HIGH ABUNDANCE mtDNA RECOMBINANTS IN HETEROPLASMIC MICE: Implications for Assisted Reproduction and Therapeutic Cloning. *D.C. Wallace, M. Crimi.* Center for Molecular and Mitochondrial Medicine and Genetics (MAMMAG), University of California, Irvine, Irvine, CA 92697-3940.

To determine if mammalian mtDNAs can recombine when mixed in the same cytoplasm, we prepared mice using female ES cell cybrids that were heteroplasmic for the NZB and the Common inbred mtDNAs. These mtDNAs differ in 109 nucleotides (nt), including a BamHI polymorphism at nt 4277. The two mtDNAs were maintained in the heteroplasmic state through back crosses to C57BL/6 males. At generations 12 through 15, the proportion of the two mtDNAs was determined using the BamHI polymorphism, revealing three classes of mice: those which maintained more than 30%, less than 30%, and no detectable NZB mtDNAs. Heteroplasmy was confirmed in heart, brain, liver, testis, muscle, ovarian, kidney, though it was highest in liver. PCR amplification, cloning and sequencing of nt 3422 to 5552 from liver and ovary mtDNAs revealed that 4/9 liver and 1/7 ovary mtDNAs contained one of more crossovers between the NZB and Common mtDNAs. This extraordinary finding was confirmed by purifying the liver mtDNA from a heteroplasmic animal using two sequential CsCl-ethidium bromide gradients, amplification, cloning and sequencing and finding that 4 of 14 clones were recombinants, with the sequence shifting from the Common mtDNA to the NZB mtDNA in two distinct regions: nt 3600-4400 including ND1-3 tRNAs - ND2 and nt 8600-9400 encompassing COX III. A related analysis revealed recombinant molecules in 1/10 heart, 1/14 brain, 5/12 kidney, 2/12 muscle, 0/6 testis, and 4/14 ovarian clones. Somatic mutations were also observed. Therefore, recombinant mtDNAs can be prevalent in heteroplasmic mammals. These results are disturbing. In assisted reproduction, the cytoplasm from younger oocytes is being injected into older oocytes resulting in heteroplasmic children (Barritt, J., et al., 2001, Hum Repro 16:513) and in therapeutic cloning heteroplasmy can be expected. Consequently, both practices could result in recombinant mtDNAs, something that evolution has gone to considerable lengths to avoid. Supported from NIH grant NS21328 (DCW) and Dept. Neurological Sciences, University of Milan, fellowship (MC) .

Development of a novel orally administered macrophage mediated gene therapy for Gaucher Disease. *E.I. Ginns, D.M. Faryna, M. Galdzicka, C. Chrzanowski, G.R. Ostroff.* Program in Medical Genetics, Pediatric Neurology, UMass Medical School, Worcester, MA 01605.

A novel orally administered macrophage delivered gene therapy is being developed for treatment of Gaucher disease. Current enzyme replacement therapy (ERT) improves blood counts and reverses hepatosplenomegaly. However, ERT is intravenously administered, costly, and has not significantly addressed bone or neurological complications. To evaluate the efficacy of our orally administered gene therapy method, DNA encoding human glucocerebrosidase (huGBA)was formulated inside micron-sized yeast cell wall particles (YCWP). YCWP-huGBA formulations were used to introduce huGBA DNA into J774 murine macrophages in culture and into long-lived Gaucher mice generated by gene targeting. As observed in human patients, the reduced GBA activity in these Gaucher mice results in glucocerebroside storage and Gaucher cells in tissues. The clinical manifestations in these mice can be accelerated by short courses of conduritol--epoxide. Following oral intake, YCWP-huGBA formulations are taken up through intestinal Peyers Patches where they are phagocytosed by macrophages that then migrate to organs of the reticuloendothelial system. Within the macrophage endosome the huGBA DNA is released at acid pH, migrates to the nucleus, and is expressed to produce normal huGBA. This macrophage mediated treatment results in huGBA expression in J774 murine macrophages *in-vitro,* and in tissues of Gaucher mice. Preliminary findings suggest that this therapy sufficiently corrects tissue GBA activity to ameliorate symptoms in treated, compared to untreated, severely affected Gaucher mice. As a consequence of improved delivery of huGBA, we expect that this approach will achieve significant reversal of tissue pathology, including bone. If macrophages containing huGBA migrate into brain, then resulting increased GBA levels could also provide clinical benefit for neurologic manifestations of the disease. The successful development of this therapy should provide a safer, more efficient and cost effective treatment for patients with Gaucher disease, as well as other lysosomal diseases.

Adiponectin: An Inherited Survival Factor in Families with Exceptional Longevity. *A.R. Shuldiner[1], J. Crandall[2], T.I. Pollin[1], K. Tanner[1], M. Rincon[2], R. Lipton[2], N. Barzilai[2], G. Atzmon[2].* 1) University of Maryland School of Medicine,Baltimore; 2) Institute for Aging Research AECOM, New York.

Adiponectin (ADIPOQ), a serum protein expressed by adipose tissue, is lower with obesity and has a protective role against insulin resistance and atherosclerosis. To test the hypothesis that ADIPOQ influences survival, we examined ADIPOQ levels and genetic variation in the ADIPOQ gene in subjects with exceptional longevity. We studied unrelated Ashkenazi Jews between the ages of 60 and 108 years (n=366), of which 169 where over the age of 95 years. To test heritability, ADIPOQ levels were also measured in 222 of their offspring. Homozygosity for the ADIPOQ +2019 del/del increased from 12% at age 65 to 31% at age 105, (=0.35, p=0.05) and was associated with significantly higher serum ADIPOQ levels, independent of BMI (p = 0.01). Serum ADIPOQ levels were greater in subjects with exceptional longevity (13.00.5 ug/mL vs. 17.1 0.6 ug/mL in age 60-94 years and 95 years, respectively, p=0.0001), an effect that was independent of gender or BMI. Subjects with high serum ADIPOQ levels had a greater percentage of large HDL and LDL particle sizes(by NMR spectroscopy), higher HDL-cholesterol levels, lower insulin resistance (by HOMA) and lower prevalence of the metabolic syndrome (by NCEP III guidlines)compared to those with low ADIPOQ levels. The distribution of adiponectin levels in the offspring was bimodal, and ADIPOQ levels were significantly heritable (h2=0.36, p=0.05) in offspring, suggesting inheritance of a high (protective) ADIPOQ phenotype in families with exceptional longevity. Exceptional longevity is associated with high levels of ADIPOQ and with favorable lipoprotein profile and protection from the metabolic syndrome. This phenotype is inherited in part by a novel ADIPOQ genotype. We suggest that ADIPOQ may be an inherited survival factor in exceptional longevity acting by increasing insulin sensitivity and providing protection from the metabolic syndrome and cardiovascular disease.

Homozygous HOXA1 mutations disrupt human brainstem, inner ear, cardiovascular, and cognitive development. *M.A. Tischfield[1,3], T.M. Bosley[4,5], M.A.M Salih[6], I.A. Alorainy[7], E.C. Sener[8], M.J. Nester[5], D.T. Oystreck[4], W. Chan[1], C. Andrews[1], R.P. Erickson[9], E.C. Engle[1,2,3].* 1) Dept of Medicine, Program in Genomics, Children's Hosp Boston; 2) Dept of Neurology, Children's Hosp Boston; 3) Program in Neuroscience, Div Med Sci, Harvard Med School, Boston; 4) Neuro-ophthalmology Div, King Khaled Eye Specialist Hospital, Riyadh, SA; 5) Neuroscience Dept, King Faisal Specialist Hospital and Research Centre, Riyadh, SA; 6) Division of Peds Neuro, Depart of Peds, College of Medicine, King Khalid Univ Hosp, Riyadh, SA; 7) Depart of Radiology & Diagnostic Imaging, College of Med, King Saud University, Riyadh, SA; 8) Dept of Ophthal, Hacettepe Univ Hospital, Ankara, Turkey; 9) Dept of Pediatrics, Mol. & Cell Biology, Univ. of Arizona College of Med, Tucson, AZ.

Using a positional cloning approach, we have identified homozygous coding mutations in HOXA1 in three genetically isolated populations in the Middle East and American southwest. Affected individuals have a pleiotropic spectrum of phenotypes including horizontal gaze abnormalities, facial weakness, deafness, hypoventilation, skull deformities, autism, mental retardation, internal carotid artery malformations, and conotruncal heart defects. Although horizontal gaze abnormalities and sensorineural deafness are the most penetrant aspects of the syndrome, the remaining phenotypes demonstrate considerable variable expressivity that can be dependent upon genetic background. This is the first report of mutations in a HOX gene critical for CNS development and the first description of viable homozygous mutations in any human HOX gene. The identified mutations, two non-sense and one frameshift, introduce premature stop codons in exon 1. Truncated mutant proteins should lack all known functional domains resulting in a complete loss of HOXA1 function. Our results demonstrate a new function for HOXA1 in vascular patterning that had not been reported in Hoxa1-/- mice. We also demonstrate that HOXA1 is necessary for proper cognitive and behavioral development, intriguing considering the canonical CNS expression domain of Hoxa1 has a rostal boundary in the brainstem.

Ancient Hybridization in the History of *Homo sapiens*. *M.F. Hammer, D. Garrigan, Z. Mobasher, S.B. Kingan, J.A. Wilder.* Div Biotechnology, Univ Arizona, Tucson, AZ.

Fossil evidence links human ancestry with populations that evolved modern gracile morphology in Africa 130,000 - 160,000 years ago. Yet fossils alone do not provide clear answers to the question of whether the ancestors of all modern *Homo sapiens* comprised a single African population or an amalgamation of distinct archaic populations. DNA sequence data have consistently supported a single origin model in which anatomically modern Africans expanded and completely replaced all other archaic hominin populations. Here we present novel sequence data from a 17.5-kb X-linked locus, Xp21.1, that exhibits ancient divergence among lineages. We analyze levels of haplotype divergence and linkage disequilibrium (LD) in the framework of models predicting patterns of nucleotide variation expected as a consequence of admixture between historically isolated subpopulations. No previous human polymorphism study has been specifically designed to utilize these measures to assess the probability of a single population origin for anatomically modern humans. The Xp21.1 locus was selected because it is located in a non-coding region of the X chromosome with moderately high levels of recombination and very low gene density. This serves to minimize the potenital impact of natural selection acting on linked functional sites. Monte Carlo computer simulations show that it is highly improbable that the pattern of nucleotide variation observed at the Xp21.1 locus could arise in a single, panmictic population, as predicted by the recent African replacement model. We consider several plausible alternative hypotheses and conclude that ancient population structure in the evolutionary lineage leading to AMH is the most likely explanation for the Xp21.1 data. This inference supports human evolution models that incorporate admixture between divergent African branches of the genus *Homo*.

The International HapMap Project: A haplotype map of the human genome with 4 million SNPs. *P. Donnelly, on behalf of The International HapMap Consortium.* University of Oxford, Oxford, UK.

The International HapMap Consortium, which includes scientists from Canada, China, Japan, Nigeria, the UK, and the US, has developed a human haplotype map describing the common properties and patterns of DNA sequence variation across the human genome. The primary data are the genotypes of about four million SNPs, their allele frequencies, and the degree of association among them, in a set of 270 DNA samples. In addition, ten 500 kb ENCODE regions were resequenced in 48 samples and the HapMap samples were genotyped for all known and newly discovered SNPs. SNPs were genotyped using technologies developed by Perlegen, Illumina, Third Wave, Sequenom, ParAllele, and Perkin-Elmer. Four quality assessment exercises found that the data are > 99% complete and > 99.5% accurate. The HapMap data are freely and publicly available at the HapMap Data Coordination Center (www.hapmap.org and hapmap.jst.go.jp) and dbSNP (www.ncbi.nlm.nih.gov/SNP), and are incorporated into the UCSC Genome Browser and Ensembl. The DNA samples were collected through processes of community engagement and public consultation with individual informed consent. The 270 samples included 30 Yoruba trios from Ibadan, Nigeria, 45 Japanese from Tokyo, Japan, 45 Han Chinese from Beijing, China, and 30 Utah CEPH trios (northern and western European ancestry). Analyses of the data were performed on both the ENCODE genotypes and the genome-wide HapMap genotypes to assess how sensitive the inferences of patterns of LD and choice of markers for tagging haplotypes are to SNP density. Specifically, we analyzed the types and patterns of LD and common haplotypes, estimated a fine-structure recombination map, searched for associations with genomic features, and sought evidence for natural selection as an explanation of specific patterns. All analyses were conducted genome-wide, for each population sampled.

Effect of mutation type and location on clinical outcome in 1081 Marfan syndrome patients or related phenotypes with FBN1 mutations : an international study. *L. Faivre[1], G. Beroud[2], A. Child[3], B. Callewaert[4], C. Binquet[1], E. Gautier[1], E. Arbustini[5], A. Kiotsekoglou[3], P. Comeglio[3], C. Beroud[2], C. Bonithon[1], D. Halliday[6], C. Muti[7], L. Ades[8], J. De Baecker[4], P. Coucke[4], U. Francke[9], A. De Paepe[4], G. Jondeau[7], C. Boileau[7].* 1) Centre dépidémiologie - investigation clinique et centre de Génétique, CHU Dijon, France; 2) IURC, Montpellier, France; 3) St. Georges Hospital, London, UK; 4) Ghent University Hospital, Belgium; 5) Policlinico San Matteo, Pavia, Italy; 6) University of Oxford, UK; 7) Hôpital Ambroise Paré, Boulogne, France; 8) Royal Alexandra Hospital, Sydney, Australia; 9) Stanford University Medical Center, USA.

Mutations in the FBN1 gene cause Marfan syndrome (MFS) and have been associated with a wide range of milder overlapping phenotypes. A large collaborative study based on the international FBN1 mutation database including 1081 patients (820 probands) allowed us to investigate the relationship between the FBN1 genotype and the nature and severity of the clinical phenotype. A set of qualitative and quantitative clinical parameters was compared for different classes of mutation. Patients with a FBN1 null mutation had a more severe skeletal, aortic and lung phenotype than patients with a mutation producing an altered protein (p=0.005, p=0.0004 and p=0.007), whereas the frequency of ectopia lentis was lower (p0.0001). A higher risk of ectopia lentis was found in patients with a missense mutation substituting or producing a cysteine when compared to patients with other missense mutations (p0.0001), as well as with a mutation within the 5 region versus 3 (p=0.0003). Patients with mutations within exons 24-32 had a more severe phenotype (younger age at diagnosis, at aortic dilatation or aortic surgery and shorter survival) than patients with mutations located elsewhere (p0.0001), even when neonatal MFS were excluded. No significant differences were found for any clinical parameter in patients with a mutation located in EGF domains versus TGFBP domains. This study is the largest ever reported and indicates high-risk groups for cardiac and ophthalmologic manifestations, and can be helpful in monitoring patients with a FBN1 mutation.

A meta-analysis of FXTAS patients with and without family history of fragile X syndrome: a probable threshold model for the toxicity of CGG repeats. *S. Jacquemont[1], L. Beckett[2], M. Leehey[3], F. Tassone[4], R. Hagerman[5], P. Hagerman[3].* 1) Département de Génétique, C H U, Nantes, France; 2) Division of Biostatistics, Department of Public Health Sciences, UC Davis, CA; 3) Department of Neurology, University of Colorado Health Sciences Center Denver, CO; 4) Department of Biochemistry and Molecular Medicine, School of Medicine, University of California Davis, CA; 5) MIND Institute, University of California Davis Medical Center Sacramento, CA.

Results of genetic screening for the FMR1 premutation (55-200 CGG repeats) have been published by 12 independent groups. 2820 patients were ascertained through movement disorder clinics independent of their family history. We conducted a meta analysis in order to determine the prevalence of FXTAS for the main movement disorder diagnoses and established guidelines for fragile X premutation screening in neurology clinics. The overall prevalence of the FMR1 premutation regardless of the movement disorder diagnosis is 1%, 7 times greater than expected based on the prevalence of the premutation in males of the general population (OR = 6.9 ; 95% CI : 1.8 , 65.5). This figure has limited relevance since the excess of premutation allele was significant only in the group of males presenting cerebellar ataxia after the age of 50 years. In that group, the prevalence of the premutation rises to 2.7% ; (21/778), 22 times greater than expected based on the prevalence of the premutation in males of the general population (OR = 22.4 ; 95% CI : 5.8, 86.7). The clinical descriptions of these patients were compared to the cases identified through fragile X families. The meta analysis of the molecular data from patients recruited with or without a family history of fragile X supports the hypothesis of a threshold model of the toxicity of CGG repeats. We conclude that the toxicity of CGG repeats below 70 may not have functional repercussions or may be associated with FXTAS related disorders. This meta-analysis has consequences for the projected prevalence of FXTAS in the general population, which is lower than the initial estimate of 1/ 3000.

FXTAS: a descriptive study of premutation carriers from fragile X families. *E.G. Allen, J. Juncos, M. Rusin, G. Novak, L. Shubeck, S.L. Sherman, R. Letz.* Emory Univ, Atlanta, GA.

We are conducting a study to further examine the symptoms, penetrance, and risk factors associated with the tremor/ataxia syndrome (FXTAS) among carriers of premutation alleles of the FMR1 gene. Our study population includes all siblings of premutation carrier males over the age of 50 identified through a survey of families with fragile X syndrome. We conducted a comprehensive battery of tests including a medical history, a neuropsychological test battery, and quantitative neurological assessment. Within the neurological assessment, we use a series of tests to obtain objective, quantitative measures of key features observed in FXTAS cases to date: 1) resting, postural, and intention upper-limb tremor, 2) reduced vibration sensation, a surrogate of possible neuropathy, 3) decreased postural stability, and 4) dysdiadokinesis, or upper limb uncoordination. We have obtained these measures on 49 males (mean age=63.8) and 20 females (mean age=65.3). Subjects were scored as expressing the above phenotypes if they scored above the 95th percentile of age-adjusted standards. Among premutation males, we have seen a significantly increased incidence of tremor (45%), peripheral neuropathy (14%), decreased postural stability (57%), and dysdiadokinesis (78%). In contrast, these phenotypes were not markedly increased in females or non-carrier male relatives. These findings as well as neuropsychological measures will be examined with molecular correlates of FMR1.

Spectrum of *CHD7* mutations in 113 patients with CHARGE Syndrome. *S.R. Lalani[1], A.M. Safiullah[1], S.D. Fernbach[1], L.M. Molinari[1], C. Bacino[1], S.L. Davenport[4], M.A. Hefner[2], J.M. Graham Jr.[3], J.W. Belmont[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, St. Louis University School of Medicine St. Louis, MO; 3) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 4) Sensory Genetics/Neuro-Development, St. Paul, Minnesota.

CHARGE is a complex birth defect, characterized by non-random occurrence of coloboma, choanal atresia, cranial nerve defects, distinctive inner ear abnormalities, heart and urogenital anomalies and growth retardation. Recently, intragenic mutation of *CHD7*, the chromodomain-helicase DNA binding protein was reported to be a major cause of CHARGE syndrome. Chromatin remodeling is a well-recognized mechanism of gene expression regulation and the gene is likely to play a significant role in embryonic development and cell cycle regulation. We report the spectrum of *CHD7* mutations in 113 individuals with sporadic and familial CHARGE. Mutations were found in 62 patients (55%) distributed throughout the gene. About 68% were truncating mutations, most likely leading to haploinsufficiency. We have obtained phenotypic information on all patients and have performed multivariate analysis conditioned on the mutation status. The analysis shows that congenital heart defects (50/55 compared to mutation negative group, p=0.014) and growth retardation (42/48 compared to mutation negative group, p=0.002) are more frequent in patients with *CHD7* mutation. Mouse embryo in situ hybridization shows expression of this gene in the oto-acoustic complex, brain, ear, pharyngeal endoderm, and heart tube. We have also performed microarray analysis of gene expression using lymphoblastoid cell lines of seven *CHD7* mutation positive patients and compared the expression pattern in these to five control subjects and four affected patients with no abnormality of *CHD7* gene by sequence analysis. Preliminary analysis shows significant gene expression differences among these three groups. The differential gene expression pattern in the *CHD7* mutation negative group may further assist in understanding the molecular basis of disorder in this group of affected children.

Phenotypic spectrum of CHARGE syndrome with CHD7 mutations. *K. Kosaki[1], M. Aramaki[1], T. Udaka[1], R. Koaki[2], Y. Makita[3], N. Okamoto[4], H. Yoshihashi[5], H. Oki[5], Y. Fukushima[6], H. Kawame[7].* 1) Dept Pediatrics, Div Med Gen, Keio Univ, Tokyo, Japan; 2) Dept of Clin Genet & Mol Med, Nat'l Children'fs Med Ctr, Tokyo, Japan; 3) Dept of Pediatrics, Asahikawa Med Col, Asahikawa, Japan; 4) Department of Planning and Research, Osaka Medical Center and Res Inst for Maternal and Child Health, Osaka, Japan; 5) Tokyo Metropolitan Kiyose Children'fs Hosp,Tokyo; 6) Dept of Med Genet, Shinshu Univ Sch of Med, Matsumoto, Japan; 7) Division of Clinical Genetics, Nagano Children's Hosp, Nagano, Japan.

CHARGE syndrome is characterized by a constellation of non-randomly associated malformations: C - coloboma of the iris or retina, H - heart defects, A - atresia of the choanae, R - retardation of growth and/or development, G - genital anomalies, and E - ear abnormalities. Recently, Vissers et al. identified the gene Chromodomain helicase DNA-binding protein-7 (CHD7) at chromosome 8q12.1 as a causative gene of CHARGE syndrome. We further delineated the phenotypic spectrum of CHARGE patients with mutations in CHD7. Twenty-three patients who fulfilled Blake'fs criteria were screened for CHD7 mutations by using DHPLC. PCR products corresponding to all variant elution profiles were sequenced bidirectionally using the dideoxy sequencing method. We identified heterozygous CHD7 mutations in 17 (71%) of the 24 patients enrolled in the study: 7 frameshift mutations, 6 nonsense mutations, 3 splice-site mutations, and 1 intragenic deletion from exon 8 to 12. These mutation classes are likely to result in a prematurely truncated protein or the loss of protein expression. Altogether, 15 of the 17 cases had coloboma of the eyes. However, only 2 patients had iridal coloboma and 5 patients had only disc coloboma, without iridal or retinal coloboma. Thus, the retina and optic disc must be thoroughly examined when CHARGE syndrome is suspected, even in the absence of iridal coloboma. Choanal atresia/stenosis was not common (5 patients) and was less frequent than oral clefts (8 patients). Severe hearing-loss, laryngomalacia, and developmental delays were prevalent. Genetic testing of CHD7 will be helpful in confirming the diagnosis and in providing accurate genetic counseling to the families.

Genotype-phenotype correlations in Rubinstein-Taybi syndrome. *E.K. Schorry[1], M. Keddache[1], B. Abiramikumar[1], N. Lanphear[2], J. Rubinstein[2], G.A. Grabowski[1].* 1) Div. of Human Genetics; 2) Div. of Developmental Disabilities, Cincinnati Children's Hospital.

Rubinstein-Taybi syndrome (RTS) is a well-described multiple congenital anomaly/mental retardation syndrome which usually occurs sporadically. Loss of function in CREBBP or EP300 genes, which encode histone acetyl transferases, has been found in about 50% of patients with RTS, with the majority of mutations in CREBBP. We performed mutation analysis of CREBBP in 98 patients who met diagnostic criteria for RTS during 2 international RTS family conferences. DNA was extracted from peripheral blood, and mutation analysis of CREBBP was performed on all 31 coding exons and exon-intron junctions by bidirectional comparative PCR sequencing. A total of 59 different variations were observed in the DNA sequence. All mutations involving a change in the protein were unique, and were equally distributed throughout the 31 coding exons. Twenty-five of the mutations created a truncated protein product or clearly altered the splice-donor/splice-acceptor consensus sequence; 11 mutations resulted in single amino acid changes. Forty-five patients did not have an identifiable mutation in CREBBP.

