); between literacy and education ( $r = .460$ ); and a negative correlation between folk beliefs and education ( $r = -.570$ ). Preliminary findings suggest that attention to reading level and preferred learning styles is needed for development of culturally/linguistically appropriate genetic educational materials to insure successful outcomes. This project is supported by MCHG Project # 97-11.

**Public Attitudes about the Importance of Genetic Factors in Determining Health.** *A.S. Brown, S.S. Wang, M.L. Gwinn, M.J. Khoury.* Office of Genetics and Disease Prevention, National Center for Environmental Health, Centers for Disease Control, Atlanta, GA.

With the increase in the amount of genetic information readily available to the public and the integration of DNA-based diagnostics into health care, it is important to understand which characteristics determine how people respond to genetic information. To assess public attitudes about the relative importance of genetic factors in determining health, we examined data from the 1998 American Healthstyles Survey. Individuals participating in this survey of health attitudes and behavior are representative of adults in the U.S. with regard to age, gender, marital status, race, income, region, household income, and residence (urban, suburban, rural). As part of this survey, participants were asked whether they agreed with this statement: "Genes determine more of a person's health than other things, like their behavior or their environment". Of 3,130 survey participants, 2,639 (84%) completed this question. Overall, 37% agreed, 26% disagreed, and 36% neither agreed nor disagreed with the statement. Those who agreed were more likely ( $p < 0.05$ ) to: 1) have a high school education or less (OR = 1.4), 2) have household incomes less than \$50,000 (OR = 1.3), 3) be widowed (OR = 2.9), and 4) be older than 45 years old (OR = 2.0) ( $p < 0.05$ ). These people were also more likely than others to believe that genetic research will prevent future disease (OR = 2.0). These findings suggest that characteristics such as education, income, and age may contribute to a person's attitudes about the importance of genes in determining health. Such people could respond with either a fatalistic or overly optimistic attitude upon learning the results of a genetic test. Providers of genetic information should be aware of these characteristics as they design education programs about the use of genetic information to make informed decisions concerning genetic testing and personal health behaviors.

**Genetics and Emergency Room Medicine.** *P.F. Giampietro, P. Kumar, J. Radhakrishnan.* Dept Pediatrics, Lincoln Hospital and Mental Health Center, Bronx, NY.

Patients with genetic disorders pose a special challenge for Emergency Room (ER) medical staff because they have more frequent admissions, longer stay and increased morbidity and mortality and complex health needs. A retrospective study of 15,258 Pediatric Emergency Room (ER) charts at our institution was undertaken in order to determine the prevalence and patterns of presentation of previously diagnosed and suspected genetic disorders among pediatric ER visits over a period of time between October, 1998 through February 1999. Patients with asthma and diabetes were excluded from our study group since referral for genetics evaluation would not be expected to impact their overall management. 318 patients (2.08%) had known or suspected genetic diseases. Known genetic disorders were observed in 80 patients (25.15%) which were further classified into single gene disorders 69(86.25%), chromosomal disorders 3(3.75%) multifactorial disorders 6(7.5%) and others 2(2.5%). The remaining 238 patients (74.85%) had presenting complaints/diagnosis that suggested the possibility of an underlying genetic disorder requiring further evaluation. These included development and behavior issues 84 (35.2%), CNS problems 59 (24.8%), skin disorders 25 (10.5%), cardiovascular system problems 20 (8.4%), hematological problems 19 (8.0%), ENT problems 10 (4.20%), psychiatric issues 6 (2.52%), musculoskeletal problems 6 (2.52%), endocrinologic disorders 4 (1.68%), metabolic 3 (1.26%), renal 1 (0.42%) and gastrointestinal disorders 1 (0.42%). Based on prior studies reported in the literature for inpatients, we believe the prevalence of 2.08% represents an underestimate, which is most likely due to incomplete secondary diagnosis documentation. A referral to genetics was not listed in the management plan for any of these patients. Since many genetic disorders are associated with acute and chronic health care issues encountered in an ER setting, these data suggest a need for genetics professionals to target ER medical staff for education regarding the acute multi system presentation of genetic disease and the important role that genetic specialists have in the long term management of patients with genetic disorders.

**Gene Therapy in Genetic Counseling: a survey of knowledge and attitudes.** *P.E. Gregory, S. Balsom.* Div. Human Cancer Genetics, Ohio State Univ, Columbus, OH.

Advances in gene therapy for both inherited and acquired disorders bring DNA-based therapies closer to being incorporated into clinical care. Consequently, genetic counselors will increasingly be called upon to explain gene therapy and its applications to their patients. In 1992, we attempted to assess the attitudes and aptitudes of genetic counselors on this subject. This study is a follow-up to that survey and is designed to identify changes that may have occurred in the past eight years. The current survey was conducted via e-mail with a third-party to anonymize the responses. Using the internet was not only more cost-effective but also increased the participation rate. Surveys were e-mailed to every genetic counselor who is a member of the National Society of Genetic Counselors, the responses were anonymized and the data entered into a database for analysis. The previous study had shown that there was a direct correlation between recent matriculation and knowledge of current gene therapies. These differences held true in this second survey. Questions concerning knowledge of gene therapy techniques showed an inverse correlation between the number of years in practice and the percentage of correct answers. The more experienced counselors, with 10 -15 years of experience, were four times less likely to include any information about gene therapy in their counseling. However, 100% of this group felt that "information on human gene therapy should be incorporated into genetic counseling training curricula. This statistic has remained the same since the original survey. Interestingly, the most substantial differences were observed in counselors' attitudes toward gene therapy. Experienced counselors were more concerned than any other group about the "unknown risks of therapy" (95% vs 62% and 68%). New counselors (with less than 5 years experience) were least concerned about gene therapy on embryos. Our results suggest that many of the findings in the original survey have held true, despite many changes in gene therapy in the past 8 years. Since gene therapy is rapidly changing, there is an even greater need for continuing education programs for genetic counselors in this area.

**A Prototype for Clinical Training in Medical Genetics for Third Year Medical Students.** *A.E. Greb<sup>1</sup>, G.L. Feldman<sup>1, 2</sup>*. 1) Center for Molecular Medicine and Genetics; 2) Departments of Pathology and Pediatrics, Wayne State University School of Medicine, Detroit, MI.

While advances in medical genetics are causing fundamental changes in the way physicians think about health and disease in their practice of medicine, similar changes in medical school curriculums have been slower to develop. The average number of hours devoted to coursework in medical genetics is 29 (based on a 1995 survey of U.S. and Canadian medical schools performed by the Association of Professors of Human and Medical Genetics). Most medical genetics courses are taught during the preclinical years, prior to the medical students knowledge of clinical pathophysiology and patient care. At most institutions, there is no formal mechanism during the 3rd or 4th years to reinforce the genetics information introduced during their preclinical introductory course. Through funding received from the Michigan Department of Community Health, we developed an interactive computer-assisted learning exercise using a problem-based approach to integrate genetic principles into a primary care clerkship. Students are provided information about a hypothetical case, including a referral letter, family history and physical symptoms. The student works through a differential diagnosis and decides upon appropriate tests and is asked to provide the family information about prognosis, etiology, recurrence risks, available options and appropriate resources. Ethical, legal and social issues are included in the case study. Students learn to use available Internet sites such as OMIM, GeneClinics, GeneTests and the Genetic Alliance to assist in their decision-making process and patient counseling. A post-test is administered to evaluate whether the student achieved the learning objectives. We have initially incorporated this as part of the 2-month internal medicine clerkship and will present the prototype in an interactive presentation. We plan to develop similar models in other primary care clerkships, such as pediatrics, obstetrics/gynecology and family practice. This type of resource can be easily updated, offering a fluid model of interactive genetics integration into medical school education.

**Information needs of women at risk for hereditary breast cancer.** *W.F. Cohn<sup>1</sup>, G. Fraser<sup>2</sup>, S.M. Jones<sup>3</sup>, M.E. Ropka<sup>1</sup>, S. Miesfeldt<sup>4</sup>.* 1) Dept. of Health Evaluation Sciences; 2) Dept. of Anthropology; 3) Cancer Center; 4) Dept. of Int Med, University of Virginia, Charlottesville, Va.

**Problem:** Breast cancer survivors facing the possibility that their cancer may be associated with an inherited syndrome may have unique information needs. **Purpose:** To identify and understand information needs related to concern for hereditary breast cancer (HBC). **Method:** A multi-method approach combining qualitative data from in-person interviews and quantitative data from mailed surveys. 314 women with a history of breast cancer, recruited from 34 Virginia Hospitals, completed a family history questionnaire to identify those at presumed risk for HBC. Of the 138 respondents at risk for HBC, 20 from diverse backgrounds were selected for an in-depth interview. Interviews were conducted using an interview guide about HBC issues developed by literature review and clinical expertise. The qualitative data were content analyzed yielding information themes. All 138 at-risk women were mailed a survey to assess knowledge, beliefs and attitudes regarding HBC. Survey topics included: 1) health history and experience; 2) knowledge about HBC; 3) beliefs about breast cancer causes; 4) information resources about HBC. **Results:** Content analysis of the interviews identified the following major themes related to breast cancer information: needs, timing/delivery, sources, comprehension. Questionnaire results revealed that only 53% of women reported looking for information regarding HBC following their diagnosis. Women who sought information were interested in: (1) how their diagnosis affected their children's risk, 41%; (2) how their diagnosis affected other family members' risks, 23%; (3) DNA testing information, 13%; (4) treatment differences for inherited breast cancer, 13%; (5) genetic counseling, 10%. Most women, 78%, reported that they were able to find the information they sought. **Conclusions:** Many at-risk breast cancer survivors may not pursue information about HBC. Among respondents there was a greater interest in information concerning their children's breast cancer risk than in information about genetic counseling or testing. Work supported by NHGRI (R29 HG01554).

**The Genetics of Psychiatric Disorders: Clients Perspectives on and Expectations of Genetics.** *K.K. Milner, K. Neudoerffer, L.B. Smith, A.C. Madeo, E.M. Petty.* University of Michigan Medical School, B1D102, UH, Ann Arbor, MI 48109-0020.

Genetic contributions to chronic mental illnesses (eg. schizophrenia, bipolar disorder) are complex and poorly defined. Pedigree, twin, biochemical, and genetic analyses suggest that genetic factors contribute to these conditions. Some specific alterations (eg. del 22q) are associated with an increased predisposition to psychiatric problems. Previously we found that mental health care providers in Michigan rarely referred clients to Genetics. Most were unsure if genetic services were available. Interestingly, clients and/or their family members independently seek genetic services for recurrence risk counseling, teratogen information, and sometimes, gene tests. While this is not surprising given media portrayals of psychiatric genetics, we were interested in learning more about the level of understanding and related expectations people with mental illness and their families and friends have regarding genetics. We administered a written survey in Southeast Michigan to examine their genetic literacy, understanding of the causes of psychiatric conditions, knowledge about genetic services, and desire for such services. Most respondents (n=100) noted that a variety of genetic and non-genetic factors contribute to mental illness but could not define basic genetic concepts. Many saw potential benefits of genetics for themselves or family members. Most did not know if specific genetic tests were available in psychiatry. Most wanted to obtain new information about genetics from physicians rather than media. In conclusion, even though people affected by chronic mental illness demonstrate a limited understanding of genetics they want to better understand genetic contributions to mental illness and desire genetic services. This may increase as knowledge about the human genome leads to genetically based prognostic and therapeutic options in psychiatry in the future. Thus, it will be critically important to consider the needs of the people most directly affected by this knowledge as we develop health and educational initiatives utilizing new genetic knowledge.

**Genetics education for health professionals: What works, What doesn't work and Why.** *E.V. Lapham<sup>1</sup>, J.O. Weiss<sup>2</sup>, C. Kozma<sup>1</sup>, M.A. Wilson<sup>2</sup>, J.L. Benkendorf<sup>3</sup>*. 1) Dept Pediatrics, Georgetown Univ - CDC, Washington, DC; 2) Genetic Alliance, Washington, DC; 3) Dept Obstetrics/Gynecology, Georgetown University, Washington, DC.

A three-pronged approach to genetics education of health professionals has been carried out for three years (1997-2000) as part of the Human Genome Education Model (HuGEM) Project of Georgetown University and the Genetic Alliance. Seven national health professional organizations collaborated with HuGEM to do genetics education for national staff and boards, educators and other leaders, and practitioners. The seven associations were American Dietetic Association, American Occupational Therapy Association, American Psychological Association, American Physical Therapy Association, Council on Social Work Education, and National Association of Social Workers. Preliminary outcomes show differing results both within and between the three approaches. Following orientation sessions with 130 national staff and board members, professional culture, commitment and outside endorsement influenced the extent to which each organization made progress toward integrating genetics into activities and policies. Follow-up activities of 60 educators who took a 5-day genetics course also varied and depended upon method of selection, organization responsibility, and technical assistance. While 1200 professionals attended the 36 training workshops, about one-third signed up to do training. However, the majority of practitioners did not follow through because their supervisors did not see the relevance to practice, colleagues were not interested, family and personal crises intervened, or they forgot. Educators attending the workshops did use the video and other materials to educate students and colleagues. From this analysis, a recommendation is made to start education with national boards and staff, provide intensive courses for educators selected by the associations, but focus training workshops on educators who have the experience and outlets to educate both students and colleagues. Educating field supervisors may be a better way of reaching practitioners.

**Genetics Program for Nursing Faculty: Nursing school curriculum outcomes.** *C.A. Prows, N. Johnson, C. Hetteberg, K.K. Latta.* Childrens Hospital Med Ctr, Cincinnati, OH.

The Genetics Program for Nursing Faculty (GPNF) is a multifaceted program that aims to increase faculty knowledge about genetics and to increase the amount of genetics content in entry-level nursing education program curricula. From 1997 to 1999, three on-site Genetic Summer Institutes (GSIs) provided genetics education and curriculum resources for a total of 94 nursing faculty participants representing 85 different nursing schools in 27 different states and the District of Columbia and Puerto Rico. Pre-test and post-test tools were used to measure change in knowledge. Statistically significant improvement ( $p < 0.01$ ) in post test scores was demonstrated. Change in nursing curricula genetics content was determined using a pre-GSI and post-GSI curriculum survey. A base line curriculum survey was sent to each participant prior to the 1997 and 1998 GSIs and shortly after the 1999 GSI. A post survey was sent in April, 1999 to the 1997 and 1998 GSI participants. Pre-GSI surveys were completed and returned by 53 participants (90% return rate). Completed post-GSI surveys were returned by 39 out of the 53 participants who returned a pre-GSI survey (74% return rate). Paired sample t tests were used to measure change in the average total number of genetic topics and conditions taught within the 39 nursing schools from time 1 (pre-GSI) to time 2 (post GSI). Paired sample t tests were also used to measure change in average total time spent on genetic topics and conditions from time 1 and time 2. There was statistically significant ( $p < 0.001$ ) improvement in the mean total number of genetic topics and conditions (18.6 at time 1 and 23.6 at time 2 with a t score of 4.4) and statistically significant ( $p < 0.001$ ) improvement in the mean total time spent on genetics topics and conditions (13.3 hours at time 1 and 22.5 hours at time 2 with a t score of 3.7). The average amount of time spent per program on most genetic topics and genetic conditions increased. Therefore, schools were improving the scope of content covered and the amount of time devoted to genetics.

Program Nr: 1111 from the 2000 ASHG Annual Meeting

**PHYSICIAN ASSISTANTS' KNOWLEDGE OF GENETICS.** *C. Tarantina, T.W. Kurczynski.* Mercy Children's Hospital, Medical College of Ohio, Toledo, OH.

A questionnaire modified from one used to assess physicians' knowledge of genetics and genetic tests (K.J. Hofman et al, *Acad. Med.* 68:625-632, 1993) was used to survey physician assistants in regard to genetics knowledge and attitudes. The modified questionnaire was mailed to a national sample of 500 randomly selected physician assistants who were members of the American Academy of Physician Assistants (AAPA). The survey included demographic and educational information as well as questions pertaining to genetic risk assessment, pedigrees and hypothetical clinical situations. A total of 81 physician assistants (17%) responded. Twenty-six percent had a required genetics course as part of their training program. The respondents correctly answered 59% of the knowledge questions but 77% felt their training programs did not adequately prepare them for handling genetic issues. Eighty-six percent of the respondents indicated it was important to detect potential or actual genetic conditions. Although the response rate was low, the majority of respondents recognized the increasing importance of genetics in the care of patients and improving their preparation for handling genetic issues surrounding their patients.

**DNA goes to school! A pioneer educational project in Rio de Janeiro, Brazil.** *M. Rufier, M. Lachtermacher.* DNA goes to School!, Rio de Janeiro, Brazil.

In the beginning of this new century, headlines about DNA catch our attention everyday. As the Human Genome Project approaches completion, it is critically important to bring science closer to the society, to have educational projects that focuses on DNA and to stimulate discussions of the issues inherent to the introduction of this new technology in our society. For this reason, we have developed DNA goes to school, a pioneer educational project launched in 1999 in Rio de Janeiro, Brazil. The project was developed in order to provide an opportunity for high school students to have a closer contact with DNA science. It combines hands-on DNA experiments with a variety of other activities dealing with DNA and the "genetic era". DNA goes to School! is a mini-molecular biology unit that fits inside a small suitcase and it literally goes to different schools. During the first year of establishment, the unit went to several high schools in the Rio de Janeiro area and more than 200 students have attended to the course. The complete course is a 12 hours class divided into 4 different sections of 3 hours and is limited to a group of 12 students. In the first class the students perform DNA extraction from *E.coli*. By performing the step-by-step procedure, they get important insights about DNA. The second section focuses on restriction enzymes. In this section they digest the DNA extracted in the class before and perform agarose gel electrophoresis. We also have open discussions about Genetically Modified Food. The third class focuses on DNA paternity where they perform a number of activities with colorful pens that symbolize alleles. The fourth class focuses on genetic tests and DNA sequencing. They also have discussions where they learn about the power and the limits of genetic tests. We have evaluated the course and 98% of the students pointed that the course is adequate for their level of knowledge, it has clarified important concepts and it has been a unique opportunity to have discussions about different issues concerning the "new genetic" era.

**Cultural and ethical issues associated with subjects' participation in genetic family studies.** *N.H. Arar<sup>1</sup>, R. Plaetke<sup>1</sup>, H. Hazuda<sup>2</sup>, R. Duggirala<sup>2</sup>, P. Pergola<sup>1</sup>, B. Kasinath<sup>1</sup>, M. Stern<sup>2</sup>, H. Abboud<sup>1</sup>.* 1) Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Div Clinical Epidemiology.

There is evidence of a genetic susceptibility for the development of diabetic nephropathy (DN) because it clusters in a subset of families with type 2 diabetes mellitus (T2DM). Little is known about subjects' opinions regarding this clustering and their participation in genetic family studies (GFS). Understanding cultural and ethical issues associated with GFS will enhance the enrollment process, and help to establish strategies for genetic counseling of patients with T2DM, DN, and their relatives. We will: (1) determine whether subjects' beliefs about the hereditary aspects of DN influence participation in GFS, (2) explore subjects' awareness of ethical issues related to their participation, and (3) analyze ethnic differences in participation in GFS. This study will combine qualitative and quantitative methods. In Phase I (qualitative), semi-structured interviews will be performed with 60 participants. Interviews will be tape-recorded, transcribed and content analyzed. We will recruit subjects from the ongoing Family Investigation of Nephropathy and Diabetes (FIND) study at UTHSCSA. In Phase II (quantitative), we will develop a quantitative questionnaire that will be tested, validated, and applied on participants in our Center. Then, it will be mailed to a larger sample of patients enrolled in other centers of the FIND study. Informal interviews at our dialysis unit suggest that patients are willing to participate in the FIND study because they want to learn more about their T2DM. Patients have also recognized that T2DM clusters in their families, and perceived this clustering as an important risk factor. However, patients did not view DN as a genetic disease, and were not aware of its clustering in their families. We will present: the rationale for using a combined qualitative and quantitative methods, ethnographic reports about subjects' experience regarding participating, and examples of family pedigrees to illustrate the clustering of DN in families. The ascertainment of DN families has been funded by a grant of the San Antonio Area Foundation and the NIH (DK-57295).

**There is a need for graduate training in the ethical aspects of genetics research.** *S.I. Bidichandani.* Master Teachers' Fellowship Program, Baylor Col of Medicine, Houston, TX.

Recent advances in genetics have raised a multitude of ethical, legal and social issues. Students enrolled in the Molecular and Human Genetics graduate program at the Baylor College of Medicine were surveyed in order to perform a "needs analysis" for formal training in the ethical aspects of genetics research. An anonymous, web-based survey was designed and utilized for this purpose. Responses were obtained from 49 of the 56 students surveyed.

A need for graduate training in the ethical aspects of genetics research was established based on the following data: (a) 43 / 49 (88%) students strongly agreed with Statement A: "It is important for the Genetics program to teach students to recognize and address ethical issues in genetics as part of graduate student training", (b) 30 / 49 (61%) strongly disagreed with Statement B: "Teaching/discussion of ethical issues in genetics in the current curriculum is adequate", and (c) The mean response of all 49 respondents to Statements A and B, 4.34 and 2.36, differed significantly ( $P = 1.6 \times 10^{-16}$ ), indicating a substantial discrepancy in the perception of the importance of ethics training versus the adequacy of the current curriculum in providing it. A varied student population was ascertained with respect to their individual research activities. The 49 respondents reported having at least some involvement with the following activities: (a) Gene identification (71%), (b) Use of human DNA samples as controls (55%), (c) Genetic testing (39%), (d) Clinical genetics (29%), (e) Gene therapy (24%), (f) Genome sequencing (20%), (g) Commercialization of genetic tests (16%), and (h) Genetic counseling (14%). An effective graduate course would therefore have to be broad-based. Of the various educational formats, "small group discussion" was the most preferred forum to address ethical issues; significantly preferred over "lectures" ( $P = 3.7 \times 10^{-5}$ ), "journal club" ( $P = 0.0003$ ) and "web-site" ( $P = 8.3 \times 10^{-11}$ ). Our data indicate a need for training genetics graduate students in the ethical aspects of genetics research, and may be pertinent to other programs similar in scope to the one at Baylor.

**Evaluation of an Educational Intervention for Pediatric Providers on Genetic Testing and Ethics.** *M.J. O'Neill, L.A. Demmer.* Pediatrics, U. Mass Memorial Health Care, Worcester, MA.

**OBJECTIVE:** To evaluate the short and long term effectiveness of a pediatric educational session on genetic testing and related ethical issues. **BACKGROUND:** Advances in genetic technology will ultimately pose many new challenges for pediatricians. The advent of genetic testing is also raising many ethical questions. Surveys have demonstrated a strong desire on the part of primary care physicians for continuing educational efforts in this area. **METHODS:** A three hour educational session was conducted for 22 pediatricians. The focus was on the availability and appropriateness of genetic testing. Format consisted of a didactic session, role play and discussion. Pre and post session surveys containing 7 genetics/ethics questions were distributed to all participants. The same survey was sent to the participants 9 months later to evaluate long term retention of information. Nine month data was received from 8 participants. **RESULTS:** Ethics questions were graded as to whether they were answered in accordance with standards used by most geneticists. The pre and post surveys demonstrated improvement for 6 of 7 questions. The average number of correct responses for the seven questions was 47% for the pre-test, 71% for the immediate post-test and 67% for the 9 month follow-up. **CONCLUSIONS:** Pediatricians demonstrated fair knowledge of genetic technology and related ethical issues, which improved with a focused educational session. Knowledge was well retained after nine months, at least by those choosing to respond to the long term survey. Ethical principles emphasized during the session were retained more consistently than details of testing techniques. This demonstrates that a focused intervention can successfully increase short and long term knowledge regarding genetic testing and related ethical issues for practicing pediatricians. Future studies should be directed toward the integration of this material into everyday practice.

**Maternal serum screening from the patient perspective - a pilot study.** *M. Care*<sup>1</sup>, *S. Conacher*<sup>2</sup>, *C. Meier*<sup>3</sup>, *A. Summers*<sup>3</sup>. 1) Clinical & Metabolic Genetics, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 2) Prenatal Diagnosis Unit, University Health Network, Toronto General Hospital, Toronto, ON; 3) Clinical Genetics Diagnostic Centre, North York General Hospital, Toronto, ON.

Maternal serum screening (MSS) is a blood test which combines the levels of alphafetoprotein, human chorionic gonadotropin and unconjugated estriol in maternal blood, with maternal age to determine the risk of a fetus having Down syndrome, spina bifida and trisomy 18. MSS has been available to all pregnant women in Ontario since July, 1993. The service includes pre-test counselling and information and access to appropriate services following a positive test. Some concerns have been raised regarding the use of MSS in mainstream practice, including the high number of false positive, and whether women are making informed decisions.

The current study was designed to assess knowledge, information acquisition, how MSS was presented, decision-making, knowledge of whether testing had been done, motivations for testing, communication of results and level of satisfaction. A total of 70 women from prenatal education classes at Toronto General Hospital participated in the study.

The results showed that in this well-educated population, knowledge of MSS was high. However, of the 65 women whose records we were able to access, 8% did not know their true MSS status. The results also showed that 30% of women were presented with MSS as a routine test, and 21% had testing because their health care provider (HCP) told them to. This project also illustrated different practice patterns between obstetricians and family practitioners. A significantly higher number of obstetricians presented MSS as a routine test ( $p < 0.02$ ) and a greater number of women being cared for by obstetricians reported having the test because their HCP told them to ( $p < 0.001$ ). Although these results cannot be generalized due to the small numbers and high education level of this sample, they indicate that education about the importance of informed decision-making should continue to be a priority.

**Ascertainment effort in genetic research studies for common diseases.** *A.E. Bazyk, E. Neumeister, B. Lynch, P. Watson-Clevenger, L. McFarland, J.L. Haines.* Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

As we become more aware of how genetic factors play a role in most common diseases, increasing numbers of researchers are trying to identify the responsible genes. An under appreciated component of such gene mapping studies is the labor-intensive effort of ascertaining and collecting families. To quantify the effort involved, 4 coordinators of the Family Ascertainment Core of the Program in Human Genetics at Vanderbilt University kept logs for 2 months of the year (Nov. 1999 and Mar. 2000) to determine time and effort spent in ascertaining and collecting families. The focus of the logs was on the amount of time spent on the phone, in outpatient clinics, on field trips. The 4 coordinators spent an average of 60.6 hrs/month on the phone; 15.2 hrs/coord/month. This included calls to patients, family members, physicians, nursing homes and averaged 52.9 phone calls/coord/month. Time in outpatient clinics averaged 34 hrs/month for the 4 coordinators; 8.5 hrs/coord/month. Time on field trips, including travel and time with the family, averaged 116.2 hrs/month for the core; 29.0 hrs/coord/month. Performing medical record searches to ascertain new families, averaged 31.5 hrs/month for the core; 7.9 hrs/coord/month; searching a total of 816 records in the 2 months. The core averaged 134 letters each month to participants and physician offices; 33.5 letters/coord/month. The core sent a total of 4390 letters in 3 mass mailings for recruitment. We received a total of 590 responses, a 13.4% response rate. Each coordinator spent an average of 60.6 hours each month, about 1/3 of their time, on the phone, in clinics, on field trips, or searching medical records. Time spent writing letters, reading medical records of participants, database entry, pedigree construction, and organization of field trips, required about 2/3 of each coordinators' time. The core collected an average of 41.5 participants each month; an average of 10.4 participants/coord/month. Actual labor time spent to collect one participant averaged 5.8 hours. Ascertainment and collection for genetic linkage studies on common diseases is time consuming, averaging 23.2 hours to collect a family of 4 members.

**Evaluating Consent Materials for Pharmacogenetic Research.** *S.C. Ray, E.C. McPherson, T.E. Arledge, P.K. Manasco.* Division of Clinical Genetics, Glaxo Wellcome Inc., RTP, NC.

The informed consent process is one of the cornerstones in the clinical development process. There can be significant difficulty in explaining the benefit, risks and procedures of a clinical study to patients. Adding a pharmacogenetic (PG) component to a clinical study can compound these challenges. Given these challenges, GlaxoWellcome chose to develop a brochure and video to help increase patient understanding. A qualitative research study was conducted to evaluate the clarity and effectiveness of the consent form, brochure and video developed to educate patients about PG research. To evaluate the materials, 54 respondents were recruited from five metropolitan cities: 57% lived in the US and 43% lived in the UK. About half of the respondents (48%) had previously participated in a clinical study. The materials were presented to respondents in order to solicit feedback via individual interviews. Respondents were asked to highlight on the consent form any areas of confusion or concern. Respondents were divided in their overall opinion of the consent form. The main area of concern with the consent was the confidentiality of the DNA samples. Although the majority made a choice about which part of the research to participate in, some did not clearly understand their options. Next respondents were asked to highlight on the brochure any areas of confusion or concern and anything that was particularly liked. The majority said that they liked/thought the brochure good or excellent. After reading the consent form and brochure, the percentage who understood the research options increased by 19%. Lastly respondents watched a video that explained the research. They were asked to write down on a notepad any parts that were confusing or noteworthy. Overall, reactions to the video were very positive. Having read the consent form and brochure and seen the video, the percentage who understood the research options increased by 36%. To supplement the PG consent, it is recommended that patients have access to additional educational materials. Materials should be given to the patient prior to the research visit so there is sufficient time for review.

**Psychosocial issues of burden for genetic conditions in the Chinese population.** *T.T. Chiu<sup>1</sup>, D.H.K. Chui<sup>2</sup>, C. Shuman<sup>1</sup>*. 1) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 2) Provincial Hemoglobinopathy DNA Diagnostic Laboratory, McMaster University Medical Centre, Hamilton, Ontario, Canada.

Health services which address medical and emotional needs such as social work, psychology, and genetic counseling may be under-used by the Chinese community due to issues of privacy, protection of family, and avoidance of the stigma of illness. It was anticipated that this community would perceive a greater burden for genetic conditions, because of issues unique to their cultural framework, when compared with a control population with a similar risk for the condition. A questionnaire was developed to ascertain the perception of burden for b-thalassemia, a genetic disorder relevant to the Chinese community given the gene frequency in this population. Low scores for a set of questions pertaining to disclosure and help-seeking behaviors indicated a reluctance to seek help or to share information with others. Additional questions examined perception of burden for individuals in the hypothetical event of having a child with thalassemia, and were scored with a Likert-type scale. This survey was distributed to individuals of Chinese and Mediterranean descent to determine if there were differences between these two communities. As expected, the Chinese study sample scored consistently lower than the Mediterranean study sample for all the questions related to disclosure and help-seeking behavior, and higher on most of the questions regarding perception of burden related to having a child with thalassemia. Trends in the data indicate that the Chinese population may feel a greater sense of burden for genetic conditions such as thalassemia when compared to a control population; however the majority of differences between the two groups were not statistically significant. Factors such as the scoring system design, sociodemographics of the study population, and use of hypothetical situations in ascertaining perception of burden may have confounded the attempt to draw clear conclusions. Additional research is indicated in order to improve access to and provision of genetic counseling for the Chinese community.

**Family and individual coping in Ehlers-Danlos syndrome.** *L.R. Jay*<sup>1</sup>, *J. Farmer*<sup>2</sup>, *W. Afifi*<sup>3</sup>. 1) Genetic Counseling Program, Beaver College, Glenside, PA; 2) Hospital of the University of Pennsylvania, Division of Medical Genetics, Philadelphia, PA; 3) Penn State University, Speech Communication, University Park, PA.

The present study explores family relationships, support resources, and communication patterns of individuals with Ehlers-Danlos syndrome (EDS). The purpose of the study was to determine which variables are significant predictors of family and individual coping with EDS. Information provided in a genetic counseling session often has medical, psychological and social implications for multiple members in a family. EDS is a collection of disorders that affect the skin, connective tissue, joints, and blood vessels. A survey was created using questions based on Rolland (1994), on Eunpu (1997) and with the framework of a family stress model, such as Patterson (1989). The survey measured variables such as perception of illness severity, family communication, sources of emotional, spiritual, social support, and family and individual coping. Participants were recruited from the 1999 Ehlers-Danlos National Foundation Annual conference. Seventy-six individuals with EDS completed the survey. Regression analysis was used to analyze the relationship between family and individual coping, with several potential predictors assessed by the survey. Results demonstrate that family communication, individual coping, and role in the family are significant predictors of family coping. The two predictors of individual coping are spousal support and perception of illness severity. Findings will be illustrated with participant responses. This investigation has highlighted the importance of support, genetic counseling, and family communication as predictors of family and individual coping with illness. Not only can genetic counselors provide support and education about EDS to patients, but genetic counselors can also help educate patients about the importance of family communication and relationships in coping with illness. Using tools such as genograms are appropriate methods for learning about how families communicate, helping patients understand their family's influence on their perception of illness, and their coping with illness.

**Psychosocial implications of familial primary pulmonary hypertension.** *E.A. Lientz, E.W. Clayton.* Medicine, Vanderbilt University, Nashville, TN.

Primary Pulmonary Hypertension (PPH) is a disorder characterized by increased pulmonary vascular resistance leading to right-sided heart failure, which affects 1-2 people per million. Of these cases, six percent appear to be inherited as an incompletely penetrant autosomal disorder (FPPH). The inherited form appears to demonstrate genetic anticipation, with earlier onset of disease in succeeding generations. Many individuals in the affected families have contributed blood samples to a registry at Vanderbilt in an effort to find the responsible genes. This study explores how members of families with FPPH learn about the disease and its inheritance, their sources of emotional support, and the impact of the disease on their lives. Of the 47 individuals who have been interviewed to date, two-thirds are women. Thirteen have FPPH themselves; 22 have blood relatives with FPPH, while 11 have experienced FPPH only in their spouse or in-laws. 75% of respondents understood how FPPH was inherited. Respondents reported wide variability in their ability to discuss FPPH with their relatives and with their friends. One-third reported having been offered a genetic test; of these, 70% accepted. Of those who had not been offered testing, two-thirds said they probably or definitely would be tested if it were available. The most frequently cited reason (>50%) to be tested was to learn about their children's risk. Almost one-third of those interviewed said there was no reason not to be tested. Among the rest, the most frequently cited reasons (each <20%) for avoiding testing were fears about impact on the family, ability to handle the results, and insurance. Despite extensive education, respondents appeared to be confused about the difference between diagnostic tests and donation of blood for research. These results, as well as those of >40 interviews still to be conducted, will be presented and their implications identified, particularly as they compare with other disorders that present primarily in adulthood.

**Strategies for disseminating genetic education to the medical and nonmedical communities.** *M.G. Banke<sup>1</sup>, W.S. Rubinstein<sup>1,2</sup>, E. O'Rourke<sup>1</sup>, T.B. Tanner<sup>3</sup>, J.A. Barranger<sup>1</sup>*. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Cancer Genetics Program, UPMC Health System/University of Pittsburgh Cancer Institute and Magee-Womens Hospital, Pittsburgh, PA; 3) Clinical Tools, Inc., Chapel Hill, NC.

The Genetics Education and Counseling Program (GECPC) at the University of Pittsburgh is a public health initiative for community and professional education on genetics. The goal of the program is an increased awareness of the advances in genetics and their impact on public health services and policy. The program aims to narrow the gap between what is learned in the laboratory and the understanding of that knowledge by professionals and the public. The GECPC offers educational workshops, referral information, brochures, a hotline (800-640-GENE), and a comprehensive website (<http://www.pitt.edu/~edugene>). The program extends the community outreach activities of the Center for the Study and Treatment of Jewish Genetic Diseases, the Gaucher Disease Diagnosis and Treatment Program, and the Cancer Genetics Program. To continue and expand the educational services, online educational tools will be used to provide broader access and an alternative or supplement to the standard types of learning environments such as lectures, classroom instruction, and written materials. Online learning environments are being developed for genetics education for physicians, medical students, and young children. An interactive website entitled "Community Genetics: A Public Health Guide" is also in progress. Satisfaction and effectiveness of these learning environments will be measured by scores of increased knowledge, attitude change, counseling skill development, and improved self-efficacy. These learning modules will discuss genetics, genetic counseling, testing and other services, and the ethical, legal, and social implications (ESLI) that surround these topics.

**Working with the media: Lessons learned from delivering predictive test results on camera.** *W. Meschino<sup>1</sup>, K. Doran<sup>1</sup>, L. Garon<sup>2</sup>.* 1) Genetics, North York General Hospital, Toronto, ON, Canada; 2) Porcupine Health Unit, Timmins, ON, Canada.

With the explosion of genetic information in recent years, media reports announcing new discoveries are a daily occurrence. Increasingly, genetics professionals are being sought to simplify this complex knowledge for the public audience. As well as being interviewed themselves, they may be asked to choose patients who will provide first-hand accounts of how these discoveries have affected their lives. Geneticists and counsellors may even be asked to contact patients who are willing to have the most intimate details of their experiences in genetics recorded on film.

We report our experience with two film documentaries in which patients undergoing predictive testing for late-onset disorders were given results of genetic tests on camera. In the first case, we were asked to select a patient at risk for Huntington disease who was willing to have her genetic counselling and test results sessions captured on film. In the second case, the 19 year-old daughter of a woman with early-onset Alzheimer disease was approached by the director of a popular TV nature series, in the course of filming a story about her family. Previous to this, she had been ambivalent about learning her genetic status.

Common themes emerging from these 2 experiences include: 1) the patient's decision about whether to have genetic testing may be influenced by the media opportunity, 2) the professional's motivation for participating may not match the film-maker's vision for the project, and therefore should be thoroughly explored before agreeing to be involved, 3) some counselling sessions with the patient alone are necessary to explore issues that the patient chooses not to reveal on camera, 4) the film crew and director may become emotionally involved in the story and attempt to interfere with the medical process, 5) potential exists for a perceived "lack of choice" to postpone testing because of commitment to the film project, 6) adverse effects on family members may occur including lack of privacy, and 7) involvement in such projects entails extensive time commitments for patients and professionals alike.

**Breast Cancer Survivors' Attitudes about Educating their Children Regarding Breast Cancer Risk.** *S. Miesfeldt, W.F. Cohn, S.M. Jones, J. Weinstein, M. Ropka.* Univ Virginia Health System, Charlottesville, VA.

**Introduction.** We explored the attitudes of a group of breast cancer survivors concerning whether and how children from a breast cancer-affected family should be educated about their potential genetic risk for cancer development. **Methods.** Women with a history of breast cancer, recruited from 34 Virginia hospitals, responded to two mailed surveys. 1) The Family History Questionnaire ascertained information allowing for the separation of participants into women with presumed hereditary breast cancer (HBC) and women with presumed sporadic breast cancer (SBC). 2) A subsequent survey included questions addressing children's concerns about their breast cancer risk and participants' preferred information sources for their children about HBC. **Results.** A total of 273 women returned both surveys. Participants' average age was 47.5 years; 91% were Caucasian, 7% were African-American and 2% were Asian-American. A total of 231 (85%) participants reported having children. Of these, 82% of participants indicated concern about their children's breast cancer risk. A total of 127 (55%) reported expressions of concern from their children about their breast cancer risk, due to the mother's breast cancer history. The mean age of children's reported expression of concern was 19.4 years (range 6-38 years) for daughters and 18.6 years (5-35 years) for sons. Of 257 respondents, 156 (61%) believed the appropriate age for their children's education about HBC to be the teens (up to age 18 years). Fewer (n=59) felt this to be 18-21 years, and a minority (n=12) felt this to be > 21 years. When asked who should provide HBC information to children (more than one choice offered), of the 254 respondents, 214 selected the child's parent(s), 166 the child's PCP, 83 a gynecologist, and 48 an oncologist. Only 30 chose a genetic counselor and 7 a geneticist. There was no difference in responses when comparing HBC women vs. SBC women. **Conclusions.** These data show concern among breast cancer survivors and their children about HBC, and raise questions about the adequacy and availability of educational resources for both daughters and sons of affected mothers. Supported by NHGRI (R29 HG01554).

**The need for a genetics education program for General Practitioners in Victoria, Australia.** *S. Metcalfe*<sup>1</sup>, *R. Hurworth*<sup>2</sup>, *R. Robins*<sup>3</sup>, *J. Newstead*<sup>4</sup>. 1) Education Unit, Murdoch Childrens Res Inst, Parkville, Australia; 2) Centre for Program Evaluation, The University of Melbourne, Parkville, Australia; 3) Department of History & Philosophy of Science, The University of Melbourne, Parkville, Australia; 4) The Victorian Faculty of the Royal Australian College of General Practitioners, Melbourne, Australia.

The revolution in molecular technology and the explosion of genetic information resulting from the Human Genome Project has major implications on the practice of clinical medicine in countries all over the world. In Australia, clinical genetics services are being stretched and, as has been seen in the USA and the UK, it is the primary health care domain that is being sought increasingly to provide these services. In Australia there is little published information regarding knowledge and attitudes to genetics among general practitioners (GPs). This information is essential for developing and implementing appropriate continuing education strategies, and for evaluating their effectiveness. A study was recently performed to collect data about Victorian GPs' needs for genetics education, using focus groups and surveys. GPs reported that they had some recent, if sporadic, experience in managing patients with genetic conditions, with management often being patient-driven. GPs were often confused about ordering genetic tests and admitted that their knowledge of genetics was poor. They acknowledged there was a need to strengthen their knowledge in particular areas, and reported that they needed to improve their counselling skills for families with, or at risk of having, a genetic condition. GPs made quite clear requests that genetic education programs needed to be relevant to their practice, that information needed to be concise and simple, and furthermore, that the programs should be interesting and lively. GPs asked for resources to be provided in a variety of formats, both printed and electronic, and for these to supplement case-based seminar programs. The results from this study are now being used to develop appropriate education programs and resources in genetics for GPs in Victoria, Australia.

**GeneTests™ usage patterns by occupational affiliation.** *N.B. Hanson<sup>1</sup>, M.L. Covington<sup>1</sup>, W. Neufeld-Kaiser<sup>1</sup>, J. Edwards<sup>2</sup>, P. Tarczy-Hornoch<sup>2</sup>, R.A. Pagon<sup>1,2</sup>.* 1) GeneTests™, Children's Hospital, Seattle, WA; 2) University of Washington, Seattle, WA.

GeneTests™ (formerly Helix) was funded by the NIH in Fall 1992 as a Genetics Laboratory Directory used primarily by genetics service providers. It was originally password restricted to healthcare providers and laboratorians. Additional funding from Maternal and Child Health Bureau in Fall 1998 permitted outreach to a broader audience. New search strategies, a primer on genetic testing, a Genetics Clinic Directory, and a teaching module have been added to the Web site. A new registration system launched in September 1999 permits aggregate examination of use patterns by occupational affiliation of our registrants. Prior to 9/99, there were 9664 "original registrants". About half were medical geneticists and genetic counselors who, as a group, were responsible for 75% of the laboratory searches. Since implementation of the new registration system, there have been 7949 new registrants, including: ~30% Healthcare Providers (physicians and allied health professionals), ~30% Public, ~20% Students/Faculty and ~14% Laboratorians. Most members of the Healthcare category are physicians, and 27% of these are geneticists. Geneticists currently use the lab directory more frequently than do other specialty physicians. However, other specialties have a significant presence as well. For instance, 23% of physician registrants are neurologists who, as a group, demonstrate fairly frequent lab directory use. Genetic counselors are the largest allied healthcare professional group and continue to show the highest use of the lab directory. Public use of the lab directory is small. The Genetics Clinic Directory has been available only since January 2000, and therefore, has been used less than the lab directory. To date (6/12/00), "original registrants" have conducted 3218 searches, while new registrant use includes: Healthcare Providers 967, Public 896, Students/Faculty 440, Laboratorians 271. Of interest is that Public use of the clinic directory is nearly as high as that of Healthcare Providers. Use of the primer and teaching module is still under evaluation and will be reported in the future.

**Familial aggregation of absolute pitch.** *S. Baharloo*<sup>1</sup>, *S. Service*<sup>1</sup>, *N. Risch*<sup>3</sup>, *J. Gitschier*<sup>2</sup>, *N. Freimer*<sup>1</sup>. 1) Neurogenetics laboratory, University of California San Francisco, San Francisco, CA; 2) Howard Hughes Medical Institute, University of California San Francisco, San Francisco, CA; 3) Department of Genetics, Stanford University, Stanford, CA.

(AP) is a behavioral trait that is defined as the ability to identify the pitch of tones in the absence of a reference pitch and is considered to be an ideal phenotype for investigating gene and environment interactions in the development of complex human behaviors. Although previous studies have pointed to the possibility of a genetic predisposition for development of AP, there has been a paucity of systematic evidence for such a genetic contribution to AP. We have now attempted to quantify the familial aggregation of AP by estimating the lambda sib (ls) for a particularly distinct form of AP, termed AP-1. Earlier we reported that music training before age 6 is required for the development of AP-1 (Baharloo et. al. 1998). Therefore for the purpose of determining ls we have estimated the prevalence of AP-1 in populations consisting of individuals who have experienced early music training. We estimated the range for recurrence risk of AP-1 in the siblings of AP-1 probands (22.6% to 43.5%). The population frequency of AP-1 was determined by pitch testing of 625 students at a music camp. An AP-1 prevalence of 2.9% was estimated among the population of students with music training before age 6. Considering the two different ranges for the sib recurrence risks, we have estimated a lower bound ls value of 7.8 and an upper bound ls value of 15.1 for AP-1. The implications of our findings for genetic mapping studies of AP-1 will be discussed.

**Jervell and the Lange-Nielsen Syndrome in a Mexican Endogamic Population.** *F. Huesca-Hernandez<sup>1</sup>, J.E. DominguezAburto-Lopez<sup>1</sup>, L.M. Cuesta-Cordova<sup>2</sup>, C. Zamora-Gutierrez<sup>3</sup>, M.R. Romero-Gonzalez<sup>4</sup>, S. Frias-Cortina (RIP)<sup>1</sup>.* 1) Genetica, Instituto Nacional de la Comunicacion Humana, S. Sa. Mexico City, D.F., MEXICO; 2) Hospital General de PEMEX Tampico, Mexico; 3) Instituto Nacional de Cardiologia, S. Sa., Mexico City; 4) Hospital Central de PEMEX. Mexico.

Jervell and Lange-Nielsen syndrome has an autosomic recessive inheritance pattern that consists on congenital bilateral sensorineural hearing loss and a consistent prolonged QT interval that can cause arrhythmia. Patients with this syndrome may suffer of syncopal attacks and sudden death during the early childhood and the beginning of adolescence. The molecular basis of this disorder is explained by the action of four genes that affect essential membrane proteins that act on the electric activity of the heart, mainly exchange of ions in the potassium channel. The incidence of this syndrome varies from one to six individuals in one million. One of the challenges of genetics is to detect carriers of hereditary diseases. In the Jervell and Lange-Nielsen syndrome, the presence of the QT interval has to be either within borderline high normal range, or within higher than normal range. The QT interval is a reliable genetic marker. The cardiologic and genetic follow up process in patients with this condition is mandatory. The findings and the analysis of the segregation pattern of the pedigree of 513 individuals, in 498 positions, distributed in seven generations, including 179 audiologic studies and 179 electrocardiographic studies are presented. We also present the identification of carriers of Jervell and Lange Nielsen syndrome by segregation analysis and cardiologic tests, including EKG which has been already reported in the literature. Additionally we report a new audiometric finding. Given the low incidence of this syndrome, we consider that it is very important to have an endogamic population, which in our case was studied in a multidisciplinary way. We aim to increase our knowledge and our perspective of this syndrome in population genetics and in a future to perform molecular studies.

**Genetic risk factors in pediatric ischemic stroke - a retrospective study.** *A. Ferro<sup>1</sup>, J. Pinto-Basto<sup>1</sup>, S. Barreirinho<sup>2</sup>, M. Santos<sup>2</sup>, C. Barbot<sup>2</sup>, E. Costa<sup>2</sup>, A. Sousa<sup>1</sup>, J. Barbot<sup>2</sup>, J. Sequeiros<sup>1</sup>, P. Maciel<sup>1,3</sup>.* 1) UnIGENE, IBMC, Porto, Portugal; 2) HECMP, Porto, Portugal; 3) ISCS-N, Porto, Portugal.

The aim of this study was to identify hereditary thrombophilic conditions related to the occurrence of stroke in children (estimated incidence: 2.5/100,000/year). A retrospective study performed at a pediatric hospital identified 22 children with ischemic stroke, confirmed by CT and/or MRI scan. Genomic DNA was extracted and mutation detection for FV Leiden (G1691A) and FII (prothrombin) G20219A variant was carried out by PCR-RFLP with MnlI and HindIII, respectively. The thermolabile variant of methylenetetrahydrofolate reductase (MTHFR C677T) was detected by SSCP and sequencing. We found three FV Leiden heterozygous carriers (14%) and two heterozygotes with the FII variant (9%). Previous studies in the normal population in Portugal (n=38) had shown carrier frequencies of 2% and 3%, respectively. Characterization of a larger control population (n=115), matched to our sample of patients by gender and region of origin, is currently underway. The large frequency of carriers of the MTHFR polymorphism observed (54% heterozygous and 9% homozygous), was identical to the frequency described for the normal population, suggesting that this variant, as opposed to the previous ones, is not associated with an increased risk for stroke during childhood. Additionally, medical and surgical conditions known to be associated to thrombosis were present in 16/22 patients and coagulation abnormalities were biochemically detected in 10/22. In conclusion, and excluding the MTHFR variant, genetic risk factors (including hyperlipidemia and hyperhomocystenemia) were identified in 14 patients (63%), with six (27%) having two different mutations/polymorphisms. Medical/surgical risk factors coexisted with coagulation abnormalities in 13 patients (68%), medical/surgical risk factors alone were present in two (9%), and in two (9%) none of the risk factors studied were present. Our study confirms that stroke in children is commonly associated with a combination of predisposing conditions, both genetic and environmental, often with the presence of multiple risk factors.

**The discovery of single nucleotide polymorphisms and inferences of human demographic history.** *J. Wakeley*<sup>1</sup>, *R. Nielsen*<sup>2</sup>, *K. Ardlie*<sup>3</sup>, *S.N. Liu-Cordero*<sup>3</sup>, *E.S. Lander*<sup>3,4</sup>. 1) Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Biometry Department, Cornell University, Ithaca, NY; 3) Whitehead Institute/MIT Center for Genome Research, Cambridge, MA; 4) Department of Biology, Massachusetts Institute of Technology, Cambridge, MA.

A method of historical inference which accounts for ascertainment bias is developed and applied to single nucleotide polymorphism data in humans. Ascertainment bias is the deviation in allele frequencies (from what would be observed in a random sample) caused by the discovery process. The most common type of ascertainment bias is when polymorphisms are discovered in a small sample then surveyed in a larger one. Three data sets are analyzed, and these differ in their levels of ascertainment bias. We use maximum likelihood to fit a subdivided population model which includes a possible change in effective size at some time in the past. Incorrectly assuming that ascertainment bias does not exist causes errors in inference. Two effects of this are that migration rates among subpopulations are overestimated and that the human population appears to be shrinking. Correct inferences are made when ascertainment bias is modelled properly, and these do not support any extreme changes in the effective size of the human population.

**Stratification for complex disorders with genetic heterogeneity comprising both X-linked and autosomal dominant forms of inheritance: Families with familial idiopathic scoliosis.** *C.M. Justice<sup>1</sup>, N.H. Miller<sup>2</sup>, B. Marosy<sup>2</sup>, E.W. Pugh<sup>3</sup>, A.F. Wilson<sup>1</sup>.* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD; 3) CIDR, Johns Hopkins University, Baltimore, MD.

Idiopathic scoliosis (IS) is a structural lateral curvature of the spine present in the late juvenile or adolescent period in otherwise normal individuals. Population studies indicate that 11% of first degree relatives are similarly affected, with the prevalence in females about 4-5 times greater than that in males. Previous studies from a number of populations have suggested autosomal dominant, X-linked and/or multifactorial modes of inheritance. As part of a large ongoing study of familial scoliosis, 200 families with at least two individuals with scoliosis have been ascertained and clinically characterized. Phenotypes include degree of lateral curvature, curve type, age of onset and sex. A genome-wide screen for 1200 individuals was performed at the Center for Inherited Disease Research. It is likely that the sample includes both X-linked and autosomal dominant forms of the disorder. Therefore, the families were stratified on the ratio of the likelihood of each family given an X-linked model relative to that of an autosomal model. Families were then ranked based on this ratio. The mode of inheritance for families in the upper tail of the distribution was assumed to be X-linked, while the families in the lower tail were assumed to be autosomal dominant. Model-dependent and model independent linkage analysis was performed on subsets based on the ranked distribution from both tails of the distribution. However, ascertainment for a trait with X-linked inheritance and subsequent linkage analysis of markers on the X chromosome can be considered to be ascertainment on both the trait and marker data, which is known to cause an increase in the type I error rate. Issues involving ascertainment of an X-linked disorder and subsequent linkage analysis of X-chromosome markers are considered. A regional test for X-linkage based on a moving average is also presented.

**Vertebral scalloping in Neurofibromatosis (NF1): A quantitative approach.** *E. Kwok<sup>1</sup>, B. Sawatzky<sup>2</sup>, P. Birch<sup>1</sup>, J.M. Friedman<sup>1</sup>, S. Tredwell<sup>2</sup>.* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Orthopaedics, BC Children's Hospital, Vancouver, BC, Canada.

Scoliosis occurs in 10-25% of individuals with NF1. Vertebral scalloping is often found in NF1 patients, but its clinical significance remains unknown. We measured and compared vertebral scalloping in children ascertained from a pediatric tertiary referral hospital. We used lateral radiographic films of lumbar vertebrae from 13 NF1 children with scoliosis and 14 non-NF1 scoliosis patients to derive a scalloping ratio, which was estimated by taking three width measurements from each vertebra: superior, inferior, and waist. Digital images of the radiographs were measured using electronic calipers. The average of the superior and inferior measurements was divided by the waist measurement to obtain a scalloping ratio for each lumbar vertebra.

Only the highest ratio from each patient was used in data analysis. Scalloping ratios from the non-NF1 patients were normally distributed, with a mean of 1.13 and a standard deviation of 0.03. A Z-test gave a probability of 0.003 that a randomly chosen non-NF1 patient will have a ratio greater than 1.20. Scalloping ratios from the NF1 patients are bimodal, with 31% exhibiting ratios greater than 1.20.

We conclude that this method provides a useful and cost effective way to characterize vertebral scalloping in children with NF1. There appear to be two groups of NF1 patients with scoliosis: those with vertebral scalloping and those without. Further studies are needed to define the natural history and pathogenesis of vertebral scalloping and to determine whether it contributes to the severity or progression of scoliosis in NF1 patients.

*This study was funded in part by the British Columbia Neurofibromatosis Foundation. Details can be found at: <http://www.medgen.ubc.ca/friedmanlab/index.html>.*

**Genetic Association Study under Epidemiologic Design for the Three-Locus Genotypes --- the Susceptibility of Parkinson's Disease in Taiwan with Dopamine-Metabolizing Enzyme Genotypes of MAO-B, COMT & CYP2E1.**

*K.H. Chen*<sup>1</sup>, *R.M. Wu*<sup>2</sup>. 1) Institute of Epidemiology, Public Health College, National Taiwan University, Taipei, Taiwan; 2) Neurology Department, Medical College, National Taiwan University, Taipei, Taiwan.