Extensive phenotypic data was also collected on the patients during the conference. All patients had the characteristic facies, broad thumbs, and mental retardation. We analyzed phenotypic data to determine correlations with specific mutation types, i.e., truncating, splice site, single amino acid substitutions, or no identifiable mutation. There were no differences in the facial and broad thumb phenotype between the 4 groups, with all groups displaying the characteristic dysmorphology. Degree of mental retardation and growth retardation were similar in all groups. Congenital heart disease was seen in 40% of the group overall, but was less frequent (18%) in patients with single amino acid substitutions. Interestingly, duplication of the great toe was seen in 8 patients with no identifiable mutation, but in none of the patients with CREBBP mutations. Further research is needed to determine the additional genes which cause this phenotype.

Phenotypic characterization of familial oculo-auriculo-vertebral (OAV) spectrum: assessment of 19 additional families. *A.E. Beck[1], L. Hudgins[2], A.W. Grix[4], N.H. Robin[5], E. Chen[6], L.C. Lazzeroni[3], H.E. Hoyme[2], U. Francke[1,2].* 1) Dept Genetics and; 2) Dept Pediatrics, Div Medical Genetics and; 3) Dept Health Research & Policy, Div Biostatistics, Stanford Univ, Stanford, CA; 4) Permanente Medical Group, Sacramento, CA; 5) Dept Genetics, Univ Alabama at Birmingham, Birmingham, AL; 6) Permanente Medical Group, Oakland, CA.

Although the OAV spectrum is considered a sporadic condition, a few large studies suggest that up to 45% of probands with hemifacial microsomia or microtia have affected relatives. In the present study, we evaluated 19 families in which probands with OAV had additional family members with OAV features. We ascertained 54 affected family members (including probands) and 18 normal relatives who were apparently transmitting carriers. Of those phenotypically affected, 57% were female and 43% were male. 63% had unilateral and 37% had bilateral findings. 93% exhibited auricular anomalies including preauricular tags (23 cases) and microtia (30 cases, often with canal narrowing/atresia and conductive deafness). Eye malformations in 20% included epibulbar dermoids (8/11), microphthalmia, and iris/retinal colobomas. Mild facial asymmetry was seen in 30%, but the marked hemifacial microsomia often seen in sporadic OAV was uncommon. Renal (4%), vertebral (11%) and cardiac (7 %) anomalies occurred less frequently than in sporadic cases. Only 2 affected subjects had intellectual impairment. Chromosomal studies in probands were normal. Although mouse models and candidate regions in the human genome are under investigation, no human gene mutations for OAV are known. Our new data suggest that there are genetic subtypes within the OAV spectrum consistent with autosomal dominant and possibly X-linked inheritance of a single gene displaying variable expressivity and incomplete penetrance. Careful evaluation of relatives for minor manifestations of OAV is essential before quoting recurrence risks. Since microtia can result from aberrant migration of neural crest cells into the 1st/2nd branchial arches during embryonic weeks 4-5, it is tempting to postulate that the altered gene(s) in our familial cases are involved with neural crest regulation.

Array CGH identifies chromosome abnormalities with unexpected clinical variability in contiguous gene syndromes. *B.A. Bejjani, B.C. Ballif, C.D. Kashork, E. Rorem, K. Sundin, L.G. Shaffer.* Signature Genomic Laboratories, LLC, Spokane, WA.

Array CGH provides distinct advantages over conventional cytogenetics by detecting aneuploidy, microdeletions, microduplications, and subtelomeric rearrangements in a single, simultaneous assay. The SignatureChip was designed to detect the common microdeletions, reciprocal microduplications, subtelomeric and pericentromeric alterations, unbalanced translocations, and aneuploidy, while avoiding most common population variants. The design also allows for distinguishing the common-sized microdeletions that are flanked by low copy repeats from larger deletions through the use of flanking control loci. The array uses 831 BACs covering 126 clinical and 104 control loci in 3-6 clone contigs. Of the 1,300 clinical cases submitted to our laboratory for diagnostic testing, we identified 73 cases (5.6%) with clinically relevant abnormalities. The majority of these cases have had at least one previous cytogenetic study. Among these, 22 telomeric deletions or unbalanced rearrangements and 21 cases with syndromic deletions were identified. We also identified 3 cases of interstitial deletions of 1p36 and three cases of interstitial duplications on 3q, 4q and 16q, none of which would be detected using available sets of subtelomere probes. The finding of 21 cases with syndromic microdeletions most of which were submitted by clinical geneticists after at least one previous cytogenetic study suggests that these well-characterized syndromes have unrecognized variability in clinical presentation that may prevent the clinician from readily reaching a diagnosis. The clinical variability of these syndromes will be reviewed. In addition, microduplications of 15q12, 17p11.2, and 22q11.2 have been identified, confirming that reciprocal products of common microdeletion syndromes will be detected. These microduplications are unlikely to be identified by conventional metaphase FISH assays. Thus, array CGH is a powerful approach for uncovering subtelomeric rearrangements, microdeletions and microduplications, even in patients who are not suggestive of a particular syndrome.

9q34.3 microdeletion syndrome: clinical and genetic insights. *S.A. Yatsenko[1], H. Firth[4], S. Tomkins[5], O. Rittinger[6], E. Lammer[7], K.S. Lewis[8], S.W. Cheung[1], P. Stankiewicz[1], J.R. Lupski[1,2,3].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX; 4) Addenbrookes Hospital, Cambridge, UK; 5) St. Michael's Hospital, Bristol, UK; 6) Klinische Genetik, Landeskinderklinik Salzburg, Salzburg, Austria; 7) Children's Hospital and Research Center at Oakland, Oakland, CA; 8) St. Joseph's Hospital And Medical Center, Phoenix, AZ.

9q34.3 microdeletion syndrome is a contiguous gene syndrome characterized by craniofacial dysmorphism, neonatal hypotonia, childhood obesity, microcephaly, mental retardation and absence of expressive speech. Depending on the deletion size, additional clinical features can include congenital heart defects, seizures, abnormal male genitalia, limb and brain anomalies. Recently we identified an ~700 kb critical region at the most distal portion of 9q34.3 encompassing genes *EHMT1* (euchromatic histone methyltransferase) and *CACNA1B* in association with a minimal phenotype (Yatsenko et al. 2005). Haploinsufficiency of *EHMT1* in all our patients and disruption of *EHMT1* identified in a child with features of 9q deletion syndrome (Kleefstra et al. 2005) provide the first evidence that dysregulation of histone modifications and chromatin structure can be a pathophysiological mechanism underlying mental retardation and neurobehavioral disorders.

Here we present the FISH mapping of the breakpoints in six new patients with del(9)(q34.3) using BAC and fosmid clones, and compare the deletion sizes and clinical manifestations. We constructed a deletion map of 9q34.3 chromosome region using cell lines from eleven affected individuals. In addition molecular cytogenetic analysis revealed one patient with der(9)del(9)(q34.3)dup(9)(q34.3q34.2). Our investigation showed that the 9q34.3 deletions varied from ~700 kb to 3.5 Mb in size and complexity of the rearrangement can be detected only by FISH or microarray CGH analyses. These observations provide new insights for genetic counseling and for the search of new candidate genes. We discuss genotype-phenotype correlation, and the possible molecular mechanism of deletion.

Overgrowth in association with chromosomal anomalies. *G.S. Ball, R.K. Aldrich, J. Lee, S. Li, K.A. Casas.*
Department of Pediatrics, University of Oklahoma, Rare Chromosomal Anomalies Registry, Oklahoma City, OK.

Overgrowth is a feature of very few chromosomal syndromes. We report two new patients with overgrowth. Patient 1 presented at birth with distal joint contractures and failed newborn hearing screen. Imaging studies revealed agenesis of the corpus callosum and left cystic kidney. Routine chromosome analysis performed shortly after birth showed extra material on chromosome 6q. Subtelomeric fluorescent in situ hybridization (FISH) using a 10p subtelomeric probe confirmed that the extra material on 6q was derived from 10p, resulting in terminal deletion of 6q and trisomy 10p. At 5 months of age, her length was 4 standard deviations above the mean for age. Weight and occipitofrontal circumference were at the 75th centile. Palm length was greater than the 97th centile for age, and there was an advanced bone age of 2 years. Patient 2 presented at 15 years of age with mild mental retardation and recent onset of seizures and hypertension. Her height was over 3 standard deviations above the mean for an adult female, weight was 4 standard deviations above the mean for an adult female, and occipitofrontal circumference was 3 standard deviations above the mean for an adult female. Palm length was at the 97th centile for an adult female. Routine chromosome analysis had been performed in early childhood with normal results. Subtelomeric FISH testing at 15 years of age revealed an unbalanced rearrangement with deletion of 8p and trisomy of 12p. Overgrowth is not a reported feature of the 6q deletion or 10p duplication syndromes, suggesting a fusion gene or other mechanism unique to the (6;10) translocation in Patient 1. Overgrowth is not a reported feature of the 8p deletion syndrome, but increased birth length and birth weight have previously been associated with duplication 12p and tetrasomy 12p, suggesting a dosage effect of a growth factor gene. Results in Patient 2 narrow the candidate region for this gene(s) to the 12p subtelomere.

Identification of Segmental Chromosomal Duplications and Deletions in Prostate Cancer. *A. Pearlman, M. Salman, H. Ostrer.* Human Genetics Program, New York University School of Medicine, New York, NY.

Recurrent somatic genetic alterations contribute to the development and progression of prostate cancer. These events can be identified using arrayCGH, a high-resolution technique that maps the duplicated or deleted segments onto arrays of well-characterized bacterial artificial chromosomes (BACs) or oligonucleotides. As part of our efforts to identify somatic alterations that are predictive of racial differences or prognosis, and to aid the identification of tumor suppressor genes, we compared the performance of Affymetrix 10K SNP chips and 19K BAC arrays using three Gleason 7 prostate cancers and their matched normal tissue. We analyzed the Affymetrix 10K SNP chip arrays using GDAS 2.0, dChipSNP and the Affymetrix copy number tool and the BAC arrays using the CGH Explorer, DNAcopy, vMAP, and GLAD segmentation tools. SNP chips provided calls for 93-98% of the probes. The gender calls were as expected for all samples and the concordance between replicates was 97%. No duplication events were identified with confidence. LOH events were observed on chromosomes 1, 13, and 21 for tumor 3 and in an overlapping region on 13 for tumor 1. Among the 60,000 events sampled, 4 small, LOH events occurred in single samples, but not in their replicates, suggesting that the frequency of false positives was <10-4. BAC arrays demonstrated duplications and deletions on multiple chromosomes for each sample, some of which overlapped. Applying CGH Explorer segmentation to the recurrent chromosome 13 deletion, we observed identical proximal breakpoints for tumors 2 and 3 and an overlapping breakpoint for tumor 1. Different distal breakpoints were observed for all 3 tumors. Sensitivity analysis using this program did not alter the segmentation on chromosome 13, nor create new chromosome 13 segments for the corresponding normal samples, indicating the robustness of the data and the tool. We compared the different methods for precision of segmentation and observed virtually identical breakpoints. These observations demonstrate that BAC arrays and SNP chip arrays provide precise and complementary identification of different types of chromosomal events in prostate cancer.

Finding prostate cancer susceptibility genes using linkage-based and candidate gene approaches. *E.A. Ostrander, on behalf of The International Consortium of Prostate Cancer Genetics.* Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD.

Identification of prostate cancer (PC) susceptibility genes has been hampered by the phenotypic heterogeneity associated with the disease, the large number of contributing loci, and the associated difficulties in accurately stratifying families based on features of disease, family history, or clinical presentation. Although genome-wide screens have been performed in over a dozen independent studies, few chromosomal regions have been consistently identified as regions of interest. The International Consortium for Prostate Cancer Genetics (ICPCG) was formed to facilitate the identification of PC susceptibility genes. The ICPCG has undertaken analyses aimed at utilizing the large family resources available (over 1800 PC families). These include: 1) combining genome-wide screen linkage data from a total of 1,233 PC families collected by members of the ICPCG. Using parametric and non parametric analyses five regions were identified with suggestive linkage (LOD score >1.86) on 5q12, 8p21, 15q11, 17q21 and 22q12, as well as a significant linkage at 22q12 (LOD 3.57) in a subset of families with 5 or more affected members. These findings are consistent with the hypothesis of multiple PC susceptibility genes with modest effects, or several major genes segregating in small subsets of families; 2) multi-locus analysis of genome wide scan data in all families using ordered subset analysis and pedigree covariate analysis using recursive partitioning; 3) a genome wide scan for linkage in 189 families that have three or more first degree relatives with aggressive prostate cancer; 4) genome wide scans for linkage in families with both prostate and other cancers (e.g. gastric cancer) and prostate cancer families of Ashkenazi Jewish descent. Finally, we have undertaken replication studies for previously described loci on the X chromosome, and testing of provocative candidate genes such as CHEK2 and NBS1. In addition, novel methodologic approaches are being developed and implemented to analyze this large and informative data set.

Genome-wide linkage scan for prostate cancer susceptibility loci in men with aggressive disease: The University of Michigan Prostate Cancer Genetics Project. *L.A. Ho[1], J.B. Dimmer[2], Y. Wang[1], E.M. Gillanders[3], K.A. Cooney[2], E.M. Lange[1].* 1) University of North Carolina, Chapel Hill, NC; 2) The University of Michigan, Ann Arbor, MI; 3) NHGRI, NIH, Bethesda, MD.

Identifying prostate cancer susceptibility genes using linkage analysis has proven to be a difficult challenge. It is clear that there is considerable genetic heterogeneity which results in reduced power to detect linkage signals. Another likely complication in mapping prostate cancer susceptibility genes is that there is considerable heterogeneity in the phenotype of prostate cancer, with a considerable range in the aggressiveness of the disease even among family members. We performed a genome-wide nonparametric linkage scan for genes that predispose to aggressive forms of the disease based on 405 genetic markers and 79 informative pedigrees with two or more cases of aggressive disease. Only individuals defined to have aggressive disease were coded as "affected" in our analyses. An indicator variable for aggressive disease was created using the following criteria: 1) Regional or distant stage (based on pathology if radical prostatectomy done, otherwise clinical stage, T3, T4, N1, M1) or 2) Gleason score of 7 or higher or poorly differentiated grade (if no Gleason score is available) or 3) PSA at diagnosis 20 or higher or 4) prostate cancer listed as primary cause of death on death certificate. We found strong evidence for linkage on chromosome 15q (LOD = 3.43) near marker D15S1002. Suggestive linkage was found on chromosome 6p (LOD = 2.21) near marker D6S422. Additional LOD scores greater than 1 were found on chromosomes 3q (1.43), 18q (1.17), 20q (1.05) and Xp (1.02). Using a more rigid definition of prostate cancer will result in a severe reduction in the effective sample sizes available for linkage analysis. However, the reduction in heterogeneity or "noise" in the phenotype may ultimately prove to increase the statistical power to detect susceptibility genes for this complex trait.

Single locus gene mutations and prostate cancer: Can mutations in the androgen receptor gene be directly linked to the occurrence of prostate cancer? *B. Gottlieb[1,3,5], C. Alvarado[1], L.K. Beitel[1,2], K. Sircar[4], A. Aprikian[4], M. Trifiro[1,2,3].* 1) Dept Cell Genetics, Lady Davis Inst Medical Res, Montreal, PQ, Canada; 2) Dept Medicine, McGill University, Montreal, PQ, Canada; 3) Dept Human Genetics, McGill University, Montreal, PQ, Canada; 4) Dept Urology, McGill University, Montreal, PQ, Canada; 5) Dept Biology. John Abbott College, Ste Anne De Bellvue, PQ, Canada.

One of the Holy Grails of cancer genetics has been to find mutations in a specific gene linked directly to a specific cancer. A possible candidate has been the androgen receptor gene (*AR*), which recent evidence has shown is important in all prostate cancer (CaP) stages. However, numerous studies that have examined the possible association between *AR* mutations and CaP have produced very inconclusive results. To resolve this issue we have considered the fact that tumor tissue heterogeneity has rarely been considered an indicator of genetic heterogeneity. To see if *AR* genetic heterogeneity does indeed exist we have conducted a micro-genetic examination of tumors from CaP patients using laser capture microdissection (LCM) to isolate specific pathologically-identified tissues and then sequence their *AR*. To help correlate mutations with tissue type, we have prepared cancerous and benign tissue micro-arrays from prostates from men with CaP. To date we have found a number of different mutations, in distinct areas isolated from a single prostate, all of which appear to be unique. Mutations were found in both cancerous and benign tissue from the central zone of the prostate, but not from benign peripheral and transitional zones. Even more intriguing is that different mutations were found in cancerous and benign tissues. Thus, it appears that somatic mosaicism of the *AR* occurs within CaP tumors, although the exact relationship between *AR* mutations and CaP must await an analysis of many more prostate tumors. We believe that this study, which is the first to conduct a micro-genetic analysis of *AR* mutations in CaP by utilizing LCM, points the way to an approach that can much more accurately monitor genetic events that lead to the initiation and progression of cancer.

Allele-specific expression in familial pancreatic cancer. *J. Fan[1], A. Maitra[2], M. Bibikova[1], E. Chudin[1], E.W. Garcia[1], D. Barker[1], P. Chen[2], C. Karikari[2], M.G. Goggins[2], R.H. Hruban[2], A. Chakravarti[2].* 1) Illumina, Inc, San Diego, CA; 2) Johns Hopkins University, Baltimore, MD.

Pancreatic cancer afflicts over 30,000 individuals each year in the United States, and is mostly lethal within months of diagnosis. About 10% of pancreatic cancer is familial due to an inherited predisposition. Despite considerable effort, germline mutations have been identified in less than 20% of families, in a few genes such as BRCA1/2. To enhance gene discovery, we analyzed germline allele-specific expression (ASE) patterns in familial pancreatic cancer (FPC). Our central hypothesis is that the gene responsible for FPC would be hemizygously mutated in the germline of affected individuals, and hence, would only or predominantly be expressed hemi-allelically from the wild-type allele (at least for a subset of mutations such as nonsense mutations or deletions). A microarray-based ASE assay was developed for 2,140 coding SNPs (cSNPs) derived from 680 cancer-associated genes, such as cell cycle checkpoint and apoptosis-inducing genes. Lymphoblastoid cell lines from 48 age-matched individuals (16 CEPH family trios) were analyzed for genomic heterozygosity and allele-specific differences in expression, if any, at heterozygous cSNPs. Genes demonstrating significant ASE in these normal individuals were catalogued for reference. Subsequently, lymphoblastoid cell lines from 109 individuals with FPC were examined for ASE variations. Overall, 331 genes demonstrated potential ASE in at least one of the 157 samples, of which 201 demonstrated ASE in both CEPH and FPC samples. These include known imprinted genes as well as multiple X-chromosome transcripts, confirming the overall validity of our platform. The remaining 130 genes demonstrated ASE in one or more of the 109 FPC patient samples only, and include both known genes implicated in FPC (e.g., BRCA1/2) as well as novel candidate genes (e.g., XRCC5, BPAG1, AGO, etc.). We are currently validating array-based ASE on a gene-by-gene basis using quantitative RT-PCR. Mutational screening will be performed for genes that display confirmed ASE variation in FPC patients but not (or at a significantly lower frequency) in CEPH controls.

***PRKAR1A* mutations leading to Carney complex, PPNAD and related disorders: Analysis of the largest database to date, identification of large gene rearrangments and other novel disease-causing alterations, and functional characterization of expressed mutants.** *A. Horvath, S. Boikos, F. Weinberg, E. Meoli, S. Stergiopoulos, T. Bei, L. Matyakhina, I. Bossis, C. Stratakis.* Section on Endocrinology & Genetics, DEB, NICHD, NIH, Bethesda, MD.

Carney complex (CNC) and primary pigmented nodular adrenocortical disease (PPNAD) are caused by inactivating mutations in *PRKAR1A*, the main regulatory subunit of cAMP-dependent protein kinase (PKA). We have screened for *PRKAR1A* sequence changes a total of 655 individuals from 171 non-related affacted kindreds, by DHPLC and genomic sequencing; negative samples were then screened by Southern blotting; 161 patients have been found to have 55 (33 novel) different disease-causing single base substitutions or small insertions/deletions scattered over the coding sequence and the splice junctions. Six index cases have shown alternative patterns in heterozygote state by Southern analysis using EcoRI; further analysis confirmed two distinct deletions, one ~5 kb from the exon3/intron3 region, and another deleting ~4 kb from between exons 4 and 8. These data were confirmed by long distance PCR; FISH did not show any abnormalities. Four specimens were sharing common EcoRI altered restriction pattern, suggesting mutations of EcoRI site. In contrast to previous studies, where the vast majority of the mutations were proven to lead to NMD, and subsequently, not to be expressed, we identified 10 different expressed mutations, which allowed us to assess the genotype-phenotype correlations. Two of the expressed mutations were associated with particularly aggressive clinical phenotype, two other were associated almost exclusively with PPNAD only. We conclude that (1) there is a large number of new PRKAR1A mutations associated with CNC and PPNAD, (2) the existence of large gene rearrangements confirms the complex *PRKAR1A* disease-mutation spectrum (3) approximately 20% of the mutations do not undergo NMD and lead to the expression of various mutant PRKAR1A proteins, and (4) there is genotype-phenotype correlation. This study has important implications for counseling, and for the molecular pathophysiology of PKA-associated tumorigenesis.

A mouse model employing the tet-off system in an antisense construct to *Prkar1a* confirms tTA-independent expression of the transgene and develops tumors consistent with Carney complex (MIM160980). *K.J. Griffin, F. Weinberg, S. Stergiopoulos, L. Matyakhina, L. Kirschner, C. Stratakis.* SEGEN, DEB, NICHD,NIH, Bethesda, MD.

Carney complex (CNC) is a multiple neoplasia syndrome associated with adrenal, pituitary, thyroid, and gonadal neoplasms, caused by *PRKAR1A* mutations inactivating the type IA regulatory subunit of protein kinase A (PKA). A transgenic line carrying an antisense transgene for exon 2 (X2as) of *Prkar1a* was crossed with a tTA-transgene-expressing line. The resulting tTA/X2as mouse mimicked CNC in many respects (Cancer Res 2004;64:8811, J Med Genet 2004;41:923), and developed lymphoid hyperplasia. The mice with only the X2as transgene also developed abnormalities that were not present in mice carrying tTA alone or in wild type mice of the same background. Previous reports have suggested that the tet-off system is leaky, allowing for the occasional expression of the target construct without the tTA factor. This study reports 136 mice: wild type (16), those carrying only the X2as transgene (60), those expressing tTA only (15), and the tTA/X2as (45) line published recently. The X2as mice developed a variety of tumors that were not present in controls, and not different from those in tTA/X2as mice. These include follicular adenomas of the thyroid, pigmentation and x-zone vacuolization of the adrenal cortex, uterine cysts, and abnormalities of the testis. The X2as mice did not develop lymphoid hyperplasia or lymphoma as frequently as tTA/X2as mice. PKA activities in X2as tissues were intermediate between tTA/X2as and controls. Genetic analysis of X2as-derived sarcomas showed involvement of the mouse chromosome 11 *Prkar1a locus*. Expression of the X2as transgene was confirmed by protein and mRNA studies; proliferation assays of X2as and tTA/X2as mouse-embryonic fibroblasts were similar. We conclude that the X2as mice developed tumors similar to those seen in CNC, tTA/X2as, and $Prkar1a^{+/-}$ mice. These studies confirm the leakiness of the tet-off system but also provide the opportunity to test which features are related to *Prkar1a*-down regulation vs. expression of the tTA transgene.

Mutations and Interstitial Deletions Involving Exon 3 of the Beta-catenin Gene are Detected in Sporadic Adrenocortical Tumors. *I. Bourdeau, A. Lampron, M. Tadjine.* Division of Endocrinology, Department of Medicine, Centre hospitalier de lUniversité de Montréal (CHUM)-Hôtel-Dieu, Montréal, Québec, Canada H2W 1T8.

Adrenocortical lesions are diagnosed frequently as benign adenomas or nodular hyperplasias, and more rarely as malignant adrenocortical carcinomas. The genetic background of sporadic adrenocortical lesions is poorly characterized. In our previous work, involving large-scale cDNA microarray analysis, we demonstrated aberrant differential expression of a number of Wnt/-catenin signaling-related genes implicated in adrenocortical hyperplasias. To further explore the role of Wnt/-catenin signaling in adrenocortical tumorigenesis, we conducted a search for mutations of exon 3 of the -catenin gene. DNA was extracted from 48 human adrenocortical samples and the human adrenocortical cancer cell line NCI-H295R. The adrenal tissue samples included 28 patients with adenomas, 4 with carcinomas, 13 with ACTH-independent macronodular adrenal hyperplasia (AIMAH) and 3 with ACTH-dependent adrenal hyperplasia. The samples were screened for somatic mutations in exon 3 of the -catenin gene using deletion screening by polymerase chain reaction (PCR) and direct sequencing. We found genetic alterations in 6 out of 28 adenomas (21,4%). There were no mutations detected in adrenocortical carcinomas, AIMAH, ACTH-dependent hyperplasia and the NCI-H295R cell line. Three point mutations occurred at potential serine/threonine phosphorylation residues of codons 37 or 45 [S37C (n=2) and S45F n=1)]. The remaining 3 tumors contained deletions of 6, 55 and 271 bp, each including part of exon 3. Reverse transcription-PCR experiments with RNAs isolated from the adenoma with the 271bp deletion detected transcripts that lacked exon 3, in addition to the normal transcript. These mutations, as previously reported in several types of tumors, but never in adrenocortical tumors, abrogate the phosphorylation-dependent interaction of -catenin known to lead to transcription activation of Wnt target genes. Our results suggest, for the first time, that -catenin gene mutations are frequent in adrenocortical adenomas. Possible involvement of -catenin activation could contribute to adrenocortical tumorigenesis.

Genome-wide localization of menin and assocated histone methytransferase complex members. *P.C. Scacheri[1], S. Davis[1], D.T. Odom[2], S. Perkins[1], A.M. Spiegel[3], P.S. Meltzer[1], F.S. Collins[1].* 1) NHGRI, Bethesda, MD; 2) Whitehead Institute, Cambridge, MA; 3) NIDCD, Bethesda, MD.

Multiple Endocrine Neoplasia, type I (MEN1) is a familial cancer syndrome characterized primarily by multiple tumors of the endocrine glands. The gene for MEN1 encodes a ubiquitously expressed tumor suppressor protein called menin. Menin was recently shown to interact with several components of a trithorax family histone methyltransferase complex including ASH2, Rbbp5, WDR5, and the leukemia proto-oncoprotein MLL. These findings suggested a role for menin in transcriptional regulation, potentially mediated through covalent modification of histone H3 at lysine 4. To gain insights into menin's role as a tumor suppressor, we determined the genomic occupancy of menin, MLL, and Rbbp5, using a strategy that couples chromatin immunoprecipitation with DNA microarray technology (ChIP-chip). The microarrays used in this approach were custom designed to contain high density oligonucleotide tiling paths across 20,000 human promoter segments. Given that MLL is reported to regulate homeobox (HOX) transcription, these arrays also harbored tiling paths across all four HOX clusters. Our data in HeLa cells indicate that menin, MLL, and RBBP5 co-localize with RNA polymerase II to transcriptional start sites, where histone H3 lysine 4 trimethylation occurs. Binding to the HOX clusters is strikingly different, with broad footprints that extend across inter- and intragenic regions of the HOX A and C clusters. To gain insights to the endocrine-specific tumor phenotype in MEN1, we compared these binding sites to those we mapped in primary human pancreatic islets, a common site of tumor formation in MEN1 patients. Menin was found to bind to a similar set of target genes in pancreatic islets, but with notable exceptions at the HOX clusters and elsewhere. Targets bound by menin exclusively in islet cells include key transcription factors involved in pancreatic endocrine development and insulin regulation. We suggest that absence of menin initiates tumorigenesis by mediating epigenetic changes in chromatin structure, potentially at the promoters of these key endocrine-specific genes.

Expression profiling identifies similar expression pattern of uveal melanomas with chromosome 3 isodiosmy to those with monosomy 3. *M. Abdel-Rahman[1,2], Y. Yang[2], F. Davidorf[2], C. Eng[1].* 1) Clinical Cancer Genetics Prog, Ohio State Univ, Columbus, OH; 2) Department of Ophthalmology, Ohio Sate Univ, Columbus, OH.

Purpose: Monosomy of chromosome 3 (M3) is the most frequent somatic alteration in uveal melanomas (UMs). M3 has been suggested as a useful marker for detection of aggressive UMs. Contrary to earlier reports, recent studies indicate a high frequency of partial chromosome 3 deletion in UMs. Moreover, chromosome 3 isodisomy has been reported in up to 16% of UMs without M3. The aim of the study is to identify the expression pattern associated with chromosome 3 isodisomy and partial chromosome 3 alterations compared to M3 in UMs. Methods: We used a combination of comparative genomic hybridization (CGH), high resolution genotyping utilizing 38 microsatellite markers on chromosome 3 and gene expression profiling to study 13 primary UMs. The frequency of partial chromosome 3 alterations was studied in a total of 47 UMs. Results: 7/13 UMs with available CGH data and expression profiling showed M3. In addition 2/13 showed isodiomy of chromosome 3 indicated by minimal or no alteration of chromosome 3 by CGH and LOH of most of the markers on both chromosome 3 arms. The remaining 4/13 UMs showed partial gains and/or loss of chromosome 3. All samples with partial chromosome 3 alterations were confirmed by genotyping. Expression profiling identified similar expression patterns of samples with chromosome 3 isodisomy to those with M3. Expression profiling identified several regions of common decreased expression on both chromosome arms 3p and 3q. Finally we identified a high frequency (22/47) of UMs with partial chromosome 3 alterations. Conclusions: Our data have revealed similar expression patterns of UMs with chromosome 3 isodisomy to those with M3, suggesting that isodisomy 3 may portend similar poor prognosis as M3. These results also indicate that partial chromosome 3 alterations are under-diagnosed in UMs. The clinical significance of partial chromosome 3 alterations will need to be further explored. Taken together, our results are important in designing clinical diagnostic strategies for the detection of chromosome 3 alterations in UMs patients.

Advanced genetic analyses on migraine: Trait component analysis and mouse model expression study. *M. Wessman[1,2], G. Oswell[3], M. Kallela[4], V. Anttila[1], M. Kaunisto[1], P. Tikka[1], E. Hämäläinen[1], D. Nyholt[5], J. Terwilliger[6], J. Kaprio[7], M. Färkkilä[4], L. Peltonen[8], A. Palotie[1].* 1) Finnish Genome Center and Dept of Clin Chem, Univ Helsinki, Finland; 2) Folkhälsan Research Center, Helsinki, Finland; 3) Dept of Pathology, UCLA, USA; 4) Dept of Neurology, Helsinki University Central Hospital, Finland; 5) Queensland Inst of Med Research, Brisbane, Australia; 6) Columbia Genome Center, Columbia University, NYC, USA; 7) Dept of Public Health, Univ Helsinki, Finland; 8) Dept of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland.

Migraine is a common chronic severe headache disorder with a strong genetic component and a prevalence of ~ 15% in the Caucasian population. We have collected nearly 700 multiple case families and based the diagnosis on the International Headache Society (IHS) criteria. This enables us to use medium-to-large size families for genome-wide linkage analysis and to perform case control association studies. Our previous genome-wide linkage study identified a locus on 4q24 linked to the endpoint diagnosis migraine with aura. We subsequently performed a trait component linkage analysis to test which IHS trait components provide best evidence of linkage to the 4q24 locus and whether additional susceptibility regions could be localized. Strongest evidence of linkage to 4q24 was achieved with unilaterality (parametric two-point LOD score 4.20), photophobia (3.73) and phonophobia (3.52). Pulsation was linked to 17p13 (4.65) and the IHS C-criteria to 18q12 (3.27). To identify positional candidate genes we performed whole transcriptome expression analysis with the Affymetrix 430 2.0 GeneChip on primary cultures of neurons and glial cells from the *tottering* mouse with a mutation in *Cacna1a*. Using a novel pathway identifying algorithm we identified 238 genes comprising 108 GeneOntology pathways as being differentially regulated including Ca^{2+} channel genes *Cacna1b* and *Cacng7*, Na^{+}/K^{+} pumps *Atp1a1* and *2*, *Atp1b1, 2* and *3*. We also identified several genes in our Chr 4 and Chr 17 restricted regions. Candidate genes identified in the mouse expression study are to be tested in our case control sample of 1800 subjects.

A common non-synonymous SNP in the BRI3 (ITM2C) gene accounts for a significant portion of the linkage evidence for Parkinson disease on chromosome 2q. *N. Pankratz[1], L. Byder[2], C.A. Halter[1], A. Rudolph[3], C.W. Shults[4,5], P.M. Conneally[1], T. Foroud[1], W.C. Nichols[2], Parkinson Study Group-PROGENI Investigators.* 1) Medical & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Children's Hospital Research Foundation, Cincinnati, OH; 3) Univ Rochester, Rochester, NY; 4) Univ California, San Diego, CA; 5) VA San Diego Healthcare System, San Diego, CA.

Previously, we identified significant linkage to chromosome 2q35 using a sample of individuals with familial Parkinson disease (PD). The linkage was strongest among those families with verified PD and those with a stronger family history (four or more affected or an affected sibpair with an affected parent). The disease allele appeared to be inherited in an autosomal dominant fashion, and penetrance appeared to be high in those individuals with a strong family history. Subsequently, we have genotyped six additional markers in the linkage region. With these additional markers, the autosomal dominant LOD score for the subset remained significant, and the non-parametric linkage evidence of the verified PD sample increased from a LOD score of 2.5 to 4.0. One candidate gene in this region is BRI3 (ITM2C), which belongs to a family of integral membrane proteins. One of its homologs (BRI2) is associated with familial dementia. Little is known about BRI3, except that it is highly enriched in human brain and that it interacts with BACE1, an enzyme responsible for converting beta-amyloid, a protein involved in Alzheimer disease pathogenesis. When we screened our PD sample for mutations in the BRI3 gene, we identified a rare non-synonymous point mutation (Arg236Trp) in one of our patients, as well as a non-synonymous polymorphism (Gly53Ser) that appears to be common in the general population (allele frequency = 0.40). Using the Genotype-IBD Sharing Test (GIST) under the same hypothesis of autosomal dominant inheritance, we have shown that this common SNP accounts for a significant portion of the linkage to chromosome 2q (p=0.03). It is therefore possible that this polymorphism is a common PD susceptibility gene with low penetrance (similar to APOE for Alzheimer disease).

High-density linkage screen in multiple sclerosis. *J. Haines, for the International Multiple Sclerosis Genetics Consortium.* Ctr Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN.

Ten centimorgan microsatellite map have been the standard tool used for whole genome linkage screening since the mid 1990s and to date 11 screens employing this methodology have been published in multiple sclerosis. Inspection of these data shows that average genotyping success and information extraction rates are disappointing (80% and 44% respectively). Moreover available evidence suggests that genotyping errors rates in these studies (particularly the older ones) are likely to be > 1% for many if not most of the markers typed. The advent of high throughput cost effective SNP genotyping has provided new whole genome linkage screening tools promising significantly improved genotyping success rates and accuracy, which at high density should substantially enhance information extraction. Prompted by the potential benefits of these new tools we have typed the Illumina BeadArray linkage mapping panel (version 4) in a set of 730 multiplex families from Australia (97), Scandinavia (165), the United Kingdom (298) and the United States (170), which together provide 945 affected relative pairs (830 sib pairs, 14 half sib pairs, 54 cousin pairs and 47 avunclular pairs). After excluding 474 markers with genotyping success rates of <98% and 776 markers found to be in linkage disequilibrium with flanking markers (with r2 > 0.16) data is available from 4506 markers spanning the genome. A total of 2709 samples have been typed. The mean information extraction is 79.3% (range 42.4 - 91.3%) and the observed Mendelian inconsistencies suggest that within this data the genotyping error rate is just 0.002%. Highly significant linkage is observed in the region of the MHC (MLS 11.7) while suggestive linkage is seen on chromosomes 17q23 and 5q33. This screen provides the most definitive linkage map for multiple sclerosis currently available and illustrates the substantial increase in power that can be achieved using high density SNP linkage mapping sets. It is clear that future attempts to identify non-MHC susceptibility genes in multiple sclerosis will have to involve large sample sizes and association based methodology.

Homozygosity mapping with high-density SNP arrays identifies a novel gene for Bardet-Biedl Syndrome. *A.P. Chiang[1], J.S. Beck[1,2], A.L. Ferguson[1], K. Elbedour[3], R. Carmi[3], H.-J. Yen[1,2], M.K. Tayeh[1,2], J. Wei[1,2], D.Y. Nishimura[1], T.A. Braun[1], E.M. Stone[1,2], T.L. Casavant[1], V.C. Sheffield[1,2].* 1) University Iowa, Iowa City, IA, USA; 2) Howard Hughes Medical Institute, Iowa City, IA, USA; 3) Genetic Institute, Ben Gurion University of the Negev, Beer-Sheva, Israel.

The identification of mutations in genes that cause human diseases has largely been accomplished through the use of positional cloning, which relies on linkage mapping. In studies of rare diseases, the resolution of linkage mapping is limited by the number of meioses and marker density. One recent technological advance is the development of high density Single Nucleotide Polymorphism (SNP) microarrays for genotyping. The SNP arrays overcome low marker informativity by using a large number of markers to achieve greater coverage at finer resolution. To determine the utility of this technology for homozygosity mapping using small pedigrees, we genotyped a small consanguineous Israeli Bedouin (AT) family with autosomal recessive Bardet-Biedl Syndrome (BBS; obesity, pigmentary retinopathy, polydactyly, hypognoadism, renal and cardiac abnormalities, and cognitive impairment). While eight genes have been identified to cause BBS, over half of BBS patients have unknown genetic defects, leaving the possibility of additional genes, that when mutated, cause BBS. The AT family was a good candidate for homozygosity mapping with high density SNP arrays because it was not linked to any of the known BBS loci and a genome-wide scan with microsatellite markers at ~10 cM density did not reveal a linked locus. DNA from all four individuals affected with BBS from the family was hybridized to the HindIII chip of the Affymetrix 100K SNP chip set and the resulting data analyzed for regions of homozygosity. Regions of homozygosity were prioritized based on the physical distance, the number of consecutive homozygous SNPs, and marker density. Mutation analysis in the best candidate homozygosity region identified a gene with a conserved homozygous missense mutation. Functional analysis of this gene in a zebrafish system provides additional evidence that this is a BBS gene (BBS9).

Genomeutwin-European twin cohorts: Combined analysis of genome scans guide to two QTL:s for body stature including one common Caucasoid X-chromosomal locus. *L. Peltonen[1], S. Sammalisto[1], T. Hiekkalinna[1], N. Martin[2], J. Harris[3], D. Boomsma[4], K. Christensen[5], K. Ohm Kyvik[5], N. Pedersen[6], T. Andrew[7], T. Spector[7], E. Widen[8], A. Palotie[8], M. Perola[1], GenomEUtwin.* 1) Dept Med Genetics & Molec Med, Univ Helsinki & Nat Pub Hth In, Helsinki, Finland; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Norwegian Institute of Public Health, Oslo; 4) Free University, Amsterdam, Netherlands; 5) University of Southern Denmark, Odense, Denmark; 6) Karolinska Institutet, Stockholm, Sweden; 7) St Thomas Hospital, London, United Kingdom; 8) University of Helsinki, Finnish Genome Center, Finland.

Twin cohorts provide a unique advantage for investigations of the role of genetics and environment in the etiology of common traits. Co-twins share environment throughout critical fetal period and early years of life and twin design harmonizes this component of complex traits in a unique manner. The EU-funded GenomEUtwin (www.genomeutwin.org) consortium consists of eight twin cohorts (Australian, Danish, Dutch, Finnish, Italian, Norwegian, UK and Swedish) with the total number of 600000 twin pairs. Federated database with open source code has been created to share the data across the cohorts. We performed QTL analysis of stature (body height) using genome-wide scans performed for 8775 individuals: Australia (n=3730), Denmark (628), Finland (772), Netherlands (1313), Sweden (102) and United Kingdom (2230). The marker maps were combined and related to the sequence positions using computer program developed by us which uses DeCode genetic map markers as an anchoring set (www.bioinfo.helsinki.fi/cartographer). We used the program Merlin for variance components analysis with age, sex and country-of-origin as covariates. The covariate adjusted heritability was 82% for stature in the pooled data set. We found evidence for two major QTLs for human stature on 15q24 (LOD=3.75, 1-lod drop 11cm) and Xq25 (LOD=2.73, 15cM). Especially the evidence for linkage for the X-chromosomal locus is contributed by most of the cohorts, thus suggesting an evolutionally old genetic variant having effect on the growth in European-based populations.

Evidence for association between hepatic nuclear factor 4, alpha and triglycerides in Finnish familial combined hyperlipidemia families. *D. Weissglas[1], E. Suviolahti[1,2], J. Lee[1], A. Jokiaho[1], M-R. Taskinen[3], P. Pajukanta[1].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Department of Molecular Medicine, National Public Health Institute, Biomedicum, Helsinki, Finland; 3) Department of Medicine, University of Helsinki, Finland.

Familial combined hyperlipidemia (FCHL), characterized by increased levels of serum total cholesterol, triglycerides (TGs) or both, is observed in up to 20% of patients with premature coronary heart disease. Previously we identified a locus linked to elevated TGs on chromosome 20q13.11 in Finnish FCHL families. Numerous linkage studies of type 2 diabetes mellitus (T2DM) have also found evidence of linkage to this region. Recently, several independent groups identified associations between single nucleotide polymorphisms (SNPs) in the hepatic nuclear factor 4, alpha (HNF4A) gene on 20q12-q13.1 and T2DM in Finnish and Ashkenazi Jews. Because there is a clear phenotypic overlap between FCHL and T2DM, we tested this gene region for association with FCHL in Finnish families. To date no association between plasma lipid levels and HNF4A has been identified in FCHL. We constructed the linkage disequilibrium (LD) structure of the HNF4A region by using both the HapMap data and recently published Finnish LD data. Based on that information, we genotyped the seven SNPs, previously associated with T2DM, and three additional tag-SNPs from distinct haplotype blocks to capture most of the genetic variation within the HNF4A gene, including promoters 1 and 2. A SNP in promoter 2 of the HNF4A gene was significantly associated with high TGs (P=0.007) in 720 family members of 60 FCHL families. Haplotype analyses also showed significant associations with TGs as well as with plasma apolipoprotein B and high-density lipoprotein levels for several HNF4A haplotypes. The most significant haplotype for high TGs (P=0.008) has a frequency of 0.289 in the Finnish FCHL families. In conclusion, this study is the first to provide significant evidence for association between the intragenic variants of the HNF4A gene and plasma lipid levels in FCHL.

A new method to correct for population stratification in genetic case-control association studies: centralizing the non-central chi-square. *P. Gorroochurn[1], G.A. Heiman[2], S.E. Hodge[1,3], D.A. Greenberg[1,3].* 1) Division of Statistical Genetics,Dept Biostatistics, Columbia Univ, New York, NY; 2) Department of Epidemilogy, Columbia Univ, New York, NY; 3) Clinical-Genetic Epidemiology Unit, New York State Psychiatric Institute, New York, NY.

Recently, several authors have investigated the use of genomic information in an attempt to eliminate bias due to population stratification (PS) in case-control association studies. We here present a new method, the delta-centralization (DC) method, to correct for PS. DC works well even when there is a lot of bias due to PS. In the presence of PS, the usual chi-square statistics used to test for association have non-central chi-square distributions. Other methods approach the non-centrality indirectly, but we deal with it directly, by estimating the non-centrality parameter itself. Specifically: (1) We define a quantity delta, a function of the relevant subpopulation parameters, that exactly predicts (in relatively large samples) the elevation of the false positive rate due to PS, when there is no true association between marker genotype and disease. (Delta is quite different from F_ST and can be large even when F_ST is small.) (2) We show how to estimate delta, using a panel of unlinked neutral loci. (3) We show that the square of delta corresponds to the non-centrality parameter of the chi-square distribution. Thus, we can centralize the chi-square using our estimate of delta; this is the DC method. (4) We demonstrate, via computer simulations, that DC works well with as few as 25-30 unlinked markers, where the markers are chosen to have allele frequencies reasonably close (within 0.1) to those at the test locus. (5) We compare DC with genomic control and show that whereas the latter becomes over-conservative when there is considerable bias due to PS (i.e. when delta is large), DC performs well for all values of delta.

A Spatial Clustering Approach to the Analysis of Genetic Association Studies. *E.R.B. Waldron[1], J.C. Whittaker[1,2], D.J. Balding[1].* 1) Epidemiology and Public Health, Imperial College London, London, United Kingdom; 2) Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London.

Haplotype-based approaches to the analysis of genetic association studies have important advantages over single-marker analyses, but they nevertheless suffer from limitations. For instance, rare haplotypes may not analysed effectively. Furthermore, the relationships between distinct but similar haplotypes that may share recent common ancestry are often not accounted for. We have developed an algorithm based on spatial statistics techniques, employing a simple distance in haplotype space that reflects evolutionary processes. The algorithm searches for case-rich clusters of similar haplotypes. Membership of this cluster corresponds to predicting the allele at an unobserved causal SNP. The algorithm can be applied to fine-mapping if the distance metric depends on the putative location of a causal allele. Using this algorithm to analyse data for the CYP2D6 gene, for which the true causal polymorphism is fully characterised, we correctly predicted nearly 98% of the genotypes at the major causal polymorphism and the functional mutation was mapped accurately. Simulation studies also revealed consistently better performance than alternative fine-mapping algorithms and allowed us to identify situations in which multi-point approaches offer a substantial improvement over single-point analyses.

Admixture-Matched Case-Control Study: A Practical Approach for Genetic Association Studies in Admixed Populations. *J. Kho[1,2], H.J. Tsai[1,2], N. Shaikh[1,2], S. Choudry[1,2], M. Navqi[1,2], D. Navarro[1,2], H. Matallana[1,2], R. Castro[1,2], C. Lilly[3], H.G. Watson[4], K. Meade[5], M.L. Noir[6], S. Thyne[1], E. Ziv[1], E.G. Burchard[1,2].* 1) UCSF, San Francisco, CA; 2) Lung Biology Center, San Francisco General Hospital, SF, CA; 3) Brigham and Womens Hospital, Boston, MA; 4) The James A. Watson Wellness Center, Oakland, CA; 5) Children's Hospital and Research Institute, Oakland, CA; 6) Bay Area Pediatrics, Oakland, CA.

Case-control genetic association studies in admixed populations are known to be susceptible to genetic confounding due to population stratification. The transmission/disequilibrium test (TDT) approach can avoid this problem. But, the TDT is expensive and impractical for late-onset diseases. Case-control study designs, in which cases and controls are matched by admixture, can be an appealing alternative for genetic association studies in admixed populations. We applied this matching strategy when recruiting our African American participants in the Study of African American, Asthma, Genes and Environments (SAGE). Group admixture in this cohort consists of 83% African ancestry and 17% European ancestry. By carrying out several complementary analyses, our results show that there is substructure, but that the admixture distributions are almost identical in cases and controls, and also in cases only. We performed association tests for asthma-related traits with ancestry, and only found that FEV_1, a measure of asthma severity, was associated with ancestry after adjusting for socio-economic and environmental factors (p=0.01). We did not observe an excess of type I error rate in our association tests for ancestry informative markers and asthma-related traits when ancestry was not adjusted in the analyses. Furthermore, using the association tests between genetic variants in a known asthma candidate gene, $_2$ adrenergic receptor ($_2$AR) and FEF_{25-75}, a measure of bronchodilator drug responsiveness to the asthma medication, albuterol, as an example, we showed population stratification was not a confounder in our study. Our work demonstrates that admixture-matched case-control strategies can efficiently control for population stratification confounding in admixed populations.

Analysis of fine structure recombination patterns in a human chromosomal region not previously known to harbor a recombination hot spot. *I. Tiemann-Boege[1], P. Calabrese[1], D.M. Cochran[1], R. Sokol[2], N. Arnheim[1].* 1) Molecular and Computational Biology Program, University of Southern California, Los Angeles, CA; 2) Health Science Center, University of Southern California, Los Angeles, CA.