The genetic study of multiple loci for disease susceptibility under a case-control epidemiology design recommends the continuous genotype frequencies in the logistic analysis. Determining a candidate genotype of disease concludes in a risk factor, a protective factor, or neither of the two. If a dummy variable of a genotype has to be employed for the genotypes of studied loci, the code of 1 or 0 for a genotype subject or not should replace a relative code system with a designated baseline system for a logistic regression. There exists no genotype for a patient or a healthy subject to be set as a baseline of the disease. The hospital based susceptibility survey in Taiwan of Parkinson's disease (PD) investigates genotype polymorphism of dopamine-metabolizing enzymes of COMT/L (Val158/Met) with gene encoded on the 22nd chromosome, MAO-B intron 13 encoded on the X chromosome and CYP2E1 encoded on the 15th chromosome. The risk factor for male PD patients is the genotype MCC311 with the mutant type for MAO-B locus, the wild type for COMT locus and the wild type for CYP2E1 locus. Neither environmental nor genetic factors are further required. For female PD susceptibility, there exists neither risk nor protective factor among genotypes of 3-, 2- and 1-locus, other than the genotype MCC2\*2 of the heterozygote for both of MAO-B locus and CYP2E1 locus, a protective factor. For female PD patients, risk and/or protective factors other than these 3 loci exist and have to be identified. The survey recruited 222 PD patients and 197 individuals with age-, gender- and birth place-matched subjects. The laboratory typing for the genotype polymorphisms of MAO-B, COMT and CYP2E1 was performed using PCR-based RFLP analyses.

**Methylenetetrahydrofolate reductase (MTHFR) A1298C polymorphism as a NTD risk factor for the Italian population.** *V. Capra<sup>1</sup>, P. De Marco<sup>1</sup>, L. Arata<sup>1</sup>, A. Moroni<sup>1</sup>, E. Merello<sup>1</sup>, M.G. Calevo<sup>2</sup>, A. Cama<sup>1</sup>.* 1) Lab Servizio Di Neurochirurgia, Ist. Scientifico G. Gaslini, Genova, Italy; 2) Servizio di Epidemiologia e Biostatistica, Ist. Scientifico G. Gaslini, Genova, Italy.

Periconceptional folic acid intake prevents about 70% of all Neural Tube Defects (NTDs). It has been demonstrated that alterations in folate and homocysteine metabolism may play a role, since NTD patients as well as mothers have moderately increased levels of plasma homocysteine. Homozygosity for the C677T mutation of the methylene tetrahydrofolate reductase (MTHFR) gene is associated with an increased risk for NTD, even in Italian population, which has a relatively low prevalence of NTD. However, this genetic risk factor could not account for all folic acid-preventable NTD. Another mutation in the same gene, the A1298C mutation, results in decreased MTHFR activity, which is more pronounced in the homozygous than heterozygous state. We studied the A1298C mutation in the Italian population to evaluate its role as risk factor for NTD. We used 141 children with mostly sporadic myelomeningocele, 91 mothers and 53 fathers and 111 volunteers as control group. Genetic analysis revealed homozygosity for the A1298C mutation in 15.3% of the controls versus 23.4% of the affected children, 34.1% of the mothers, 17% of the fathers. The frequency of the mutated C allele was 36% in controls versus 48% in patients, 57% of the mothers and 42% of the fathers. Thus, we observed increased frequency of the mutated allele in the NTD patients and their parents when compared with controls. The determined odd ratios showed an increased risk of 1.85 (95% CI:1.01-3.38) for the prevalence of the A/C genotype in the affected children versus controls. The odd ratio increased to 2.39 (95%CI:1.09-5.25) if the affected children have the 1298CC genotype. These data, although preliminary, indicate that both heterozygosity and homozygosity for the A1298C mutation in the MTHFR gene is associated to an increased risk in Italian population. Large groups of patients and controls need to be studied to confirm our tentative conclusion. Supported by Ricerca Finalizzata Ministero della Sanita`-Italy (grant ICS 34.1/RF 95.219).

**Relationship between Wolfram Syndrome carrier status and suicide.** *J. Crawford*<sup>1</sup>, *R.D. Goldney*<sup>2</sup>, *G.R.*

*Sutherland*<sup>1,3</sup>. 1) Department of Cytogenetics & Molecular Genetics, Women's & Children's Hospital, North Adelaide, 5006, Australia; 2) Department of Psychiatry, University of Adelaide, Adelaide, 5000, Australia; 3) Department of Genetics, University of Adelaide, Adelaide, 5000, Australia.

Suicide is an important health problem in Australia with over 2,700 people committing suicide each year. Over 90% of those who commit suicide are suffering from some form of mental illness at the time. Our aim is to elucidate genetic factors that may play a role in suicide. Family studies in Wolfram Syndrome (WFS1) have led to the identification of the disease causing gene, wolframin. WFS1, defined by the occurrence of juvenile-onset diabetes mellitus and progressive optic atrophy, is a neurodegenerative autosomal recessive disorder with an incidence in the US of 1/100,000. Many WFS1 patients develop paranoid delusions, progressive dementia, severe depression and attempt suicide. It has also been reported that carriers of the disease have an increased incidence of clinical depression and suicide, with family studies showing a 26-fold increase in psychiatric morbidity in obligate heterozygotes compared to non-carriers. Characterisation of specific genetic changes that predispose to psychiatric illness will lead to a means of identifying at risk individuals, more precise psychiatric diagnosis and more effective treatment. It is therefore important to determine if carrier status for WFS1 is a significant factor in individuals who have committed suicide. We have a series of 100 suicides and are testing for an increased incidence of WFS1 mutations in this group as compared to blood donors who are not known to have psychiatric illness. Preliminary screening of the WFS1 ORF has been completed in approximately a third of our sample panel, and 18 sequence variants have been detected. Eight of these have not previously been reported and two cause unique amino acid changes. These results indicate the WFS1 gene is highly polymorphic and further analysis is necessary to identify disease causing mutations. We are continuing our screen with the aim of establishing a positive correlation between completed suicide and carrier status for the Wolfram Syndrome gene.

**DAT AND Adult ADHD: Combining Data from Care-Controls and Nuclear Families.** *P. Muglia<sup>1</sup>, U. Jain<sup>2</sup>, M. Neves-Pereira<sup>1</sup>, J. Byam<sup>1</sup>, J.L. Kennedy<sup>1</sup>*. 1) Neurogenetics Section, CAMH, Clarke Site, Univ Toronto, Toronto, ON, Canada; 2) Adult and Adolescence Clinic, CAMH, Clarke Site, Univ Toronto, Toronto, ON, Canada.

Attention deficit hyperactivity disorder (ADHD) is a frequent psychiatric disorder with a lifetime prevalence of 3-5 percent in school age children. Several follow up studies have shown that roughly one third of subjects diagnosed during childhood continue to suffer from ADHD during adulthood. Convincing data support a genetic role in the aetiology of ADHD. A dopamine dysfunction in the prefrontal and striatal regions has been described in ADHD subjects. The dopamine transporter, that is responsible for the reuptake of dopamine from the synaptic cleft, is the primary site of action of methylphenidate, the treatment of choice for ADHD patients. Previous studies have investigated the dopamine transporter gene (DAT) VNTR in children with ADHD reporting an association of the disorder with the 480-bp allele. In this study we described the preliminary result from the genotyping of the DAT VNTR in two independent samples: one comprised of cases and ethnically, sex and age matched controls, and the second made up of nuclear families. The Transmission Disequilibrium Test (TDT) analysis of the genotypes in the nuclear families showed no evidence of association for the DAT VNTR with ADHD ( $N = 47$ ; chi-square = 0.07;  $df = 1$   $p = 0.81$ ). Similar evidence for no association was found in 30 case-controls where the frequency of the 440 and 480 bp repeat alleles were 0.3 and 0.7 in the cases respectively and 0.23 and 0.77 in the controls (chi-square of 0.38;  $df = 1$ ;  $p = 0.53$ ). To test the overall effect of the two independent samples, we made use of the inverse normal method as previously applied in this sample for the dopamine D4 receptor gene (Muglia et al. 2000) that gave a  $z = 0.75$ ;  $p = 0.45$ . The results from our study did not confirm the associations previously shown in child ADHD and suggest that the DAT is not playing a major role in the etiology of ADHD in our sample.

**Familial aggregation of neurofibromatosis 1 (NF1) clinical features.** *J. Szudek*<sup>1</sup>, *H. Joe*<sup>2</sup>, *J.M. Friedman*<sup>1</sup>. 1) Departments of Medical Genetics and; 2) Statistics, University of British Columbia, Vancouver, BC, Canada.

The relationship of genetic factors at the *NF1* locus or other loci to development of specific disease features is poorly understood. This study examines familial aggregation of NF1 features among different classes of affected relatives.

The National NF Foundation International Database contains data on 320 families with 32 members affected with NF1, including 223 sib-sib, 290 parent-child and 70 second degree relative pairs. For this study, we selected 10 NF1 clinical features: café-au-lait spots, intertriginous freckling, cutaneous, subcutaneous and plexiform neurofibromas, Lisch nodules, seizures, scoliosis, macrocephaly and short stature. The probit of each feature was set as the response in a different model. Two separate regressions were simultaneously applied with each feature as the response. One accounted for related features and covariates such as age and gender. The other measured aggregation of the response variable between affected sibs, parent-child pairs and second degree relatives.

All of the features except seizures and scoliosis appear to be familial. Among the familial features, correlations between sibs ranged from 0.30 (95% CI 0.07-0.54) for plexiform neurofibromas to 0.72 (95% CI 0.52-0.92) for Lisch nodules. Correlations between parents and children ranged from 0.24 (95% CI 0.04-0.44) for subcutaneous neurofibromas to 0.73 (95% CI 0.48-0.98) for Lisch nodules. Correlations between second degree relatives ranged from -0.18 (95% CI -0.40-0.04) for Lisch nodules to 0.59 (95% CI 0.06-1.00) for macrocephaly. Three distinct patterns were observed among the correlations for familial features: 1) Some features had similar correlations for all relationships; 2) Others had higher correlations between first degree relatives than between second degree relatives; 3) Others had higher correlations between sibs than between parents and children. These familial patterns suggest that 1) the mutant NF1 allele, 2) unlinked modifying genes and 3) the normal NF1 allele may all be involved in the development of particular clinical features of NF1, but that their relative contributions vary for different features.

**Familial aggregation of coronary artery calcification in families with Type 2 diabetes.** *D.W. Bowden<sup>1,2</sup>, L.E. Wagenknecht<sup>3</sup>, J.J. Carr<sup>4</sup>, C.D. Langefeld<sup>3</sup>, B.I. Freedman<sup>2</sup>, S.S. Rich<sup>3</sup>.* 1) Depts. of Biochemistry; 2) Internal Medicine; 3) Public Health Sciences; 4) Radiological Sciences, Wake Forest Univ. School of Medicine, Winston-Salem, NC.

Type 2 diabetes is recognized as a major risk factor for atherosclerotic cardiovascular disease including subclinical atherosclerosis as measured by non-invasive procedures. The role which genetic factors contribute to various measures of subclinical atherosclerosis is largely unknown. We hypothesize that subclinical atherosclerosis, measured as coronary artery calcification (CAC), will be extensive in persons with type 2 diabetes, and that its presence depends on both genetic and environmental factors. The genetic factors will result in the familial aggregation of CAC. To determine the extent of familial aggregation of CAC in the presence of type 2 diabetes, we studied 72 persons with diabetes (mean age 60 years) and 12 persons without in 33 families. CAC was measured by fast gated helical computed tomography. Other measured factors included blood pressure, body size, lipids, glycated hemoglobin, and self-reported medical history. CAC was detectable in 75% of persons with diabetes (median score = 77, range 0 - 5776). Over 20% of diabetes patients had CAC values over 400. Equally striking were the number of patients, approximately 25%, with CAC of 0 even though this group has multiple CVD risk factors. Presence of CAC was positively associated with age and increased albumin/creatinine ratio. Extent of CAC, adjusted for age, was associated with male gender, high fasting glucose, low total cholesterol and LDL, high HDL, cigarette pack-years, and history of stroke. CAC, adjusted for age and sex, was highly heritable ( $h^2 = 0.53$ , 95% CI: 0.028 - 1.00). In multivariate analysis,  $h^2 = 0.83$  (95% CI: 0.26, 1.00), after adjusting for diabetes status, race, LDL, BMI, hypertension, and smoking. These results suggest that strong (independent) genetic factors as well as environmental factors contribute to the variance of CAC in persons with type 2 diabetes. In these data, CAC is highly heritable, an important element in designing studies to map genes contributing to both atherosclerosis and type 2 diabetes.

**Coronary artery calcification is associated with two polymorphisms in the beta-2 adrenergic receptor gene.** *L.A.*

*Lange*<sup>1</sup>, *S.L.R. Kardia*<sup>1</sup>, *L.F. Bielak*<sup>1</sup>, *S.T. Turner*<sup>2</sup>, *E. Boerwinkle*<sup>4</sup>, *P.F. Sheedy*<sup>3</sup>, *P.A. Peyser*<sup>1</sup>. 1) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 2) Division of Hypertension and Department of Internal Medicine, Mayo Clinic, Rochester, MN; 3) Department of Diagnostic Radiology, Mayo Clinic, Rochester, MN; 4) Institute of Molecular Medicine and Human Genetics Center, University of Texas, Houston, TX.

Coronary artery calcification (CAC), which quantifies coronary atherosclerosis, is a marker of coronary artery disease (CAD). The beta-2 adrenergic receptor gene (ADRB2), on 5q, is a candidate gene for CAC because of the receptor's role in blood pressure regulation and lipid metabolism, risk factors for CAD and CAC. We examined the relationship between quantity of CAC and the Arg16Gly and Gln27Glu polymorphisms of ADRB2 in 97 unrelated Caucasian men and 117 unrelated Caucasian women. Quantity of CAC was measured non-invasively by electron beam computed tomography in the four major epicardial arteries. The association between CAC and genotype was investigated with Tobit regression models three ways: 1) main genotype effects without adjusting for CAD risk factors (age, lipids, blood pressure, body size, glucose and smoking); 2) main genotype effects after adjusting for individual CAD risk factors; and 3) interaction effects between genotype and individual CAD risk factors. Tests were considered significant if  $p < 0.05$ . In men, there were no significant associations with Arg16Gly. The unadjusted main effects of Gln27Glu were significant, but were no longer significant after adjusting for most CAD risk factors. In women, there were no significant main effects of Arg16Gly, while some interactions were significant. The main effects of Gln27Glu were significant in women both before and after adjusting for most CAD risk factors. Some interactions were also significant. The Arg16Gly and Gln27Glu polymorphisms were in strong linkage disequilibrium, with a marked under-representation of Gly16-Glu27 and Arg16-Gln27 haplotypes based on estimated allele frequencies. This study suggests that ADRB2 may predict quantity of CAC in women after adjusting for established CAD risk factors.

**Concordance for cardiovascular risk factors in affected sib pairs (ASPs) with early-onset coronary artery disease (CAD).** *E.R. Hauser<sup>1,3</sup>, V. Mooser<sup>3</sup>, S. Schmidt<sup>1,3</sup>, D.C. Crossman<sup>3</sup>, J.L. Haines<sup>3</sup>, C. Jones<sup>3</sup>, B. Winkelmann<sup>3</sup>, C. Foster<sup>2,3</sup>, C. Haynes<sup>1,3</sup>, Z.E. Dowdy<sup>1,3</sup>, S.E. Estabrooks<sup>1,3</sup>, L.T. Middleton<sup>2,3</sup>, P. Manasco<sup>2,3</sup>, A.D. Roses<sup>2,3</sup>, C.B. Granger<sup>1,3</sup>, W.E. Kraus<sup>1,3</sup>, M.A. Pericak-Vance<sup>1,3</sup>.* 1) Duke Univ. Medical Center, Durham, NC; 2) Glaxo Wellcome, Inc., RTP, NC; 3) for the GENECARD Genetics Network.

The genetic analysis of CAD is complicated by the presence of environmental risk factors and gene-environment interactions. Population-based data suggest that the risk to relatives of an affected individual is greater at younger age of onset and that the relative contribution of environmental factors to disease susceptibility in younger individuals is lower. As a prelude to the analysis of a genome screen for CAD susceptibility genes, we examined the presence of cardiovascular risk factors in a large sample of sib pairs affected with early-onset CAD. Both sibs were required to have onset of CAD by age 50 for males and age 55 for females. ASPs were ascertained by 4 European and 2 US sites. Clinical, family and risk factor data were obtained on 456 independent ASPs from 391 families. We examined concordance for CAD risk factors, including concomitant disease, overall, by age of onset, and by site. The frequency of risk factors for the probands (and for presence in both sibs) was 79% (67%) for dyslipoproteinemia, 59% (38%) for obesity, 60% (35%) for hypertension and 19% (8%) for diabetes. The frequency of presence in the sibling given presence in the proband is 85% for dyslipoproteinemia, 65% for obesity, 58% for hypertension, and 42% for diabetes. The concordance among sibs, especially for diabetes, might be expected given the significant genetic components demonstrated for these diseases. The ASP concordance for these risk factors does not appear to be modulated by age of onset. There is also substantial ASP concordance for smoking history and weekly exercise. We will discuss the implications of these results for the analysis plan including the value of stratified or covariate-adjusted analysis. These data establish the importance of metabolic abnormalities in premature, familial CAD and the need to consider these factors in the analysis.

**G Protein beta three subunit gene polymorphism and pregnancy induced hypertension.** *A. kumar*<sup>1</sup>, *X. Tang*<sup>1</sup>, *C. Isler*<sup>2</sup>, *J.N. Martin*<sup>2</sup>. 1) Pathology, New York Medical College, Valhalla, NY; 2) Department of Obstetrics and Gynecology, University of Mississippi Medical Center, Jackson, MS.

Pregnancy induced hypertension (PIH) is a major cause of maternal and infant mortality. Earlier studies have suggested an association of the angiotensinogen gene with this disease. However, this association was not confirmed in later studies. We have analyzed the genomic DNA from 30 women with PIH and 30 pregnant women with normal blood pressure for C/T polymorphism at nucleoside 825 in exon 10 of the beta-3 subunit of pertussis toxin sensitive G-type protein. The DNA was amplified by PCR using suitable primers, cut with BsaJ1 restriction enzyme and analyzed by 3 percent agarose gel electrophoresis. Our results indicate that women with PIH had increased frequency of TT homozygotes (61 percent) as compared to pregnant women with normal blood pressure (44 percent). Our results suggest that women with TT allele have increased incidence of PIH.

**Genetic screening of the lipoprotein lipase gene for mutations associated with high triglyceride/low HDL-cholesterol levels.** *H. Razzaghi<sup>1</sup>, C.E. Aston<sup>1</sup>, R.F. Hamman<sup>2</sup>, M.I. Kamboh<sup>1</sup>*. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Preventive Medicine and Biometrics, University of Colorado, Denver, CO.

The lipoprotein lipase (LPL) enzyme plays a major role in lipid metabolism, primarily by regulating the catabolism of triglyceride (TG)-rich lipoprotein particles. The gene for LPL is an important candidate for affecting the risk of atherosclerosis in the general population. Previously, we have shown that the HindIII polymorphism in intron 8 of the LPL gene is associated with plasma TG and HDL-cholesterol variation in Hispanics and non-Hispanic whites (NHWs). However, since this polymorphism is located in an intron, the hypothesis is that this may be in linkage disequilibrium with a functional mutation in the coding region or intron-exon junctions of the LPL gene. The aim of this study was to initially screen the LPL coding region and the intron-exon junctions by SSCP for mutation detection in a group of 86 individuals expressing the phenotype of high TG/low HDL followed by association studies in a population-based sample of 1014 Hispanics and NHWs. Four sequence variations were identified by SSCP and DNA sequencing in the coding region of the gene, including two missense mutations (D9N in exon 2 and N291S in exon 6), one same-sense mutation (V108V in exon 3), and one nonsense mutation (S447X in exon 9). Multiple regression analyses, including these four mutations and the HindIII polymorphic site, indicate that the association of the HindIII site with plasma TG ( $P=0.001$  in NHWs and  $P=0.002$  in Hispanics) and HDL-cholesterol ( $P=0.007$  in NHWs and  $P=0.127$  in Hispanics) is independent of all other LPL variable sites examined. These observations reinforce the concept that the intronic 8 HindIII site is functional by itself and provide a strong rationale for future comprehensive functional studies to delineate its biological significance.

**Importance of polymorphic variants of the TNF $\beta$  gene in coronary artery disease (CAD).** *U. Schagdarsurengin<sup>1</sup>, S. Schulz<sup>1,2</sup>, P. Greiser<sup>1</sup>, E. Archoukieh<sup>1</sup>, D. Rehfeld<sup>1,2</sup>, T. Suess<sup>1,2</sup>, K. Werdan<sup>2</sup>, I. Hansmann<sup>1</sup>, C. Glaeser<sup>1</sup>.* 1) Inst. of Human Genetics, Univ. Halle, Halle, Germany; 2) Dep. of Internal Med., Univ. Halle, Halle, Germany.

TNF $\beta$  is a potent cytokine, mediates proinflammatory and antiviral responses, alters the proliferative status of different cell types. It is an essential factor of the degenerative processes in the vessel wall leading to CAD. Methods: We investigated 5 polymorphic sites of TNF $\beta$  (A249G, G365C and TNF $\beta$ -microsatellite of intron1, C492T of exon2, C720A of exon3) in 191 patients (0,79 male, mean 51.5y) with angiographically proven severe CAD (MI: n=66, ACVB or PTCA: n=125) and 229 healthy controls (0,668 male, mean 43y) of Caucasian origin. The patient group was analyzed regarding: age at 1.MI (<or >45y), survival time after 1.MI at the moment of inclusion in the study (<or>1y), number of affected vessels, age of onset (<or>45y) and the therapy (PTCA or ACVB). Results: A249G: we found significantly more homozygous mutant allele carriers, considered to be a cardiovascular genetic risk constellation, in ACVB patients compared with healthy blood donors (0.186 vs. 0.965, p<0.04). MI patients who had survived the 1.MI more than one year had also more frequently the GG type compared to healthy blood donors (0.203 vs. 0.951, p<0.04) suggesting a possible protective influence of the mutation on adaptation after MI. C720A: homozygous mutation carriers were significantly more frequent in patients who had survived the 1.MI more than one year compared to control group (0.210 vs. 1.000, p<0.05). TNF $\beta$  and C492T: in both cases the homozygous mutant type was significantly increased in ACVB-patients (multi-vessel disease) compared to PTCA-patients (one or two vessel disease) (TNF $\beta$ : 0.036 vs. 0.904, p<0.03; C492T: 0.037 vs. 0.944, p<0.03). G365C: comparing the control group with MI patients who had survived the 1.MI more than one year we found a significantly increased frequency of C-allele carriers in the control group (0.312 vs. 1.000, p<0.05). Conclusion: Our results suggest the TNF $\beta$ -polymorphisms as specific potential risk marker for CAD dependent on progression of the disease.

**Cardiovascular disease candidate gene polymorphisms : A comparative study of frequencies between a French and an Italian population.** *C. Pallaud*<sup>1</sup>, *C. Stranieri*<sup>2</sup>, *C. Sass*<sup>1</sup>, *M. Grow*<sup>3</sup>, *G. Siest*<sup>1</sup>, *S. Cheng*<sup>3</sup>, *P.F. Pignatti*<sup>2</sup>, *S. Visvikis*<sup>1</sup>. 1) Centre de Medecine Prventive , Nancy, France; 2) Dpt. Mother-Child-Biology-Genetics, Univ. Verona, Italy; 3) Dpt. Hum. Genet., Roche Molecular Systems, Alameda, CA.

A multilocus assay was used to genotype up to 29 variable sites in 15 genes in a French and in an Italian presumed healthy population (n=1480, n=162, respectively). These genes are involved in lipid metabolism (apoE, apoB, apoCIII, CETP, LPL, PON), homocysteine metabolism (CBS, MTHFR), blood viscosity (Fibrinogen, Factor V), platelet aggregation (GPIIIa), leukocyte adhesion (E-Selectin), and renin-angiotensin system (AT1R, ACE, AGT). Allele frequencies for all the markers were estimated in each population and compared between the two populations. The genotype distributions for each marker were in Hardy-Weinberg equilibrium in the two countries with the exception of CBS Ile278Thr polymorphism in the French population sample. Five allele frequencies were different between the two European countries: ApoB 71Ile allele (p£ 0.001), E-selectin 98T allele (p£ 0.001), E-selectin 128Arg allele (p£ 0.01) Apo E e4 allele (p£ 0.01), MTHFR 677T allele (p£ 0.01), suggesting the existence of a North-South gradient in European allele frequencies. The other frequencies were similar between the two populations, and to those observed in other European countries.

**Statistical genetic analysis of a G-protein beta 3 subunit C825T allelic variant in the Old-Order Amish. G.J.**

*Papanicolaou<sup>1</sup>, W. Siffert<sup>2</sup>, A.J. Stunkard<sup>3</sup>, A.F. Wilson<sup>1</sup>, P. Platte<sup>4</sup>.* 1) Genometrics Section, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Department of Pharmacology, University Hospital Essen, Germany; 3) University of Pennsylvania, Dept. of Psychiatry, Philadelphia, PA; 4) Center for Psychobiology and Psychosomatic Research, University of Trier, Germany.

Independent studies have suggested an association between the G-protein beta 3 subunit (GNB3) 825T allelic variant and hypertension in Caucasian individuals of Germanic ancestry with a family history of hypertension. This allele has also been associated with obesity in males of German, African, and Chinese descent. As part of an ongoing study of obesity in the Old-Order Amish, the 825T variant was determined for 157 individuals in seven families. Given that the Old-Order Amish are of Germanic descent, are genetically isolated, and have a uniform socio-economic status, this was an ideal population in which to study the C825T G-protein variant on measures of obesity and blood pressure. Although there were a substantial number of individuals with obesity in these families, the prevalence of hypertension was quite low. Standard statistical methods were used to investigate allelic and genotypic associations between this G-protein variant and quantitative measures of systolic and diastolic blood pressures and body mass index (BMI). Intrafamilial tests of association, allowing for the familial dependencies inherent in family data, were performed. The frequency of the 825T allele, allowing for familial dependencies, was estimated to be about 0.29. The data suggested significant allelic ( $p=0.012$ ) and genotypic ( $p=0.01$ ) associations between the 825T allele and increased systolic blood pressure in this genetic isolate.

**Familiality of Subclinical Atherosclerosis in Mexican American Families.** *A.H. Xiang<sup>1</sup>, T.A. Buchanan<sup>1</sup>, L.J. Raffel<sup>2</sup>, L. Cheng<sup>2</sup>, M. Quinones<sup>3</sup>, C.R. Liu<sup>1</sup>, C.H. Liu<sup>1</sup>, J. Diaz<sup>1</sup>, E. Toscano<sup>1</sup>, S. Tan<sup>1</sup>, W.A. Hsueh<sup>3</sup>, J.I. Rotter<sup>2</sup>, S.P. Azen<sup>1</sup>, H.N. Hodis<sup>1</sup>.* 1) University of Southern California; 2) Cedars-Sinai Medical Center; 3) University of California Los Angeles, Los Angeles, CA.

Because clinical atherosclerosis is the late stage of a complicated process, epidemiologic and genetic studies would benefit from an earlier measure of the atherosclerosis process, such as carotid artery intima-media thickness (IMT) measured by ultrasonography. Although IMT is commonly used to quantify subclinical atherosclerosis, heritability ( $h^2$ ) of IMT has been less well documented. As part of an ongoing genetic study of Hispanic families ascertained via a proband with hypertension, we estimated the  $h^2$  of IMT.

The study cohort consisted of 365 subjects from 109 families with complete measurements of IMT, age, gender, body mass index (BMI), systolic and diastolic blood pressure (SBP and DBP), and fasting lipids and glucose. The  $h^2$  of IMT was estimated using a variance component approach; cardiovascular risk factors were included as covariates. Because the relationship of IMT and the covariates was different in parents and their offspring, statistical analyses were conducted for parent and offspring combined, and for offspring only.