For decades, evidence has suggested that crossing over is not homogenous across the human genome but can be highly localized in hot spots. Recent molecular studies of regions known to contain a hot spot based on classical methods have revealed that hot spots can be present where strong linkage disequilibrium (LD) is interrupted by patterns of very low LD. Whether recombination is generally restricted to hot-spots and whether hot spots can be found in larger chromosomal regions without exceptional frequencies of crossing over is yet to be addressed. Using sperm typing that selectively amplifies only recombinants in a pool of sperm genomes, we analyzed the recombination fractions in small contiguous intervals (~5 kb) of a 104 kb region of human chromosome 21 that showed no exceptional crossover activity. The observed recombination intensity ranges from 0.10 (95% confidence interval: 0.01, 0.29) to 12.21 (9.67, 15.05) times the human genome average rate. We identified two hot-spots with a recombination activity of 11.17 (9.98, 12.42) and 12.21 (9.67, 15.05) times the human average and four regions with a frequency ranging between 0.93 (0.59, 1.33) and 3.62 (3.09, 4.19) fold human average. The remaining regions all have an estimated frequency below 0.55 times the human average (all have a 95% upper bound below 0.84). The recombination patterns observed by sperm typing were compared with the patterns predicted by LDHat, Hotspotter and a third algorithm developed by one of us (P.C.). Patterns are roughly congruent with the recombination inferred from the population estimators with some exceptions. Our data suggests that it is likely that hotspots are usually found in larger chromosomal regions without exceptional frequencies of crossing over. Clearly, studies on other chromosomal intervals are needed to get a better genome-wide picture of the extent to which recombination is generally restricted to hot-spots and the degree to which LD analyses can predict recombination intensities.

Improved Association Analyses of Disease Subtypes in Case-Parent Triads. *M.P. Epstein[1], I.D. Waldman[2], G.A. Satten[3].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept Psychology, Emory Univ, Atlanta, GA; 3) Centers for Disease Control and Prevention, Atlanta, GA.

The sampling of case-parent triads is an appealing strategy for conducting association analyses of complex diseases. In certain situations, one may have interest in using the triads to identify genetic variants that are associated with a specific subtype of disease, perhaps related to severity of symptoms or sensitivity to medication. A straightforward strategy for conducting such a subtype analysis would be to analyze only those triads with the subtype of interest. While such a strategy is valid, we show that triads without the subtype provide additional genetic information that increases power to detect association with the subtype. We incorporate this additional information using a likelihood-based framework that permits flexible modeling and estimation of allelic effects on disease subtypes and also allows for missing parental data. Using simulated data under a variety of genetic models, we show that our proposed association test consistently outperforms association tests that only analyze subtype triads. We also apply our method to a triad study of attention-deficit hyperactivity disorder and identify a genetic variant in the dopamine transporter gene that is associated with a hyperactive-impulsive subtype.

Estimating genetic effects from genomewide association scan data. *S. Zollner, J. Pritchard.* Dept Human Genetics, Univ Chicago, Chicago, IL.

Genomewide association studies are a powerful method to detect loci harboring variants that affect complex traits. After a successful scan for association it is of great interest to estimate the impact of a detected variant on the phenotype of a carrier (penetrance) and on the population as a whole (frequency). These estimates allow to assess the importance of a mutation, they may provide information about its biological effect and facilitate planning replication studies. As these estimations are usually performed based on the same data that were used to identify a variant, the results are affected by ascertainment bias, causing the genetic effects of a variant to be overestimated if not corrected for. This overestimation is considered the main reason that many replication studies fail as the sample size needed is underestimated. The magnitude of this bias depends on the power of the initial association study. Here, we present an approach that corrects for the ascertainment effect and generates an approximate maximum-likelihood estimate of the frequency of a variant and its penetrance parameters. The method produces both a point-estimate and a confidence region for all parameters. We apply this estimator to simulated datasets and study its performance and its ability to distinguish between different models of penetrance. We show that by taking epidemiological data into account, it is often possible to obtain fairly precise estimates of all parameters, even if the power of the genome scan is low. We also show that the error of the estimate decreases with sample size, independent of the power of the original test for association. Finally, we demonstrate that the same algorithm can be used to assess interactions between a genetic variant and environmental risk factors.

Regression-Based QTL analysis method incorporating parent-of-origin effect. *O. Gorlova, L. Lei, D. Zhu, Y. Zhang, W. Li, S. Shete, R.A. Price, C. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

We present an extension of Sham et al.s (2002) regression-based quantitative-trait linkage analysis method to incorporate parent-of-origin effects. We separately regressed total, paternal, and maternal IBD sharing on traits squared sums and differences. We also developed a test for imprinting that indicates whether there is any difference between paternal and maternal regression. We use a panel of statistics to detect imprinting, which includes an overall T statistic (a test for total linkage), both parental T statistics (tests for parental-specific linkages), and the D index (a test for imprinting). We performed an extensive simulation to examine the performance of the panel. We found that when using empirical percentiles the method is very powerful in detecting parent-specific linkage with correct type I error rate for the non-linked parental component. Missing parental genotypes increase the type I error rate of both the linkage and imprinting tests and decreases the power of the imprinting test. When the major gene has low heritability, the power of the method decreases dramatically but the panel still performs well. We also used a permutation algorithm, which can ensure the appropriate type I error rate. We applied the method to a data from a study of 6 body size related measures and 23 loci on chromosome 7 for 255 nuclear families. Multivariate identities-by-descent were obtain using a modification of SIMWALK program. A parent-of-origin effect consistent with maternal imprinting was suggested at 99.67-111.26 Mb for body mass index, bioelectrical impedance analysis, waist circumference, and leptin concentration.

Quantitative Trait Linkage Analysis using Gaussian Copulas. *M. Li[1], P. Song[2], G.R. Abecasis[1], M. Boehnke[1].* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Statistics and Actuarial Science, Univ Waterloo, Canada.

An important problem in gene mapping studies is to locate genetic variants that influence quantitative traits, such as cholesterol level, body mass index, and systolic/diastolic blood pressure. The quantitative traits can be interesting themselves or if they are closely related to diseases, because any quantitative trait locus (QTL) identified might also act as a disease susceptibility locus. Traditional QTL mapping uses the variance-components approach with the key assumption that the trait values in a family follow a multivariate normal distribution. Violation of this assumption often leads to an increase in false-positive linkage findings and biased parameter estimates. To accommodate non-normally distributed data, we describe a modified variance-components method that directly models the non-normal distribution, which we call the "Gaussian copula variance-components method". With Gaussian copulas, handling of a multivariate distribution can be separated into a marginal model and a model for the joint distribution of the transformed phenotype scores, where the dependence structure is characterized by genetic components. The Gaussian copula variance-components method allows the analysis of continuous, discrete, and censored data. In particular, the traditional variance-components method becomes a special case when the data are distributed as multivariate normal. Through the use of link functions, the Gaussian copula variance-components method can easily incorporate covariates. Our simulation results indicate that the proposed method yields unbiased parameter estimates and correct type I error rates for testing linkage with a variety of non-normal distributions. We also show that the proposed method provides a modest increase in linkage power as compared with the traditional variance-components method. The Gaussian copula variance-components method should provide a useful arsenal of tools for the mapping of genes that influence non-normally distributed quantitative traits.

Extension of Variance Components Approach to Incorporate Repeated Measurements. *L. Liang, W. Chen, G. Abecasis.* Biostatistics, University of Michigan, Ann Arbor, MI.

When subjects are measured multiple times, it is important for a linkage analysis to appropriately take into account these repeated measures. In this study, we extend the variance components approach to model repeated measures in a quantitative trait linkage study. We show for the case of a balanced design where the same number of measurements is taken for each subject, a standard linkage test that takes the average of measures as the trait of interest is identical to the linkage test based on our extension of the variance components model. We give the general formulas of optimal sample size and number of repeated measures for a given power or cost. We carry out analytical calculations and perform simulations to compare power for different sample sizes and number of repeated measures across several scenarios (varying distance between markers from ~0 to ~10 cM, considering SNP and microsatellite markers, and varying major gene heritability, total heritability and measurement error from 2% to 20%, 8% to 80% and 0% to 60% of trait variability, respectively). We find that repeated measures provide substantial power improvements across genetic models. The proportional increase in expected LOD score depends mostly on measurement error and total heritability but not much on marker map or number of alleles per marker. For example, when measurement error takes up 20% of the trait variability and 4 measures per subject are taken, the proportional increase in expected LOD score ranges from 38% for trait with low heritability to 63% for trait with high heritability. When 2 measures per subject are taken, the increase ranges from 23% to 36%. For unbalanced designs, we use simulations to compare power for different sampling schemes. Finally, we give recommendations on whether to take repeated measures or to recruit additional subjects for different levels of measurement errors and ratios of genotyping, subject recruitment and phenotyping costs.

Methods for detecting gene-gene interaction in extended pedigrees. *B.S. Maher, T. Goldstein McHenry, R.J. Weyant, M.L. Marazita.* Univ Pittsburgh, Pittsburgh, PA.

Several approaches to detecting statistical non-independence between unlinked loci, with respect to a phenotype (gene-gene interaction), in a linkage framework have been proposed. Few of those approaches are applicable to multiplex extended pedigrees. We examined the power of four approaches: Nonparametric linkage score (NPL) correlation (NPLC; Cox et al 1999), NPL regression (NPLR; Langefeld & Boehnke 1999), Ordered Subset Analysis (OSA; Hauser et al 2004) and the extended conditional logistic model (CLA; Olson 1999). NPLC, NPLR and OSA are especially useful when a locus of interest due to a linkage signal has been identified but a candidate gene (marker) has not yet been characterized. NPLC examines the correlation between per family nonparametric linkage statistics at unlinked regions of the genome. NPLR is an extension of the NPL statistic that allows for the simultaneous testing of multiple loci and the interactions between them in a matched case-control conditional logistic framework. OSA is an approach to linkage analysis where evidence for linkage at one locus is maximized over subsets of families rank-ordered by evidence for linkage at another. CLA can be used to test the interaction between a candidate marker, included as a covariate, and unlinked regions of the genome. Importantly, each of these approaches tests for interaction beyond the marginal effects at each locus by examining either the LOD difference between models with and without interactions (OSA and CLA) or by examining the relationship between the linkage statistics at unlinked regions (NPLR and NPLC). To test the power of the methods and their ability to distinguish epistasis from heterogeneity, we simulated datasets consisting of 500 multiplex pedigrees under four different disease models with varying degrees of interaction. To address concerns regarding the behavior of the CLA test statistic, genomewide simulations were performed to determine the null distribution. Each approach achieved its best power under the Dominant-Dominant model. CLA had substantially more power than the other approaches, but is limited in that it relies on prior identification of a candidate marker.

A Bayesian model averaging approach to the analysis of large-scale genetic association studies allowing for two-locus epistasis. *A. Morris, L.R. Cardon.* Wellcome Trust Ctr Human Gen, Oxford, United Kingdom.

It is widely accepted that population-based association studies have the potential to locate genes contributing effects to complex traits. Large-scale studies of thousands of single nucleotide polymorphisms (SNPs) are becoming increasingly feasible as a result of improvements in the efficiency of genotyping technology and a better understanding of the extent and distribution of linkage disequilibrium (LD) throughout the genome. However, despite these advances, the issue of how best to analyse the data from large-scale association studies remains unresolved.

There is increasing evidence from model organisims to suggest an important role for epistasis in the aetiology of complex traits. The obvious approach is thus to test all possible pairs of SNPs for association. Despite the substantial penalty incurred for multiple testing, this strategy has been shown to be more powerful than a single-locus search, unless there are strong marginal effects. Alternatively, standard statistical variable selection techniques can be employed to identify the most important marginal effects and pair-wise interactions. However, this approach does not take account of uncertainty in the underlying genetic model of association, leading to inflation of false positive error rates.

Here, a novel application of Bayesian model averaging (BMA) techniques to the analysis of large-scale genetic association studies is presented. The underlying genetic model is treated as unknown, but could include marginal effects at each SNP, and interactions between each pair of loci to allow for epistasis. Markov chain Monte Carlo methods are used to sample from the posterior distribution of genetic models, and can be used to approximate the posterior probability of association of each SNP with the trait under investigation. The results of a detailed simulation study suggest BMA outperforms testing all possible pairs of SNPs except for models of "pure" epistasis with no marginal effects.

Detecting identical-by-descent DNA intervals between affected distant relatives using high-density SNP genotyping. *S. Nelson[1], B. Merriman[1], Z. Chen[1], J. Jen[2].* 1) Dept. of Human Genetics, University of California, Los Angeles, CA; 2) Dept. of Neurology, University of California, Los Angeles, CA.

Recent advances in the parallel typing of SNPs using high density oligonucleotide arrays provides a powerful tool for determining association with common alleles and linkage within pedigrees. Here we introduce a general approach to mapping a risk locus inherited from a founder, using high density SNP typing of only the affected pedigree members most distantly related through the founder. Using data from genome-wide 10K, 120K, and 500K SNP arrays, we have developed a statistical model for assessing the likelihood that genomic DNA segments are identical-by-descent (IBD) in a pair of distant relatives. We show that ~150 consecutive, independent SNP genotypes are sufficient to clearly identify intervals as IBD on one chromosome between two related individuals. The method is especially well suited to detecting IBD fragments that would exist in affected pairs in the present population that trace back to a risk allele founder 3100 generations removed. To demonstrate the approach, a previously mapped autosomal dominant mendelian disorder was mapped to the appropriate single location in the genome by typing distant relative pairs on 50K SNP arrays. Family relationships were not used in the analysis, and just three affected individuals were sufficient to map to a 14 Mb locus. This method provides a robust and powerful means to detect linkage using dense SNP maps and greatly reduces the number of typed individuals needed to determine linkage. Thus, we show that the detection of specific segments of IBD sharing between distant relatives is an effective approach for the rapid mapping of rare disease loci. By extension, we also expect it to be useful for mapping of complex traits in which risk alleles originate from ancient founders, even if the specific distant relationships are unkown in the affected population being studied.

Strategies for Detecting Epistasis via Genome-Wide Association. *D. Evans, M.S. Taylor, J. Marchini, A.P. Morris, L.R. Cardon.* Dept Statistical Genetics, Wellcome Trust Ctr, Oxford, United Kingdom.

Studies in model organisms suggest that epistasis may play an important and ubiquitous role in the etiology of complex diseases and traits in humans. With the era of large scale genome-wide association studies approaching, it is important to quantify whether it will be possible to detect statistical epistasis using realistic sample sizes in humans, and to what extent undetected epistasis will adversely affect power to detect association when single locus approaches are employed. We investigated the power to detect association for a range of two-locus quantitative trait models which incorporated varying degrees of epistasis. We evaluated the power to detect association using a single locus model which ignored interaction effects, a full two-locus model which allowed for interactions and a two-stage strategy whereby a subset of loci initially identified using a single locus test were analyzed using the full two-locus model. Despite the penalty introduced by multiple testing, fitting the two-locus model performed better than single locus tests for many of the situations considered, particularly when compared with attempts to detect both individual loci. The power of the two stage strategy depended on the first stage cut-off, the combination of allele frequencies at the loci and on the underlying model responsible for the interaction. An appropriate cut-off level increased power to detect association, whereas too strict a cut-off risked discarding target loci and too liberal increased the penalty due to multiple testing. Optimal conditions for this trade-off were model dependent and related to allele frequencies. We supplement the theoretical work with actual data from a genome-wide scan of gene expression levels for which we have found evidence of epistasis. Expression levels of IRF5, a gene implicated in Systemic Lupus Erythematosus, were associated with a SNP located in the IRF5 gene, and another SNP located close by RANKL, a gene involved in the same signaling pathways. Our results suggest that it is feasible to detect interacting loci which contribute to moderate proportions of the phenotypic variance using realistic sample sizes with appreciable power.

A Coalescent-based Marker Selection Tool for Association Studies. *E.F. Tsung, G. Marth.* Department of Biology, Boston College, Chestnut Hill, MA.

The International HapMap project is genotyping millions of SNPs in hundreds of individual reference samples from different world populations. This data set will enable the annotation of allelic association patterns within the reference samples in local genome regions or along entire chromosomes. The genotype data and the annotations will collectively form a large resource to aid marker selection for clinical case-control association studies. However, the utility of the markers selected based on the HapMap reference samples depends on the degree to which these patterns remain constant across other sets of samples such as those from clinical populations. This question may be studied experimentally, by genotyping additional individuals, and comparing the strength of association in these samples to the HapMap reference samples.

Here we describe a computational alternative to costly genotyping of such additional samples. First, using a Coalescent technique, we generate computational haplotypes where a subset of these recapitulates the allele structure observed in the HapMap reference samples, and another subset is used as a proxy for additional samples such as those that will be used in a future case-control association study. We use these computational samples to optimize SNP marker selection. The advantage of this approach is that marker selection is based not only on the HapMap reference samples, but also on a computational representation of the larger target population in the study.

The performance of this approach will depend on how well our Coalescent computational samples approximate the haplotype structure of actual samples. To assess this, we will test our method under various marker distances, recombination rates, and perturbations in demographic model parameters. Furthermore, we will compare at available regions of the genome and at the same marker locations present in HapMap, our computational samples to genotype data collected from non-HapMap samples. Our method, combined with current tag SNP selection techniques, will form the basis of an interactive software tool to aid marker prioritization for disease association studies.

Fukutin interacts with and modulates POMGnT1. *H. Xiong[1], K. Kobayashi[1], M. Tachikawa[1], H. Manya[2], T. Chiyonobu[1], Y. Nagai[1], T. Endo[2], T. Toda[1].* 1) Division of Clinical Genetics, Department of Medical Genetics, Osaka University Graduate School of Medicine, Osaka, Japan; 2) Glycobiology Research Group, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan.

Recent identification of mutations in certain genes encoding proteins with demonstrated or putative glycosyltransferase has revealed a novel mechanism for congenital muscular dystrophy. Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain disease (MEB), Walker-Warburg syndrome (WWS) and Large^{myd} mice all are characterized by hypoglycosylated -dystroglycan (-DG), as evidenced by a ~60kDa reduction in the relative molecular weight of -DG. However, only POMGnT1 (MEB) and POMT1 (WWS) are known to possess intrinsic glycosyltransferase activity. Here we show that fukutin lacks the enzymatic activity needed for *O*-mannosyl glycosylation of -DG but co-localizes with POMGnT1 in the Golgi apparatus. Fukutin and POMGnT1 (but not LARGE) co-immunoprecipitated from transfected cell lines and an *in vitro* binding assay. Two-hybrid analysis confirmed the fukutin-POMGnT1 interaction. When co-expressed with the ER-localized Y371C mutant fukutin, POMGnT1 relocated from the Golgi to the ER. The transmembrane domain of fukutin mediates its localization to the Golgi apparatus and participates in the interaction with POMGnT1. Finally, we demonstrate that POMGnT1 enzymatic activity in knock-in mice carrying the human retrotransposal insertion in the 3 noncoding region of *fukutin* decreased approximately 30% relative to wild type controls. From these findings, we suggest that fukutin forms a complex with POMGnT1 and modulates its enzymatic activity.

Deficiency of a Neuron-specific Isoform of the TAF1 Gene Is Associated with X-linked Dystonia-Parkinsonism. *S. Makino[1], S. Ando[1], M. Tomizawa[2], H. Ando[2], S. Goto[3], S. Matsumoto[1], D. Tabuena[4], E. Maranon[4], M. Dantes[5], L.V. Lee[5], K. Ogasawara[6], I. Tooyama[7], H. Akatsu[8], M. Nishimura[1], R. Kaji[1], G. Tamiya[1].* 1) Department of Neurology, Tokushima Univ Sch Medicine, Tokushima, Japan; 2) Department of Molecular Life Science, Tokai Univ Sch Medicine, Kanagawa, Japan; 3) Department of Neurosurgery, Sch Medical Sciences, Kumamoto University, Kumamoto, Japan; 4) Department of Neurology, West Visayas State University Hospital, Iloilo, Panay, Philippines; 5) Department of Health, Philippine Children's Medical Center, Quezon Avenue, Quezon City, Philippines; 6) Department of Pathology, Shiga Univ Medical Science, Otsu, Japan; 7) Molecular Neuroscience Research Center, Shiga Univ Medical Science, Otsu, Japan; 8) Choju Medical Institute, Fukushimura Hospital Toyohashi, Aichi, Japan.

X-linked recessive dystonia-parkinsonism (XDP; OMIM#314250) is a sex-linked recessive movement disorder endemic to the Philippines, with pathological similarities to Huntington disease (HD; OMIM+143100). The disease gene, *DYT3*, has been mapped to Xq13.1. In a search for the causative gene, we performed genomic sequencing analysis based on the shotgun strategy using a BAC contig constructed from genomic DNA of an XDP patient, followed by expression analysis using the patient'fs brain tissue. We found a disease-specific SVA retrotransposon insertion in an intron of the *TAF1* (TATA-binding protein-associated factor 1) gene, which encodes the largest component of the TFIID complex, and significantly decreased expression levels of a neuron-specific isoform of *TAF1* in the caudate nucleus. We also identified an abnormal pattern of DNA methylation in the retrotransposon and its surrounding region in the genome, which could account for decreased expression of the isoform. The *TAF1* gene may have a tissue-specific role in RNA polymerase II-mediated expression of genes that are essential for caudate neurons, such as the dopamine receptor D2 (*DRD2*) gene, whose expression is also decreased in HD. XDP and HD, together with other neurological diseases associated with transcriptional dysregulation, may comprise an expanded spectrum of transcription syndromes.

Generation and characterization of a mouse model of paroxysmal non-kinesigenic dyskinesia. *J. Nakayama, Y. Xu, H.Y. Lee, R. Tu, M. Vo, P.D. Ptacek, J. Cheung, Y.H. Fu, L.J. Ptacek.* Department of Neurology, University of California San Francisco, San Francisco, CA.

Paroxysmal non-kinesigenic dyskinesia (PNKD) is an autosomal dominant episodic movement disorder characterized by spontaneous attacks of dystonia, chorea, and athetosis begin in childhood through early adulthood. The attacks are precipitated by alcohol, coffee, stress and fatigue. PNKD has been mapped on chromosome 2q33-q35, and two mutations in the myofibrillogenesis regulator 1 gene (MR-1) were recently identified in PNKD families. The mutations cause changes (Ala to Val) in the N-terminal region of two MR-1 isoforms. The MR-1 gene function is unknown, and it is still not understand how mutations in this gene lead to manifestation of the PNKD phenotype. In order to elucidate the function of the MR-1 protein, we have begun developing animal models. We created transgenic mice with a mouse BAC clone (RP24-112K19) containing the wild-type murine ortholog (mMR-1). This BAC clone was modified to introduce the Ala7Val and Ala9Val mutations. Analysis of transgene copy number showed that two lines contained 2-3 copies and one line had one copy. Transgene expression in these mice were confirmed by RT-PCR. These mice were subsequently bred with C57/Bl6 mice. Transgenic mice showed normal development and their neurological reflexes, as assessed thus far, are normal. The body weight in transgenic mice was significantly lower (10-15%) than their wild type littermates. Transgenic mice appear to recapitulate the human phenotype as they have dystonic attacks precipitated by caffeine and ethanol. Transgenic mice from all three lines showed these attacks. We also generated mMR-1 knockout mice. Homozygous knockout mice were viable and reproductive, and had no gross phenotypic abnormalities. They did not show attacks by either caffeine or ethanol. Our results suggest that the gain-of-function mutations in MR-1 might be responsible for the PNKD phenotypes. Using the PNKD mouse model, we hope to elucidate the function of the MR-1 protein and understand the pathophysiology of this disorder.

Neuropathy target esterase gene mutations cause motor neuron disease. *S. Rainier[1], M. Bui[1], L. Ming[1], E. Plein[1], D. Thomas[1], D. Tokarz[1], C. Delaney[1], J.W. Albers[1], R.J. Richardson[1,2], J.K. Fink[1,3].* 1) Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109; 2) Toxicology Program, University of Michigan, Ann Arbor, MI 48109; 3) Geriatric Research, Education and Clinical Center, Ann Arbor Veteran's Affairs Medical Center,Ann Arbor, MI 48109.

We evaluated two unrelated kindreds in which affected subjects exhibited autosomal recessive, slowly progressive lower extremity spastic weakness associated with wasting of distal upper and lower extremity muscles. Subjects met clinical criteria for amyotrophic lateral sclerosis (ALS) and conformed to Troyer syndrome. Magnetic resonance imaging demonstrated spinal cord atrophy and electromyography identified motor axonopathy. Genetic analysis of one consanguineous kindred suggested linkage between the disorder and a 22 cM locus on chromosome 19p13, a region containing neuropathy target esterase (NTE). Analysis of NTEs coding sequence in this family showed an M1012V mutation disrupting an inter-species conserved residue in NTEs catalytic domain in both affected individuals but not unaffected individuals or 98 control subjects. Analysis of NTEs coding sequence in the second non-consanguinous kindred showed that affected subjects were compound heterozygotes for two NTE mutations: one allele had 2826A>G mutation which causes substitution of an inter-species conserved residue R890H in NTEs catalytic domain; the other allele had a 4 bp insertion (NTE mRNA position 3104) which causes protein truncation after residue 1020. These mutations were present separately in each carrier parent and absent in 98 control subjects.

Discovering that NTE mutations cause corticospinal and peripheral motor axon degeneration in these families indicates the importance of the NTE pathway in maintaining axonal integrity; raises the possibility that NTE pathway disturbance contributes to other motor neuron disorders including ALS and primary lateral sclerosis; and supports the role of NTE in the pathogenesis of organophosphorous compound-induced delayed neurotoxicity. Understanding the pathogenesis of NTE-mutation motor neuron disease will provide insight into the treatment of this and other motor neuron diseases.

A high-throughput metabolomics-guided screening of ENU mice for mouse models of human metabolic diseases: identification of mouse model of LCHAD deficiency. *J.Y. Wu[1], H.J Kao[1], C.C. Huang[1], R. Stevens[2], D. Millingon[2], Y.T. Chen[1, 2].* 1) Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan, Taiwan; 2) Dept of Pediatrics, Duke University Medical Center, Durham, North Carolina, USA.

Our laboratory has long interests in rapid analysis of metabolites at the whole-organism level (a metabolomics approach). We previously reported the use of tandem mass spectrometry screening for amino acid and acyl carnitine profiles to detect the derangement in the pathways of amino acid and fatty acid metabolism in mice treated with the N-ethyl-N-nitrosourea (ENU) and identified a mouse model resembling human maple syrup urine disease (J Clin Invest 113: 434, 2004). With only 25 l of whole blood spotted on the Guthrie card, this method could detect more than 20 metabolic diseases with defect in amino acid and fatty acid metabolism. Here we report, in a recessive screening of 2,300 G3 mice from 61 families, we identified mice with elevated blood long chain acyl carnitines (C16-OH, C18-OH, and C18:1-OH carnitines). Those mice had poor weight gain but survived to adulthood despite a shorter life span (affected died at age 12 to 18 months as compared to > 24 months for non-affected sibs). The elevation of long chain acyl carnitines reappeared in the F2 generation confirms its heritability. Affected mice were outbred to C3H for disease gene mapping. A panel of 299 SNPs was used for whole genome SNP homozygosity mapping. Genotyping results (performed on the MassARRAY SNP genotyping platform) showed homozygosity in 5 consecutive SNPs on chromosome 5 spanning from 34 Mb to 63 Mb where candidate genes, Hadha and Hadhb, coding for mitochondria trifunctional proteins and subunit, locate nearby. Direct sequencing identified a nucleotide T to A transversion in exon 14 (c.1210T>A) of Hadhb which resulted in a missense mutation of methionine to lysine (M404K). This is the first viable late-onset animal model of LCHAD (Long-Chain 3-HydroxyAcyl-CoA Dehydrogenase) deficiency due to Hadhb mutation. These mice could provide an important animal model for study of long chain fatty acid metabolism, investigating the pathogenesis of LCHAD deficiency and development of more effective therapies for this disease.

PGC-1-alpha transcription interference produces deranged thermoregulation in Huntingtons disease transgenic mice. *P. Weydt, V.V. Pineda, S. Luquet, R.T. Libby, A.R. La Spada.* Lab Medicine, Univ Washington, Seattle, WA.

Huntington's disease (HD) is an inherited neurodegenerative disorder characterized by motor and cognitive impairment. The motor abnormality stems from loss of medium spiny neurons in the striatum. HD is caused by a CAG repeat expansion in the huntingtin gene, and is thus one of 9 neurodegenerative disorders due to polyglutamine (polyQ) tract expansions. An intriguing feature of HD is enhanced vulnerability of the striatum to neurodegeneration. As part of a baseline evaluation of the HD N171-82Q mice, we measured core body temperature in HD mice. We found that at ~135-140 days of age, all HD transgenic mice (but no controls) developed progressive hypothermia with core body temperatures of < 35C. With progression of motor symptoms and weight loss, HD N171-82Q mice displayed profoundly deranged thermoregulation, with core body temperatures dropping to < 30C. We then subjected HD mice and controls to a 4C cold challenge, and documented a profound adaptive thermogenesis defect, as HD mice are unable to maintain core body temperature from 60 min into the cold challenge ($p < .05$). As body temperature regulation in rodents involves PPAR co-activator 1 (PGC-1) up-regulation of UCP-1 in brown fat, we dissected the brown fat of HD mice and found it to be abnormal. We then measured PGC-1 levels in brown fat from HD mice subjected to cold challenge, and found it to be appropriately up-regulated. UCP-1 mRNA and protein levels, however, were not increased in the brown fat of HD mice. We co-transfected 3T3-L1 cells with PPAR, RXR, the UCP-1 promoter reporter construct, and exon1/2 htt 24Q or 104Q expression constructs. We found that htt 104Q markedly suppressed UCP-1 promoter reporter expression in cells treated with ligand, but that co-transfection of the PGC-1 expression vector rescued htt 104Q repression ($p < .001$). Our results indicate that polyQ-expanded htt is interfering with PGC-1-mediated up-regulation of UCP-1 expression, and suggest a role for transcription interference with PGC-1-regulated mitochondrial biogenesis and metabolic pathways in HD. Impairment of PGC-1 function may thus account for the cell-type specificity in HD.

Spinocerebellar ataxia type 5 (SCA5) is an autosomal dominant disorder characterized by incoordination, eye movement abnormalities and slurred speech. MRI findings show dramatic cerebellar cortical atrophy, with the brainstem and other regions of the brain appearing normal. We previously mapped SCA5 to chromosome 11q13 in an 11-generation American kindred. Subsequently, two additional SCA5 families from France and Germany were reported.

We have now discovered that beta-III spectrin (*SPTBN2*) mutations cause SCA5. The American and French families have separate in-frame deletions in the third of 17 spectrin repeats. Consistent with Purkinje cell degeneration in SCA5, beta-III spectrin transcripts are abundantly expressed in brain, with relatively high expression in cerebellar Purkinje cells. RT-PCR analysis of cerebellar autopsy tissue from an affected member of the American family indicates that both the normal and deleted forms of beta-III spectrin transcripts are expressed in affected tissue. Western analysis of cerebellar tissue shows dramatic solubility differences of EAAT4, a glutamate transporter and Purkinje cell specific protein normally stabilized by beta-III spectrin. A third mutation in the German family, located in the dynactin-binding site, and distribution differences in Purkinje cell proteins (EAAT4, GluR2, calbindin, parvalbumin) from SCA5 autopsy tissue, suggest disruptions in vesicle transport. Spectrin mutations are a novel cause of neurodegenerative disease that possibly affect glutamate signaling and vesicle trafficking, pathways previously implicated in Alzheimer and Huntington diseases, SCA1 and ALS.

Targeted deletion of the Sca8 ataxia locus in mice causes abnormal gait, progressive loss of motor coordination and Purkinje cell dendritic deficits. *Y. He, K.A. Benzow, H.B. Clark, M.D. Koob.* IHG and LMP, U of MN, Minneapolis, MN.

Spinocerebellar ataxia type 8 (SCA8) patients typically have a slowly progressive, adult-onset ataxia that is accompanied by significant cerebellar atrophy. SCA8 is caused by large CTG repeat expansions in the untranslated antisense RNA of the Kelch-like 1 gene (KLHL1), but the precise relationship between the SCA8 CTG expansion and the disease status of SCA8 patients is complex and is still poorly understood. In order to more fully characterize the underlying molecular mechanisms involved in SCA8, we have developed a mouse model in which Klhl1 is deleted in either all tissues or is deleted specifically in Purkinje cells only. We found that mice that were homozygous for this deletion had a significant loss of motor coordination as measured by performance on an accelerating Rotarod by 24 weeks of age, and that the performance of mice assessed at 12 weeks or younger did not significantly differ from controls. Mice with KLHL1 specifically deleted in only Purkinje cells had a loss of motor coordination that was almost identical to mice with complete KLHL1 deletions. We also analyzed the gait of mice with homozygous KLHL1 deletions by detailed computer analysis of treadmill gait (Treadscan apparatus) and found that the mice develop significant gait abnormalities by 10 weeks of age. Interestingly, we found that mice that were heterozygous for the KLHL1 deletion had gait abnormalities that also significantly differed from controls. Finally, we found significant Purkinje cell dendritic deficits, as measured by the thickness of the molecular layer, in all mice in which KLHL1 was deleted (both total and Purkinje cell specific) and an intermediate reduction in molecular layer thickness in mice with reduced levels of KLHL1 expression (heterozygous deletions). The results from this mouse model are consistent with a role for KLHL1 as an actin-organizing protein that is essential for establishing or maintaining the dendritic structure and function in Purkinje cells and indicates that loss of KLHL1 activity is likely to play a significant part in the underlying pathophysiology of SCA8.

Molecular and clinical aspects of myotonic dystrophy: seven yearsexperience of direct molecular testing on 2650 Italian DM cases, risk prediction for clinical phenotype on the basis of molecular data. *L. Baghernajad Salehi[1], E. Bonifazi[1], M. Gennarelli[2], A. Botta[1], L. Vallo[1], R. Iraci[1], A. Nardone[1], A. Pietropolli[1], E. Di Stasio[3], G. Novelli[1].* 1) Biopathology, Tor Vergata University, Rome, Italy; 2) IRCCS, Brescia, Italy; 3) UCSC, Rome,Italy.

Myotonic dystrophy type 1(DM1;OMIM #160900)is an autosomal-dominant genetic disorder with multisystemic clinical features associated with a CTG expansion in 3'UTR of the myotonic dystrophy protein kinase gene (DMPK) on chromosome 19q13.3. Subject showing less than 35 CTG can be consider normal and subjects showing from 35 to 50 CTG are defined premutated.DM1 genotypes can be divided on the basis of repetition number into E1(from 50 to 200 CTG),E2(from 200 to 1000 CTG) and E3(1000 CTG)classes.We report on a 7 years experience in providing symptomatic and prenatal molecular diagnostic services for MD over the Italian territory on 2650 symptomatic patients and 185 prenatal diagnoses.Molecular analyses were informative in all examined cases for the detection and characterization of the CTG expansion.The most frequent expanded alleles in Italian patients were in the range of 200-1000 CTG repeat (E2 class).In order to study the intergenerational CTG transmission, we subdivided the data into 3 groups: an increase of the CTG expansion from E1 to E2 class, an increase of the CTG expansion from E2 to E3 class and finally an higher increase from E1 to E3 class.In group E1-E2 anticipation is more frequent in father-child pairs whereas in the E2-E3 group anticipation is more frequent in mother-child pairs (because of DM1 male infertility or sperm selection).There is no significant difference between the distribution of contraction events within the different classes and among parental transmission.A genotype-phenotype correlation was performed in order to assess the genomic risk to manifest more than one clinical feature.We were able to demonstrate that E2 class shows an increased risk to develop more clinical complication with an OR of 8.8. Our experience has confirmed that direct molecular analysis for the myotonic dystrophy mutation has proved to be of considerable value in diagnosis and phenotype prediction.

Error-prone repair of slipped CAG/CTG repeats by human neuron proteins leads to trinucleotide expansions.

C.E. Pearson[1,2], G.B. Panigrahi[1], R. Lau[1], M. Blondin[1,2], S.E. Montgomery[1,2]. 1) Dept Genetics/Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept. Medical Genetics, University of Toronto, Toronto, ON, Canada.

Instability of trinucleotide repeats, the causative mutation of ~30 neurodegenerative/neuromuscular diseases, is thought to involve escaped repair of slipped-strand DNA intermediates. We report the first characterization of the fidelity and efficiency of slipped CAG/CTG processing by human proteins, a process that is pivotal to understanding the mechanism of trinucleotide repeat instability. Using human cell extracts and DNAs with slip-outs of (CAG)20 or (CTG)20 we observed an hierarchy of repair outcomes. A new form of error-prone repair was detected, whereby excess repeats were incompletely excised, presenting a novel path to generate expansions, but not deletions. Both the improved correction of deletion intermediates over expansion intermediates, as well as the retention of excess repeats in error-prone repair products may be sources for the expansion bias in humans. Neuron-like cell extracts yielded each repair outcome, supporting a role for these processes in CAG/CTG instability in patient post-mitotic brain cells. Curiously, expansion mutations of CAG/CTG transgenes in four transgenic mice required functional mismatch repair proteins MSH2 and MSH3; a mutagenic role which contrasts with the corrective repair role played by these proteins against other mutations. Mismatch and nucleotide excision repair proteins hMSH2, hMSH3, hMLH1, XPF, XPG or polymerase beta were not required - indicating that their role in instability may precede that of slip-out processing. We propose that through DNA-binding MMR proteins may drive expansion mutations by forming slipped DNA mutagenic intermediates. Differential processing of slipped-repeats may explain the expansion bias and different mutation patterns occurring between various disease loci or tissues including brains.

Deficiencies in different subunits of the Conserved Oligomeric Golgi (COG) complex define a novel group of Congenital Disorder of Glycosylation. *G. Matthijs[1], F. Foulquier[1], E. Vasile[2], D. Ungar[3], M. Krieger[2], W. Annaert[4].*
1) Center for Human Genetics, University of Leuven, Leuven, Belgium; 2) Department of Biology, Massachusetts Institute of Technology, Cambridge, MA; 3) Department of Molecular Biology, Princeton University, Princeton, NJ; 4) Laboratory for Membrane Trafficking KULeuven and VIB04, Leuven, Belgium.

Congenital Disorders of Glycosylation (CDG) are a group of rare, genetic disorders characterized by defects in one of the many enzymes, transporters or other functional proteins, required in the glycosylation pathway. Up to now, more than 15 defects have been described, mainly in the endoplasmic reticulum (Type I) and in the Golgi compartment (Type II). Whereas these CDG cases have defects in genes encoding proteins directly involved in the glycosylation process, recent work has shown that the abnormalities may also be due to abnormal intracellular trafficking of resident Golgi enzymes or transporters involved in glycosylation. Indeed, the function of the Golgi being dependent of the correct localization of all glycosylation enzymes and other resident proteins. This process is achieved by a careful balance between of forward and retrograde traffic of cargo and resident proteins. The Conserved Oligomeric Golgi (COG) complex which is a heterooligomeric tethering complex plays a key role in the retrograde vesicular transport. Two CDG-II patients with two different COG deficiencies (COG1 and COG8) were found. They have a multi-system disease with severe neurological involvement. Both of them have a combined N- and O-glycosylation defect characterized mainly by hyposialylation. The mutations destabilize other COG subunits, and affect the subcellular localization and hence the overall integrity of the COG complex. It further suggest that the interaction between COG1 and COG8 play a central role in the formation and the functionality of the whole COG complex. Deficiencies in this complex thus define a new group of glycosylation disorder.

Identification of the first human mutations in a component of the selenocysteine incorporation machinery. *A.M. Dumitrescu[1], X.H. Liao[2], M.S.Y. Abdullah[4], J. Lado-Abeal[2], F. Abdul Majed[5], L.C. Moeller[2], G. Boran[6], R.E. Weiss[2], S. Refetoff[2,3].* 1) Human Genetics, Univ. of Chicago; 2) Medicine, Univ. of Chicago; 3) Pediatrics and Committee of Genetics, Univ. of Chicago; 4) Pediatric Endocrinology, Security Forces Hospitals, Riyadh, Saudi Arabia; 5) Prince Abdullah Hospital, Bisha, Saudi Arabia; 6) Pathology, Adelaide and Meath hospital, Dublin, Ireland.

Incorporation of selenocysteine (Sec) through recoding of the UGA stop codon creates a unique class of proteins. Several factors are required for Sec incorporation: cis-acting sequences present in the mRNA of a selenoprotein (UGA codon and Sec insertion sequence SECIS) and trans-acting factors (elongation factor eEF^{Sec}, $tRNA^{Sec}$ and SECIS-binding protein SBP2). While mice lacking $tRNA^{Sec}$ die in-utero, the in-vivo role of all other components is unknown and no Sec incorporation defects have been described in humans. Deiodinases are selenoproteins responsible for thyroid hormone (TH) metabolism by converting the precursor T_4 into the active (T_3) or inactive (rT_3) hormone. We report two families with abnormal thyroid function tests (high T_4 and rT_3, low T_3 and high TSH) suggestive of abnormal TH metabolism. Family A is of Bedouin origin with 3 of 7 siblings being affected, and family B of Irish origin with one affected child. Administration of incremental doses of T_4 and T_3 indicated that the affected have a defect in generating the active hormone T_3 from T_4. In vitro studies using patients fibroblasts showed decreased deiodinase 2 (DIO2) enzymatic activity but normal DIO2 mRNA expression. Linkage to *DIO2* locus was negative; therefore, we considered a putative post-transcriptional defect altering the availability of active DIO2 enzyme. Systematic linkage analysis with genes involved in DIO2 synthesis and degradation led to the identification of the first inherited Sec incorporation defect, caused by recessive *SBP2* gene mutations: a homozygous mutation in family A and compound heterozygous mutations in family B. Insight into consequences of SBP2 defect is novel and represents an interesting example of an epistatic effect resulting in deficiency of selenoproteins.

A new defect in -oxidation presenting as sudden liver failure. *M. He[1], S.L. Rutledge[2], D. Kelly[2], E. Goetzman[1], J. Vockley[1].* 1) Deparment of Pediatrics, University of Pittsburgh, School of Medicine, Pittsburgh, PA; 2) Department of Pediatrics, University of Alabama, Birmingham, AL.

The ACADs are a family of at least nine flavoenzymes involved in the mitochondrial -oxidation of fatty acid. Genetic disorders have been identified in seven of the ACADs. ACAD9 is a recently identified ACAD that has maximum activity with unsaturated long chain acyl-CoA substrates. The physiologic role of this enzyme remains unclear, however, as it overlaps the substrate specificity of VLCAD. While both ACAD9 and VLCAD are abundantly expressed in liver, muscle and heart, ACAD9 is highly expressed in the brain, a pattern unique among the other known ACADs. We have now identified the first patient with a deficiency of ACAD9. The patient was a 14 year old apparently healthy boy who died of sudden liver failure following an otherwise mild viral illness. An extensive clinical evaluation was inconclusive but suggested an abnormality of long chain fat metabolism. Acylcarnitine profiling of postmortem liver and skeletal muscle extracts showed elevation of unsaturated long chain species in a pattern that matched the substrate specificity of ACAD9. Autopsy revealed hepatosteatosis and moderate to severe chronic neuronal loss in brain, mirroring the expression profile of ACAD9. Western blotting confirmed absence of ACAD9 in patient fibroblasts and significantly decreased levels in liver and muscle, while northern blotting of mRNA revealed a marked reduction of mRNA of normal size and the presence ACAD9 mRNA of abnormal size. PCR analysis of fibroblast and liver mRNA failed to detect normal ACAD9 species. Instead, multiple mis-spliced species were present, suggesting a defect in splicing. Sequencing of ACAD9 genomic DNA from the patient identified a promotor mutation on one allele that led to dramatically decreased transcription, while several potential pathogenic intron changes near intron-exon boundaries were present on the other allele. The dramatic and sudden nature of this patient's clinical presentation makes it imperative to further characterize of this disorder in individuals with unexplained liver failure and to identify the full spectrum of symptoms.

MMAHCC is mutated in patients with methylmalonic aciduria and homocystinuria, _cblC_ type. *J.P. Lerner-Ellis[1,3], J.C. Tirone[1,3], P.D. Pawelek[2], C. Doré[4], J. Atkinson[5], T.M. Fujiwara[1,3], D. Watkins[3], C.F. Morel[1,3], E. Moras[1,3], A.R. Hosack[3], C.M. Dobson[6], R.A. Gravel[6], P. Lepage[4], J.W. Coulton[2], J.M. Rommens[5], K. Morgan[1,3], D.S. Rosenblatt[1,3].* 1) Dept. Human Genetics, McGill Univ., Montreal, QC; 2) Dept. Microbiology and Immunology, McGill Univ., Montreal, QC; 3) Div. Medical Genetics, Dept. Medicine, MUHC, Montreal, QC; 4) McGill Univ. and Genome Quebec Innovation Centre, Montreal, QC, Canada; 5) Dept. Molecular and Genomic Biology, Univ. of Toronto, Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 6) Dept. Biochemistry and Molecular Biology, Univ. of Calgary, Calgary, AB, Canada.

Methylmalonic aciduria and homocystinuria, *cblC* type (OMIM 277400) (*cblC*) is the most common inborn error of vitamin B_{12} metabolism with over 250 cases now known. Clinical findings include developmental, hematologic, neurologic, metabolic, ophthalmologic, and dermatologic manifestations. There are at least two distinct phenotypes differentiated by the age of onset. The most severely affected patients present in the first year of life with systemic, neurologic, hematologic, and ophthalmologic findings. Among patients who come to medical attention after the age of 4 years, neurologic symptoms are predominant. We identified the *MMAHCC* gene in chromosome region 1p34.1 and found 17 different mutations in 31 *cblC* patients. A single mutation (c.271dupA, p.R91K-fsX14) accounted for 41% of mutant alleles and, when homozygous, was associated with severe early-onset disease. A nonsense mutation (c.331C>T, R111X) was homozygous in two unrelated patients of Cajun origin, who also had early-onset disease; another nonsense mutation (c.394C>T, R132X) was homozygous in a patient of Pakistani origin, who presented only at 12 years of age. Mutations in *MMAHCC* are consistent with a loss of function of the protein product and several correlate with the age of onset of disease. Molecular modeling predicts that the C-terminal region of the gene product folds similarly to TonB, a bacterial protein involved in energy transduction for vitamin B_{12} uptake. The TonB-like domain may function in protein-protein interactions.

Biochemical characterization of a murine model of mut class methylmalonic acidemia suggests an important role for skeletal muscle in the production of metabolites. *R.J. Chandler, A. Chen, C.P. Venditti.* Genetic Diseases Research Branch, NHGRI, NIH, Bethesda, MD.

The hereditary of methylmalonic acidemias are a devastating group of autosomal recessive metabolic disorders caused by a defect in the isomerization of L-methylmalonyl-CoA to succinyl-CoA. To study this condition, we have generated two new null alleles at the murine methylmalonyl-CoA mutase (MCM) locus and characterized the biochemical phenotype of the mutant animals. One allele has loxP sites flanking the initiator encoding second exon and is in cis with a deletion of the coenzyme A binding pocket encoded by the third exon. The other allele has the second and third exons of the MCM gene removed and replaced by a single loxP site. The homozygous mutant animals display many features seen in the human condition, including massive elevations of MMA in body fluids and increased production of 2-methylcitrate. Metabolite measurements were made in the prenatal and neonatal periods on brain, liver, kidney, skeletal muscle, urine and plasma. Plasma MMA levels in utero are elevated in affecteds (176uM) versus controls (6uM). Significant increases in the plasma compartment occur over time as the mice become ill and eventually perish but plasma levels never exceed 1.5 mM, even at the end of life. In the first few hours after birth, the MMA content per gram wet-weight is highest in the muscle and kidney. Changes occur near the end of life, with massive elevations in the liver predominating, followed by skeletal muscle, kidney and brain. Murine embryonic fibroblasts derived from homozygous animals show diminished C14-propionate incorporation and can be partly corrected by retroviral transduction with a wild-type murine cDNA. The characterization of the phenotype in this murine model provides insight into the human condition, particularly the persistent MMAemia/uria seen in patients who have received combined liver-kidney transplants and suggests that during homeostasis, the bulk of the plasma MMA in patients derives from the skeletal muscle. A metabolic profile in the mutant animals has been established and will allow future transgenic, viral and enzymatic therapies to be assessed.