The results showed that for offspring only, age and gender explained only 13.4% of the total variation of IMT; the adjusted  $h^2$  estimate was 0.60 ( $p = 0.0001$ ). Significant covariates SBP, TC, HDL-C and glucose explained an additional 9.4% of the variation of IMT (total = 22.8%) and increase the adjusted  $h^2$  estimate to 0.64 ( $p = 0.0001$ ). For parents and offspring combined, age and gender explained a larger proportion of the total variation of IMT (42.1%); the adjusted  $h^2$  estimate was 0.38 ( $p = 0.004$ ). Significant covariates SBP, TG and glucose explained an additional 7.8% of the variation of IMT (total = 49.9%) and reduced the adjusted  $h^2$  estimate to 0.30 ( $p = 0.005$ ).

The results indicate that common carotid artery IMT is heritable, supporting its use as quantitative trait for linkage studies to identify genetic determinants for cardiovascular diseases.

**Vitiligo: Identification of common autosomal dominant families in large-scale population surveys.** *P.R. Fain<sup>1</sup>, D.C. Bennett<sup>2</sup>, D.J. Curtis<sup>1</sup>, C.A. Uhlhorn<sup>1</sup>, G.L. Stetler<sup>1</sup>, K.J. Hedman<sup>1</sup>, A.J. Thody<sup>3</sup>, R.A. Spritz<sup>1</sup>.* 1) Univ Colorado Health Sci Ctr, Denver, CO; 2) St. George's Hosp. Med. School, London, UK; 3) Univ. Bradford, UK.

Vitiligo is a common, non-contagious, acquired disorder, characterized by progressive patchy loss of pigmentation of skin and overlying hair. Vitiligo occurs with a prevalence of ~0.1-3 percent in most populations, and the occurrence of family clustering has been noted previously. Vitiligo is thought to have an autoimmune origin, and is associated with various other autoimmune disorders. We have surveyed two large patient groups, the Vitiligo Society (UK) and National Vitiligo Foundation (USA), and obtained data for 2040 probands and 11853 first-degree relatives, by far the largest study of vitiligo ever done. In both groups, ~85 percent of probands were non-Hispanic whites, with similar prevalence in males and females, mean age of onset ~23 yrs., and high correlation between disease duration and severity. Among first-degree relatives, the prevalence of vitiligo was ~7 percent. Most striking, in all ethnic groups 5-10 percent of probands came from families with typical vitiligo, but with early age of onset, greater severity, and apparent autosomal dominant inheritance with high penetrance. The largest such family included 14 affecteds in 3 generations with full penetrance. The prevalence of non-vitiligo autoimmune disorders was greater among probands from the USA (43 percent) versus the UK (21 percent), about half being thyroid disease. This could reflect either different rates of disease or of diagnosis in these two populations. There was no difference in the frequency of other autoimmune disorders in probands from vertical-appearing families versus sporadic cases of vitiligo. Thus, a small but significant fraction of patients with vitiligo derive from families with apparent autosomal dominant inheritance, a paradigm similar to that of breast cancer and many other complex traits. We are currently attempting to map and identify dominant vitiligo susceptibility loci, and to investigate the role of these loci in typical non-familial vitiligo as well as in other autoimmune disorders.

**Frequency of depression among siblings of individuals with Autistic Disorder (AD): Effect of Race and Family History.** *R.K. Abramson<sup>1</sup>, K.A. Decena<sup>2</sup>, R. Walker<sup>2</sup>, H.H. Wright<sup>2</sup>, S.A. Ravan<sup>1</sup>, K.M. Wieduwilt<sup>2</sup>, M.L. Cuccaro<sup>1</sup>.* 1) Wm S Hall Psychiatric Inst, Columbia, SC; 2) Univ of South Carolina Sch of Med, Columbia, SC.

Studies have shown an increased incidence of affective disorders predating the birth of a child with AD in first and second degree relatives (Piven 1999, Bolton 1998, Smalley 1995, Abramson 1992, Piven 1991, Dumas 1991, DeLong 1988). This study examined the effects of race (Caucasian, C; African American, AA), age, gender, and family history of psychiatric illness on sibling self-report of depression. Subjects were recruited from an AD linkage study. Sibling self-report and parent report of depression in nonAD children were evaluated using the Childhood Depression Inventory (CDI) and CDIP (parent version). There were 93 surveys returned for 43 siblings (C=30, AA=13), including 30 CDIs, 35 CDIPs from mothers and 28 CDIPs from fathers. Data analysis included Pearson correlation, chi-square, and paired t-tests. No significant age or gender effects were detected. Three findings were significant: frequency of depression, race, and family history of psychiatric illness. First, depression in this group of siblings (17.2% total siblings [5/29] and 10% of preadolescent siblings [3/29]) was high compared to preadolescents (1.8%) in the general population (Anderson 1993). Second, the AA sibling and parent mean CDI scores were higher than the C sibling and parent CDI scores. There were significant differences between AA and C siblings and AA and C parents in CDI subdomain scores, indicating qualitative as well as quantitative differences in depression symptoms. Finally, CDI/CDIP scores were significantly higher where family history was positive for affective disorder/other psychiatric illness. The potential relationship between familial affective disorders and AD in the subgroup of families with affective disorders and AD has not been evaluated. Family history of affective disorder and race as stratification variables for linkage studies need to be explored.

**The broader autism phenotype: Defining genetically informative dimensions.** *L. Zwaigenbaum, P. Szatmari, J. Goldberg, S. Bryson, W. Mahoney, G. Bartolucci.* Pediatrics, McMaster University, Hamilton, Ontario, Canada.

**Background:** The Broader Autism Phenotype (BAP) refers to PDD-like traits that are found more commonly in relatives of autistic probands than controls. The standard Family History Interview (FHI) (1991; developed by Rutter and Folstein) defines the BAP along the theoretical lines of the autistic triad: communication deficits, social deficits and repetitive behaviours. However, this approach to measuring the BAP may not be the most genetically informative.

**Objective:** to empirically identify aspects of the BAP that best distinguish biologic (BR) from non-biologic (step- or adoptive) relatives (NBR) of probands with autism/PDD. **Methods:** 2nd and 3rd degree relatives of 127 probands with PDD/autism were assessed using the FHI (total: 1327 BR and 326 NBR). Individual FHI items showing differences between BR and NBR were entered into a factor analysis. Factor scores were calculated for male and female relatives, and for subgroups of relatives defined by proband characteristics (IQ>70 vs IQ<70, and single vs multiple incidence family). **Results:** 23 out of 39 FHI items significantly discriminated BR from NBR. Factor analysis (with Varimax rotation) identified 7 orthogonal factors: 1)Social isolation; 2)Learning problems; 3)Social-pragmatic; 4)Odd/inappropriate behaviour; 5)Rigidity; 6)Quality of adult relationships; and 7)Speech delay/deviance. These factors showed generally higher relative risks to BR vs. NBR than the three components of the existing algorithm. Each factor discriminates male BR from male NBR. Female BR, compared to female NBR, score higher on all factors except 4). Analysis using the proposed 7-factor structure yields both qualitative and quantitative differences between BR and NBR of high vs. low IQ probands and in single vs. multiple incidence families. The subset of factors with higher scores in BR than NBR differs by proband characteristics; as well, there are differences between BR of proband subgroups.

**Conclusions:** These results suggest that the BAP may be comprised of up to 7 genetically informative traits. Differences between BR of proband sibgroups suggest that at least some of these traits may be governed by different genetic mechanisms.

**Risk factors for liver disease in cystic fibrosis (CF).** *A.S. Rigby<sup>1</sup>, O.M. Pirzada<sup>1</sup>, C.J. Taylor<sup>1</sup>, J. McGaw<sup>1</sup>, S. Evans<sup>2</sup>, M.S. Tanner<sup>1</sup>.* 1) Sheffield Children's Hosp, Univ Sheffield, Sheffield, UK; 2) Centre for Human Genetics, Univ Sheffield, Sheffield, UK.

Life expectancy in CF has increased significantly over the last decade. With better survival non-respiratory manifestations such as liver disease are becoming more important. The aim of this study was to determine the prevalence of and risk factors for liver disease in CF (CFLD). Case notes and annual review records for all 164 patients (median age 9.4 years) registered at the Sheffield Children's Hospital over a one year period were reviewed. All patients had undergone repeated abdominal examination by CF physicians and had been through our annual review protocol. Risk factors included age, gender, pancreatic sufficiency, portal hypertension, CFTR genotype, neonatal meconium ileus, raised transaminases, gall bladder abnormalities and the Westaby score (severity of ultrasound findings). Statistical associations were calculated by odds ratios (ORs) with 95% confidence intervals (CIs). The RPE method was used to calculate allele differences. Clinical evidence of liver disease was present in 28 (17%) patients, 60% of whom had portal hypertension. There was a peak incidence in adolescence. No patient with CFLD was pancreatic sufficient. 79 (59%) of all patients were homozygous for  $\Delta F508$ . Three variables were significantly associated with liver disease after adjusting for possible confounding in a multiple logistic regression model; pancreatic insufficiency, raised transaminases (OR=18.7, 95% CI=1.4-250) and the Westaby score. Patients with Westaby scores  $\geq 7$  were 66 times as likely to have liver disease compared to patients with scores  $\leq 3$ ; a dose-response effect was evident. There were no significant associations with gender or neonatal meconium ileus. A separate analysis based on patient alleles found an excess of 1138insG (observed=3, expected=0.4, Chi-square=16.4,  $p < 0.01$ ). Liver disease and portal hypertension are more common in CF than previously reported. There was an excess of 1138insG, a frameshift mutation in exon 7, compared to the CF population in Europe ( $< 0.4\%$  of CF chromosomes). The biological significance of this needs further evaluation.

**Familial Aggregation for Traits Associated with Insulin Resistance: The IRAS Family Study.** *L. Henkin<sup>1</sup>, W.M. Brown<sup>1</sup>, J.E. Hokanson<sup>2</sup>, S.S. Rich<sup>1</sup>.* 1) Wake Forest University, Winston-Salem, NC; 2) University of Colorado, Denver, CO.

Insulin resistance (IR), a feature of Type 2 diabetes, is a cardiovascular risk factor acting through hypertension, dyslipidemia, impaired fibrinolysis, visceral adiposity, and direct atherogenic effects of insulin. Familial aggregation of components of IR has been demonstrated, suggesting genetic regulation of these factors. The IRAS Family Study proposes to identify genes for IR and their interaction with environmental factors in Hispanic and African American families. Here we report preliminary heritability estimates for factors related to IR in the initial 50 pedigrees.

The IRAS Family Study is recruiting 1440+ members from 160 extended families in San Antonio, TX, San Luis Valley, CO, and Los Angeles, CA. Phenotypic data include insulin resistance by frequency sampled intravenous glucose tolerance (FSIGT), anthropometry, visceral adiposity by computed tomography (CT), blood pressure, lipids, lipoproteins, PAI1, fibrinogen, albumin, creatinine, and health behavior interviews. DNA is collected for a genome screen. A variance components method (SOLAR) is used to estimate heritability of BMI, insulin, glucose and the HOMA index (a measure of insulin resistance). Analyses include age, gender, ethnicity, and diabetic status as covariates.

The mean±SD age for the subjects with clinical data is 48±16.0 years. In diabetics, the mean BMI is 31.9±8.1 kg/m<sup>2</sup>, fasting insulin 28.2±26.3 mU/ml, glucose 156±48.9 mg/dl, and HOMA 28.7±26.6. In non-diabetics, the mean BMI is 28.3±7.3 kg.m<sup>2</sup>, fasting insulin 14.4±13.3 mU/ml, glucose 96±17.2 mg/dl and HOMA 10.6±11.1. Heritability is estimated for BMI as 0.54±0.12 (p<.01), HOMA as 0.39±0.12 (p <.01), insulin as 0.22±0.11 (p<.01), and glucose as 0.08±0.08 (p=.12). Thus, there is evidence for significant genetic influences on insulin resistance, fasting insulin and BMI, but no significant evidence of heritability of fasting glucose after controlling for diabetic status. These results suggest that the IRAS Family Study pedigrees are useful in identifying genetic determinants of insulin resistance and related phenotypes.

**Power of Omnibus Likelihood Ratio Test for Haplotype-based Case-control Studies.** *D. Fallin*<sup>1</sup>, *N. Schork*<sup>1,2,3,4</sup>. 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Statistical Genomics, Genset Corp., La Jolla, CA; 3) Biostatistics, Harvard University, Boston, MA; 4) Jackson Laboratories, Bar Harbor, ME.

Haplotype-based analyses may have increased power over single-locus tests given their ability to capture unique chromosomal patterns. The use of haplotype-based tests for association analyses has been difficult, however, given the need for phase information. In TDT analyses, this is partly overcome through the use of family information, although many trios are still uninformative and therefore not useful. The situation is even worse in case-control analyses between unrelated individuals, where only complete, or singly heterozygous individuals are informative. We have developed a testing procedure for group comparisons that uses haplotype estimation via the E-M algorithm to predict phase in ambiguous individuals and to test differences between haplotype frequencies profiles of case and control groups. In this presentation, we demonstrate the power of such an approach compared to single locus analyses, and under several different alternative hypothesis scenarios. We show that unless the disease allele itself is included in the marker set, haplotype analysis will always be more powerful than testing single loci. We also show the power of our omnibus approach compared to other haplotype-based methods when more than one haplotype for the same gene region is associated with disease risk.

**Large-scale empirical assessment of the properties of haplotype-based tests of genetic association.** *L. Essioux<sup>1</sup>, R. Norman<sup>3</sup>, N. Tahri<sup>1</sup>, T. Chu<sup>3</sup>, S. Lissarrague<sup>1</sup>, D. Fallin<sup>2</sup>, C. Curtis<sup>3</sup>, B. Skierczynski<sup>3</sup>, N.J. Schork<sup>3</sup>*. 1) Statistical Genomics Department, Genset, Paris, France; 2) Dept of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Genset Corp. LaJolla, Ca.

Haplotype analyses have become more and more popular as genotyping costs have decreased and as the number of available genetic markers has increased. Although several different strategies for haplotype analysis have been proposed, all of them depend critically on the amount of linkage disequilibrium (LD) between alleles at loci within a genomic region of interest. This is especially the case when estimated haplotype frequencies are used in a case/control analysis setting. Modeling LD when assessing the power of haplotype analyses in such settings often involves arbitrary assumptions about its strength and the distances over which it can be found. As an alternative to making potentially unrealistic assumptions of LD strength, we designed a study of the properties of haplotype analyses, which makes use of observed haplotype frequencies in a sample of Caucasians. This sample consisted of over 200 French blood donors genotyped on over 50 markers in two fully sequenced genomic regions of over 150 kilobases in length. The empirically derived distribution of LD and haplotype frequencies observed in this sample was then used to guide power studies of different haplotype-based association analyses. Our results help put into perspective the likely yield of high-density SNP mapping initiatives for many diseases.

**Computational and algorithmic improvements in expectation/maximization (EM) algorithm-based haplotype analyses.** *S. Lissarrague, L. Essioux, N.J. Schork.* Statistical Genomics Dept, Genset Corp., La Jolla, CA.

Technological advances have greatly increased the number of applications associated with Human Genome Initiative and related initiatives. Foremost among these applications is the identification of disease genes using high-density maps of single nucleotide polymorphisms (SNPs). There are a number of issues, which plague the use of high-density maps for disease gene identification, however. Most of these issues have to do with way in which one can usefully extract information from relevant genotyping assays. The Expectation/Maximization (EM) algorithm can be used to estimate haplotype frequencies from high-density multilocus genotype data and therefore can be of great utility in gene mapping studies. We describe improvements in the EM algorithm for use in haplotype analyses involving biallelic markers. The improvements are implemented at the design, implementation, and computational levels of the algorithm and include recoding relevant items as a system of binary variables and the use of parallel computing architectures. We present several comparisons between different computational strategies and our own and consider CPU time studies as well as other issues. Our studies show great promise as computational advances in modern genomic analyses.

**Epidemiology of congenital malformations in Belarus and Chernobyl accident.** *G.I. Lazjuk, D.I. Nikolaev, R.D. Khmel.* Department of Monitoring for Congenital Malformation, Institute for Hereditary Disease, Minsk, Republic of Belarus.

At the 48<sup>th</sup> Congress of the American Geneticists (Baltimore, 1997) we reported the correlation between the prevalence of congenital malformations (CM) and Cs<sup>137</sup> contamination density of the areas. For 2 subsequent years (1998 and 1999) the situation remained unchanged. The prevalence of CMs in the areas with Cs<sup>137</sup> contamination density of 555 kBq/m<sup>2</sup> (15 Ci/km<sup>2</sup>) was registered as 7.29/1000, and in the areas with contamination density of 1.0 Ci/km<sup>2</sup> it was recorded as 7.05/1000.

However, the study of possible teratogenic efficiency of collective and individual doses for the population of these areas has found no dependence of the doses and CM prevalence. Per 1% increase of CM prevalence in Gomel region there was 155 p/Sv, and in Mogilev region it was 78 p/Sv. Similarly, 1.0 mSv of additional exposure dose in Gomel region corresponds to 3 - 6.6/1000 of CM increase, and 1.0 additional mSv in Mogilev region corresponds to 4.2 - 9.7/1000 increase. Teratogenic efficiency of equal in their composition radionuclides from both regions should be equal. The differences we found allowed us to think that increased prevalence of CM is due to not only additional exposure from Chernobyl, but also due to additional factors various in Gomel and Mogilev regions, such as various levels of soluble selen salts and stable iodine in these regions.

**Mutations on the CYP21 gene and haplotype analysis of steroid 21-hydroxylase deficiency alleles in Brazil.** *M.P. De Mello<sup>1</sup>, M. De Araujo<sup>1</sup>, S.H.V.L. Marini<sup>2</sup>, M.T.M. Baptista<sup>3</sup>, G. Guerra Jr.<sup>2</sup>.* 1) CBMEG, Univ. Estadual de Campinas, Campinas, São Paulo, Brasil; 2) Dept. Pediatria, FCM, Univ. Estadual de Campinas, Campinas, São Paulo, Brasil; 3) Dept. Clínica Médica, FCM, Univ. Estadual de Campinas, Campinas, São Paulo, Brasil.

Congenital adrenal hyperplasia (CAH) due to steroid 21-hydroxylase deficiency is a common inherited defect of adrenal steroid hormone biosynthesis. Unusually for a genetic disorder, the majority of mutations causing CAH result from recombinations between the CYP21 gene encoding the 21-hydroxylase enzyme and the closely linked, highly homologous pseudogene CYP21P. The CYP21 and CYP21P genes are located in the major histocompatibility complex class III region on chromosome 6p21.3, a region that undergoes high recombination rates. Studies on the molecular basis of steroid 21-hydroxylase deficiency in Brazil have revealed the presence of fourteen mutations distributed among 117 chromosomes. The percentages of individual mutations does not differ from other findings in different populations. We have performed haplotype analysis on a total of 111 chromosomes using Taq I CPY21 and C4 RFLP/Southern blotting, mutation-specific PCR and PCR/RFLP for two intragenic polymorphisms in order to study the chromosomal background of ten recurrent mutations and four new mutations. Fifty four different haplotypes were identified. The number of haplotypes varied from five to nine for each the five most frequent mutations. These data reflect the wide heterogeneity of the Brazilian population, and show that most recurrent mutations on the CYP21 gene are of various independent origin. Supported by Grants from: CAPES, CNPq and FAPESP.

**Self-reported health history survey (Q8) and genetic analyses in the NAS-NRC aging twin panel cohort.** *T. Reed<sup>1</sup>, J.C. Christian<sup>1</sup>, W.H. Page<sup>2</sup>.* 1) Dept Medical & Molecular Genetics, Indiana Univ Medical Ctr, Indianapolis, IN; 2) Medical Follow-Up Agency, National Academy of Sciences Washington, DC.

**Purpose:** To survey an elderly cohort of male twins for various health outcomes, estimate the heritability ( $h^2$ ) of the traits, and based on the frequency of occurrence to determine the feasibility of obtaining DNA for linkage studies.

**Methods:** The National Academy of Sciences-National Research Council World War II veteran twin registry is comprised of white male twins born between 1917-27. An epidemiologic questionnaire, Q8, contained new items about the twins' health history and repeated some items from two prior surveys concerning alcohol consumption, cigarette smoking, cardiovascular disease symptoms, hypertension, diabetes, stroke, liver cirrhosis and cataracts. Q8 was mailed between Sept-Nov 1998 to 4086 pairs with known addresses and to 908 men who had completed both of the prior surveys, but whose brother had died. Eliminating surveys returned because of bad addresses or death of the subject, 6104 of 8848 (69%) completed forms were received comprising 2058 complete pairs and 1988 singletons with a mean age of 74 years.

**Results:** Genetic analyses were undertaken using complete pairs for self-reported presence or absence of disease, including calculation of probandwise concordance rates and  $h^2$  estimates with the program Mx. A trait of "wellness" (defined as no heart attack, coronary surgery or angioplasty, stroke, diabetes, prostate cancer, or hypertension) had a concordance rate in MZ pairs (0.59) that was significantly higher than the concordance rate in DZ pairs (0.41). The best fitting model for wellness was one which included additive genetic effects and no common environmental effects with a  $h^2$  estimate of 0.57 (95% confidence interval, 0.49-0.64). Migraine, using the International Headache Society classification, had a  $h^2$  estimate of 0.34 (0.11-0.54), but too few concordant or discordant pairs to pursue linkage studies. Presbycusis, hearing loss with age, had a  $h^2$  of 0.61 (0.54-0.68).

**Mapping of genes for alopecia areata.** *M. Barsasteanu*<sup>1</sup>, *D. Papadopoulos*<sup>1</sup>, *J. Fasolo*<sup>1</sup>, *K. Ronningen*<sup>2</sup>, *A. Sinha*<sup>1</sup>, *S. Iyengar*<sup>3</sup>. 1) Dermatology, Weill Med College, Cornell U, New York, NY; 2) National Institute of Public Health, Oslo, Norway; 3) Dept of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Alopecia Areata (AA) is an autoimmune disease in which anagen hair follicles become the target of immune cell attack, with 0.05%- 0.1% of the population being affected at any one time. The cloning of the recessive gene for alopecia universalis (AU) on human 8p12 from a consanguineous family led us to hypothesize that genes for AA may segregate differently in smaller families with at least two affecteds. National Alopecia Areata Foundation (NAAF) investigational guidelines were used to define alopecia. Our investigation was limited to three forms of alopecia: patchy AA, Alopecia Totalis (AT), and AU. Patients were screened by personal interview and medical record review for a history of scalp hair loss, body hair loss, nail involvement and family history of AA, AT or AU. Of 142 AA patients, 118 (79%) consented to participate. Seventy seven percent of the patients had AA, 20% had AT/AU and 3% had AT. The racial composition was 17% African American, 56% Caucasian, 21% Hispanic and 6% Asian and was not significantly different between index cases with and without a family history. Thirty two percent of probands had a positive family history. The mean age-at-onset of the probands was 30 years. DNA from probands with and without family history of AA was typed for polymorphisms at the HLA-D locus. HLA-DR4 and DR-11 as well as HLA-DQ\*03 alleles were found to have an increased frequency in cases versus controls. Due to racial variation in allele frequencies at the HLA loci, all comparisons were race-specific. Our data suggest that AA aggregates in families with possible involvement of HLA loci in AA pathogenesis. Genotyping at additional candidate genes (eg. AU locus) in affected relative pairs with AA is in progress and should facilitate identification of genes controlling AA susceptibility.

**The familial aggregation of age-of-onset of childhood-onset type-1 diabetes in a population-based diabetes register from Western Australia.** *L.J. Palmer<sup>1,2</sup>, T.W. Jones<sup>3</sup>, E.A. Davies<sup>3</sup>, P.R. Burton<sup>4</sup>.* 1) Dept Epidemiology & Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Channing Laboratory, Brigham and Women's Hospital and Harvard University, Boston, MA; 3) Dept Endocrinology, Princess Margaret Hospital for Children, Perth, Australia; 4) Dept Epidemiology and Public Health, University of Leicester, Leicester, UK.

Insulin dependent diabetes mellitus (IDDM) is known to be under a high degree of genetic determination. However, it is currently unknown if age-of-onset of childhood-onset IDDM aggregates within families, and if so to what extent such aggregation may be due to genetic factors. Our aim was to investigate the nature of any such familial aggregation in a population- and family-based register of all incident cases of childhood (<18yrs) IDDM in Western Australia. Gibbs sampler models (BUGS) were used to perform complex variance components analysis on the right-censored trait age-of-onset. Analyses assumed a Poisson link and a proportional hazards survival model, and were adjusted for ascertainment and for potentially confounding covariates. The dataset contained 869 index cases, 869 nuclear families and a total of 4,033 subjects. Median age-of-onset of IDDM was 7.9 years (range=0.8 to 17.8 years). The  $h^2$  of childhood onset IDDM was approximately 0.20. BUGS analyses suggested IDDM age-of-onset comprised additive genetic components of variance ( $s^2_A=7.23$ , 95% CI=1.20 to 23.05), little or no familial environmental components ( $s^2_C=0.00$ ), and common sibling environmental components ( $s^2_{CS}=3.41$ , 95% CI=0.73 to 10.07). These data are consistent with the existence of a substantial degree of familial aggregation of age-of-onset of IDDM, the majority of which is due to additive genetic factors, and raise the possibility that childhood-onset IDDM ( $h^2_{20}$ ) may be under stronger genetic control than adult-onset IDDM ( $h^2_{15}$ ). Programs of gene identification in IDDM may be enhanced by the study of childhood-onset IDDM and by the use of age-of-onset as a phenotype.

**Familial Aggregation and Segregation Analysis of Some Blood Pressure Related Phenotypes in A Rural U.S. Caucasian Community.** *S.K. Nath<sup>1</sup>, A. Chakravarti<sup>2</sup>, R. Cooper<sup>3</sup>, A. Weder<sup>4</sup>, N.J. Schork<sup>1</sup>.* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Genetics, Case Western Reserve University, Cleveland, OH; 3) Department of Preventive Medicine, Loyola University, Chicago, IL; 4) Department of Medicine, University of Michigan Medical School, Ann Arbor, MI.

Familial correlation and segregation analyses of some blood pressure and obesity related phenotypes i.e., systolic blood pressure, diastolic blood pressure, body mass index etc. were performed to assess their major genetic determinants. In order to evaluate the pattern of familiarity and major gene segregation in these traits, we used the nuclear family data ascertained through a proband from a rural US Caucasian community (Tecumseh, MI). Each phenotype was adjusted for covariates, i.e., age and sex. In addition, all the phenotypes were transformed to approximate normality via Box/Cox power transformation. We used class D regressive models for segregation analyses. The pattern of familial correlation and estimated segregation parameters of some phenotypes show the involvement of major gene. We discuss the implications of our findings for gene discovery initiatives. The data for this study were generated by GenNet Network of the Family Blood Pressure Program sponsored by the National Heart, Lung and Blood Institute (HL 54998-01).

**Mitochondrial DNA variability in Turkic-speaking populations of the Altai and Sayan region from South Siberia.**

*M. Derenko*<sup>1</sup>, *G. Denisova*<sup>1</sup>, *B. Malyarchuk*<sup>1</sup>, *I. Dambueva*<sup>2</sup>, *Ch. Dorzhu*<sup>3</sup>, *Yu. Stolpovski*<sup>3</sup>, *E. Lotosh*<sup>4</sup>, *F. Luzina*<sup>4</sup>, *I. Zakharov*<sup>3</sup>. 1) Inst. Biol. Probl. of the North, Magadan, Russia; 2) Inst. of General and Experim. Biology, Ulan-Ude, Russia; 3) Vavilov Inst. General Genetics, Moscow, Russia; 4) Inst. Profess. Pathology and Hygiene Probl., Novokuznetsk, Russia.