Molecular Analysis of *AASS* in Familial Hyperlysinemia (FH). *N. Braverman[1], A. Lossos[2], U. Vester[3], E. Christensen[4], R.P. Cox[5], M.T. Geraghty[6], N.M. Kim[1].* 1) Johns Hopkins Med Ctr, Baltimore, MD; 2) Hadassah University, Jerusalem, Isreal; 3) Univ. of Essen, Germany; 4) Righospitalet, Copenhagen, Denmark; 5) Univ. Texas Southwestern Med Ctr, Dallas, Tx; 6) CHEO, Ottawa, Canada.

Inborn errors of lysine catabolism represent a rare group of incompletely characterized disorders manifesting with hyperlysinemia, saccharopinuria, aminoadipic aciduria or pipecolic acidemia. One of these, FH, is due to deficiency of the bifunctional enzyme, -aminoadipic semialdehyde synthase (AASS), which catabolizes lysine to saccharopine (lysine ketoglutarate reductase, LKR), and then to -aminoadipic semialdehyde (saccharopine dehydrogenase, SDH) and results in markedly elevated lysine in body fluids.
Less than 50 patients with FH have been described; around half have mental retardation and spasticity. However, molecular analysis has been reported for only one. We report here 9/10 *AASS* mutant alleles in 5 additional probands with FH and psychomotor retardation. These variations were not identified in 100 control genes. Furthermore, we show by RTPCR and sequencing that *AASS* undergoes alternative splicing in several tissues to produce transcripts corresponding to monofunctional SDH and LKR. To determine the effect of the missense changes on AASS activity, we developed an assay in which expression of human AASS and monofunctional SDH rescue the growth phenotype for SDH deficient yeast in lysine free media. In this system, expression of these proteins containing the patient mutations did not rescue. Finally, we localized epitope tagged-AASS and its isoforms to the mitochondria in human cells by indirect immunofluorescence. The relationship between FH and psychomotor retardation is unclear. One of our probands, the product of a consanguineous union, has a similarly affected brother and affected, but asymptomatic parents. We suggest that FH is necessary but not sufficient for neurological disease. The presence of mono- and bifunctional enzymes enables more complex regulation of lysine catabolism that might be important in determining phenotype. Ultimately these investigations will provide better understanding of phenotype determination in FH.

Secondary creatine deficiency in ornithine delta-aminotransferase deficiency. *K. Mention, N. Boddaert, S. Romano, L. Hubert, J. Kaplan, J.L. Dufier, V. Valayanopoulos, F. Brunelle, J.M. Saudubray, A. Munnich, P. de Lonlay.* Hôpital Necker-Enfants Malades, Paris, Paris, France.

Ornithine delta-aminotransferase (OAT) deficiency is an autosomal recessive condition causing gyrate atrophy of the retina responsible for blindness during the first decade, as a consequence of high plasma ornithine concentrations. Because creatine synthesis requires the reversible conversion of arginine and lysine into ornithine and guanidinoacetate, secondary creatine deficiency was expected to occur in OAT. The aim of this study was to evaluate creatine metabolism in OAT deficient patients and establish correlations with the severity of the neurological involvement. A retrospective study included 7 OAT deficient patients, aged from 12 to 28 years. The median age at diagnosis was 10 years (9-12 yrs). Interestingly, the highest plasma ornithine levels (900mol/l, N<100) were found in children with cognitive and behaviour problems (5/7), with severe mental retardation (4/7, IQ 50-60), leading to special schooling (3/7) and epilepsy (2/7). One patient had hyperactivity and severe behaviour disorder but no mental retardation (IQ=80). Two patients with mean plasma ornithine at 400mol/l had normal neuro-psychological evaluation (IQ = 80) and normal schooling. Cerebral 1H magnetic resonance spectroscopy revealed a striking creatine deficiency in the 4/7 mentally retarded OAT deficient patients and in the patient with severe behaviour disorder but not in the two patients with no mental retardation. These data were confirmed by decreased levels of plasma and urinary creatine and guanidinoacetate (plasma creatine <5mmol/l, N between 6 and 50; urinary creatine 20 mmol/mmol creatinine, N: 17-720; plasma guanidinoacetate 0.5mmol/l, N: 1-3.5; urinary guanidinoacetate <3 mmol/mmol creatinine, N >4). In conclusion, we provide here the evidence of secondary creatine deficiency in OAT deficiency. Moreover we show that the level of creatine deficiency correlated with the severity of mental retardation and hyperornithinemia. The evidence of cerebral creatine deficiency in the disease may be clinically important as creatine administration may improve the clinical course of the disease.

Expanded Newborn Screening identifies maternal primary carnitine deficiency. *S.A. Berry[1], K. Bentler[1], M. McCann[3], N. Longo[4], M. Pasquali[4], P. Rinaldo[2], D. Matern[2], L.A. Schimmenti[1].* 1) Dept Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Biochemical Genetics Laboratory, Mayo Clinic, Rochester, MN; 3) Minnesota Department of Health, Minneapolis, MN; 4) Dept Pediatrics, Univ Utah, Salt Lake City, Utah.

Expanded newborn screening (NBS) has resulted in tremendous improvement in early identification and treatment of newborns with disorders of fatty acid oxidation and other inborn metabolic errors. An additional benefit of expanded NBS is the identification of previously undiagnosed maternal metabolic conditions. We report the detection of maternal primary carnitine deficiency in two unrelated mothers through expanded NBS in the state of Minnesota. Newborn screening blood spot free carnitine values for two full-term, uncomplicated births were 3.1 uM/L and 2.5 uM/L (abnormal low<7) respectively without elevation of acylcarnitine species. Follow up studies of their asymptomatic mothers showed carnitine depletion, with plasma free carnitine values of 5 uM/L and 2 uM/L (LLN 25 uM/L). Neither mother had a history of hospitalization for Reye-like illness or cardiomyopathy and both had normal echocardiograms. Both infants were treated with low dose oral L-carnitine with rapidly increasing carnitine levels. Both mothers were treated with oral L-carnitine. After 8 months of treatment, one mother has normal plasma free carnitine levels (35 uM/L) on 2 g carnitine/day while after 6 months of treatment the second mother continues to have low plasma free carnitine levels (4 uM/L) despite dosage of 3 grams of carnitine/day. Fibroblast uptake studies show that each mother has defective carnitine uptake, 17% and 3.3% of controls respectively. Mutation analysis of the gene encoding OCTN2 is pending. These cases demonstrate an added value of expanded NBS: diagnosis of unforeseen maternal metabolic disorders.

Fabry disease: Early clinical manifestations and age at clinical events in a cohort of 1214 males and females. *C.M. Eng[1,2], W.R. Wilcox[2], S. Waldek[2], G. Linhorst[2], D. Germain[2], J. Charrow[2], C.R. Scott[2], F. Breunig[2], M. Banikazemi[2].*
1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) North American and European Fabry Registry Board of Advisors.

Fabry disease (FD) is an X-linked lysosomal storage disorder due to the deficiency of a-galactosidase A and accumulation of globotriaosylceramide (GL-3) in visceral tissues and body fluids. The early mortality is caused by end stage involvement of kidney, heart and brain. Enzyme replacement therapy for FD has been shown to clear the vascular endothelial accumulation and to decrease the incidence of significant clinical events in treated patients. Early institution of therapy may prove most effective; however, failure to diagnose affected individuals based on recognition of early symptoms compromises these efforts. The Fabry Registry (www.FabryRegistry.com) was analyzed to determine presenting symptoms, age at diagnosis, and age at clinical events in 1214 individuals with FD (males N=694 and females N=520). The median age of diagnosis was 24 yr for males (N=667) and 34 yr for females (N=476). Males with FD presented with symptoms at a median reported age of 9.0 years (N = 492). Males with FD had initial presenting symptoms most commonly present in the neurologic system (62%) (with 58% responding reporting pain), followed by skin (28%), gastroenterologic (19%), and renal (14%). Females with FD presented with symptoms at a median age of 12.0 years (N=253). At presentation, females had symptoms most commonly present in neurologic (43%), specifically pain (39%), ophthalmologic (13%), gastroenterologic (13%) and skin (11%). Information was collected regarding the age at which a serious complication occurred in a target organ. The mean age (SD) was 39.8 yr (9.8) (N=130 events reported) for dialysis or kidney transplantation, 41.5 (13.3) (N=259) for cardiac events (myocardial infarction, arrhythmia, angina, congestive heart failure or significant cardiac procedure), and 41.3 (11.9) (N=85) for cerebrovascular events (stroke). Awareness of the early course of FD and common presenting signs and symptoms in males and females may lead to improved recognition and outcome for affected individuals.

Dysfunction of endocytic and autophagic pathways in a lysosomal storage disease. *T. Fukuda, K. Zaal, E. Ralston, P. Plotz, N. Raben.* NIAMS/NIH, Bethesda, MD.

The lysosomal storage disorders are a group of more than forty diseases characterized by accumulation of undigested substrate in the lysosomes. In Pompe disease, a deficiency of acid alpha-glucosidase, glycogen accumulates primarily in cardiac and skeletal muscle. Ongoing clinical trials with recombinant human enzyme (ERT) and our pre-clinical studies with the recombinant or transgenic enzyme in KO mice have demonstrated that glycogen is cleared well from cardiac but not skeletal muscle. This modest outcome of ERT highlights the gaps in knowledge of the pathogenesis of the disease and of the downstream pathways affected as a result of lysosomal enlargement. Analysis of the KO myoblasts has shown that the deficiency results in a broad secondary expansion of all vesicles of the lysosomal degradative system. Real-time imaging revealed the overcrowding and stasis in the diseased cells as shown by significantly decreased and disordered movement of late endocytic compartments in KO cells. Similar changes, which may occur in several lysosomal diseases, were found in skeletal muscle from KO, but despite these changes, type I fibers respond better to ERT than type II fibers. We have found that various lysosomal trafficking proteins - CI-MPR, clathrin, TfR, adaptor protein AP-1 and AP-2, and GGA2 - are much less abundant in type II than type I fibers, suggesting that intrinsic properties of different fiber types may contribute to resistance to therapy. But the most striking difference between the fiber types is that only type II fibers from the KO contain enormous regions of autophagic buildup that span the entire length of the fibers. These regions can be seen best by confocal microscopy of isolated single type II fibers. Furthermore, the autophagic vacuoles remained abundant in ERT-treated type II fibers. We suggest that the role of the enzyme in skeletal muscle is broader than previously thought, and that the pathogenesis of the disease is different in the two fiber types. The vastly increased regions of autophagy, a process known to be induced by starvation, may cause skeletal muscle destruction and prevent efficient delivery of the therapeutic enzyme.

Is a genetic questionnaire as accurate as pedigree analysis in the evaluation of genetic infertility and risks to offspring? *K.L. Danziger[1], M. Brown[1], L.D. Black[2], P.J. Turek[1].* 1) University of California, San Francisco, San Francisco, CA; 2) California Pacific Medical Center, San Francisco, CA.

Introduction and Objective: For couples seeking fertility care, a comprehensive family history assessment can add valuable information about genetic etiology and possible risks for offspring. To elicit personal and family history information, we created a genetic questionnaire and asked whether it could capture information similar to pedigree analysis. Here, we report our findings on comparison of these two instruments. Methods: A consecutive series of infertility patients completed a genetic questionnaire. These patients also had a formal genetic pedigree obtained by a genetic counselor. We compared the ability of these 2 instruments to elicit information concerning 5 areas of personal and family medical history: recurrent miscarriages, stillborn births, developmental delay/learning disabilities/mental retardation, heart defects, and birth defects. The pedigree was considered the gold standard and the genetic questionnaire scored against it for accuracy. Results: Among 104 completed questionnaires and pedigrees, 76 (73 %) patients indicated relevant genetic information in one of the 5 key areas. A comparison of all findings elicited by the two methods revealed that 61 (80%) patients failed to report key genetic information that was ascertained by formal pedigree analysis. Specifically, the questionnaire missed 21/28 (75%) occurrences of stillborn births, 21/24 (88%) cases of birth defects, 14/20 (70%) cases of developmental delay/learning disabilities/mental retardation, 12/14 (86%) cases of miscarriages, and 11/13 (85%) cases of congenital heart defects. Conclusions: Family history information may provide valuable information to infertile couples about the causes and implications of their infertility. As this study shows, accuracy of family history information depends on ascertainment method. A comprehensive family medical history questionnaire is not as reliable for capturing relevant, genetic information as a pedigree analysis. The optimal method to ascertain such information will become more important as our knowledge of genetic infertility and its implications expands.

ALTERNATIVES TO TRADITIONAL GENETIC COUNSELING: USE OF AN EDUCATIONAL PRECOUNSELING CD-ROM. *S. Bhatt[1], T. Cousineau[2], D. Cutillo[1], A. Cronister[1].* 1) Genzyme Genetics, Orange, CA; 2) Inflexxion, Newton, MA.

Traditional prenatal counseling involves meeting with a genetic counselor to review the referral indication and discuss appropriate testing based on individual risk assessment. With the expanding knowledge about carrier testing, genetic counselors find themselves spending more time reviewing information unrelated to the referral indication. For patients, this results in decreased satisfaction and value of the counseling session. As a precounseling tool, an educational CD was developed to address repetitive information such as carrier testing, serum screening and diagnostic options. Two patient surveys were conducted, one by patients who had genetic counseling only, and a second by patients who viewed the precounseling CD followed by genetic counseling. Both surveys focused on patients' understanding of and decisions about genetic testing. The CD survey also asked about the ease of use and length of the CD. Results were compared to determine the usefulness of the CD. 202 patients were surveyed from four clinics in three states. 56 patients completed the GC only survey and 146 patients completed the CD survey. 97% found the CD easy to use, and 93% said it adequately addressed genetic testing information. In addition, 97% in the CD survey group indicated a good to excellent understanding of available testing, which was no different than the GC only group. The main difference noted was in the area of patient decision making. Overall and prior to counseling, about 30% of patients indicated they had already made up their mind about genetic testing; 20%; were willing to reconsider their decision and 50% had not begun, were in the process or would make a decision after learning about options. Although 40% of patients said that the CD helped them to make decision regarding genetic testing, a greater number of patients (63%)said that the genetic counseling further influenced their decision about genetic testing. Our survey indicates that the CD is easy to use and provides an excellent adjunct to the genetic counseling session. Genetic counseling continues to provide a setting for discussion of patients' specific issues and making decisions regarding testing.

Recontacting research participants: Implications for genetic banking studies. *M.E. Smith, S.A. Aufox, R.L. Chisholm, W.A. Wolf.* Ctr Genetic Medicine, Northwestern Univ, Chicago, IL.

NUgene is an IRB approved gene bank, established in 2002 at Northwestern University. Participants are recruited from a diverse population receiving care through a Northwestern University healthcare affiliate. During the consenting process, participants agree to the broad use of their DNA sample in genetic research. Initial IRB approval of the project was granted on the condition the consent form allow participants to indicate their preference to be contacted in the event that medically significant results were found during the conduct of research. The IRB was asked to reconsider this option based on ethical concerns and in November 2004 granted the request and the option was removed. An IRB approved letter and consent form addendum, allowing participants to indicate their preference about remaining in the study, were mailed to 1647 participants who had agreed to this option. Participants were informed they could indicate their decision about remaining in the study by mail, phone, or through a secure website. Between February and April 2005, letters were sent using the contact information provided during the time of enrollment. Eighty letters (4.9%) were returned as undeliverable. As of June 1, 2005, 689 individuals responded(41.8%), 551(80%) agreed to continue participation in NUgene. Of the 97(14%) declining to continue participation, the majority indicated the change in study protocol as their main reason for withdrawing. Few reports in the literature describe experiences recontacting participants in a large DNA bank. Most respondents appeared to understand the initial consent form and were willing to participate regardless of receiving personal results. Contacting and reconsenting research participants was challenging even though participants provided information for this purpose. Some researchers and ethicists have proposed that participants in DNA banking projects, like NUgene, should be consented for each study using their sample. These results may have implications for the use of blanket consent forms in genetic research and the difficulty in recontacting and obtaining consent for specific studies.

Direct contact, without considering the index patient, to offer information and counseling to HNPCC-families. *H. Kääriäinen[1], K. Aktan-Collan[2], K. Pylvänäinen[3], J-P. Mecklin[3].* 1) Department of Medical Genetics, University of Turku, Turku, Finland; 2) Department of Clinical Genetics, Hospital District of Helsinki and Uusimaa, Helsinki, Finland; 3) Department of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland.

In familial cancer syndromes, the relatives are usually offered genetic counseling, follow up examinations and/or genetic testing via the index counselees (cascade screening). In many families, however, there are branches that cannot be approached by this method. The purpose of our study was to evaluate the consequences of direct contacting of relatives in HNPCC-families without help or even consent from the index counselees.

We approached 247 high risk HNPCC-family members by a letter explaining that we do research in hereditary cancer and would like to have their written consent to receive a phone call from our research assistant (KP). After the phone call, 144 (46%) accepted to come to genetic counseling and fill in pre- and post-counseling/post- testing questionnaires. Those accepting were younger, male, and married or co-habiting more often than their counterparts. In the counseling, we did not reveal any health data of the relatives but just stated that we knew that there was HNPPC in the family and that we believed that the individual concerned had a 50% risk of having inherited the mutation. Of those accepting, 97% knew that a near relative had cancer, 3/4 felt that there was more cancer than usual in their family and 9/10 thought that directly contacting them had been a good thing.

This positive attitude encourages us to suggest that in cancer families direct contact to the relatives, without considering the index counselees opinion, is acceptable. It has even been stated that, in agreement with the paradigm that genetic information can be considered to be the property of the family, the professionals have a moral duty to try to inform relatives if the proband is unwilling to do so (De Wert: Whose information is it anyway? Eur J Hum Genet 2005:13:397-398).

The trouble with phenocopies: are those testing negative for a family BRCA1/2 mutation really at population risk? *D.GR. Evans[1], A. Smith[1], MC. Boyd[1], M. Bulman[1], E. Woodward[2], L. Smith[2], A. Moran[1], F. Lalloo[1], E.R. Maher[2].* 1) Genetics, St Mary's Hospital, Manchester UK, United Kingdom; 2) Dept of Human Genetics, Birmingham womens Hospital, Birmingham UK.

Background: The identification of BRCA1 and BRCA2 mutations in familial breast cancer kindreds allows the option of genetic testing of at risk relatives Those who test negative are usually reassured and extra breast cancer surveillance discontinued. However, we postulated that in high-risk families such as those seen in clinical genetics centres, the risk of breast cancer might be influenced not only by the BRCA1/BRCA2 mutation but also by modifier genes. One manifestation of this would be the presence of phenocopies (ie. individuals with breast cancer but without the mutation) within BRCA1/BRCA2 kindreds. Methods: We reviewed 277 families with pathogenic BRCA1/2 mutations and identified 28 breast cancer phenocopies. We assessed the relative risk of breast cancer in those testing negative using incidence rates from our local population based cancer registry. Results: Phenocopies constituted 16% of tests on women with breast cancer following the identification of the mutation in the proband. The standardised incidence ratio for breast cancer for women who tested negative for the BRCA1/BRCA2 family mutation was 5.3 for all relatives, 5.0 for all first-degree relatives (FDRs) and 3.2 (95% confidence interval: 2.0-4.9) for FDRs in whose family all cases of breast and ovarian cancer could be explained by the identified mutation. 13/107 (12.1%) of FDRs with breast cancer and no unexplained family history tested negative. Conclusion: In high risk families, women who test negative for the familial BRCA1/BRCA2 mutation had an increased risk of breast cancer consistent with genetic modifiers. In the light of this such women should be offered continued surveillance.

Different causes and outcomes of splicing defects in *PTEN*. *S. Agrawal, R. Pilarski, C. Eng.* Human Cancer Genetics, Ohio State University, Columbus, OH.

PTEN, encoding a dual phosphatase tumor suppressor, is mutated in 85% and 65% of individuals with classic Cowden Syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS), respectively. Approximately 23 germline mutations in putative splice sites have been published, but resulting downstream outcome data are limited. We sought to systematically determine splicing defects in *PTEN* in 40 germline PTEN mutation positive and 33 mutation negative cases with classic CS, BRRS and CS- or BRRS-like features, in the first instance. Altered splicing was observed in 4/40 mutation positive probands and 2/33 mutation negative probands. Two splice site mutations (IVS 3+1GA, IVS 3+5 GA) led to the splicing out of exon 3, (IVS 3-1 GA) led to exon 4 skipping and another (IVS 6+1 GT) deleted exon 6. Interestingly, 2 mutation negative BRRS patients skipped exon 3, and later genomic sequencing revealed a mutation (IVS 2-38 insG) in what could be a conserved branch site (UGUUAAU) in intron 2. We then sought to characterize the transcriptional and biochemical outcome of these 5 distinct splice site mutations, which led to the skipping of exon 3, 4 or 6. The splice site mutations leading to deletions of exon 3, 4 or 6 resulted in reduced lipid and protein phosphatase activities of PTEN. Deletion of exon 4 was associated with severely reduced lipid phosphatase activity, whereas the samples with exon 3 skipping had markedly reduced protein phosphatase activity. Furthermore, exon 3 deleted transcript and protein were stable and localized to the nucleus more efficiently than the wild-type PTEN. In contrast, exon 4 skipping resulted in unstable transcripts and severely truncated unstable PTEN protein lacking its phosphatase domain. We have therefore not only described for the first time, the effect of a deep intronic/branch site mutation on exon skipping in *PTEN*, but also found that different splice site mutations resulting in deletion of different exons lead to distinct outcomes.

Patient Attitudes Towards Follow-Up Letters Provided After Genetic Counseling for Inherited Cancer Risks. *E. Rosenthal, L. Madlensky.* Moores UCSD Cancer Ctr, La Jolla, CA.

Many cancer genetics clinics provide patients with detailed follow-up (F/U) letters summarizing the content of clinic visits. These are distinct from clinic notes used to communicate with other health care providers. Preparation of these letters is time-consuming, but very little systematic research has documented how many patients perceive these letters as useful for themselves and other family members, what content is most valued, the extent to which letters improve understanding and compliance with recommendations, and which formats are most effective. To begin addressing some of these issues we surveyed patients who had received a detailed F/U letter following genetic counseling for hereditary cancer risk at the UCSD Cancer Center between 04/01/01 and 01/30/04. Survey questions addressed demographics, patients assessment of their letters clarity, comprehensiveness, accuracy and usefulness, and attitudes towards the use of the letter as a mechanism for disseminating information within families. Of 220 invited participants, 130 (60%) completed surveys. Most participants were highly educated, Caucasian, and affluent. 80% indicated that they actively seek out health information. Overall, 94% reported reading their letter carefully, with 65% reading it more than once. 80% had retained a copy. Patients expressed high levels of satisfaction with all aspects of the letters. The majority (85 to 95%) characterized the letters as clear, comprehensive, and an accurate summary of their genetic counseling sessions. The greatest expression of dissatisfaction was that 20% would have liked more medical information. A high proportion of patients (79 to 98%) felt the letter would be a useful way to share information with varioius relatives, but a much lower percentage (10 to 33%) reported that they had actually shared their letter. The results of this exploratory study show that these patients appreciate and are satisfied with F/U letters. Further research is needed to explore other formats of providing summaries of the complex information discussed in genetic counseling sessions, particularly in more diverse patient populations.

The Genetic Discrimination Project: benefit, disadvantage and negative treatment associated with genetic information in an Australian sample of clinical genetic service clients - Australian and international implications.

K. Barlow-Stewart[1], S. Taylor[2], S. Treloar[2,3], M. Stranger[4], M. Otlowski[4]. 1) Centre for Genetics Education, NSW Genetics Service, Royal North Shore Hosp, Sydney, NSW, Australia; 2) School of Social Work & Applied Human Sciences, The University of Queensland, Australia; 3) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 4) The School of Law, University of Tasmania, Tasmania, Australia.