It is well established by anthropologists and archaeologists that the territories of South Siberia were the ultimate source of important population expansions into Eurasia. Being inhabited since Upper Paleolithic those territories act as an interaction zone between Caucasoid and Mongoloid tribes. To investigate the origins and evolution of South Siberian populations we present here the mitochondrial DNA (mtDNA) variability data in five Turkic-speaking groups of the Altai and Sayan region. The key RFLP mutations defining the main Eurasian mtDNA haplogroups (A, B, C, D, E, H, U, T, J) were analyzed in a sample of 262 individuals: the Altai-Kizhi, Khakassians, Sojots, Tuvinians and Shorians. This analysis showed that the majority of the Tuvinian and Sojot mtDNAs (86,2% and 88,2%, respectively) belong to haplogroups A, B, C, D, E, and M\* characteristic for Mongoloid populations. However, only 47,8% of the Altaians and 53,7% of the Khakassians share mtDNAs from those typically Mongoloid haplogroups. Very limited Mongoloid influence (19,1%) has been found in the mitochondrial gene pool of Shorians. 9-bp deletion in COII-tRNA(Lys) mtDNA intergenic region was found in all groups studied with the frequencies varying from 13,9% in Tuvinians to 2,4% in Shorians. Caucasoid-specific haplogroups (H, U, T, J) were identified in 35,7% of the Shorians, 22,8% of the Altaians, 18,5% of the Khakassians, 5,9% of the Sojots and 5% of the Tuvinians, with haplogroup U mtDNAs observed in all populations. Despite the same linguistic affinities, the populations studied differ considerably in the pattern of mtDNA haplogroups distributions, suggesting thereby the dual origin for Altaians, Khakassians and Shorians, whereas the Tuvinians and Sojots appear to be the typical Central Asian Mongoloids. Work supported by RFBR grants 99-06-80430 (MD), 00-06-80374 (ID).

**Y-chromosome haplotypes demonstrate the presence of paleo-Caucasoid component in Khakassians. G.**

*Denisova*<sup>1</sup>, *M. Derenko*<sup>1</sup>, *B. Malyarchuk*<sup>1</sup>, *Ch. Dorzhu*<sup>2, 3</sup>, *I. Dambueva*<sup>4</sup>, *I. Zakharov*<sup>2</sup>. 1) Institute of Biological Problems of the North, Magadan, Russia; 2) Vavilov Institute of General Genetics, Moscow, Russia; 3) Tyva State University, Kyzyl, Russia; 4) Institute of General and Experimental Biology, Ulan-Ude, Russia.

The Y-chromosomes of Turkic-speaking Khakassians (aboriginal ethnic group inhabiting the plains of the Minusin Basin of Altai and Sayan region) were analyzed with a set of five biallelic polymorphisms identifying variable loci in the nonrecombining portion of the Y chromosome. The analysis revealed the presence of two major haplotypes in male pool of Khakassians. The most frequent haplotype associated with 92R7 HindIII(-) allele, SRY1532 A allele, as well as with the ancestral states of the polymorphisms YAP, TAT, and DYS199, was found in 14,3% of Khakassians. The Y-chromosome haplotype, differing from one described above only by the mutation at SRY1532, was very frequent (10,2%) in Khakassian sample. Both of haplotypes were found in association with 92R7 allele, which defines at least seven haplotypes, that are important for the tracing of the major migrant Y-chromosome to the Americas (Santos et al., 1999). The Y-chromosome haplotypes found in Khakassians are identical apparently to haplotypes 20 and 32, derived from haplotype 10 (Santos et al., 1999), which is a common ancestor between Native Americans and Europeans, who left some rare descendants in Siberia, among the Kets and Altaians. Moreover, our preliminary data indicate that 92R7-derived Y-chromosome lineages widely distributed in the region of Altai and Sayan Mountains being also found in South Altaians, Tuvinians, and Sojots. Overall, the data received are in accordance with the paleoanthropological views (Alekseev, 1989) suggesting that the tribes with the Caucasoid morphological features were prevalent in Altai and Sayan region since Neolithic and Bronze Age. Their subsequent replacement by Central Asian and North Asian tribes led to formation of population with typical Mongoloid morphological traits. Work supported by RFBR grants 99-06-80430 (MD), 00-06-80374 (ID).

**MITOCHONDRIAL DNA VARIATION IN RUSSIANS, UKRAINIANS AND IRANIANS.** *B. Malyarchuk<sup>1</sup>, G. Denisova<sup>1</sup>, M. Derenko<sup>1</sup>, I. Zakharov<sup>2</sup>*. 1) Genetics Lab., Institute of Biological Probl. of the North, Magadan, Russia; 2) Genetics Lab., Vavilov Institute of General Genetics, Moscow, Russia.

Mitochondrial DNA (mtDNA) polymorphism in 50 Russians and 38 Ukrainians was examined by RFLP analysis and hypervariable segment I (HVS I) sequencing. Together, the Russians and Ukrainians were found to have mtDNAs belonging to nine haplogroups (H, V, T, J, U, K, I, W, X) observed in all European populations. The data received were combined with those available for other European populations and subjected to analysis of shared haplotypes distribution. It was found that the Russians and Ukrainians exhibited a high portion of identical or similar haplotypes in relation to those observed in other Europeans. On the level of rare haplotypes, the Russians were more closely linked to German and Finno-Ugric populations. For instance, subhaplogroup H1 mtDNAs were found in common only between Russians and German-speaking populations. It has been proposed by archaeologists and anthropologists (Alekseeva, 1973; Sedov, 1979), that modern Ukrainians were formed on the basis of Iranian tribes inhabited the Pontic steppes and Slavonic tribes who expanded there from Central Europe approximately 1500 years ago. To estimate the possible Iranian contribution in the gene pool of the Ukrainians, mtDNA variation of 25 Iranians collected from various regions of Iran was examined by RFLP analysis. It was found that Iranian mitochondrial gene pool is represented by West Eurasian haplogroups T (12%), J (12%), U (16%), K (4%), W (12%), I (4%) and additional lineages. However, haplogroup H, which encompasses 40% of the Ukrainian mtDNAs, is virtually absent in Iranians, as well as in Indians. The East Asian-specific macrohaplogroup M sequences were observed in 8% of Iranians. In addition, 9-bp deletion in region V on the background of +10394DdeI/-10397AluI and -10394DdeI/-10397AluI haplotypes was found in 8% of Iranians studied. The data received allow us to conclude that the modern Ukrainians appear to be closer to the European populations, than to West Asian ones. This work was supported by the Russian Fund for Basic Research (grant 00-06-80448).

**Conserved worldwide linkage disequilibrium in the human factor XI gene.** *S.M. Williams<sup>1</sup>, T. Tarumi<sup>2</sup>, D. Martincic<sup>2</sup>, J.A. Whitlock<sup>2</sup>, J.H. Addy<sup>3</sup>, D. Gailani<sup>2</sup>.* 1) Dept Microbiology, Meharry Medical Col, Nashville, TN; 2) Vanderbilt University Medical Center, Nashville TN; 3) University of Ghana Medical School, Accra, Ghana.

Factor XI is a plasma coagulation protease, the deficiency of which causes a bleeding disorder characterized by excessive post-traumatic bleeding. We evaluated the exons of the human factor XI gene that code for the mature protein (exons 3-15) to determine the frequencies of common single nucleotide polymorphisms (SNPs) and haplotype distributions. A total of 266 F11 alleles were screened from 41 Caucasians, 50 Ghanaians, and 42 East Asians (Japanese, Chinese, and Korean). Eleven SNPs were identified, four of which were in flanking non-coding regions. Only five SNPs (all coding or cSNPs) had minor allele frequencies >5% in at least one population; none of these five encoded an amino acid change. The cSNPs are all in Hardy-Weinberg equilibrium, and all cSNPs are present in the three populations (with one exception in East Asians), indicating ancient origins. Three of the cSNPs, C472T, A844G, and T1234C, that are spread across ten kilobases of DNA are in significant LD with each other. In all three populations 844G and 1234C are always found together, with the exception of one Ghanaian. Furthermore, 472T is always associated with 844G-1234C. Estimated haplotype frequencies from all three populations are significantly different from expected ( $p < 10^{-4}$ ). In contrast, the other cSNPs, C1750T and G1855T, are in equilibrium with each other and the three other cSNPs. We analyzed 40 additional individuals of East-African origin (Ethiopian Jews) and found a similar LD pattern. Our data demonstrate marked LD in the human F11 gene, and show that haplotype patterns are strikingly similar across populations, despite significantly different allele frequencies. Given the apparent old age of the 472T-844G-1234C haplotype, the distances between the nucleotide residues, and the fact that other cSNPs in this gene that are close together are in linkage equilibrium suggests an interesting evolutionary history for these polymorphisms.

**mtDNA diversity of Colombian Amerind populations.** *M.M Torres<sup>1</sup>, D. Ortiz-Barrientos<sup>2</sup>, I.D. Soto<sup>2</sup>, L.G Carvajal<sup>3</sup>, C. Duque<sup>2</sup>, G. Bedoya<sup>2</sup>, H. Groot de Restrepo<sup>1</sup>, A. Ruiz-Linares<sup>2,3</sup>.* 1) Laboratorio de Genetica Humana, Universidad de los Andes, Bogota, Colombia; 2) Laboratorio de Genetica Molecular, Facultad de Medicina Universidad de Antioquia, Medellin, Colombia; 3) Department of Medical and Community Genetics, Imperial College School of Medicine, UK.

In order to examine mtDNA diversity in Colombian Amerinds we performed a combined RFLP and D-loop sequence analysis of 73 individuals from 17 Native populations. In each sample we collected sequence data for D-loop hypervariable segments 1 and 2 and typed 5 RFLPs (the 4 sites diagnostic of lineages A to D and the HaeIII site at position 16,517). The populations examined included representatives of the 4 main linguistic South American subdivisions: Chibchan-Paezan, Ge-Gano-Caribe, Andean and Equatorial-Tucano. We identified in this sample sixty seven sequence haplotypes all carriers of most of the changes characteristic of founder mtDNA lineages A, B, C and D. These data question the existence of some proposed additional founder lineages (A2; X6 and X7). Analysis of sequence diversity across main South Amerind linguistic divisions indicates significant genetic structure and is in qualitative agreement with the linguistic classification and the geographic distribution of the populations examined. We detected evidence of recombination in mtDNA as indicated by a significant correlation between strength of linkage disequilibrium and physical distance between polymorphic sites.

**Mitochondrial D-loop sequences and genetic diversity of Chinese ethnic populations.** *Y-P. Zhang<sup>1</sup>, Y. Yao<sup>1</sup>, H. Harpending<sup>2</sup>, Y-X. Fu<sup>3</sup>.* 1) Lab, Cellular & Molecular Evol, Kunming Institute of Zoology, Kunming, 650223, People's Republic of China; 2) Department of Anthropology, University of Utah, Salt Lake City, UT 84112; 3) Human Genetics Center, University of Texas - Houston, Houston, Texas 77030.

Mitochondrial DNA control region segment I sequences were examined in 261 individuals from 8 Chinese ethnic populations and 32 Thais. 206 haplotypes were typed, confirming the high variability of the region. Both mismatch and phylogenetic analyses suggested that the marked distinction between the southern and northern Chinese ethnic groups was due to their earlier origin and differentiation and the southern groups were more ancient. Assuming a divergence rate of 33% site/myr (Ward et al. 1991), we estimated the divergence time of the southern and northern groups to be about 60,000 years before present. Linguistic and geographic classifications of the Chinese populations were not strictly reflected in their mtDNA variation. Mismatch and neutrality test analyses suggested that Chinese ethnic populations could have undergone expansions in the past, with the exception of Tibetan and Chinese Mongolian of which might have different demographic reasons. Combined with the analyses of other world populations, we tentatively propose that Southeast Asia or southwest China might be the place where subsequent human expansions originated after the initial out-of-Africa expansion.

**Evolution of the mtDNA 9-bp deletion in East and Southeast Asia populations.** *Y.Y. Shugart<sup>1</sup>, W.S. Watkins<sup>2</sup>, Y-P. Zhang<sup>1</sup>*. 1) Lab Cellular & Mol Evol, Kunming Institute of Zoology, Kunming, Yunnan 650223, China; 2) Department of Human Genetics, University of Utah, Salt Lake City, Utah 84112.

1218 Chinese from 12 ethnic groups and 9 Han geographic groups were screened for the mtDNA 9-bp deletion motif in the COII/tRNALys intergenic region using PCR-PAGE. The frequency of the 9-bp deletion in all samples was 14.7%, but ranged from 0% to 32% in different ethnic groups. There is a general decrease tendency in the deletion frequencies from the south to the north, from coastal to inland. Additionally, 3 individuals were confirmed to have a triplication of 9-bp segment. Phylogenetic and demographic analyses of the mtDNA hypervariable segment 1 (HVS1) sequences suggests that the 9-bp deletion occurred more than once in China. The majority of the Chinese deletion haplotypes (90%) have a common origin that originated from a mutational event following an initial expansion of modern humans in eastern Asia. Other deletion haplotypes and the three haplotypes with a 9-bp triplication, may have arisen independently in the Chinese, presumably due to replication error. Two possible migration routes of the 9-bp deletion in east and Southeast Asia, both were originated in China, with one route leading to the Pacific Islands via Taiwan, the other to Southeast Asia and possibly the Nicobar Islands are estimated from mtDNA HVS1 analysis. Along both routes of peopling, a decrease in HVS1 diversity of the mtDNA haplotypes with the deletion was observed. The "Polynesian motif" and the 16140 T/C, 16266 C/A or C/G polymorphisms appear specific to the each migration route, respectively.

**Melanocortin-1 receptor gene mutations and polymorphism in Chinese ethnic populations.** *X-M. Lu, P. Shi, H-R. Luo, Y-P. Zhang.* Lab Cellular & Molecular Evolution, Kunming Institute of Zoology, Kunming, Yunnan 650223, China.

Melanocortin-1 receptor (MC1R) is a seven transmembrane domain G protein-coupled receptor of 317 amino acids that belonging to the melanocortin receptor subfamily and has high binding affinity for MSH and ACTH. Previous studies have shown that MC1R is highly polymorphic in European and Asian populations, and that there are strong correlation between MC1R variants and the color of human hair and skin. Here we examined the polymorphism of MC1R gene in 438 individuals from 16 Chinese ethnic populations. Both PCR-SSCP (single-strand conformation polymorphism) and direct sequencing were used to identify the MC1R variants. Besides the three common variants (Val92Met, Arg163Gln and A942G), we also detected 10 rare variants (Val60Leu, Arg67Gln/Arg163, Ala167Glv, His216Val, Pro230Leu, Asn291Lys, Ala299Val, C478T, C414T and C645T) in total samples. For variant Ala167Glv, His216Val, Pro230Leu, Asn291Lys, Ala299Val, C478T, C414T and C645T, they were reported for the first time. The frequency of the Arg163Gln variant was variable in different ethnic groups, ranged from 85.0% (Tibetan) to 40% (Uygur), while those of Val92Met and A942G are not greatly more or less than 12.5%, with the exception of 31.8% in Dai and 38.5% in BuYi. Positive Darwinian selection on MC1R gene, as well as the random genetic drift, migration and the admixture of various ethnic groups might have account for the frequency distribution of the MC1R variant in different ethnic populations.

**Caste-and tribe-specific Y-chromosome haplotypes based on Single Nucleotide Polymorphisms in seven endogamous population groups of Andhra Pradesh, South India.** *G.V. Ramana<sup>1</sup>, B. Su<sup>1</sup>, L. Jin<sup>1</sup>, L. Singh<sup>2</sup>, P. Underhill<sup>3</sup>, R. Chakraborty<sup>1</sup>.* 1) Human Genetics Center, University of Texas, Houston, TX; 2) Center for Cellular and Molecular Biology, Hyderabad, India; 3) Department of Genetics, Stanford University, Stanford, CA.

It is now well established that Single Nucleotide Polymorphism(SNP)markers on the Y-chromosome reveal population-specific Y-haplotypes that are useful in tracing past population movements. Consequently, Y-SNP haplotypes can be used to detect male gene flow across populations. To study such utility of Y-chromosome genetic variation, we have analysed 26 Y-SNP markers in 204 males from Andhra Pradesh, South India. The individuals studied belong to 3 caste groups (Vizag Brahmins, Peruru Brahmins, Kammas), 3 tribes (Bagata, Poroja, Valmiki), and an additional group (the Siddis) of African ancestry. We have identified 11 distinct haplotypes in the total sample. Haplotypes (H5 and H14) that are present in Southeast Asia, Europe and Oceania are shared by all of the groups studied. The H4B haplotype, a derivative of the M52 mutation, is also present in all groups except the Siddis. The tribal groups lack the haplotypes H4, H4A, H5A, and H16, which are seen in the caste groups. In contrast, they exhibit the Southeast Asian haplotype H11 that is absent in the caste populations. The Valmikis have an intermediate position, in the sense that they exhibit 9 of the 11 haplotypes. The presence of haplotypes H4, H5, H14, and H16 in the Siddis indicate that they have assimilated considerable non-African admixture. The principal component analysis supports these observations, placing the Siddis, the three caste populations, and the two tribal groups in three clusters, with the Valmikis closer to the caste groups. In summary, even though these SNP-based Y-haplotypes are able to distinguish the populations, the present data indicates that male gene flow in these South Indian populations is not as negligible as that reflected from the study of Y-specific short tandem repeat markers. (Research supported by the US Public Health Service Research Grant GM 41399 from the National Institutes of Health).

**Genetic structure of world populations using polymorphic Alu retrotransposons.** *W.S. Watkins<sup>1</sup>, C.E. Ricker<sup>1</sup>, M.J. Bamshad<sup>1,2</sup>, H.C. Harpending<sup>3</sup>, A. Rogers<sup>3</sup>, S.V. Nguyen<sup>4</sup>, M.L. Carroll<sup>4</sup>, M. Batzer<sup>4</sup>, L.B. Jorde<sup>1</sup>.* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT 84112; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT 84112; 3) Department of Anthropology, University of Utah, Salt Lake City, UT 84112; 4) Department of Pathology, Biometry and Genetics, Biochemistry, and Molecular biology, Louisiana State University Medical Center, New Orleans, LA 70112.

Retrotransposition of Alu elements produces new polymorphic loci that are ideal for human genetic analyses because the ancestral state of each locus is known. We have ascertained 38 unlinked, human-specific polymorphic Alu loci and have typed 715 individuals from 31 world populations using these markers. African populations have higher Alu gene diversity (0.34) than Asian (0.25), European (0.22), and Indian (0.25) groups. A neighbor-joining tree based on Alu insertions unambiguously separates African populations from other populations (bootstrap support = 100%). The root of the tree is located among sub-Saharan African populations. Principal-components plots based on Alu genetic distances also show continental clustering, and African populations are closest to the ancestral state. Alu genetic distances show high and significant ( $p < 0.0001$ ) Mantel correlations with other genetic markers (Alu-RSP: 0.875, Alu-STR: 0.770, Alu-mtDNA: 0.796) in 15 populations typed for all systems. The fixation index ( $F_{st}$ ), indicating the diversity attributable to population subdivision, is 16% and similar to that of other nuclear markers. Alu/Alu observed homozygosity is lowest in Africa (0.25) and is significantly higher for Asian (0.45), European (0.44), and Indian (0.42) groups. The genetic distance of each population to the regional centroid indicates higher than expected heterozygosity and gene flow for African populations and expected to lower than expected heterozygosity for most non-African subpopulations.

**Origin of Haplogroup M in Ethiopia.** *D.C. Wallace*<sup>1,3</sup>, *B.P. Donham*<sup>1,3</sup>, *T.G. Schurr*<sup>2</sup>, *D.L. Donham*<sup>3</sup>, *C. Panter-Brick*<sup>4</sup>, *J.T. Lell*<sup>1</sup>. 1) Center for Molecular Medicine, Emory University School of Medicine, Atlanta, Georgia 30322; 2) Southwest Foundation for Biomedical Research, Department of Genetics, P.O. Box 760549, San Antonio, Texas 78245-0549; 3) Department of Anthropology, Emory University, Atlanta, Georgia 30322; 4) Department of Anthropology, Durham University, UK.

To elucidate the pattern of genetic variation in East Africa, we characterized the mitochondrial DNA (mtDNA) variation of 157 Ethiopians by restriction fragment length polymorphism (RFLP) and DNA sequence analyses. Ninety-four of these samples were collected in the Maale area of southwest Ethiopia, whereas 61 samples came from northern Ethiopia. In contrast to sub-Saharan Africa from which two-thirds of the mtDNAs belong to haplogroups L1 + L2, and one-third belong to L3; among Ethiopians one-fourth belong to haplogroups L1 + L2, and most of the rest belong to haplogroup L3, including a new L3 mtDNA lineage, present in the Maale. Ethiopians were also found to harbor Eurasian mtDNAs including Asian macrohaplogroup M, defined by the Dde I 10394 and AluI 10397 sites, and European haplotypes H, I, J, T, and U. To determine if Asian M arose in Northeast Africa, we compared the mtDNA sequences of six Asian M mtDNAs with nine African mtDNAs. Three mutations were found at np 14783 T®C, np 15043 G®A, and np 15301 G®A that differentiated the two groups. The 15043 G®A and 15301 G®A mutations were present in L3 and found in all M mtDNAs, but the 14783 T®C mutation was absent in L3, found in half of the Ethiopian M samples, and present in virtually all Asian M mtDNAs studied. Hence, Ethiopian M appears to represent an intermediate between sub-Saharan African and Asian mtDNAs.

**The ethnic origins of an enigmatic South Asian population, the Kalasha of northern Pakistan, as revealed by mtDNA variation.** *T.G. Schurr<sup>1</sup>, W.R. Maggi<sup>2</sup>, K. Fowler<sup>3</sup>, D.C. Wallace<sup>3</sup>.* 1) Dept Genetics, SW Foundation Biomedical Res, San Antonio, TX; 2) Department of Anthropology, University of Colorado, Boulder, CO; 3) Center for Molecular Medicine, Emory University School of Medicine, Atlanta, GA.

The origins and affinities of the Kalasha, an enigmatic population from Pakistan's North West Frontier Province, were investigated through the analysis of mtDNA variation. The mtDNAs of ~100 individuals were subjected to both RFLP haplotype and control region (CR) sequence analysis, and the resulting data analyzed with statistical and phylogenetic methods. The RFLP analysis revealed that the Kalasha lacked any mtDNAs which could readily be assigned to haplogroups typically found in southern or northern Asian populations. In fact, they lacked any haplotypes bearing the linked +DdeI 10394 and +AluI 10397 polymorphisms that define macrohaplogroup M in Asian populations. To the contrary, their mtDNAs either belonged to one of the nine haplogroups commonly found in European populations, or else to as yet defined clusters found predominately in South Asian groups. These RFLP data, as well as the CR sequences within them, suggested that the Kalasha lack any genetic affinities with East Asian populations, hence, are not Asian in origin. Instead, they may represent the ancestral Eurasian populations that settled Central Asia prior to the emergence of Indo-Aryan-speaking groups.

**Trinucleotide repeat polymorphism analysis in different populations from Russia and nearest countries.** *S.N. Popova<sup>1</sup>, P.A. Slominsky<sup>1</sup>, A.I. Mikulich<sup>3</sup>, V.A. Spitsyn<sup>2</sup>, L.A. Livshits<sup>4</sup>, N.A. Bebyakova<sup>5</sup>, S.A. Limborska<sup>1</sup>*. 1) Dept Human Molec Genetics, Inst Molecular Genetics, Moscow, Russia; 2) Medical Genetic Scientific Center, Moscow, Russia; 3) Institute of Ethnography, Minsk, Belarus; 4) Institute of Molecular Biology and Genetics, Kiev, Ukraine; 5) Archangelsk State Medical Academy, Archangelsk, Russia.

Various trinucleotide repeat variability analysis were carried out in different ethnic groups. We investigated CTG and CAG polymorphism associated with some neurodegenerative diseases - myotonic dystrophy (DMPK), dentatorubropalladoluisian atrophy (DRPLA) and spinocerebellar atrophy type 1 (SCA1) - in Slavonic (Russians from Archangelsk, Kostroma, Bellarusians and Ukrainian), Finno-Ugric (Udmurts) and Turk (Khant, Yakut and Komi) populations. Allelic spectrums distinctions were observed among different entice groups for all analysed loci. Statistically significant differences were found for Yakut population comparing with Kostroma (Middle Russian population) by G-statistic ( $p=0,0000$ ). No remarkable distinguishes were observed for Slavonic populations compared with Chant and Komi. We found the tendency for allele distribution spectrums to be varied in South-West and North-East direction, where character of different repeats spectrum change correlating with populations geographic location. Genetic diversity for all populatios were estimated with F-statistic using jackknifing. Fst amount for different population hesitates from 0.016 to 0.041 for DRPLA locus, from 0.005 to 0.21 for SCA1 locus and from 0.005 to 0.024 for MD locus. For all analysed loci Fst quantity for Yakut population were lowest among all populations, suggesting most closeness and genetic distance for this population. Also we constructed genetic tree (using GDA computer program) for investigated populations based on three loci. Phenogram for genetic shows that Yakut population situated far from other population which forms cluster with populations of Caucasian origin having his own relations. Thus two smaller clusters can be obtained first formed by non-Slavonic populations, and second - with mainly Slavonic populations.

**Univariate and multivariate analysis of Mexican-American GENNID data.** *M.M. Barmada, C.E. Aston.* Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

The etiology of type 2 diabetes, though acknowledged to be complex, is still largely unknown. Familial aggregation and concordance in monozygotic and dizygotic twins argue strongly for a genetic component in the etiology of type 2 diabetes. However, studies of putative candidate genes, except in rare subtypes of type 2 diabetes, have not yielded any significant risk factors. We have undertaken an analysis of the phase I Mexican-American data provided as part of the Genetics of Non-Insulin Dependent Diabetes (GENNID) study (Raffel *et al.* 1996). Regression techniques were used to adjust our trait variables (which were derived from the time points of oral glucose tolerance tests) for the effects of several measured covariates. The resulting adjusted quantitative traits were then used to search for quantitative trait loci (QTLs) controlling each trait. Regression models were also developed in a separate, population-based epidemiological cohort from the San Luis Valley Diabetes Study (Hamman *et al.* 1989), and then applied to the GENNID data. Multivariate modeling techniques (principal component and factor analysis) were also used to examine the possibility that there are major genes in diabetes which control susceptibility through pleiotropic action on a number of different quantitative traits. The univariate trait analyses uncovered a number of previously identified type 2 diabetes susceptibility loci, including regions of chromosome 2, 5, 6, 7, 10, and 17. The multivariate trait analyses, though plagued by missing-data issues, still retained enough power to identify similar regions of chromosomes 6 and 17, and also identified new regions of interest on chromosomes 11 and 12.

**Analysis of autosomal dominant polycystic kidney disease (ADPKD) in the Newfoundland population.** *D.S. Compton<sup>1</sup>, W.S. Davidson<sup>1</sup>, J.S Green<sup>2</sup>, E.L. Dicks<sup>2</sup>, P.S Parfrey<sup>2</sup>.* 1) Molecular Biology and Biochem., Simon Fraser University, Burnaby, BC, Canada; 2) Faculty of Medicine, Memorial University of Newfoundland, St.John's, NF, Canada.

The Newfoundland population is ideal for examining founder effects and for studying the incidence of hereditary disease in what is essentially a closed community. Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common genetic diseases in humans. Mutations in any one of at least three different genes are thought to be responsible for this disease and two genes, PKD1 and PKD2, have been mapped to 16p13.3 and 4q21-q23, respectively. Thirteen Newfoundland families with ADPKD have been examined using microsatellite markers flanking and within the PKD genes on chromosome 16 and chromosome 4. Nine of the thirteen families showed linkage to PKD1 whereas two were linked to PKD2. The other two families were uninformative due to the structure of the family. Comparisons of the haplotypes of the families linked to PKD1 revealed that five families share a partial haplotype suggestive of an ancestral founder disease chromosome. The other four PKD1 haplotypes suggest that these all resulted from independent mutation events. Mutational analysis is currently underway to determine the exact number of founder mutations for ADPKD in the Newfoundland population. (Supported by the Kidney Foundation of Canada and the Medical Research Council of Canada).