Genetic discrimination is defined as differential treatment, either positive or negative, of asymptomatic individuals on the basis of real or assumed genetic status. The Genetic Discrimination Project (GDP) has investigated the experiences of a sample of Australian adults who presented at 15 clinical services regarding predictive genetic testing for various conditions between 1998 and 2003. Of 2362 individuals who received a questionnaire, 1185 (50.2 percent) responded. This paper reports findings relating to respondents perceptions and experiences of benefit, disadvantage and negative treatment associated with having genetic information. On scales measuring perceived overall benefit and disadvantage, 94 percent (905/959) of respondents gave scores indicating some to great benefit and 47 percent (438/932) gave scores indicating some to great disadvantage. Variations occurred across conditions and perceptions of benefit and disadvantage were significantly associated with test result. Specific incidents of alleged negative treatment or discrimination against asymptomatic individuals involving life insurance products,employment, health professionals and family relations were reported by 7.3 percent (87/1185) of respondents. Data contextualising perceived benefits and disadvantage, incidents, responses to them by the consumers and third parties and perceived barriers to making complaints are presented. These 87 accounts comprise part of a total of around 100 accounts of alleged discrimination and negative treatment within this first empirical study that will inform public policy both in Australia and internationally.

Physician Knowledge and Opinions on Genetic Discrimination. *K. Lowstuter[1], S. Sand[1], C. Lee[2], B. Schwerin[3], G. Uman[4], K. Blazer[1], J. Weitzel[1].* 1) City of Hope Cancer Center, Duarte, CA; 2) California Medical Assoc Foundation, Sacramento, CA; 3) Cancer Legal Resource Ctr, Los Angeles, CA; 4) Vital Research, LLC, Los Angeles, CA.

There is concern that many physicians have inadequate knowledge of genetic discrimination or protective legislation. Perceptions about genetic discrimination may limit access to genetic testing and consequently to risk-appropriate cancer screening and prevention. To explore physician knowledge and opinions on genetic discrimination law, and the extent to which these influence referral practices, we are surveying a representative sample of the 35,000 California Medical Association (CMA) member physicians. **Methods** The survey contains demographic items and 37 items on knowledge, practice, and opinions regarding genetic testing for cancer predisposition. Invitation letters and pre-qualification postcards were sent to a stratified random sample of 1601 CMA members. The survey is available online or on paper. Interval reminders were sent to non-responders using a modified Dillman method (Dillman et al 1974). **Preliminary Results** Of the 226 responders to date (target N=400), 85% chose to complete the online version of the survey rather than paper (p0.001). More agreed with the statement that genetic testing creates health insurance problems for patients without cancer (54%)than for those with cancer (44%) p=0.038. The majority (64%) did not know that federal law prohibits health insurance discrimination in the group market on the basis of genetic information. Of the 83 respondents (37%) who have never referred patients for genetic cancer risk assessment, 17% indicated concern over health insurance discrimination as the reason and 43% stated the referral process was unclear. **Conclusions** Consistent with our previous observations in a population of clinicians attending CME activities at our cancer center (Nedelcu et al 2004), results to date indicate gaps in knowledge and misperceptions that may lead to barriers to referral for cancer risk assessment. Comprehensive and well-publicized protective federal legislation along with direct physician education may help promote access to appropriate care.

Whose Genetic Profile Is It Anyway? Challenges in Forensic Investigations. *A. Chidambaram, M. Collins, C. Duda, J. Cohen, J. Schuerman, H. Hamilton, C. Beheim.* Alaska State Crime Detection Laboratory, Anchorage, AK.

The need to establish and enforce guidelines for appropriate use of genetic information for medical or research purposes has been widely acknowledged. Varying degrees of state specific regulations currently exist in this country to protect people's right to confidentiality pertaining to their genetic make-up. The US Senate has unanimously voted to pass the Genetic Information Nondiscrimination Act of 2003 (S. 1053). This may adequately address genetic privacy issues regarding equal access to health insurance and employment decisions if the ownership of the genetic information is not in question. However, in the case of identical twins, where 2 individuals have identical genetic profiles, one twin's forfeiture of the right to privacy, voluntarily or involuntarily, could affect the other twin who might be disinclined to compromise his or her genetic privacy. Genetic analysis in forensic investigations can pose ethical dilemmas when defining or determining what constitutes ownership of a genetic profile. Database entry of a convicted (twin) felon's genetic profile automatically enters that of the other twin as well. Requesting fingerprint data to distinguish between the twins could also be viewed as violation of privacy rights. Ethical and analytical dilemmas also arise when one person has 2 distinct genetic profiles. If identified as a suspect in an investigation, a bone marrow transplant recipient's medical history may be subject to disclosure to enable collection of reference sample(s) from appropriate biological tissue(s) to make meaningful genetic comparisons with other forensic sample data. The transplant recipient as well as the donor's right to medical and genetic privacy is in jeopardy here. Civil litigation such as paternity disputes can also be adversely affected by such circumstances. Informed consent policy protocols and education regarding the health, legal / forensic as well as social / ethical implications of undergoing certain medical procedures are necessary as medical technology and human identification methodologies continue to outpace and challenge legal and social expectations of an individual's right and priviledge to privacy.

A targeted chromosomal microarray for CGH-based analysis of clinically relevant chromosomal disorders and subtelomeric regions. *S. Cheung, C. Shaw, J. Li, Z. Ou, A. Patel, E. Brundage, S. Yatsenko, L. Cooper, S. Trilochan, P. Ward, P. Stankiewicz, W. Cai, J. Lupski, C. Chinault, A. Beaudet.* . Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

A CGH-based microarray was developed for clinical diagnosis of well-characterized chromosomal disorders while minimizing detection of variations of uncertain clinical significance. This array contains 366 FISH-verified clones that span genome regions implicated in over 55 known human genomic disorders. The array has multi-clone replication for each disease, with an average of 3-4 clones representing each deletion or duplication syndrome, and 4 or more clones for 41 subtelomeric regions to integrate information and to enhance the specificity and sensitivity of our findings. To accomplish the data integration, we developed custom analysis software in R open source statistical computing language. Our system is also integrated with a relational database so that historical results can be mined to identify polymorphic clones and their genomic contexts. To date, we have completed 728 analyses in which chromosome tests were previously reported normal or performed simultaneously. We identified 1) clinically relevant and well characterized disorders in 47 cases, and 2) deletion and reciprocal duplications of a region in 15q11.2 that includes the breakpoint 1 region for Prader-Willi syndrome (8 cases), the NF1 region in 17q11.2 (2 cases), and the STS and SHOX regions in Xp22.32 and Xp22.33, respectively (4 each). We also detected other single clone abnormalities leading to discovery of genomic imbalances of the nearby region. The major advantages of this selected human genome array include: interrogation of clinically relevant genomic regions, the ability to test for a wide range of duplication and deletion syndromes in a single analysis, and ease of confirmation of suspected genomic changes by conventional FISH tests currently available in the cytogenetics laboratories. Although not intended to substitute for a standard karyotype, this array is an attractive alternative to telomere and locus-specific FISH analysis. Additional results from an updated V.5 array with 860 clones will also be presented.

Identification of cytogenetic abnormalities by microarray analysis: a study of 1,300 consecutive clinical cases.
L.G. Shaffer, C.D. Kashork, B.C. Ballif, B.A. Bejjani. Signature Genomic Laboratories, LLC, Spokane, WA.

Array-based comparative genomic hybridization (CGH) allows for the simultaneous interrogation of hundreds or thousands of discrete loci for the detection of unbalanced chromosomal constitutions. We present the results of the largest study to date of 1,300 consecutive clinical cases submitted to our diagnostic laboratory for array CGH. Clinical geneticists submitted most cases, with a smaller proportion submitted by neurologists, developmental specialists, and pediatricians. Our laboratory uses the SignatureChip^{TM}, which was designed to detect the common microdeletions, reciprocal microduplications, subtelomeric and pericentromeric alterations, unbalanced translocations, and aneuploidy. The design also allows for distinguishing the common-sized microdeletions that are flanked by low-copy repeats, from larger deletions, through the use of flanking control loci. The array utilizes 831 BACs covering 126 clinical and 104 control loci in 3-6 clone contigs. If the case was known to us to have a chromosome abnormality submitted for clarification, that case was not included in this report. Of the 1,300 clinical cases submitted to our laboratory for diagnostic testing, most had previous or concurrent cytogenetic analysis, subtelomere FISH, and/or locus-specific FISH. We identified DNA copy number alterations in 108 (8.3%) cases. Of these, 22 (1.7%) represent population variants; in 13 (1.0%) cases, the clinical significance is unclear because parental samples were unavailable for testing; and in 73 cases (5.6%) clinically relevant abnormalities were identified. In this latter group, 22 telomeric deletions or unbalanced rearrangements were identified. Interestingly, 21 cases showed syndromic deletions. Our data demonstrate that targeted array CGH detects a substantial proportion of abnormalities even in patients who have already had extensive cytogenetic/FISH testing. Further use of this approach will expand the phenotypes of recognized cytogenetic disorders, uncover the chromosomal etiology of known syndromes, and identify new syndromes.

Array-MAPH: A novel microarray technology for genomic analysis. *A. Kurg[1], K. Männik[1], L. Kousoulidou[2], C. Sismani[2], C. Pitta[2], D. Andreou[2], O. Zilina[1], S. Parkel[1], C. Tryphonos[2], C. Antoniadou[2], N. Tõnisson[1], P. Palta[1], T. Möls[1], M. Remm[1], P.C. Patsalis[2].* 1) Inst. of Molecular & Cell Biol, University of Tartu, Tartu, Estonia; 2) Dept. of Cytogenetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

The development of accurate and sensitive genome-wide screening methods to detect small genomic imbalances has been a technical challenge for a long time. The focus of this study was to develop a new array-based technology using Multiplex Amplifiable Probe Hybridization (MAPH) principle that will enable the fast, accurate and reliable determination of copy-number changes in any loci of complex genomes. We have developed methodology and software for designing of PCR-amplifiable hybridization probes (200-600 bp) that can be used for microarray MAPH and Comparative Genomic Hybridization (CGH). Probe uniqueness is achieved using MegaBLAST and SSAHA programs and the uniqueness of PCR primers using the GenomeMasker package. We have designed 560 probes for human chromosome X, which cover it uniformly with median distance of 250 kb, while in certain regions of interest with resolution up to 3 kb. Additional 107 probes from the autosomal chromosomes were selected and used as normalization controls. Candidate probes were amplified by PCR with success rate of 95%, and 80% of probes worked with 95% call rate on array. For validation of array-MAPH, we used patient samples with known chromosome X aberrations in the blind studies. Array-MAPH determined exactly the same mutations, showing that the new method is equally accurate and sensitive as array-CGH. Additional FISH and STS analysis precisely confirmed all of the above genomic imbalances found by array-MAPH. The new array-MAPH method offers an alternative methodology to array-CGH and further provides several advantages for high-throughput diagnostic screening and research applications by enabling high specificity and sensitivity as well as a high flexibility to study virtually any region in the human genome. Furthermore, it allows extremely high resolution of genomic analysis by detecting known small size deletions and large-scale copy-number variations of genes or exons.

Novel Approaches to the Analysis and Detection of Chromosomal Abnormalities: 22q as a Model. *B.S. Emanuel[1], J.A. Vorstman[1], G.R. Jalali[1], A.E. Urban[2], S.M. Weissman[2], M. Snyder[2], NimbleGen Inc..* 1) Children's Hosp of Philadelphia, Philadelphia, PA; 2) Yale University School of Medicine, New Haven, CT.

Non-random, constitutional abnormalities of 22q include translocations and deletions associated with DGS/VCFS, duplications associated with the supernumerary bisatellited marker chromosome of CES and translocations that give rise to the recurrent t(11;22) malsegregation-derived +der(22) syndrome. Cytogenetics and FISH are the methods of diagnosis. The positions of the rearrangement breakpoints have been localized in a large patient group. Most breakpoints cluster in 22q low copy repeats. Deletions span a typically deleted region (TDR) of ~3 Mb in >85% of patients. There are recurrent variant breakpoints and atypical deletions. Further, there are patients with the del(22) phenotype in whom deletions have not been detected and some in whom duplications of the TDR have been detected. The frequency of abnormalities of 22q makes it an attractive model for developing more sensitive diagnostic assays. Toward this end, we have utilized a multiplex ligation dependent probe amplification (MLPA) kit (MRC-Holland, Amsterdam) and oligonucleotide-based array CGH to assess DNA copy number. Both methodologies have been used on a training set of known samples containing one, two, three and four copies of 22q DNA sequence as well as unknown 22q abnormalities. We have shown that MLPA provides a rapid, sensitive, quantitative multiplex PCR approach to copy number determination as an initial screening method. Using a maskless array synthesis platform, in situ synthesis of 393,000 oligonucleotide probes has been performed on a single microarray. Probes are spaced ~85 bp apart (repeat sequences are masked) tiling through both strands (sense and antisense) of 22q. An isothermal format is employed where probe lengths range from 45 to 85 nt (Tm = 76C), resulting in more consistent probe performance. This high-density approach enabled ultra-high resolution mapping of DNA copy number and successfully identified all abnormalities detected by FISH and MLPA with exquisite precision. Thus, oligonucleotide-based aCGH is emerging as a powerful method for investigating changes of chromosomal structure.

Interstitial deletion of chromosome 9q22.32-q22.33 : a novel cause of syndromic overgrowth. *R. Redon[1], G. Baujat[2], D. Sanlaville[2], M. Le Merrer[2], M. Vekemans[2], N. Carter[1], A. Munnich[2], L. Colleaux[2], V. Cormier-Daire[2].* 1) The Wellcome Trust Sanger Inst, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 2) Department of Medical Genetics and INSERM U393, Hôpital Necker Enfants Malades, Paris, France.

Overgrowth syndromes are characterized by a height over<+>2 SD in association with a variable combination of macrocephaly, mental retardation, facial dysmorphic features, advanced bone age, and hemihyperplasia. Apart from well know conditions and chromosome anomalies - such as Sotos syndrome or del(22)(q13.1q13.2) - a number of overgrowth patients remain undiagnosed. In the course of a systematic screening using array-based Comparative Genomic Hybridization (array-CGH) of patients with unexplained overgrowth syndrome, we identified two children with congenital overgrowth and nearly identical de novo interstitial deletions del(9)(q22.32-q22.33). The clinical manifestations include macrocephaly, pre and postnatal overgrowth (<+>2.5 SD), and distinctive facial features (frontal bossing, down-slanted palpebral fissures, epicanthal folds, long tubular nose, small triangular mouth with thin upper lip, long philtrum, low-set ears). In addition, both children present with psychomotor delay, hyperactivity and strabismus. Further analysis with a custom microarray covering the whole breakpoint intervals with fosmids, allowed to delineate the deletion breakpoints within 100-kb intervals and demonstrated that the deletion boundaries, although close, are different for the two patients. Interestingly, the common deleted region encompasses the TGFBR1 gene, a gene which mutations are responsible for craniofacial, neurocognitive and skeletal development anomalies. We suggest therefore that the 9q22.32-q22.33 micro-deletion syndrome is a novel cause of overgrowth and mental retardation with distinctive facial features. Ongoing studies on TG signalling will provide further evidence of the involvement of TGFBR1 in the pathogenesis of this novel phenotype.

Cleidocranial Dysplasia Plus Vascular Anomalies With 6p21.2 Microdeletion Spanning RUNX2 and VEGF. *K. Izumi[1], N. Yahagi[2], Y. Fujii[2], R. Kosaki[3], M. Higuchi[4], Y. Naito[1], G. Nishimura[4], T. Takahashi[1], K. Kosaki[1].* 1) Dept Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept of Pediatrics, Yokohama Municipal Citizen's Hospital, Kanagawa, Japan; 3) Dept of Clin Genet & Mol Med, Nat'l Children's Med Ctr, Tokyo, Japan; 4) Dept of Radiol, Tokyo Metropolitan Kiyose Children's Hosp, Tokyo, Japan.

Vascular endothelial growth factor (VEGF) is an endothelial-cell-specific mitogen and angiogenic factor, as well as a potent mediator of vascular permeability. Recently, a critical role of Vegf in embryonic vasculogenesis was documented in mice. Loss of Vegf function (Vegf164 isoform) led to abnormal pharyngeal arch development, reminiscent of the condition seen in del22q11 patients. In humans, a genetic epidemiology study revealed that a VEGF polymorphism shown to reduce VEGF expression in vitro was associated with an increased risk for cardiovascular defects in del22q11 individuals. Based on the mouse mutant model and human epidemiological data, researchers hypothesized that a human VEGF mutation would lead to congenital malformations of arterial patterning in the pharyngeal arch arteries. However, no patients with germline mutations in VEGF have been reported to date. We here describe a patient with cleidocranial dysplasia (CCD) who had the classic features such as large fontanelles and hypoplasia of the clavicles plus an aberrant patterning in the pharyngeal arch arteries, including a vascular ring around the trachea and esophagus and an absent left internal carotid artery, and developmental delay. FISH analyses revealed a microdeletion of chromosome 6p21 encompassing the RUNX2 and VEGF loci. An array CGH analysis revealed an interstitial deletion of the short arm of chromosome 6, as indicated by hemizygosity of three BAC (RP3-447E21, RP11-79F13, and RP11-121G20) spanning 1.8 megabases. To our knowledge, the patient described in this report is the first patient with a germline mutation of the VEGF locus. The similarity between the vascular phenotype of the present case and that of Vegf-deficient mice strains suggests that the abnormal arterial patterning in the present case may be attributed to hemizygosity at the VEGF locus.

ZNF674: A NOVEL XLMR GENE IDENTIFIED THROUGH ARRAY CGH. *A.P.M. de Brouwer[1], D. Lugtenberg[1], M. Banning[1], A. Oudakker[1], H.V. Firth[2], L. Willatt[2], J. Chelly[3], J.P. Fryns[3], H.H. Ropers[3], C. Moraine[3], H.G. Brunner[1], H.G. Yntema[1], H. van Bokhoven[1].* 1) Department of Human Genetics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Department of Medical Genetics, University of Cambridge, Addenbrooke's Hospital, Cambridge, UK; 3) European XLMR consortium: www.EURO-MRX.com.

Array-based comparative genomic hybridization (array CGH) is a promising new technique that allows the detection of submicroscopic chromosomal aberrations that cannot be discovered by traditional cytogenetic methods. We analyzed a boy with a possible X-linked contiguous gene deletion syndrome by array CGH. Hybridization of full coverage X-chromosomal BAC arrays revealed a deletion of approximately 1 Mb in Xp11.3 harboring RP2, SLC9A7, CHST7 and two hypothetical zinc finger genes ZNF673 and ZNF674. Partial deletion of the RP2 gene is very likely responsible for the retinal degeneration in the patient. The other genes were considered candidates for the XLMR and were screened for mutations in 28 non-specific XLMR families with an overlapping linkage interval at Xp11.3. One nonsense mutation, p.E171X, was identified in ZNF674. Therefore, another 306 XLMR patients without a linkage interval were tested for mutations in this new KRAB-containing zinc finger (KRAB/ZNF) gene. Two more nucleotide changes, p.P464L and p.M395T, were identified. These three changes were not present in 350 control X-chromosomes. The nonsense mutation p.E171X leads to a truncated protein that has no zinc finger domains. The Pro to Leu change is present in a conserved linker between two zinc finger domains and probably causes a disturbance of its DNA binding property. The second missense mutation, p.M395T, is located between two zinc fingers but involves an amino acid that is not conserved in other zinc finger genes. Besides ZNF41 and ZNF81, ZNF674 is the third gene in the Xp11 KRAB/ZNF gene cluster that is mutated in XLMR patients. Interestingly, this KRAB/ZNF gene cluster on Xp11 seems to be specific for primates. These results show that ZNF674 plays a role in XLMR and is important for cognitive functioning in humans.

High-resolution analysis of genomic imbalance in children with mental retardation. *J.M. Friedman[1], L. Arbour[1], L. Armstrong[1], D. Bailey[3], A. Baross[4], P. Birch[1], M. Brown-John[4], M. Cao[3], S. Chan[4], D.L. Charest[4], A. Delaney[4], P. Eydoux[2], N. Farnoud[4], N. Fernandes[1], S. Flibotte[4], W. Gibson[1], A. Go[4], R. Hanson[4], R. Holt[4], S. Jones[4].* 1) Dept. of Medical Genetics, U. of British Columbia, Vancouver, Canada; 2) Dept. of Pathology and Laboratory Medicine, U. of British Columbia, Vancouver, Canada; 3) Affymetrix, Inc., Santa Clara, CA; 4) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, Canada.

The most frequent recognized cause of mental retardation (MR) is gain or loss of genomic material. Some pathogenic genomic copy number variants (CNVs) can be identified by conventional cytogenetic studies, but most require molecular cytogenetic techniques for detection. Submicroscopic CNVs are also frequent in normal individuals, and these normal variants must be distinguished from the pathological genomic imbalances that cause MR.

We are studying constitutional CNVs in 100 trios comprised of a child with idiopathic MR and both clinically normal parents using genomic arrays with 50-100 kb resolution. De novo CNVs identified in an affected child but absent in both parents are presumed to be potentially pathogenic, while CNVs found in at least one parent are presumed to be polymorphisms unrelated to the childs MR. Whole-Genome Sampling Analysis using Affymetrix 100K GeneChip Mapping Arrays with Affymetrix CNAT, dChip or custom segmentation analysis software reveals apparent CNVs in these children and their normal parents. Some of the de novo changes detected in the children with MR have been confirmed by locus-specific FISH and are likely to be pathogenic, while other apparent changes cannot be confirmed by independent techniques and probably reflect limitations of the technology or our current approaches to bioinformatic analysis. The samples are also being studied by comparative genomic hybridization on our 32K BAC arrays (Krzywinski et al. Nucleic Acids Res. 2004; 32:3651) and on a whole-genome oligonucleotide platform to permit direct comparisons of these high-resolution technologies and the software for detection of pathogenic genomic CNVs in children with MR.

Rapid prenatal diagnosis by microarray-based comparative genomic hybridization: Experience of a pilot program. *T. Sahoo, A. Patel, P. Ward, S. Darilek, J. LI, D. DelGaudio, S. Kang, S. Lalani, I. Van den Veyver, S. McAdoo, A. Burke, B. Roa, C. Shaw, C. Chinault, S. Cheung, A. Beaudet, C. Eng.* Molec & Hum Gen, Baylor Col Medicine, Houston, TX.

Microarray-based comparative genomic hybridization (a-CGH) is a new tool for the identification of chromosomal aberrations. We conducted a study in the prenatal setting to evaluate 1) reliability of a-CGH to detect abnormalities in amniocentesis and CVS samples, 2) a program to provide patient education and support, and 3) acceptance of a-CGH as a prenatal test when offered at no additional cost. Our microarray included 366 genomic clones covering all sub-telomeric regions and loci implicated in over 55 genetic disorders. A counseling protocol and educational materials addressing the risks and benefits of a-CGH were discussed during the informed consent process. For the 77 couples participating (44 AF, 32 CVS and 1 fetal blood), indications included advanced maternal age (n=50), fetal ultrasound anomalies (n=15), previous history of affected child (n=9), and abnormal serum screening (n=3). For 35 samples, DNA extracted directly from uncultured amniocytes or CVS samples gave successful a-CGH analysis often with a whole-genome-amplification step, permitting rapid result reporting. There was 100% concordance between the standard karyotype and a-CGH including 4 cases of trisomy 21. In 12 cases, initial a-CGH analysis detected a gain or loss requiring study of parental samples; a familial variant was confirmed in most cases. For 53 participants seen by a single counselor, 45 (85%) couples agreed to prenatal testing, and 33 of those 45 (74%) agreed to add a-CGH as a testing method. Reasons for accepting a-CGH testing included a previous affected child or an abnormal ultrasound, while rarity of the disorders tested and concern for an increased level of anxiety that may be raised by the test were reasons for declining. This study demonstrated a high level of acceptance in this population already undergoing amniocentesis or CVS, a high level of accuracy when compared to the standard karyotype, and a relative low level of results requiring additional testing to clarify clinical significance.

An algorithm for cgh microarray in clinical practice. *E. Aston, H. Whitby, T. Maxwell, B. Milash, B. Issa, J. Xu, Z. Chen, A. Brothman.* University of Utah Health Sciences Center, Salt Lake City, UT.