**Genome scans for quantitative trait loci using variance components linkage analysis: upward bias in heritability estimates attributable to individual quantitative trait loci at lod score peaks.** *H.H.H. Goring<sup>1</sup>, J.D. Terwilliger<sup>2</sup>, J. Blangero<sup>1</sup>*. 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Columbia University and NY State Psychiatric Institute, New York, NY.

While the primary goal of a genome scan is to map the loci underlying the trait of interest, it is also desirable, particularly in the analysis of human diseases and from a public health perspective, to estimate the importance of the identified loci. One such measure of importance is the trait heritability attributable to a mapped locus, i.e. the proportion of overall phenotypic variance in a specific population and environment due to the locus. Variance components-based analyses are widely used to map quantitative trait loci (QTLs). An attractive feature is that these methods not only provide estimates of QTL location, but also of QTL heritability.

Several studies have examined the statistical properties of QTL heritability estimates at a specific point in the genome, such as the location of a known QTL, finding little evidence for systematic bias. We have examined the properties of these estimates in genome-wide scans on simulated data. We have found the QTL heritability estimate associated with the first order statistic, i.e. the highest lod score in the genome, to be biased upwards in general. The explanation is that the locus-specific heritability estimate is positively correlated with the lod score (the heritability estimate associated with a lod score of zero is also zero), such that when the lod score is maximized over the whole genome - containing regions with QTLs as well as many more without QTLs - the QTL-specific heritability estimate associated with the highest lod score peak is likely to be high - often higher than the true heritability of the most "important" QTL. Joint estimation of location and heritability of QTLs is thus complicated by the positive correlation between both measures, such that QTL-specific heritability estimates obtained in genome-wide scans must be interpreted with caution. The same reasoning applies to estimates of locus-specific values of  $l_s$ , the relative risk to sibs of an affected individual.

**A variance components method of linkage analysis to assess parent-of-origin effects on body mass index.** *R.S. Lindsay, S. Kobes, W.C. Knowler, R.L. Hanson.* NIDDK, NIH, Phoenix, AZ.

We have examined the hypothesis that imprinted genes may affect the propensity to obesity. Multipoint linkage to age and sex adjusted body mass index (BMI) was carried out on 846 individuals in 235 nuclear families with 516 autosomal microsatellite markers in a genome wide scan. Parental genotyping, available either directly or by estimation, was then used to calculate identity by descent separately for alleles transmitted from father ( $p_{FA}$ ) and mother ( $p_{MO}$ ). Multipoint linkage for BMI was calculated by modification of the variance components method: separate models were examined with ( $LOD_{IMP}$ ) and without ( $LOD$ ) parent specific effects and a P value for the difference derived ( $P_{DIFF}$ ). In addition separate estimates of linkage to paternally ( $LOD_{FATHER}$ , using sole effects of  $p_{FA}$ ) and maternally ( $LOD_{MOTHER}$  using sole effects of  $p_{MO}$ ) derived alleles were obtained. The strongest evidence of linkage was detected on chromosome 11q (at map position 142cM), in keeping with previous analysis of a larger sample of this population (966 individuals,  $LOD=3.6$ ). No evidence of imprinting effects were found at this site ( $LOD=2.7$ ,  $LOD_{IMP}=2.1$ ). Tentative evidence of linkage with significant parent specific effects ( $LOD_{IMP}>1$ ,  $LOD_{IMP}>LOD$  and  $P_{DIFF}<0.05$ ) was found in two regions. Stronger linkage of BMI to maternally derived alleles was found at 72cM on chromosome 5 ( $LOD_{IMP}=1.2$ ,  $LOD=0.1$ ,  $LOD_{MOTHER}=1.7$ ,  $LOD_{FATHER}=0$ ,  $P_{DIFF}<0.01$ ). Stronger linkage of BMI to paternally derived alleles was found at 20cM on chromosome 10 ( $LOD_{IMP}=1.1$ ,  $LOD=0.8$ ,  $LOD_{MOTHER}=0$ ,  $LOD_{FATHER}=1.7$ ,  $P_{DIFF}<0.05$ ). No evidence of linkage of BMI was found in areas known to contain clusters of imprinted genes on chromosomes 11p or 15. In conclusion, we have developed a variance components technique to assess parent of origin effects, and determined two areas where tentative evidence of parent specific effects in inheritance of BMI is present.

**A General Framework for Comparing the Power of Mean Effects and Variance Component Linear Models for Quantitative Group Comparisons.** *H.K. Tiwari<sup>1</sup>, N.J. Schork<sup>1,2,3,4</sup>*. 1) Dept Epidemiology/Biostatistic, Case Western Univ, Cleveland, OH; 2) The GENSET Corporation, 875 Prospect Street, Suite 206, La Jolla, CA; 3) Department of Biostatistics and program for population genetics, Harvard School of Public Health, Boston, MA; 4) The Jackson Laboratory, Bar Harbor, ME.

There are a number of ways one can test for the effect of certain groupings on a quantitative outcome. Standard ANOVA designs test the equality of the mean outcomes across the groups. An alternative test procedure involves determining if the amount of variation explained by a grouping is greater than 0. This alternative test procedure can be constructed as a one degree-of-freedom test of a variance component in a random effects linear model. We consider and compare the power and sample size requirements for the variance component testing approach as well as direct, ANOVA-like, tests of the equality of means across the groups using standard asymptotic theory for multivariate normal linear models. We also describe the conditions under which each test is favorable. In general, we find that ANOVA-like tests are favorable when there are few groups, but inefficient relative to the variance component tests when there are a large number of groups, due to the large number of degrees of freedom associated with testing the equality of the means. We also comment on the limitations of our comparison strategy as well as assumptions that need further consideration.

**Identification of a putative recombination hotspot in the promotor of the TNFa gene.** *K.C.C. Wong, D. Kwiatkowski, A.E. Richardson, W.O. Cookson, M.F. Moffatt.* WTCHG, University of Oxford, Oxford, Oxfordshire, UK.

Patterns of linkage disequilibrium (LD) with the genome may be the result of mutation, selection and drift. In addition, regions of increased recombination may contribute to the regional distribution of LD, with important implications for the LD mapping of genes influencing disease. As part of our studies of the role of tumour necrosis factor  $\alpha$  gene (TNFa) polymorphisms in the aetiology of asthma, we have examined 10 polymorphisms in the TNFa gene and its promoter. One thousand and four subjects from 230 families of a general population sample from Busselton in Western Australia were typed, yielding a total of 10,357 genotypes. The SIMWALK2 program was used to construct haplotypes from the family data, accurately defining haplotypes spanning approximately 4.4Kb between the TNFa gene and a *Nco* I polymorphism in the first intron of the Lymphotoxin  $\alpha$  gene. The 10 polymorphisms of TNFa are in the first 2376bp of the 4.4Kb region. Seven single recombinants within the 4.4Kb were found in 1112 meioses, when only 0.05 would have been anticipated from a typical genomic region of this extent (based on a recombination frequency of 1% / Mb)( $c^2=11122$ ,  $p=0.00000$ ). Examination of pair-wise linkage disequilibrium (LD) between all markers within the region showed an area of discontinuity of LD on either side of a limited 650 bp segment sited centrally within the TNFa promoter. The region therefore contains a putative recombination hotspot, the second to be identified in the MHC region.

**Frequencies of pERT87-8/Tag1 and pERT87-15/BamH1 alleles linked to the Duchenne muscular dystrophy gene in Moldavian populations.** V.C. Sacara. Nat.Center of Med.Genetics , S R I C & M H C, Kishinev, Moldova.

For define pERT87-8/Tag1 and pERT87-15/BamH1 polymorphism in Moldavian population were study 15 females and 40 males (total 70 unrelative chromosomes). The RFLPs identified for pERT87-8/Tag1 are of 145bp (allele A1) and 74bp + 71bp (allele A2) and for pERT87-15/BamH1 are of 216 bp (allele F1) and 166bp + 50bp (allele F2) . These alleles were present in these ethnic group and no new allele was found. The allele frequencies calculated from the total number of chromosomes tested in population Moldova. The heterozygote numbers are counted by Hardy-Weinberg equilibrium. The allele A2 frequency (pERT87-8) in the Moldavian sample (0,815) is similar to the English population and Nigerian. The frequency of allele A1 is 0,185. The expected heterozygote number in the Moldavian population is 0,30. We also study RFLP pERT87-8/Tag1 on DMD patients (total 70 unrelative pathology chromosomes). The frequency of allele A2 is 0,428 and the frequency of allele A1 is 0,571. Since the allele A1 are found in 4 times more often on pathology chromosomes and its linked the Duchenne muscular dystrophy. The frequency of allele F1 (pERT87-15/BamH1) is 0,05 significant low and the frequency of allele F2 is 0,95. The expected heterozygote number 0,095. Polymorphism pERT87-15/BamH1 is likely to be of limited value in Moldavian population. To conclude, different populations may differ greatly in their frequencies of various RFLPs.

**Fetal programming of insulin resistance: the use of twins to control for genotype.** *R. Loos, R. Fagard, G. Beunen, C. Derom, R. Vlietinck.* Katholieke Universiteit Leuven, Leuven, Belgium.

Low birth weight and fetal thinness have been associated with non-insulin dependent diabetes mellitus and insulin resistance in adulthood. It has been suggested that this association may result from fetal programming in response to the intrauterine environment. An alternative explanation is that the same genetic influences alter both intrauterine growth and adult glucose tolerance. In the present study we investigated the association between birth weight and insulin resistance using twins. The use of twins allows perfect matching for gestational age, maternal height and birth order. Monozygotic twins (MZ) have identical genotypes and allow controlling for putative genetic influences. Birth records of 131 male and 145 female same-sex and 42 opposite-sex twin pairs (70 DZ, 206 MZ, 25.7±4.8 years) were obtained from the East Flanders Prospective Twins Survey. Fasting plasma insulin and glucose concentrations were measured to assess insulin resistance with the homeostasis model assessment (HOMA). A multiple regression analysis was used to study the association between birth weight (BW) and insulin resistance (IR), controlling for gestational age, age, and body composition. BW explained 2% ( $p=0.02$ ) of the variance of IR in female twins: per kg decrease in BW the IR increased with 0.25. Age and body composition explained 12%. In males, BW did not contribute significantly. We hypothesized that within pairs, the leanest (lowest BW) would have a higher IR compared to his heavier sib (highest BW) as an adult. Therefore we analyzed the intra-pair BW difference with the intra-pair IR difference at adulthood of MZ twins. An inverse relation was found between BW difference and IR difference in female twins: per kg difference in BW the leanest had a 0.43 higher IR compared to her heavier sib ( $p=0.14$ ). In males this tendency was less apparent ( $p=0.39$ ). These results show for insulin resistance that the fetal origin hypothesis applies to female twins, but not to male. Even in MZ pairs, sharing the same genotype, the leanest (at birth) tends to have the highest insulin resistance as an adult compared to her heavier sib (at birth).

**Excess of rare polymorphisms in the genomic sequence of Fibroblast Growth Factor Receptor 3.** *D.L. Lind, D.R. Cox.* Department of Genetics, Stanford University, Stanford, CA.

There are at least twelve diseases, all inherited in an autosomal dominant fashion, which are caused by recurrent spontaneous mutations in members of the Fibroblast Growth Factor Receptor (FGFR) gene family. If the high frequency of spontaneous mutations in FGFR2 and FGFR3 is caused by a high mutation rate, this might also cause a change in the amount or distribution of polymorphisms in the genomic sequence of these genes compared to genes where new mutations do not occur as frequently, such as FGFR1 or FGFR4. We sequenced PCR products covering the genomic regions for three of the FGFRs in 36 normal individuals. FGFR2 and FGFR3 covered 48 and 14 kb, respectively, and are used as examples of regions with a potentially high mutation rate. FGFR4 covered 12 kb, and is used as an example of a region with a potentially lower mutation rate as no disease-causing mutations have yet been identified in this gene. We found no significant difference in the overall amount of sequence variation in these three genes, though we did find a difference in how the variation is distributed. Using Fu and Li's  $D^*$  test, for FGFR2 and FGFR4 the results were slightly negative, though not significantly different from neutral expectations. For FGFR3,  $D^*$  is -2.42 ( $p < 0.025$ ). A negative  $D^*$  value indicates an excess of rare polymorphisms relative to the overall amount of variation, and may be the result of population expansion, population stratification, or a selective sweep. Population expansion or stratification is unlikely to be able to account for such a large deviation from neutral, though may account for some of the difference. This would suggest a selective sweep has taken place in FGFR3, removing some of the common polymorphisms.

**Mitochondrial DNA diversity in East European populations.** *O.V. Belyaeva<sup>1</sup>, S.P. Markina<sup>1</sup>, M.A. Bermisheva<sup>2</sup>, N.A. Bebyakova<sup>3</sup>, A.I. Mikulich<sup>5</sup>, L.A. Livshitz<sup>4</sup>, E.K. Khusnutdinova<sup>2</sup>, S.A. Limborska<sup>1</sup>.* 1) Human Molecular Genetics, IMG RAS, Moscow, Russia; 2) Inst. of Biochemistry and Genetics, Ufa, Russia; 3) Arkhangelsk State Medical Academy, Arkhangelsk, Russia; 4) Inst. of Molec. Biology and Genetics, Kiev, Ukraine; 5) Inst. of Ethnography and Anthropology, Minsk, Republic of Belarus.

Mitochondrial DNA diversity widely employed in population and evolutionary studies is investigated insufficiently among East European peoples. We have performed the mtDNA sequence analysis in a set of population from Russia and neighboring countries underrepresented in worldwide mitochondrial polymorphism studies. The first hypervariable segment of the mitochondrial control region was sequenced in representative samples of native Slavic population of Belarus, Ukraine and Russia, including very peculiar isolated rural populations. Frequencies of main haplogroups were determined based on phylogenetically informative positions of HVSI. The median network constructed for samples studied revealed branches corresponding to main haplogroups determined from these positions. The comparison of haplogroup frequencies, as well as intrapopulation diversity characteristics obtained to mitochondrial DNA data described by others for previously studied European and Asian samples revealed that variations among our samples are within European mtDNA variations in total. Nevertheless the comparison of different East European populations to each other revealed the complicated structure of Russian gene pool. The distribution of mtDNA variations between different Russian samples reflects old migrations proposed by historical data.

**Genome-wide distribution of linkage disequilibrium in the population of Palau and its implications for gene flow in Remote Oceania.** *W.F. Byerley*<sup>1</sup>, *K. Roeder*<sup>2</sup>, *K. Otto*<sup>3</sup>, *S. Tiobech*<sup>3</sup>, *B. Devlin*<sup>4</sup>. 1) Bldg 837, Rm 2119, ZC 4260, Univ California, Irvine, Irvine, CA; 2) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 3) Palau National Hospital, Palau; 4) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Linkage disequilibrium (LD) between alleles on the same human chromosome results from various evolutionary processes and is thus telling about the history of populations. Recently, LD has garnered substantial interest for its value to map and fine-map disease genes. We examine the distribution of LD between Short Tandem Repeat (STR) alleles on autosomes and between STR alleles on sex chromosomes in the Remote Oceanic population of Palau to evaluate two related issues: (1) Are the data consistent with a recent hypothesis about the origins of genetic variation in Palau, specifically that the population experienced extensive male-biased gene flow following initial settlement (Lum et al., *Am J Hum Genet* 63:613-624); and (2) Could the Palauan population be useful for LD mapping of disease genes due to its population history? Consistent with evolutionary theory based on effective population size, LD between X-linked alleles is stochastically greater than LD between autosomal alleles; however, small but detectable LD occurs for autosomal markers separated by substantial distances. By contrast, while Y-linked alleles experience only one-third the effective population size of X-linked alleles, their mean value for pairwise LD is slightly smaller than X-linked alleles. For a small population known to experience at least two extreme bottlenecks, Y haplotypes exhibit remarkable diversity (0.96, based on 6 STRs) and fall into six distinct clusters. We argue these data are consistent with waves of male-biased gene flow. Theoretical analyses, combined with the empirical LD analyses, also show that Palau could be a promising population for LD mapping of disease genes.

**Estimating the rate of decay of linkage disequilibrium with distance.** *L. Frisse<sup>1</sup>, A. Bartoszewicz<sup>1</sup>, A. Pluzhnikov<sup>1</sup>, R. Hudson<sup>2</sup>, A. Di Rienzo<sup>1</sup>.* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Ecology & Evolution, University of Chicago, Chicago, IL.

The rate at which linkage disequilibrium (LD) decays with physical distance in human populations is of great interest for designing disease association studies. In addition to the rate of mutation and recombination, LD is affected by two main evolutionary forces: population history and natural selection, which operate on different scales. Natural selection affects LD locally, while population history typically has genome-wide effects. In order to characterize how LD was shaped by population history in human populations, we have developed an efficient scheme for surveying LD in neutrally evolving genomic regions. Several independent regions of 10 kb are amplified and segments of 1 kb at each end of these regions are sequenced in population samples from three major ethnic groups. The haplotype phase is subsequently determined by cloning the 10 kb fragment of each multiply heterozygous individual. This scheme for data collection allows us to estimate the extent of LD over the entire frequency spectrum, which is informative for the reconstruction of population histories. In particular, we can survey LD within each 1 kb segment as well as between segments over a 10 kb distance. The preliminary results of this survey show that LD between sites separated by distances of up to 1 kb is not complete while it shows substantial, but incomplete decay between sites separated by distance of up to 10 kb. Furthermore, LD appears to decay at a different rate in different ethnic groups.

**Skin pigmentation and individual admixture estimates.** *H.L. Norton<sup>1</sup>, C.L. Pfaff<sup>1</sup>, E.J. Parra<sup>1</sup>, N. Sylvester<sup>2</sup>, D. Parrish-Gause<sup>2</sup>, R.A. Kittles<sup>2</sup>, M.D. Shriver<sup>1</sup>*. 1) Pennsylvania State University, University Park, PA; 2) Howard University Cancer Center, Washington, D.C.

Variation in human pigmentation has been studied objectively using reflectance spectroscopy for over 50 years. The identification of the genes responsible for pigmentary variation among human populations is the first step in understanding the molecular and evolutionary history of human pigmentation. African-American populations provide a valuable opportunity to investigate the genetics of pigmentation due to their unique demographic history. DNA samples were collected from 162 African-American individuals from Washington D.C. and genotyped for 11 population-associated alleles (PAAs). Skin reflectance measurements were taken from the subjects using the DermaSpectrometer instrument, which separates the reflectance due to melanin absorbance from that of hemoglobin and summarizes this value as the Melanin (M) index. Individual admixture proportions were calculated from the PAA multilocus genotypes using maximum likelihood. Regression analysis showed a significant correlation between the estimate of percent of African ancestry and M index ( $R^2 = 0.15$ ,  $p < 0.001$ ). Individuals showing lower values of the M index (i.e. lighter skin color) showed lower percentages of African ancestry. One major source of variation (as seen in the low  $R^2$ ) may be the small number of PAAs available, resulting in imprecise individual admixture estimates. We then tested for association between any PAA and M index with individual admixture as a covariate. Two of the PAAs that are also pigmentation candidate genes, OCA2 and GC (KIT), were significantly associated with higher M indices even after individual admixture was taken into account. These results demonstrate that phenotypes that are divergent in parental populations may reflect the proportion of admixture in individuals of admixed populations. We also provide an example of a way to use the individual admixture estimate to identify the genes underlying the phenotype. The important consequences for research on complex diseases in African-American and Hispanic populations are also discussed. This work was supported by a grant from NIH/NHGRI (HG02154).

**Q318X is the Common Mutation of CYP21 gene in Tunisian Population.** *M. Kharrat*<sup>1</sup>, *R. Mrad*<sup>1,2</sup>, *N. Smaoui*<sup>1,2</sup>, *F. Maazoul*<sup>2</sup>, *A. Masmoudi*<sup>2</sup>, *L. Ben jema*<sup>1,2</sup>, *H. Chaabouni*<sup>1,2</sup>. 1) Laboratory of Human Genetics. , Medical School Tunis, Tunis, Tunisia; 2) Department of Hereditary Diseases .Charles Nicolle hospital. Tunis,Tunisia.

Congenital adrenal hyperplasia is an autosomal recessive disease with heterogeneous phenotype. The most common form is due to 21-hydroxylase deficiency (21-OHD) resulting from lesions in the CYP21 gene. Up to date more than 20 different mutations have been reported in CYP21 gene, widely distributed. Mutations analysis have been investigated in 50 unrelated Tunisian families. All affected members have classic phenotype with severe salt wasting syndrome and impaired cortisol and aldosterone synthesis. Molecular study of 100 chromosomes shows that in 38 % Q318X mutation (GlyStop at 318) that abolishes a site for PstI cleavage is present. Comparing our results with those observed in Caucasian population where the incidence is about 1 to 10 %, leads us to conclude that the frequency of Q318X seems very high in Tunisian population. According to high incidence of consanguinity in affected families (70 %) it could be possible to explain Q318X mutation frequency by a founder effect in our region.

**Allelic homoplasy of STR due to variable allelic flanking sequences: SNPs in STR.** *W. Wang, A.H. Bittles.* Centre for Human Genetics, Edith Cowan University, Perth, Australia.

Single tandem repeats (STRs) and single nucleotide polymorphisms (SNPs) are widely used as markers in human genome studies. We have characterized a highly polymorphic STR locus (D20S85) with (AAAG)<sub>n</sub> repeats, by a combination of direct DNA sequencing and single-strand confirmation polymorphism (SSCP) analysis. Eight STR alleles were identified on denaturing gels, and SSCP gels (6% acrylamide/bisacrylamide containing 5% glycerol, 400x200x0.35mm) were then used to demonstrate homoplasy of the locus on the basis of variable allelic flanking sequences. This was confirmed by direct sequencing of the alleles using a Taq Dye Deoxy Terminator Cycle Sequencing Kit (Applied Biosystems, Foster City, CA). Four transitions, two of G to A and two of A to G, occur in the 5' flanking region of the locus at positions 14, 22, 24 and 26, which effectively subdivide the STR alleles into two groups. The results indicate that the mutational processes which generated the polymorphisms involved both simple changes in the number of AAAG repeats, and single nucleotide mutations in the region flanking the repeat, i.e. SNP changes. Using direct analysis of SSCP gels, the frequencies of the two sets of sequence polymorphisms were estimated to be 0.431 and 0.569 respectively. The two families of markers exist at the same locus and give rise to STR homoplasy involving allele size and composition. Thus the findings have potential application in the avoidance of false linkage and association. More importantly, a locus of this nature, with separate STR and SNP evolutionary histories and resulting from different mutation processes, should have wide application in studies of selection, drift, migration and inbreeding.

**Intraethnic genetic differentiation of Evenks by mtDNA polymorphism.** *T.P. Muravyova*<sup>1,2</sup>, *M.V. Goloubenko*<sup>1</sup>, *V.P. Puzyrev*<sup>1,4</sup>, *V.B. Salioukov*<sup>1,4</sup>, *E.P. Bychina*<sup>1,3</sup>. 1) Institute of Medical Genetics, Tomsk, Russia; 2) Institute of Pediatrics, Chita, Russia; 3) Tomsk State University, Tomsk, Russia; 4) Siberian Medical University, Tomsk, Russia.

Mitochondrial DNA polymorphism in the sample of Evenks living in Chita region of Russia (three settlements, N=85) has been investigated by restriction and length polymorphisms (HaeIII663, DdeI 10394, AluI 5176, 10397, 13262, V region length polymorphism) to determine the spreading of the A, B, C, D mtDNA haplogroups in Evenk population. The sample harbors haplogroups A, C and D with overall frequency as 76.18% with the prevalence of haplogroups C (35.71%) and D (34.52%), and with the frequency of haplogroup A about 6%. Some other lineages have been revealed. Evenks living in Chita region lack the deletion in V region and, consequently, haplogroup B. The investigated sample has been compared with the Evenks living in Krasnoyarsk region (N=51), studied by A. Torroni et al. (1993). In Krasnoyarsk sample, most of mtDNAs belong to the haplogroup C (84.31%), with the frequencies of A and D about 10% and 4% respectively. So, although these two populations have similar spectrum of main haplotypes (A, C, and D), they differ significantly by their frequencies. Such intraethnic differentiation may be the result of the population history of Evenks, which are not numerous but at the same time live separately on the large territory of Siberia, so genetic drift may significantly influence the mtDNA polymorphism.

**Evolution of Y-chromosome haplotypes in populations of North Eurasia.** *V.A. Stepanov*<sup>1,2</sup>, *V.P. Puzyrev*<sup>1</sup>. 1) Inst for Medical Genetics, Tomsk, Russia; 2) Tomsk State University, Tomsk, Russia.

Distribution of Y-chromosome haplotypes in 18 native populations of Siberia and Middle Asia was investigated in order to reconstruct the evolution of paternal lineages in North Eurasia. Compound Y-chromosome haplotypes were constructed using four biallelic loci (SRY3225, YAP, DYF155S2 and Tat) and seven microsatellites (DYS19, DYS389I, DYS389II, DYS390, DYS391, DYS392 and DYS393). Automated genotyping of STR loci was performed with HEX-, TET- or FAM-labeled primers with the ABIPrism310 genetic analyzer and Genescan software. High level of gene diversity ( $H=1.00$ ) and substantial degree of genetic differentiation of male-specific gene pool ( $F_{st} = 0.212$ ,  $P=0.000$ ) in modern North Eurasian populations were found. Haplotypic lineages and their evolutionary relationships were reconstructed. It was shown that most haplotypes in modern North Eurasian population have common ancestry traced back to the Upper Paeolithic period (about 15000 years ago). Using the molecular variance of microsatellites within the biallelic haplogroups the age and origin of ancestral haplotypes for DYF155S2 - (6900 years) and TatC (4200 years) lineages, specific for population of North Eurasia were estimated. Phylogenetic analysis of genetic relationships between populations, performed with the Y-chromosome haplotypes, reveals the close affinity of Y-chromosome gene pool in Altaic populations of Middle Asia and Indo-European populations on the one hand and clear clustering of Turkic-speaking Siberian ethnic groups on the other hand.

**TSER Length Polymorphism in Chinese population: Allele Frequency and mechanism of evolution of the Novel Alleles.** *H-R. Luo, Y-P. Zhang.* Lab Cellular & Molecular Evolution, Kunming Institute of Zoology, Kunming, Yunnan 650223, China.

Thymidylate synthase (TS) is an essential enzyme that must be expressed in all proliferating cells and a target enzyme for cancer chemotherapy drugs such as 5-fluorouracil (5-FU). The tandemly repeated 28-bp segment in the 5'-terminal regulatory region of the human thymidylate synthase (TSER), which have been reported to be polymorphic in different populations, was surveyed in 668 Chinese from 9 Han geographic groups and 8 ethnic populations, 36 individuals representing a three-generation pedigree and three apes. Amplified fragments were analyzed by electrophoresis on 4% agarose gel. In addition to the reported double and triple repeats of the 28-bp segment in TSER, we also detected 5 repeats in this region. All the three alleles of the repeat type (2,3 and 5) were further confirmed by direct sequencing. Based on the pedigree analysis, these three alleles were found to be inherited in accordance with Mendel's laws. By direct comparison of the repeat types among apes and human, the length polymorphism in TSER could be explained by slipped-strand mispairing (SSM) during DNA replication. The frequencies of the TSER allele 2 and 3 were 18.82% and 81% in unrelated whole Chinese samples. The highest frequency of allele 3 was found in Wa population (95%) from Yunnan province, while the lowest was presented in Kazak (62%) and Uygur (63%) from Xinjiang, with values that are similar to the reported Caucasian's (60%). The remained 14 ethnic populations had a considerably high frequency with a range from 72% to 90%. Furthermore, the distribution of the TSER polymorphism in world populations might be helpful to understand the relationships of the racial and ethnic groups.

**Sampling properties of estimators of nucleotide diversity at discovered SNP sites.** *A. Renwick<sup>1</sup>, P. Bonnen<sup>2</sup>, D. Triikka<sup>2</sup>, D. Nelson<sup>2</sup>, R. Chakraborty<sup>3</sup>, M. Kimmel<sup>1</sup>.* 1) Department of Statistics, Rice University, Houston, TX; 2) Dept. Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 3) Human Genetics Center, Univ. Texas School of Public Health, Houston, TX.

SNP sites are discovered generally by sequencing regions of the genome in a limited number of individuals. This may leave SNP sites present in the region, but containing rare mutant nucleotides, undetected. Consequently, estimates of nucleotide diversity obtained from assays of detected SNP sites are biased. In this research we present a statistical model of the SNP discovery process, which in turn is used to evaluate the extent of this bias. Under various models of gene frequency distributions at the SNP sites, we show that nucleotide diversity is always underestimated. However, the extent of bias rarely exceeds 10%. This same effect leads to an underestimation of the number of segregating sites as well. Applications of this theory to new SNP data at ATM, BLM, RQL and WRN gene regions as well as to the literature data at the LPL gene region indicate that in spite of such ascertainment biases, the observed differences of nucleotide diversity across these gene regions are real. This suggests heterogeneity of rates of nucleotide substitution rates across the genome. **Minisatellite DNA diversity in East Slavs.** *D.A. Verbenko<sup>1</sup>, O.P. Balanovsky<sup>1</sup>, T.V. Pogoda<sup>1</sup>, A.I. Mikulich<sup>2</sup>, L.A. Livshits<sup>3</sup>, L.V. Bets<sup>4</sup>, N.A. Bebyakova<sup>5</sup>, S.A. Limborska<sup>1</sup>*. 1) Institute of Molecular Genetics, Moscow, Russia; 2) Institute of Arts, Ethnography and Folklore, Minsk, Byelorussia; 3) Institute of Molecular Biology and Genetics, Kiev, Ukraine; 4) Moscow State University, Moscow, Russia; 5) Arkhangelsk State Medical Academy, Russia.

Genetic diversity in native peoples from Russia, Byelorussia and Ukraine has been analyzed. The polymorphism of hypervariable DNA markers, namely minisatellite loci D1S80 (pMCT118) and 3'ApoB was examined. More than 1000 unrelated individuals from 18 Slav population samples were studied.

Allele typing was performed using the PCR and subsequent electrophoresis followed by silver staining. We detected 25 alleles of the D1S80 locus (from 16 to 41 tandem repeats) and 23 alleles of the 3'ApoB locus (from 25 to 53 tandem repeats). Genotype frequencies for these loci in all populations met Hardy-Weinberg expectations. Observed allele distributions were similar to other Caucasoid populations ones.

Genetic distance analysis demonstrated that genetic diversity of the 3'ApoB locus was greater in comparison to the D1S80 locus. Genetic trees were constructed and multidimensional scaling of allele distributions with allocation populations in multidimensional space was made. These methods indicate certain differentiation between ethnic groups of East Slavs. In spite of great heterozygosity (around 0,8) and high degree of polymorphism in minisatellite loci Nei's  $G_{st}$  value is less in four times in contrast to classical immunobiochemical markers. The method of computer genegeography with reliability theory was used to prepare maps of geographic variability for all alleles. East-West gradient of variability was traced on the first principal component map for the D1S80 locus. We also investigated Yakut population belongs to Mongoloid group. Allele distribution in Yakut statistically differed from East Slavs but simulate with other Asian populations.

**Short tandem repeat-based Y-chromosome haplotype data reveals a high level of admixture in the migrant population, the Siddis, with local Indian populations.** *L. Singh*<sup>1</sup>, *G.V. Ramana*<sup>2</sup>, *N. Wang*<sup>2</sup>, *R. Chakraborty*<sup>2</sup>. 1) Director, Ctr Cellular & Molec Biol, Hyderabad, Andhra Pradesh, India; 2) Human Genetics Center, Univ. Texas School of Public Health, Houston, TX.

Earlier studies on haplotype distributions based on short tandem repeat (STR) loci in the Indian subcontinent reflected negligible male gene flow across populations. To investigate whether it holds for the migrant population, the Siddis (a population of African descent), we analyzed five STR loci (DYS19, DYS389, DYS390, DYS391, and DYS393) in 94 males belonging to two caste populations (Brahmins and Kammas) and the migrant Siddis of Southern India. We observed 83 different haplotypes in our sample. In other words, like the data of the literature, we also observed low levels of haplotype sharing between populations. Utility of these markers for differentiating populations of the Indian subcontinent is studied through a phylogenetic analysis of haplotype distributions in our samples together with data from 12 other populations from India, Pakistan, and Ethiopia. With haplotypic distinctions measured in terms of repeat size differences at these five STR loci, we observe that the populations cluster by their geographic location, rather than by their caste affiliation. This is consistent with the sociological theory of caste origin in India. Additionally, the Siddis clustered with the two South Indian caste groups, rather than being closer to the Ethiopian population, from where they are presumed to have migrated. Coalescence theory-based estimation revealed that the Siddis, in their male gene pool, has approximately 60% genes of local origin, a value somewhat smaller than the 72% admixture estimate, based on nuclear blood group and protein polymorphism data. From these observations, we conclude that restricted male gene flow does not appear to be true in this migrant population, and the presumed theory that only male migrants arrived from Africa to establish the community of the Siddis in India does not have a genetic support. (Research supported by US Public Health Service Research grant GM 41399 from the National Institutes of Health).

**Genetic estimation of biogeographical ancestry.** *C.L. Pfaff, E.J. Parra, M.D. Shriver.* Pennsylvania State University, University Park, PA.

Ethnicity is comprised of both biological and cultural components. Biogeographical ancestry (BGA) refers to the component of ethnicity that is biologically determined and can be estimated using genetic markers that have distinctive allele frequencies for the populations in question (referred to as population-associated alleles - PAAs). We have developed a method that uses a maximum likelihood (ML) approach to estimate the primary population source(s) of an unknown DNA sample. Once the potential source populations have been narrowed to the two or three populations with the highest log likelihood ratios (LLR), individual admixture proportions are estimated for the multilocus genotype observed in order to characterize the proportional ancestry of the sample.

We have explored the potential of this method by examining the multilocus genotypes of African, European, and African-American DNA samples using a panel of 10 PAAs that have high allele frequency differences between Africans and Europeans. In each of the 906 African and European samples BGA was correctly estimated using a maximum likelihood approach. In 863 cases the LLR for the estimation was  $> 3$  (avg. LLR = 4.7), indicating a strong confidence in the estimation of ancestry. However, as expected, the ML estimate is less precise for African-American samples. In these cases the inaccurate and low-confidence estimates tend to be for individuals with relatively high admixture proportions, making population distinctions more difficult. A second source of inaccuracy is the relatively low number of informative markers currently available. In order to examine this cause, we simulated 2000 individuals with multilocus genotypes at 20 loci. Of these, ancestry estimation was correct in every case, and only 2 individuals had LLR  $< 3$ . While the utility of this method is currently limited by the restricted number of PAAs available for various populations, it is clear that as larger numbers of ancestry-informative markers become available, estimation of BGA may become a powerful tool for the elucidation of an individual's genetic and population history, as well as the identification of unknown samples in forensic cases.

**Pattern and dynamics of admixture in US African-American populations: a global perspective.** *E.J. Parra<sup>1</sup>, C.L. Pfaff<sup>1</sup>, K. Hiester<sup>1</sup>, D. Sosnoski<sup>1</sup>, Y. Jien<sup>1</sup>, F. Gulden<sup>1</sup>, P. McKeigue<sup>2</sup>, M.D. Shriver<sup>1</sup>*. 1) Dept Anthropology, Penn State Univ, University Park, PA; 2) Dept Epidemiology and Population Health, London School of Hygiene & Tropical Medicine. London, UK.

Initial attempts to characterize admixture in African Americans using genetic markers date back to the 50s. Since then, many studies have been devoted to this subject, yet no single survey has attempted a comprehensive study of admixture in African Americans from many different geographic areas, using a select panel of ancestry informative markers. We have been studying admixture in 16 geographically diverse African-American populations using 10 autosomal genetic markers showing large frequency differences between the relevant parental populations, as well as informative mtDNA and Y-specific polymorphisms. We observe that the European contribution to African Americans ranges from 3.5 to 25 per cent in these populations. The geographic pattern of admixture is complex, but can be interpreted in light of historical and demographic information. We consistently find a higher genetic contribution from European males than from European females, indicating sex-biased gene flow. In some African-American populations, we see evidence of a Native American genetic contribution, but globally this contribution is low (less than 2 per cent). Using computer simulations, we have compared the effect of two admixture models (continuous gene flow and hybrid isolation), in terms of the associations created between linked and unlinked markers. In our samples, we observe significant associations between linked markers, but also between unlinked markers in many of the pairwise comparisons. These results are consistent with the simulations of the continuous gene flow model, although other factors, such as assortative mating, could also explain the observed results. We have seen, both in our population samples and in the computer simulations, that irrespective of the admixture model, the linkage disequilibrium introduced by the admixture process can be used for mapping genes. This work provides further insights regarding admixture and the applicability of admixture mapping in African American populations.

**(AC)<sub>n</sub> dinucleotide repeat polymorphism in 5B-globin gene in native and Mestizo Mexican population.** F.

*Salamanca-Gomez<sup>1</sup>, R. Peñaloza<sup>1</sup>, P. Delgado<sup>1</sup>, D. Arenas<sup>1</sup>, C. Barrientos<sup>1</sup>, L. Buentello<sup>2</sup>, F. Loeza<sup>3</sup>.* 1) Unit Investigation Human Gen, National Medical Ctr, Mexico, D F, Mexico; 2) Anthropology Investigation Institute, UNAM; 3) San Nicolas de Hidalgo University, Michoacn, Mexico.

Repeated sequences are dispersed along the human genome. These sequences are useful as markers in diagnostic of inherited diseases, forensic medicine and in tracking the origin and evolution of human populations. (AC)<sub>n</sub> repeated element is the most frequent in human genome. In the present paper, (AC)<sub>n</sub> repeated element located in the 5' flanking region of the globin gene was studied by SSCP in four ethnic Mexican groups (Mixteca, Nahuatl, Otom, Purpecha) and in a Mestizo population. We observed three alleles called A [(AC)<sub>16</sub>], B [(AC)<sub>14</sub>] and C [(AC)<sub>18</sub>] with a frequency between 68.2% and 86.9% for first case; between 13.1% and 18.2% for second one and finally 6.7% and 13.6%, in the last one. The allele C was present only in Purpecha and Mestizo groups, suggesting evidence about the different origin of Purpecha group. The absence of this allele in the other ethnic groups studied also suggests that there is no genetic admixture with the Purpecha and that this is a relative isolated population. The (AC)<sub>n</sub> repeat polymorphism in the globin gene has not been previously studied in Amerindian populations.

**Evidence for marked genetic differentiation within and among eastern rural Chinese population.** *M.T. Seielstad<sup>1</sup>, X. Xu<sup>1</sup>, M. Wang<sup>1</sup>, B. Wang<sup>1</sup>, J. Rogus<sup>1</sup>, D. Wu<sup>4</sup>, X. Xu<sup>1</sup>, N.J. Schork<sup>2,3</sup>.* 1) Program Population Genetics, Harvard Sch Public Health, Boston, MA; 2) Dept of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Genset Corp., LaJolla, CA; 4) Anhui Medical University, Hefei, China.

Considerable genetic variation is known to exist among and between individual humans and populations. The degree to which this variation correlates with historical views of the origin and relationships of racial and ethnic categories is unclear and controversial. For example, it is generally acknowledged that there is often more genetic variation within many racial groups than there is between or across racial groups. The degree and causes of this variation are the subject of a great deal of current research. In this paper, we consider evidence for genetic differentiation in eastern rural Chinese communities gathered from three independent studies. We find striking evidence for genetic differentiation, especially with respect to Y chromosome variation. We argue that this differentiation likely reflects both social practices in rural China as well purely geographical and mobility factors. Our studies document the utility of assessing genetic variation within groups thought to be fairly homogeneous to settle questions about the degree and causes of genetic and phenotypic variation in the population at large,.

**Population diversity of a 45 bp VNTR associated with Usher Syndrome Type IC and exclusion of a positional candidate gene.** *S. Savas*<sup>1</sup>, *B. Frischhertz*<sup>2</sup>, *M. DeAngelis*<sup>1</sup>, *Z. Den*<sup>1</sup>, *J. Doucet*<sup>3</sup>, *M. Pelias*<sup>1</sup>, *C. Petit*<sup>4</sup>, *P. Deininger*<sup>2</sup>, *M. Batzer*<sup>1</sup>, *B. Keats*<sup>1</sup>. 1) LSU Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Ctr. New Orleans, LA; 3) Nicholls State Univ. Thibodaux, LA; 4) Institut Pasteur, Paris, France.

Type IC Usher syndrome is an autosomal recessive disorder characterized by deafness, absent vestibular function, and progressive retinal degeneration. The USH1C gene was localized to chromosome 11p in Acadian families. Lebanese families mapping to this region have also been reported. Additionally, DFNB18, an autosomal recessive deafness locus, was mapped to the USH1C region. The DelGEF gene, isolated from that region, was suggested as a positional candidate for USH1C and DFNB18. We excluded DelGEF as the USH1C gene by direct sequencing. Recent evidence suggests that a gene encoding a PDZ domain containing protein may be the USH1C gene. Sequence analysis of DNA samples from Acadian USH1C patients did not detect a mutation in the coding region, but a nine times tandemly-repeated 45 bp VNTR in intron 5 was homozygous in all Acadian patients. In a control population, 2, 3, 6, and less frequently 4 and 8 repeats were found. To determine the distribution of this VNTR in different populations (Asian, African-American, Hispanic, African, European, Acadian) we screened 390 unrelated individuals. In one heterozygous Hispanic sample, a fragment larger than 9-repeats was amplified. Also, a fragment size corresponding to the 9-repeat Acadian allele was detected in a heterozygous Hispanic sample. In one Hispanic and one African heterozygous sample, we detected the presence of a single repeat allele. Two other previously unreported alleles (5 and 7 repeats) have been detected with frequencies of 0.25% and 0.5%. The most frequent alleles in the combined populations were 2, 3, and 6 repeats (46.3%, 25.6%, and 23.9%, respectively). The repeat region could also be amplified from several primates and rodents suggesting evolutionary conservation.

**Analysis of the *UGT1A1* promoter polymorphism in a population of patients with hyperbilirubinemia and suspected Gilbert syndrome.** S. Das, M. Song, D. Shamoun, J.L. Jensen. Department of Human Genetics, University of Chicago, Chicago, IL.

Gilbert syndrome is a benign form of unconjugated hyperbilirubinemia. It occurs at a very high frequency with an estimated incidence of 2-12% in the general population. A polymorphism in the promoter of the UDP glucuronosyl transferase 1 (*UGT1A1*) gene, in which 7 instead of 6 TA repeats occur, has been identified, and homozygosity for the '7' allele has been associated with Gilbert syndrome. Ninety one patients with hyperbilirubinemia and/or jaundice and a suspicion of Gilbert syndrome were referred to our DNA diagnostic laboratory between June 1998 and June 2000 and were analyzed for the *UGT1A1* promoter polymorphism. Patients were primarily of caucasian origin and were made up of 67 males and 24 females with 7 patients being less than 9 months of age. DNA samples were fluorescently amplified for the *UGT1A1* promoter polymorphism and sized on a polyacrylamide gel. Of the 91 patients, 65 had a 7/7 genotype, 15 had a 6/7 genotype and 11 had a 6/6 genotype. The 7/7 genotype frequency in this population was 0.7 while the frequency of the '7' allele was 0.8. The frequency of the '7' allele in this group of patients is over twice that observed in the general caucasian population which has been calculated to be 0.38 in previous studies. This association is highly significant ( $p < 0.0001$ ) and these results further support a strong association between the '7' allele and Gilbert syndrome in the caucasian population. The frequency of the '7' allele in those patients less than 9 months was 0.57 indicating that factors other than Gilbert syndrome are more likely to account for the hyperbilirubinemia in this group, however a larger number of patients would need to be studied to say this definitively. Genotyping of the *UGT1A1* promoter polymorphism provides a useful molecular test for Gilbert syndrome. Such a test is clinically useful as a positive result provides a definite diagnosis for Gilbert syndrome, where diagnosis has generally been based on exclusion. Patients are therefore relieved of further anxiety and any lingering doubts of a more serious disorder.

**Heritability estimates of intelligence in twins: effect of chorion type.** *C. Derom<sup>1</sup>, S. Van Gestel<sup>1</sup>, N. Jacobs<sup>1</sup>, E. Thiery<sup>2,3</sup>, R. Derom<sup>3</sup>, P. Vernon<sup>4</sup>, R. Vlietinck<sup>1</sup>.* 1) Catholic University Leuven, Belgium; 2) University Gent, Belgium; 3) Association for Scientific Research in Multiple Births, Belgium; 4) University Western Ontario, Canada.

Twins are widely used to estimate the genetic and environmental components of complex traits in the general population. The classical twin study is based on the assumption that monozygotic twins (MZ) are genetically identical, whereas dizygotic twins (DZ) share on average half of their genes. The different prenatal environment of MZ monozygotic twins (MZ-MC) as compared to the MZ dichorionic (MZ-DC) twins is seldom taken into account. However, MC placentation allows the exchange of blood, hormones, enzymes, etc during prenatal life. As predicted by the fetal-origin hypothesis, MZ-MC twins might therefore show a higher concordance rate for some phenotypes in later life, due to a more similar prenatal environment. This study investigates the basic assumption of homogeneity of MZ twins on the heritability estimates of IQ. We determined the IQ of 451 same-sexed twin pairs of known zygosity and chorion type with the Wechsler Intelligence Scale for Children-Revised (WISC-R). The twins (181 DZ, 95 MZ-DC, 175 MZ-MC, aged 8-14 yrs) were selected at random from the East Flanders Prospective Twins Survey. Zygosity was determined by placental examination, blood groups and DNA fingerprints, reaching a probability of at least 0.99. We adapted the classical genetic model fitting by including a chorion type factor. High heritability estimates were found for almost all subscales and IQ-scores. The heritability of total IQ was 83%, when MZ twins were considered as a homogeneous group. A significant effect of chorion type was found on the subscales Arithmetic and Vocabulary: as hypothesized the MZ-MC twins resembled each other more than the MZ-DC twins. The effect accounts for respectively 14% and 10% of the total variance. Although the effect of chorion type does not play in all measures and although the contribution is moderate, it constitutes a possible confounder and urges twin researchers to take chorion type into account. As far as the heritability of total IQ is concerned, no chorion effect was found.

**Frequency of the hemochromatosis associated mutations C282Y and H63D in Argentina.** *F.F. Fay<sup>1</sup>, M.E. Campodonico<sup>1</sup>, M. Taborda<sup>1</sup>, G. Revelant<sup>1</sup>, H. Tanno<sup>2</sup>, M. Lopez<sup>3</sup>, O.H. Fay<sup>4</sup>.* 1) Dept Molecular Biol, CIBIC, Rosario, Argentina; 2) Hospital Centenario, Rosario; 3) CAC-ALAC, Corrientes; 4) CTSP-UNR, Rosario.

Background: In north-European populations Hereditary Hemochromatosis (HH) is caused in 90-100% of the cases, by two common mutations of the HFE gene, and affects 1 in 300 individuals. However, lower mutation prevalences were found in different ethnic groups. Objectives: To determine the prevalence of the HFE gene HH associated mutations (C282Y and H63D) in the general Argentine population. Methods: Three hundred and fifty unrelated healthy subjects were studied for the C282Y and H63D mutations. DNA was extracted from blood EDTA samples. Mutations detection was performed using a multiplex - ARMS test. Genotypic results were correlated with serum iron and transferrin saturation (TS) levels. A group of 21 clinically diagnosed HH patients, was also studied for those mutations. Results: We found that 13 out of 350 subjects (3.7%) were heterozygous for the C282Y mutation; no homozygotes were found; 97 out of 350 subjects (27.7%) were H63D heterozygous and eleven were homozygous (3.1%). Only three subjects (0.9%) were heterozygous for both mutations (compound heterozygotes). The observed frequencies are consistent with those predicted by the Hardy-Weimberg equation. Genotypic-phenotypic correlation showed that the H63D homozygotes have a significantly higher TS mean value compared with wild type subjects ( $p=0.007$ ). In the HH group, 7 out of 21 (33.3%) were C282Y homozygotes, 5 out of 21 (23.8%) were H63D homozygotes, and no compound heterozygotes were found. Conclusions: We found a lower prevalence of the C282Y mutation, compared with that observed in other caucasian populations. According to our observations, the carrier frequency for C282Y is 1 in 27 with an expected homozygous frequency of 1 in 2800 in the general population. Our findings are in accordance with published data, taking into consideration that our population is a mixture of Spanish, Italians, a lower degree of Portugueses, native Indians and other minor ethnic groups. Regarding the H63D, our findings suggest that the H63D mutation alone, could have a role in iron overload development in our population.

**Assessing risk factors of human complex diseases by Akaike and Bayesian information criteria (AIC and BIC).**

*W. Li*<sup>1</sup>, *A. Sherriff*<sup>2</sup>, *X. Liu*<sup>3</sup>. 1) Lab Statistical Genetics, Rockefeller Univ, New York, NY; 2) Institute of Child Health, University of Bristol, Bristol, UK; 3) Department of Statistics, Columbia University, New York, NY.

The complex etiology of many human diseases requires a new framework for data analysis in epidemiology and genetic epidemiology (as well as pedigree linkage analysis). The traditional frameworks of hypothesis testing and maximum likelihood have their limitations. In hypothesis testing, only a simple enough question can be answered with certainty; but for complex diseases, the question posed by a usually unrealistic null hypothesis can be far from relevant. In the likelihood framework, parameter estimation is meaningful only if the model used is correct; but one typically does not know which model describes the relationship between risk factors and a complex disease. We propose the use of Akaike information criterion (AIC) and its close relative, Bayesian information criterion (BIC), in data analysis of complex diseases. AIC is solidly founded in information theory, and is a natural extension of both the maximum likelihood and likelihood ratio test frameworks. We have applied AIC/BIC to assess risk factors in three data sets: child asthma, alcoholism, and limb-girdle muscular dystrophy. We are able to address the following issues: measuring the amount of information (non-randomness) in the data set, comparing between single-factor and all-factor analysis, excluding irrelevant factors, selecting important factors, determining (roughly) the number of factors involved, selecting between competing models such as logistic regression and neural networks, and delineating range of models by using BIC to select the under-fitting model. All these issues can be studied within a single consistent framework using a single measurement (AIC or BIC).

**Myotonia congenita in Northern Norway shows high frequency and a characteristic spectrum of *CLCN1***

**mutations.** C. Sun<sup>1</sup>, M. Van Ghelue<sup>1</sup>, T. Torbergesen<sup>2</sup>, E.P. Hoffman<sup>3</sup>, L. Tranebjærg<sup>1</sup>. 1) Dept. of Medical Genetics, University Hospital of Tromsø, Tromsø, Norway; 2) Dept. of Neurology, University Hospital of Tromsø, Tromsø, Norway; 3) Research Center for Genetic Medicine, Children's National Medical Center, Washington DC, USA.

Myotonia congenita is a genetic muscle disorder characterized by hyperexcitability of the skeletal muscle membrane. Mutations in the muscle chloride channel gene, *CLCN1*, lead to either autosomal dominant (Thomsen's) or autosomal recessive (Becker's) myotonia. We have investigated 18 families from Northern Norway and Northern Sweden in order to characterize the spectrum of *CLCN1* mutations and detect possible genetic heterogeneity. Direct sequencing of all 23 exons was undertaken in 18 probands, and 53 relatives were studied with respect to the relevant mutations detected. We found a high prevalence of 9.4:100,000 in Northern Norway, similar to Northern Finnish figures. Eight *CLCN1* mutations and three polymorphisms (T87T, D718D, P727L) were identified. Three mutations (F287S, A331T, 2284+5C>T) were novel. Three previously reported mutations, A531V, F413C, and R894X, accounted for 42% of the identified mutations in all patients. The majority of our cases was compound heterozygotes of which the combination A531V/R894X dominated. The same three mutations comprised the entire *CLCN1* mutational spectrum in Northern Finland where F413C was predominating. A reliable genotype-phenotype correlation could only be established for patients with A531V/R894X. Variable penetrance was found in patients being heterozygous for either. The population frequencies of A531V and R894X were 0.3% and 0.87%, respectively. Our findings support that myotonia congenita is significantly more prevalent in Northern Scandinavia than elsewhere. Possible explanations include fairly high population frequencies of particular *CLCN1* mutations, selective advantages of heterozygotes, cold climate and yet unidentified genetic factors. Future studies aim at expression studies of identified missense mutations and clarifying the apparent genetic heterogeneity illustrated by the fact that 2/18 probands had no *CLCN1* mutations detected.

**Beta-globin gene cluster haplotype frequencies in Colombia suggest different origins for Afro-Caribbean populations.** *M.C Mondragon*<sup>1</sup>, *F. Cuellar-Ambrosi*<sup>1</sup>, *G. Bedoya*<sup>2</sup>, *M.C. Bortolini*<sup>3,4</sup>, *A. Ruiz-Linares*<sup>2,4</sup>. 1) Servicio de Hematología, Facultad de Medicina, Universidad de Antioquia, Medellín, Colombia; 2) Laboratorio de Genética Molecular, Facultad de Medicina, Universidad de Antioquia, Medellín, Colombia; 3) Departamento de Genética, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 4) Department of Medical and Community Genetics, Imperial College School of Medicine, UK.

The sickle cell mutation was introduced in the American continent mainly by gene flow from Africa during the slave trade in the 15th-19th centuries. This mutation occurs in different haplotypic backgrounds and these have been used to trace the origin in Africa of the individuals brought to America. To examine the African ancestry of individuals introduced in Colombia we examined five RFLPs (HincII/e, XmnI/Gg, HindIII/Gg, HindIII/Ag, HincII/3'yb) in the b-globin gene cluster. Seventy eight unrelated sickle cell patients and an additional twenty heterozygote individuals (HbAS) were investigated, with a total of 176 HbS chromosomes available for study. The b-S haplotype frequencies observed were: Bantu (51.5%); Benin (42%); Senegal (3%); Cameroon (2%); other (1.5%). Previous studies have shown that the Benin haplotype is the most frequent (51-74%) in the US and in several Caribbean populations (Cuba, Jamaica, Guadeloupe, Venezuela). Despite being located on the Caribbean, our findings in Colombia differ from those results in showing the highest frequency for the Bantu haplotype and a relatively lower frequency for the Senegal haplotype. We are currently assessing the role of drift and population substructure in explaining the observed differences. As has been suggested for Brazil, b-S haplotype frequencies in Colombia could indicate that a relatively important fraction of African individuals introduced in this country during colonial times originated in Angola. For the US and in most Caribbean Countries an origin in West African seems predominant.

**The association between low density lipoprotein receptor-related protein (LRP) and Alzheimer's disease is modified by apolipoprotein E and alpha-2 macroglobulin.** *J.M. Kwon*<sup>1</sup>, *S. Chakraverty*<sup>2</sup>, *M. Martinez*<sup>2</sup>, *J.C. Morris*<sup>1</sup>, *A.M. Goate*<sup>2</sup>. 1) Dept Neurology, Washington Univ, St Louis, MO; 2) Dept Psychiatry, Washington Univ, St Louis, MO.

Alzheimer's disease (AD) is etiologically complex, with genetic factors playing an important role. Mutations in three genes, amyloid precursor protein (APP), presenilin-1 gene, and presenilin-2 gene are known to cause early onset familial AD. These genes, taken together, probably directly cause 1% of AD cases overall. Apolipoprotein E remains an important susceptibility gene, accounting for nearly 40-50% of the genetic risk for developing AD. Recent linkage studies of late-onset AD suggest that another susceptibility locus lies on chromosome 12. Two candidate genes on chromosome 12, low density lipoprotein receptor-related protein (LRP) and alpha-2 macroglobulin (A2M) are biologically relevant to the development and pathogenesis of AD. While a number of association studies have been done to determine whether the polymorphic variants of these two genes are associated with AD, the results have been contradictory. No study, however, has looked at the joint effects of the two genes, though A2M is a ligand of LRP. We have looked at A2M and LRP variants in a large number of sporadic AD cases and age-matched controls and found that they are not associated with AD in unstratified analysis. However, the 5' tetranucleotide polymorphism of LRP and the exon 18 polymorphism of A2M are both associated with AD in individuals who are e4 carriers. In addition, the degree of LRP association with AD is modified by the A2M genotype. Our data suggest that it is the interaction between the genetic variation in LRP and A2M which confers risk for AD.

**Linkage and Association Analyses of Sequence Variants of the GABRA6, GABRB2, and GABRG2 gene cluster and Alcohol Dependence in a Finnish Sample.** *M. Radel<sup>1</sup>, R.L. Vallejo<sup>1</sup>, N. Iwata<sup>1</sup>, R. Aragon<sup>1</sup>, H. Naukkarinen<sup>2</sup>, M. Virkkunen<sup>2</sup>, J.C. Long<sup>1</sup>, D. Goldman<sup>1</sup>.* 1) Laboratory of Neurogenetics, DICBR/NIAAA/NIH, Rockville, MD 20892; 2) Department of Psychiatry, University of Helsinki, Finland.

In an autosomal genomic scan in Finnish pedigrees, evidence for linkage to alcohol dependence was observed at the long arm of chromosome 5 coinciding with the location of a cluster of GABAA receptor subunit genes, which include GABRA6, GABRB2, and GABRG2. In this study, the role of GABRA6, GABRB2, GABRG2 in alcoholism in a data set from Finland was evaluated by sib-pair linkage analysis. In addition, association between variant alleles and alcohol dependence was evaluated by comparing genotypic and allelic frequencies between unrelated cases and controls from the same population. The 473 psychiatrically interviewed Finns included 89 alcoholic offender probands, 277 relatives and 107 unrelated controls. There were 73 concordant sib pairs for alcoholism (DSMIII-R alcohol dependence), 67 discordant, and 98 unaffected. We genotyped six single nucleotide polymorphisms (SNPs) of the chromosome 5 long arm GABAA gene cluster (i.e., GABRG2 IVS8+99, GABRG2 IVS9+3415A>G, GABRA6 1031G>C, GABRA6 1236 C>T (Pro385Ser), GABRA6 1519T>C, and GABRB2 1412C>T) by PCR-RFLP analysis. Hardy-Weimberg equilibrium, as well as differences in allelic and genotypic frequencies were tested by Chi-square analysis and Fishers exact test (one and two tailed analyses). Sib-pair regression was performed with the Sibpal module included in S.A.G.E. (1996). Genotypic distributions were in Hardy-Weimberg equilibrium and did not differ significantly between cases and controls. Sib-pair linkage of GABRG2 to alcohol dependence was observed ( $P=0.034$ ). There was no evidence of association between GABRG2 and alcohol dependence in our samples. Taken in conjunction with the evidence mentioned above, these results are consistent with genetic variation at or near the GABAA gene cluster on chromosome 5 playing a role in differential susceptibility to alcohol dependence.

**Genomic control for association studies: A semiparametric test to detect excess haplotype-sharing.** *K. Roeder<sup>1</sup>, L. Wasserman<sup>1</sup>, W. Byerley<sup>2</sup>, B. Devlin<sup>3</sup>*. 1) Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA; 2) Dept. Psychiatry, University of California, Irvine; 3) Dept. Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Individuals who share a disease mutation from a common ancestor often share alleles at genetic markers adjacent to the mutation even if the common ancestor is remote. Ideally, for a sample of affected individuals, this dependence -- measured as haplotype-sharing -- will be greater in the vicinity of disease genes than in other regions of the genome. We present a semiparametric test for haplotype-sharing. We begin by developing a model assuming that the ancestral haplotype is known and thus the extent of haplotype-sharing from a common ancestor can be determined unambiguously. The amount of overlap at markers far from the disease is treated as a random variable with an unknown distribution  $F$ , which we estimate nonparametrically. Overlap of markers surrounding disease genes are modeled as a mixture,  $pF(x-f) + (1-p)F(x)$ , in which  $p$  is the fraction of subjects with the disease mutation and  $f$  is the average excess overlap with the ancestral haplotype for that fraction of haplotypes that have the disease mutation. Testing for a disease gene then amounts to testing whether  $p=0$ . Next we drop the assumption that the ancestral haplotype is known. To detect excess clustering of haplotypes, we measure the pairwise overlap of a set of haplotypes. As in the simpler scenario, this distribution is modeled as a location-shift mixture. To test the hypothesis we construct a score test with a simple limiting distribution. These ideas are illustrated using a statistic designed for a less refined grid of markers. The data are a sample of schizophrenics and controls from the Remote Oceanic population of Palau.

**Development of a DNA-diagnostic protocol for X-linked Mental Retardation (MRX).** *H.G. Yntema, A.O. Oudakker, J. Theelen, E. Sistermans, E.C.M. Mariman, D.F.C.M. Smeets, H.G. Brunner, B.C.J. Hamel, H. van Bokhoven.* Dept Human Genetics 417, Univ Hosp Nijmegen, Nijmegen, Netherlands.

The high prevalence of mental retardation (MR) in the population poses an important medical and socio-economical problem to our society. In spite of extensive medical investigations, in most patients the etiology of the mental handicap remains unexplained. It has been estimated that up to 25%; of all MR in males is caused by X-chromosomal gene defects (MRX). Eight MRX genes have been identified in the last four years, but in each of these genes in only 1-2%; of the patients tested the underlying genetic defect has been found. Since more than 70 different linkage intervals on the X-chromosome have been identified, it can be estimated that 50 or more MRX genes exist. Together with research groups in Leuven, Paris, Tours and Berlin we participate in the European X-linked Mental Retardation Consortium. Due to this collaboration we all have access to more than 200 well-characterized families. The consortium participated actively in the identification of five of the MRX genes identified so far: *GDII*, *OPHN1*, *IL1RAPL*, *TM4SF2*, and *aPIX*. To identify new MRX genes, we are performing a high-throughput mutation analysis in X-chromosomal candidate genes by direct sequencing of PCR amplified exons in the cohort of 200 families. Newly identified genes and known MRX genes that are found to be most frequently mutated in the 200 MRX families, will subsequently be tested in a cohort of 500 males with unexplained MR. This work will allow us to determine exactly the contribution of each gene to the incidence of mental retardation in the west-European population. The only diagnostic test currently available is for Fragile X Syndrome, which explains approximately 5%; of all MR. By determining the contribution of other MRX genes, we intend to establish a cost-effective DNA-diagnostic protocol. Worldwide use of such a protocol should at least double the number of etiologic diagnoses in males with MR.

**Genetic epidemiology of malaria infection in the Western Amazon region.** *F.P. Alves*<sup>1</sup>, *M.M. Moura*<sup>2,3</sup>, *V. Engracia*<sup>2,3</sup>, *M.F. Feitosa*<sup>4</sup>, *L.H. Silva*<sup>3</sup>, *E.P. Camargo*<sup>1,3</sup>, *B. Beiguelman*<sup>1</sup>, *H. Krieger*<sup>1,3</sup>. 1) Instituto de Ciências Biomédicas, Univ. São Paulo, SP, Brazil; 2) Universidade Federal de Rondonia, RO, Brazil; 3) Centro de Pesquisas Medicina Tropical, RO, Brazil; 4) Washington University School Medicine, MO, USA.

Malaria, the world's most important cause of infectious morbidity and mortality has a widespread geographical distribution while its endemicity is very heterogeneous. The Amazon region, due mainly to its relatively low demographic index, is characterized as an oligo-endemic region. A population of 182 individuals, living in Portuchuelo, State of Rondonia, Brazil, right bank of the Madeira river (8<sup>0</sup>37' S, 63<sup>0</sup>49'W) was surveyed, in order to ascertain data on the epidemiological aspects of malaria and some other infectious diseases. Two main phenotypes involved with *Plasmodium* infection were studied: a) the presence of asymptomatic infection *i.e.*, presence of *Plasmodium*, diagnosed by traditional thick smear and/or by PCA amplification of *Plasmodium* ribosomal DNA in blood samples; b) the reported number of previous malaria episodes. Segregation analysis using the unified model of Lalouel et al. (1983) was applied to both phenotypes. There were no evidences of any type of familial mechanisms acting on the distribution of the asymptomatic phenotype in this population, since there was no significant sign of familial aggregation for this trait. As for the number of malarial episodes, this phenotype showed clear signs of Mendelian inheritance. The most parsimonious model includes a co-dominant major gene with frequency of  $q = 0.15$  and a small multifactorial component ( $h = 0.08$ ). This finding seemed to be independent of the Hb, Fy or G-6-Pd polymorphisms. (FAPESP, CNPq, CAPES).

**Heritability of age at death in the Old Order Amish.** *B.D. Mitchell<sup>1</sup>, W.-C. Hsueh<sup>1</sup>, T.M. King<sup>2,3</sup>, T.I. Pollin<sup>4</sup>, J. Sorkin<sup>4</sup>, A.R. Shuldiner<sup>4</sup>.* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) UT MD Anderson Cancer Center, Houston, TX; 3) Genometrix, Inc., The Woodlands, TX; 4) University of Maryland School of Medicine.

There are approximately 30,000 Old Order Amish (OOA) currently living in Lancaster County, PA, virtually all of whom can trace their ancestries back to a small number of descendents who settled in the area between 1727 and 1780. Extensive genealogical information, including birth and death dates, has been maintained throughout this time, thus providing the opportunity to evaluate the familial components of age at death in this unique population. Our analyses were based on 1,655 individuals, representing all those born prior to 1890, surviving until at least age 30, and with known date of death.

Mean age at death ( $\pm$  s.d.) in this population was  $70.7 \pm 15.6$  yrs, and this did not change appreciably over time. Mortality rates were similar between men and women, except at ages 30-50, during which time mortality rates were slightly higher in women than in men. There was a strong association between parental and offspring age at death. Mean age at death was  $69.4 \pm 15.3$  yr. in individuals for whom both parents died before the age of 75 ( $n = 280$ ),  $71.5 \pm 15.1$  yr. in individuals for whom one parent died before the age of 75 ( $n = 567$ ), and  $73.5 \pm 16.0$  yr. in individuals for whom neither parent died before the age of 75 ( $n = 311$ ). These differences were highly significant ( $p = 0.006$ ). Using maximum likelihood methods, we estimated heritability of age at death by partitioning the phenotypic variance into genetic and non-genetic sources. From these analyses we estimated that additive genetic factors accounted for 25% ( $\pm 5\%$ ) of the total variance in age at death. We conclude that longevity is moderately heritable in the OOA.

**Pseudodominant transmission of hereditary hemochromatosis in a family from a small geographic area: genealogical and genetic analysis.** *L. Mota-Vieira<sup>1</sup>, P. Macedo<sup>1</sup>, C. Paiva<sup>1</sup>, L. Serpa<sup>1</sup>, H. Brandao<sup>1</sup>, J. Almeida-Mello<sup>2</sup>, P. Rodrigues<sup>3</sup>, G. Porto<sup>3</sup>.* 1) Hospital Divino Espirito Santo, Ponta Delgada, Azores; 2) Azores Genealogical Club; 3) Molecular Immunology Unity - IBMC, Porto, Portugal.

In a small village of the Azores (Portugal) we identified one family with vertical inheritance pattern of hereditary hemochromatosis (HH), an inborn error of iron metabolism that leads to progressive iron overload. The HH is an autosomal recessive disorder frequent among Caucasians but rare in the Azorean population. Homozygosity for a C282Y mutation in the hemochromatosis (*HFE*) gene is the underlying defect in 80% of HH patients. Based on clinical study and family history we identified 6 affected individuals in 3 consecutive generations: the paternal grandfather in the 1st generation, the father and a paternal uncle and aunt in the 2nd generation, and the proband and his brother in the 3rd generation. These affected siblings have the HH classical profile, including all biochemical variables related to iron metabolism. However, their uncle has a minor form of HH with only increased serum ferritin and transferrin saturation. In order to understand the HH pseudodominant transmission in this family, we performed a genealogical study and an HFE mutation screening. Based on church registers, civic records and pedigree analysis we identified 4 consanguineous marriages and 2 distinct surnames that can be related to the disease. The molecular analysis revealed homozygosity for the C282Y (+/+) mutation in 3 HH patients (proband, his brother and his uncle) and in 1 asymptomatic proband sister, and detected 6 carriers for the same mutation (+/-). Due to geographic isolation and small size of the village (560 inhabitants), we performed genotyping of the spouses, homozygous and carriers, in order to be more selective in the investigations of their children.

This study suggests that in this family the HH transmission is due to the segregation of three C282Y alleles, most probably having the same chromosomal background. To test this hypothesis, the haplotype analysis is being performed, in association with the search for a unique founder couple or for common links between surnames.

**Recurrence risks of stuttering in family relatives and their genetic implications.** *N.S. Viswanath<sup>1</sup>, H. Lee<sup>2</sup>, J.P. Alexander<sup>1</sup>, D.B. Rosenfield<sup>1</sup>, R. Chakraborty<sup>2</sup>.* 1) Stuttering Center Speech Motor Control Lab., Dept. Neurology, Baylor College of Medicine, Houston, TX; 2) Human Genetics Center, Univ. Texas School of Public Health, Houston, TX.

Stuttering is an early childhood speech motor disorder characterized by repetition and prolongation of sounds and syllables and blockage of flow of speech. It affects all aspects of individual's life, as speech is the primary mode of communication in the human society. For this reason, multiple epidemiological as well as genetic studies have been undertaken to characterize the etiology of stuttering. General prevalence of stuttering is about 1% or less in most Western populations, with a conspicuous sex dimorphism (3:1 male-female ratio). Concordance rate in monozygotic twins is significantly higher than that of dizygotic twins, and family relatives of stutterers have a significantly higher recurrence risk than that in the population. In spite of these results, the mode of inheritance of stuttering still remains controversial. We collected 56 multigenerational families, each ascertained through a single proband (38 male and 18 female), from which information about stuttering were collected on 1235 blood relatives, and 326 other family members married into the families. These data show that the biological relatives of stutterers have a nearly 10-fold higher risk than that in the population and recurrence risks in relatives decrease with the degree of kinship. Recurrence risks for male relatives are greater than for female relatives in each kinship category. However, recurrence and relative risk rates are not affected by the proband's sex. This last observation is incompatible with a polygenic threshold model of inheritance. Decay of recurrence risks with the kinship coefficients of relatives is not consistent with a simple monogenic mode of inheritance either. Complex segregation analysis is underway to better elucidate the mode of transmission and to detect pedigrees for subsequent linkage analysis to locate gene(s) for susceptibility of stuttering. (Research supported by M. R. Bauer Foundation and by the US Public Health Service Research grant GM 41399 from the National Institutes of Health).

**Background linkage disequilibrium in 18q21-q22 in the Finnish and Costa Rican populations.** *L.N. Bull<sup>1</sup>, S.K. Service<sup>2</sup>, A.-E. Lehesjoki<sup>3</sup>, A. de la Chapelle<sup>4</sup>, M. Slatkin<sup>5</sup>, N.B. Freimer<sup>2</sup>*. 1) Liver Center Laboratory, Dept. of Medicine, SFGH, UCSF, SF, CA; 2) Neurogenetics Laboratory, Dept. of Psychiatry, UCSF, SF, CA; 3) Folkhälsan Institute of Genetics, and Dept. of Medical Genetics, Haartman Institute, Helsinki, Finland; 4) Comprehensive Cancer Center, Ohio State U., Columbus, OH; 5) Dept. of Integrative Biology, UC Berkeley, Berkeley, CA.

We investigated the distribution of background linkage disequilibrium in multiple populations, using 26 polymorphic microsatellite markers in a well-mapped 22 cM region on chromosome 18q21-q22. We typed these markers in a Finnish population sample containing 96 chromosomes, and in a population sample from the Central Valley of Costa Rica containing 54 chromosomes. Half the individuals in the Finnish sample are from a population founded ~2000-2500 years ago, and the other half, from a population founded ~400 years ago. The current population of the Central Valley of Costa Rica was founded 300-400 years ago; little subsequent immigration occurred until quite recently. LD was assessed using the Fisher's exact test, applied to the data from the two Finnish samples separately and together, and also to the Costa Rican sample. In the younger Finnish sample, in each of the 5 marker pairs with LD  $p < 0.01$ , the markers are within 2 cM of each other. In the older Finnish and Costa Rican samples respectively, markers in 4 of the 12 pairs and 4 of the 10 pairs with LD  $p < 0.01$ , are  $> 2$  cM apart. The Mantel test was applied to data for all marker pairs to test for evidence of a relationship between LD and genetic distance, and evidence was found in all four analyses (p-values ranged from  $< 0.00001$  to 0.015). The LD p-value between markers increased between 0.0066 and 0.013 for every increase of 1 cM in genetic distance, depending on the sample. The rate of decay of LD with increasing genetic distance appears faster in the younger, than in the older, Finnish sample, and slowest in the Costa Rican sample.

**Creating an LD map of a long genomic region.** *M.J. Daly, J.D. Rioux, E.S. Lander.* Whitehead Institute/MIT Center for Genome Research, Cambridge, MA.

We have developed a conceptual framework for elucidating and visualizing ancestral haplotypic diversity in densely SNP genotyped genomic regions. The basic concept is the identification of short blocks of DNA in which historical recombination has played little or no role creating diversity. These blocks can, for all practical purposes, be considered single loci and the linear connection of these blocks (across intervals in which recombination has played an assortative role) over long genomic regions provides an "LD map" of the entire genomic region. This map allows one to specify a greatly reduced subset of SNPs from a dense genomic region that together fully explain the ancestral haplotype diversity in the region for genotyping in subsequent samples. Having created such a representation of several regions, it will further allow us to estimate a general density of random SNPs that would be needed in unexplored genomic regions to achieve the same information. Additionally, once identified, the blocks themselves become extremely powerful tools. Treating them as single multi-allelic loci enables more powerful and accurate tests of linkage disequilibrium than may be offered by any of the component SNPs individually. Missing and ambiguous genotypes within a block may be filled in with very high accuracy since the diversity within any block is fully characterized. The application of the method is presented using data from several high density SNP genotyping projects ongoing at the MIT Genome Center.

**Low linkage disequilibrium at the dopamine D4 receptor (DRD4) gene in the telomeric region of chromosome 11.**

*A. Morishima*<sup>1</sup>, *M.I. Jensen-Seaman*<sup>2</sup>, *F.M. Chang*<sup>3</sup>, *K.K. Kidd*<sup>1</sup>. 1) Genetics, Yale University, New Haven, CT; 2) Ecology & Evolution, University of Chicago, Chicago, IL; 3) Obstetrics & Gynecology, National Cheng Kung Univ. Hospital, Tainan, Taiwan.

The DRD4 gene is near the telomere in 11p15.5. The protein product has a high affinity for the neuroleptic Clozapine and localizes in GABAergic neurons. There is debate about whether polymorphisms in this gene are implicated in personality traits and psychiatric disorders. We typed samples from 32 globally distributed populations for two SNP polymorphisms in the 5' UTR of DRD4. One consists of 2 adjacent bases (-616,-615) with 3 haplotypes (CA,GA,GG) and is 100bp from the other site (-514). Both were polymorphic in all populations (estimated heterozygosity, .27-.66 and .27-.50, respectively). One of these polymorphisms (-615A/G) has not previously been reported. We also incorporated the data for 2 polymorphisms we previously reported--a 120bp tandem duplication in 5'UTR about 1 kb upstream, and the 12bp duplication in exon 1 about 1kb downstream (Am J Med Genet, 1999, 88:705-9). Haplotype frequencies and linkage disequilibrium (LD) were analyzed for these four sites spanning a 2 kb region. African populations have more haplotypes and higher heterozygosities, ranging up to .94, than most other populations, but heterozygosity is greater than .65 even in the populations with the fewest haplotypes. By a permutation test, overall LD is nominally significant only in some East Asian populations, in the one Melanesian sample, and in most Native American groups, but in the context of multiple tests only the LD in the Melanesian sample remains significant. In finding that LD per kb at this telomeric locus is greatly reduced compared to that in non-telomeric loci (such as DM, DRD2, PAH, CD4), we show that the value of association studies based on one marker at DRD4 is severely limited. We gratefully acknowledge the help of A.T. Quinones, J.R. Kidd, A.J. Pakstis, and J. Fisher in collection and analysis of these data. This work was supported in part by MH30929, GM57672, and a NARSAD grant.

**Linkage disequilibrium in the ADH gene cluster.** *M.V. Osier, A.J. Pakstis, J.R. Kidd, K.K. Kidd.* Genetics, Yale Univ, New Haven, CT.

The ADH gene family consists of seven known genes in a "cluster" of undetermined molecular extent on 4q21-24; the three class I genes are evenly spaced in 80 kb of that cluster, and are the best studied because two of them, ADH3 and ADH2, have SNPs resulting in amino acid substitutions yielding enzymes with different efficiencies metabolizing ethanol. We have previously demonstrated that the functional variation at ADH2 (exon 3) contributes to substantially different levels of protection against alcoholism in a case-control study of Chinese Han samples but that the functional variation at ADH3 (exon 8) does not have a detectable effect (Osier et al, 1999, AJHG,63:1147-1157). Understanding linkage disequilibrium (LD) between the variants at the two loci was crucial to that analysis. Because other functionally relevant variation may exist at these and/or other loci in the ADH family, we are extending LD studies to more sites and additional populations. To date we have identified three new SNPs (ADH3 intron 2 and exon 5, ADH6 intron 2), converted one RFLP to PCR (ADH2 intron 3), and typed these and the two functional SNPs (ADH3 exon 8, ADH2 exon 3) in samples from 31 populations (mean  $2N=101.0$ ). Allele frequencies of the ADH3 and ADH2 sites are strikingly different in the East Asian samples from those in samples from all other parts of the world:  $F_{st}$  values for the three non-functional SNPs in the Class I genes decrease from 0.10,0.20,0.79 (across all 31 populations) to 0.07,0.16,0.14 (across 24 populations) when the East Asian samples are removed. There is strong evidence of LD across these five sites ( $0.58 < x < 4.08, p < 0.01$ ). The SNP at ADH6 is an unknown distance away and does not show a clear pattern of LD with the five Class I SNPs. Using a segment version of a permutation test comparing the ADH6 SNP to the haplotypes of the Class I SNPs gives nominally significant evidence of LD in 6 population samples (1 African,  $p < .05$ ; 1 European,  $p = .004$ ; 1 East Asian,  $p < .05$ ; 2 North American,  $p < .05$ ; and 1 South American,  $p < .001$ ), while one would expect at most two by chance. Recent, population-specific factors, such as random drift or selection, would seem the most likely explanation since no regional or global pattern is evident. Supported by AA09379.

**The extent of linkage disequilibrium in European Americans.** *F.J. McMahon<sup>1</sup>, Y.-S. Chen<sup>1</sup>, M.G. McInnis<sup>2</sup>, C. Yarnes<sup>1</sup>.* 1) University of Chicago, Chicago, IL; 2) Johns Hopkins University, Baltimore, MD.

The success of SNP-based linkage disequilibrium (LD) mapping may depend on the extent of LD between adjacent markers, but little is known about the extent of inter-marker LD in non-isolated human populations. Preliminary to SNP-based studies, we have mapped 11 chromosome 18q microsatellite markers on the Stanford TNG radiation hybrid panel at estimated mean inter-marker distances of 237 kb. These markers were genotyped in a set of 58 European-American pedigrees collected for a linkage study of bipolar disorder. Genotypes were generated using semi-automated fluorescent methods and assembled into haplotypes. Haplotype data was analyzed for inter-marker LD in the founders by use of a Monte Carlo permutation of the Fisher Exact Test. Significant ( $p < 0.001$ ) LD was observed between 6 of 10 adjacent marker pairs and 11 of all 55 possible marker pairs. Eight markers showed significant LD with at least one other marker. The distances between markers in LD were significantly smaller than the distances between markers showing no detectable LD. Significant LD was detected between 3 different marker pairs with an inter-marker distance of  $>450$  kb. These results demonstrate that linkage disequilibrium can be detected over relatively large physical distances on chromosome 18q in European Americans who share a common complex genetic disease.

**Generation of linkage disequilibrium in an African American population by recent gene flow from diverse populations.** *R.A. Kittles, C. Rotimi, G. Bonney, G. Dunston.* National Human Genome Center at Howard University, Washington, DC.

The African American population is a heterogeneous macro-ethnic group due to its unique history. Because of this history, increased attention has focused on the African American population for disease gene mapping studies that take advantage of admixture linkage disequilibrium (LD). While most studies have focused on admixture with European Americans, sparse data exist about the contribution other populations, including Africans, have had on generating LD in the population. Here we evaluated genetic contributions from different populations by examining haplotypic variation for two genes. African American (n=520) samples were from Columbia, SC. West African samples were from Ghana (n=95), Liberia (n=75), Nigeria (n=83), Senegal (n=85), Sierra Leone (n=180) and the Cameroon (n=70). For non-African comparisons, European Americans (n=87), Asians (n=60), and Amerindians (n=80) were included. Haplotypes were constructed using three polymorphic markers (1 SNP and 2 STRs) separated by 1 kb within exon 1 of the androgen receptor gene (AR), and three markers (2 SNPs and an STR) separated by 40 kb within the 5-alpha reductase gene (SRD5A2). While the high mutation rate may have randomized alleles at the STR loci, significant disequilibrium was observed between markers for both genes in African Americans and Amerindians. A common AR haplotype was shared among all non-African populations however, for 4 of the 6 African populations the most common haplotype was different. Of the significant allelic associations between AR markers in the South Carolina population, 26% originated from European Americans, 13% from Ghanaians, 26% from Sierra Leone, and 26% were shared among west African populations. Although a similar pattern of haplotypic variation was observed for the SRD5AR locus, significant differences in levels of LD was observed for several of the non-African populations. These results reveal that the LD generated in African American's from Columbia, SC may be due to recent migration of African Americans from diverse rural communities following urbanization, recurrent gene flow from distinct West African populations, and admixture with European Americans.

**Conflicting estimates of the population recombination rate.** *M.F. Przeworski*<sup>1</sup>, *J.D. Wall*<sup>2</sup>. 1) Statistics, Oxford University, Oxford, United Kingdom; 2) Dept. of Org. Evol. Biol., Harvard University, Cambridge, USA.

The efficient design of association mapping studies relies on a knowledge of the rate of decay of linkage disequilibrium with distance. This rate depends on the population recombination rate,  $C$ . An estimate of  $C$  is usually obtained from a comparison of physical and genetic maps, assuming an effective population size of approximately 10,000. We demonstrate that, under both a constant population size model and a model of long-term exponential growth, there is evidence for more recombination in polymorphism data than is expected from this estimate. An intriguing possibility is that the majority of meiotic recombination events are gene conversion without exchange of flanking markers.

**Linkage Disequilibrium in Isolated and Outbred Chinese Populations.** *J. Xiao*<sup>1,2</sup>, *J.M. Akey*<sup>2</sup>, *M.M. Xiong*<sup>2</sup>, *L. Jin*<sup>1,2</sup>. 1) Inst Genetics, Fudan Univ, Shanghai, China; 2) Human Genetics Center, University of Texas, Houston, TX.