High resolution genomic (cgh) microarrays to detect copy number changes have been used in research since 1998. Several commercial platforms are available for use of this technology, and it has recently been applied to diagnostics. The University of Utah Cytogenetics laboratory has used both the SpectralChip 2600 (1Mb) and the Constitutional Chip from Spectral Genomics Inc. (Houston, TX) since 2003 for research and validation, and began clinical testing in January 2005. While the techniques are relatively new, results have shown promise in detection and detailed characterization of cytogenetic aberrations. An algorithm has been defined to determine which chip is used and how testing is performed. With few exceptions, most clinical studies have been processed according to this formula. High resolution G-band karyotypes are required before an array is run. If an abnormality requires further characterization, the 1Mb chip is recommended, as this chip contains BAC clones which cover the human genome at ~1Mb intervals. When normal karyotypes are observed but phenotype is indicative of described genetic syndromes, the Constitutional Chip is recommended. In some circumstances, both chips may be used. Pooled normal male or female genomic DNAs are used for controls. Any detected imbalances are confirmed with FISH using the same or representative clones, and parental DNAs are analyzed when appropriate and available. To improve sensitivity, we developed a statistical model that reduces noise on the array which may be an artifact of the manufacturing process, and provides improved discrimination between normal and abnormal chromosomal regions. Recognition of copy number polymorphisms (several unreported sites identified in this lab) and interpretation of their significance remains the largest challenge in our analyses. We have used this algorithm to evaluate 40 patients to date, (17 1Mb and 23 Constitutional) and have elucidated new information in all cases. Eleven (65%) and 7 (30%) abnormalities were detected with each chip, respectively. As this technology approaches the accepted standard of care, the field must cautiously move forward in implementation.

Case-control linkage disequilibrium difference (CCOLDD): a linkage disequilibrium mapping method in genome-wide association studies. *M.G. Hayes[1,2], N.J. Cox[1,2].* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Sctn Genetic Medicine, Dept Medicine, Univ Chicago, Chicago, IL.

Multipoint linkage disequilibrium (LD) mapping methods currently available are too computationally intensive to feasibly apply to large scale genome wide association data. We have developed a much less computationally intensive visualization method, called case-control linkage disequilibrium difference (CCOLDD) for rapidly determining regions that contain differences in the extent of LD between cases and controls. The increased frequency of common, historically-related derived susceptibility allele(s) in a region reduces the haplotype diversity in cases relative to controls and increases the extent of LD. We utilize LDU maps of cases and controls over the region or chromosome of interest and calculate the slope of the LDU difference between cases and controls in windows of varying size to pinpoint regions with rapidly changing differences in the extent of LD in cases and controls. CCOLDD efficiently detected the regions harboring susceptibility alleles in two densely typed positional cloning data sets: the *CAPN10* gene in the *NIDDM1* region associated with type 2 diabetes, and the *CFTR* gene associated with cystic fibrosis. Using Affymetrix 10K SNP chip data from a genome-wide linkage and association study of persistent stutterers, regions highlighted by the CCOLDD method correspond to regions showing evidence for linkage as measured by Kong and Cox LOD scores. Regions showing sex-specific linkage also showed sex-specific differences in the case-control LD comparison. Additionally, we report here on our recent results (1) determining the impact of window size, marker density, and Hardy Weinberg disequilibrium on CCOLDD results, (2) contrasting CCOLDD results with results obtained using more computationally intensive LD mapping methods such as decay of haplotype sharing (DHS) and TreeLD, (3) investigating the consequences of ancestral vs. derived susceptibility alleles on the extent of LD in cases and controls, and (4) piloting the approach in even denser data such as the Affymetrix 100K SNP chip set.

Combined analysis of 4500 Single Nucleotide Polymorphisms from chromosome 1q21-25 in samples from eight linked populations reveals shared type 2 diabetes susceptibility variants. *M.I. McCarthy[1], E. Zeggini[1], W. Rayner[1], C.J. Groves[1], B.D. Mitchell[2], J. O'Connell[2], S.C. Elbein[3], R. Hanson[4], L.J. Baier[4], W.C. Knowler[4], P. Froguel[5], W.P. Jia[6], M.C. Ng[7], J.C. Chan[7], L.R. Cardon[1], K. Xiang[6], C. Bogardus[4], S.E. Hunt[8], P. Deloukas[8], A.R. Shuldiner[2], International Type 2 diabetes 1q consortium.* 1) University of Oxford, Oxford, United Kingdom; 2) University of Maryland, Baltimore MD; 3) University of Arkansas for Medical Sciences, Little Rock, AR; 4) Phoenix Epidemiology and Clinical Research Branch, NIDDK, Phoenix, AZ; 5) CNRS UMR 8090 Lille, France; 6) Shanghai Diabetes Institute, China; 7) Chinese University of Hong Kong, Shatin, Hong Kong; 8) Wellcome Trust Sanger Institute, Hinxton, UK.

Chromosome 1q ranks as amongst the best replicated linkage regions for type 2 diabetes (T2D). The international T2D 1q consortium has initiated dense LD mapping of the ~20Mb region of maximal linkage in samples from eight linked populations (Amish, Utah, UK, French, Hong Kong, Shanghai, Pima Indians, African Americans). To date, ~4500 SNPs have been genotyped in 4500 individuals. A Mantel-Haenszel approach has been used to combine association results across populations. Several regions showed multiple, clustered, replicated associations. The strongest evidence for association observed to date across all populations lies around 152.1Mb, near *PKLR*, where the most-associated SNPs generate a combined odds ratio of 1.49 (95% CIs: 1.27-2.14, $p<10^{-6}$). This association is restricted to the Europid populations, is strongly supported by haplotype analyses (e.g. in European subjects, $p<2x10^{-5}$ using GENEBPM, based on 50,000 replicates), maps to a region implicated as a diabetes locus in both the GK and Torii rat and includes several strong positional candidates in addition to *PKLR* (*SCAMP3*, *CLK2*, *FDPS*). In the Chinese samples, the strongest association signals lie at ~156, 158 and 161Mb; in Pimas, the clearest signals lie around 160Mb and 163Mb. This work has highlighted several regions containing shared T2D susceptibility loci. Detailed investigation of positional and functional candidates is currently underway.

Combining multiple susceptibility polymorphisms can increase the predictive power of genetic information: a study of replicated type 2 diabetes variants. *A.T. Hattersley[1], M.N. Weedon[1], M.I. McCarthy[2], M. Walker[3], G. Hitman[4], B. Shields[1], K.R. Owen[1], T.M. Frayling[1].* 1) Diabetes and Vascular Medicine, Peninsula Medical School, Exeter, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Churchill Hospital, Old Road, Headington, UK; 3) Department of Medicine, School of Medicine, Newcastle upon-Tyne, UK; 4) Department of Diabetes & Metabolic Medicine, Barts and the London, Queen Mary School of Medicine and Dentistry, University of London, UK.

Alleles of polymorphisms at the *Kir6.2* (K23), *PPARG* (Pro12), *Calpain10* (SNP44 C), *HNF4A* (P2 haplotype) and *HNF1A* (V98) genes predispose to type 2 diabetes mellitus (T2D). Individually each polymorphism only moderately increases risk (~20%) and they are thought to be unhelpful in assessing subjects risk clinically. The impact of looking at multiple alleles simultaneously is not known.

To assess the combined effect of multiple susceptibility alleles we genotyped these variants in a large case/control study (1608 controls, 2396 cases). Individual allele odds ratios (OR) ranged from 1.09 [0.97, 1.23] to 1.33 [1.15, 1.53]. We found no evidence of gene-gene interaction. Each of the SNPs was consistent with a simple multiplicative model. The allelic odds ratios at each of the SNPs did not differ significantly from each other (P = 0.22). This suggested a simple model where subjects were classified according to number of risk alleles. There was a log-linear increase in odds of diabetes with increasing number of risk alleles (Chi-Sq test for log-linear trend, P 0.0001); each additional risk allele increasing the odds of a subject having T2D by 1.16 [1.09, 1.23] times. The 2.5% of subjects with 6 risk alleles had an odds ratio of 2.21 [1.27, 3.83] against the 4% of subjects with 1 risk alleles.

In conclusion, although individual susceptibility alleles only moderately increase the risk of T2D the effects are multiplicative. Combining alleles allows the identification of subgroups of the population with markedly differing risks of developing T2D. This approach may have a role in targeting preventative approaches in the future.

The effects of genetic variation in *PSARL* on diabetes risk. *J. Curran[1], J. Jowett[2,3], K. Elliott[2], L. Kerr-Bayles[4], S. Wanyoni[4], J. Skelton[5], K.H. Kim[5], T. Dyer[1], K. Walder[3,4], G. Collier[3,4], P. Zimmet[2,3], J. Blangero[1,3], A. Kissebah[5].* 1) Southwest Foundation for Biomedical Research, TX, USA; 2) International Diabetes Institute, Vic, AUS; 3) ChemGenex Pharmaceuticals LTD, Vic, AUS; 4) Metabolic Research Unit, Deakin University, Vic, AUS; 5) Medical College of Wisconsin, WI, USA.

Following linkage studies, the next step of identifying a disease gene from many genes in a region presents a formidable task. Our approach combines human linkage and animal model data to aid in identifying genes involved in diabetes risk. Results of differential gene expression in skeletal muscle of *Psammomys obesus* identified *PSARL*, presenilins-associated rhomboid-like protein, as a strong positional candidate in the 3q27 metabolic syndrome linkage region. Studies have supported *PSARL* as a key regulator of mitochondrial function and data strongly suggests this gene is involved in insulin resistance. To further assess the role of *PSARL* on diabetes risk, we re-sequenced 6.5kb, identifying 14 SNPs and genotyped these in 1031 Caucasian individuals from 162 families (where the original linkage signal was obtained). Fasting plasma insulin levels were used as a measure of diabetes status. Bayesian quantitative trait nucleotide analysis revealed four SNPs, A-309G, C384T, C42440T and C44233G, showing significant association with plasma insulin (p=0.0027, p=0.0024, p=0.005 and p=0.0026 respectively). In addition to influencing plasma insulin levels, C44233G showed strong evidence for a genotype-by-age interaction. A combined test of the influence of this SNP on plasma insulin levels strongly supported the hypothesis that this coding variant is either directly involved or correlated with another causal variant (p=0.00025). A promoter variant, A-309G, was identified as being in linkage disequilibrium with this coding variant. Functional analysis of A-309G in L6 myotubes has shown the promoter with the A allele has a significantly higher activity compared to the promoter with the G allele (p=0.0001). These results highlight *PSARL* as a positional candidate gene for diabetes risk and indicate a likely contribution to the 3q27 linkage signal.

Population genetics of the metabolic syndrome. *A. Di Rienzo[1], V.J. Clark[1], Y. Qian[1], R.R. Hudson[2].* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept. Ecology & Evolution, Univ Chicago, Chicago, IL.

Based on the thrifty genotype hypothesis, variants that increase susceptibility to metabolic syndrome phenotypes (i.e. type 2 diabetes (T2D), obesity, cardiovascular disease, and dyslipidemia) under modern life style conditions provided a survival advantage in past environments by increasing the efficiency of energy use and storage. While this framework provides a good explanation for the pathophysiology and epidemiology of the metabolic syndrome, no population genetic model has been proposed in connection with this evolutionary hypothesis. Our previous work on candidate genes for T2D and hypertension suggested that, at least in some cases, ancestral alleles are the ones that increase risk to disease. This suggests a testable population genetic model in which thrifty alleles were ancestral adaptations maintained in ancient human populations by purifying selection. We investigated this model by population genetics simulations to compare the expected patterns of LD around ancestral vs. derived alleles for a range of frequencies. We also characterize the expected association signal for ancestral risk alleles. Additionally, we characterize empirical patterns of variation in candidate genes for the metabolic syndrome, e.g. *KCNJ11*, *USF1*, *HNF4A*, *GAD2*, and *APM1*. A trend emerges from the analysis of these genes. For variants in which the ancestral allele increases disease risk, the derived protective alleles tend to be advantageous as they appear to carry the signature of natural selection. However, for those variants in which the derived allele increases disease risk, these alleles behave as neutral. Interestingly, in some genes, different derived alleles appear to carry the signature of positive selection in different populations. This raises the possibility that natural selection acting on derived protective alleles may generate relatively high levels of inter-ethnic diversity of disease variants. Overall, our simulations and empirical studies indicate that a broader evolutionary framework may aide in the design and analysis of SNP-based association studies as well as suggest approaches to identify novel, interesting variants for future study.

GENOMEWIDE HAPLOTYPE SIGNATURES OF HYPERTENSION WITH AND WITHOUT METABOLIC SYNDROME. *P. Hamet[1], O. Seda[1], E. Merlo[2], J. Tremblay[1], U. Broeckel[4], D. Gaudet[3], G. Bouchard[7], F. Gagnon[5], G. Antoniol[6], P.L. Brunelle[1], A. Gurau[1], F. Gossard[1], J. Pintos[1], T.A. Kotchen[4], Z. Pausova[1], S.N. Orlov[1], R. Wan[1], M. Labuda[1], M. Jomphe[7], A.W. Cowley[4].* 1) CR CHUM, Montreal, PQ, Canada; 2) Ecole Polytechnique de Montreal, Montreal, PQ, Canada; 3) Complexe hospitalier de la Sagamie, Chicoutimi, PQ, Canada; 4) Medical College of Wisconsin, Milwaukee, WI; 5) University of Ottawa, , Ottawa, ON, Canada; 6) University of Sannio, Benevento, Italy; 7) UQAC, Chicoutimi, Quebec, Canada.

Hypertension (HT) is perceived as a constitutive part of the metabolic syndrome (MS), though not being its requisite in any of MS definitions. We tested a hypothesis that genomic determinants may be distinct in hypertension with and without MS. In 120 French-Canadian families from the Saguenay-Lac-St-Jean region of Quebec, Canada, we identified hypertensive families showing extremes in presentation of MS. After comparing the families using battery of >50 anthropometric, metabolic and humoral phenotypes, we genotyped 208 individuals from hypertensive families with high density of MS (HDMS, n=126) and low-density of MS (LDMS, n=84) using Affymetrix GeneChip Human Mapping 50K Array to identify the HT genomic signatures (specific haplotype sets) in the respective family sets. Using a method of layered founders, we assessed the separability of HDMS and LDMS families in terms of specific ancestry. The LDMS families showed clearly distinct clinical features in comparison to HDMS, e.g. significantly lower volume of extracellular water. In LDMS families, the HT genomic signatures were associated with genomic determinants of blood pressure on chromosomes (chr.) 2, 5, 6 and 10. In contrast, in HDMS families HT is highly predicted based on haplotypes related with mostly metabolic MS attributes on chr. 1, 3, 7, 14, 15 and 18. At the depth of 14 layers/generations, the ancestors of LDMS families showed a higher specificity of genetic contribution to the recent generation in contrast with HDMS (84% vs. 60%). Using a genomewide SNP typing approach combined with genealogical analyses, we have identified specific genomic signatures of distinct forms of hypertension - with and without features of MS.

The RET Gene is a modifier of the PHOX2B gene for the Hirschprung disease phenotype. *L. de Pontual, A. Pelet, D. Trochet, Y. Espinosa-Parrilla, A. Munnich, F. Jaubert, J. Feingold, S. Lyonnet, J. Amiel.* Genetics, Hopital Necker, Paris, France.

Hirschsprung disease (HSCR, MIM 164761) is a frequent congenital malformation of the hindgut defined by the absence of enteric neurons. HSCR stands as a model in the study of diseases with a complex mode of inheritance. When observed as an isolated malformation, the transmission is non mendelian with low sex-dependant penetrance. A multiplicative oligogenic model with 3 loci has been proposed with RET proto-oncogene being the key player. Indeed, almost all HSCR patients harbor either a heterozygous mutation of the coding sequence or, more frequently, a hypomorphic allele located in a conserved non gene sequence in intron 1. In roughly 30/100 of the cases however, HSCR is associated to other malformations. Hitherto, the disease causing gene is known in 4 syndromic HSCR forms with mendelien inheritance among which CCHS (MIM209880, PHOX2B mutation) and Mowat-Wilson (MIM235730, ZFHX1B mutation). The penetrance of the HSCR phenotype is estimated about 20/100 for PHOX2B gene mutation and 60/100 for ZFHX1B mutation. To test whether RET could be regarded as a modifier gene for the enteric phenotype in these 2 syndromes, we genotyped the RET locus in patients for which the disease-causing mutation had been identified previously for CCHS (N=143) or MWS (N=30). Splitting patients into 2 groups (with or without HSCR) for each syndrome showed a statistically significant over representation of the RET hypomorphic allele in CCHS patients only (=11.52; $p<0.001$). Therefore RET acts as a modifier gene for the enteric phenotype to occur in patients with a PHOX2B gene mutation. The study of a family where a PHOX2B mutation segregates with neuroblastome predisposition in one branch and HSCR in another branch further strengthen the role of the RET gene for the enteric phenotype to occur. These data illustrate the concept of a developmental gene being either a major disease-causing gene or a modifier gene depending on the clinical context. Finally, we also suggest the possibility of RET dependent and RET independent HSCR cases.

Differential liabilities of coding and non-coding mutations in complex disease. *G. Burzynski[1], J. Amiel[2], G. Antinolo[3], S. Borrego[3], I. Ceccherini[4], E. Emison[5], C. Eng[6], R. Fernandez[3], M. Garcia-Barcelo[7], P. Griseri[4], R. Hofstra[1], C. Kashuk[5], F. Lantieri[4], S. Lyonnet[2], P. Tam[7], A. Tullio-Pelet[2], K. West[5], A. Chakravarti[5].* 1) Dept Medical Genetics, Univ Groningen, The Netherlands; 2) UC Genetica y Reproduccion, HH UU Virgen del Rocio, Seville, Spain; 3) Dept Genetique et Unite INSERM U-393, Paris, France; 4) Lab di Genetica Molecolare, Ist Gaslini, Genova, Italy; 5) Inst Genetic Medicine, Johns Hopkins Univ Baltimore, USA; 6) Dept Molecular Genetics, Ohio State Univ, Columbus, USA; 7) Dept Surgery, Genome Research Centre, Univ Hong Kong, China.

Hirschsprung disease (HSCR), a developmental disorder characterized by absence of enteric ganglia in the gut, is multifactorial. RET plays a central role; high-penetrance RET coding sequence (CDS) mutations occur in ~50%; of familial HSCR and linkage has been found in ~90%; of families. To determine whether RET non-coding sequences (NCDS) mutations contribute to risk, we studied 876 HSCR families from three continents. A common, disease-associated haplotype was constructed at the 5 RET region in all populations. The largest contribution to risk was made by an enhancer mutation in intron 1. HSCR risk varies by segment length affected (S/L, short/long; TCA, Total Colonic Aganglionosis), gender and the finding of CDS mutations. The NCDS mutation makes a greater contribution to susceptibility for S-HSCR than for the most severe TCA. Conversely, CDS mutations are detected more frequently in TCA than in S-HSCR. We also tested the contributions of CDS and NCDS mutations by proband gender as the incidence of HSCR is 4:1 (M:F). The NCDS variant makes a bigger contribution to risk in boys than in girls, while female HSCR patients carry more CDS mutations. We suggest a model in which the enhancer mutation contributes more to disease liability in the most frequent presentations of disease (male, S-HSCR, CDS mutation negative) and the rare, CDS mutations make the greatest contributions to the less frequent manifestations of HSCR (female, TCA). The types and parental origin of mutation is also skewed. Our data provide a consistent explanation of the genetic features of a classical multifactorial disease.

A dense genome SNP scan identifies a common determinant of obesity. *A. Herbert[1], N.P. Gerry[1], M. McQueen[2], I. Heid[3,4], A. Pfeufer[5,6], T. Illig[3,4], H.-E. Wichmann[3,4], T. Meitinger[5,6], X. Zhu[7], R. Cooper[7], K. Ardlie[8], H.N. Lyons[9], J.N. Hirschhorn[9], N.M. Laird[2], M.E. Lenburg[1], C. Lange[2], M.F. Christman[1].* 1) Dept Genetics & Genomics, Boston University School of Medicine; 2) Dept of Biostatistics, Harvard School of Public Health; 3) KORA Group, GSF National Research Center, Neuherberg; 4) Institute of Epidemiology, GSF National Research Center, Neuherberg; 5) Institute of Human Genetics, Technical University Munich, Munich; 6) Institute of Human Genetics, GSF National Research Center, Neuherberg; 7) Loyola University Medical Center; 8) Genomic Collaborative Inc; 9) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard.

Obesity contributes to the risk of common diseases such as diabetes, heart disease, metabolic syndrome and hypertension and is estimated to contribute to over 100,000 premature deaths in the United States annually. Heritability of BMI has been estimated to be in the range of about 50%. Despite this, common genetic determinants of obesity risk are largely unknown. To identify human genes affecting body mass index, a surrogate measure of obesity, we genotyped and analyzed 86,604 sites of common genetic variation using Affymetrix 100K Genechips in 694 participants from families in the NHLBI-Framingham Heart Study Offspring Cohort using the public release dataset. Employing a novel family-based screening procedure (Van Steen et al., 2005), a SNP (MAF =0.35)was identified that had a genome-wide significant association with elevated BMI. The association has been replicated in the MONICA/KORA population-based study of 4000 unrelated individuals of Western European ancestry (p=0.013), in a case-control study of 3000 individuals of European ancestry from the US and Poland (p = 0.01), and in a combined family-based and case-control study of 1000 African-Americans. The predisposing homozygous genotype is present in about 10% of individuals and may explain up to 4% of the population-attributable risk of obesity. The findings support the common disease/common variant hypothesis for BMI and illustrate the power of genome-wide family-based association studies to uncover genetic determinants of common phenotypes and disease.

A Network Approach to Genetic Studies of Complex diseases. *X. Zhou[1], F. Arnett[1], M. Xiong[2].* 1) Dept Internal Medicine, Univ Texas, Houston, Houston, TX; 2) Human Genetics Center, University of Texas - Houston, Houston, TX.

Revealing mechanisms underlying complex diseases poses great challenges to biologists. The traditional linkage and linkage disequilibrium analysis that have been successful in the identification of genes responsible for Mendelian traits, however, have not led to similar success in discovering genes influencing the development of complex diseases. Emerging functional genomic and proteomic (Omic) resources and technologies provide great opportunities to develop new methods for systematic identification of genes underlying complex diseases. In this report, we propose a systems biology approach, which integrates omic data and identify hierarchically organized network structure of biochemical pathways, to find genes responsible for complex diseases. This approach consists of five steps: (1) generate a set of candidate genes using gene-gene (or protein-protein) interaction data sets; (2) reconstruct a genetic network with the set of candidate genes from gene expression data and calculate gene flows in the network; (3) identify differentially regulated genes between normal and abnormal samples in the network based on distributions of gene flows in the genetic network; (4) validate regulatory relationship between the genes in the network by perturbing the network using RNAi and monitoring the response using RT-PCR; and (5) genotype the differentially regulated genes and test their association with the diseases by direct association studies. To prove the concept in principle, the proposed approach is applied to genetic studies of the autoimmune disease scleroderma or system sclerosis which resulted in identifying SPARC gene in TGF beta pathway.

Discovering human diseases genes with the help of mouse models. An example with Dup(17)(p11.2p11.2) syndrome. *K. Walz, J. Yan, W. Bi, R. Paylor, J.R. Lupski.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Genomic disorders are a result of recurrent DNA rearrangements involving unstable genomic regions, and are frequent diseases (~1 per 1,000 births). In a subset of such conditions the rearrangements comprise multiple unrelated contiguous genes that are physically linked(contiguous gene syndromes, CGS). Smith Magenis syndrome (SMS) is a CGS associated with a microdeletion within chromosome 17 band p11.2. The birth prevalence is estimated at 1/25,000. The clinical phenotype includes craniofacial abnormalities, brachydactyly, self injurious behavior, seizures, sleep abnormalities and mental retardation. Molecular studies revealed a common deleted region of ~4 Mb in 70-80% of SMS patients. A duplication of the same genomic region gives an independent CGS called Dup(17)(p11.2p11.2). Patients with Dup(17)(p11.2p11.2) are underweight, with hyperactivity and learning disabilities. Importantly, due to the small number of patients aviable, and that the size of the duplication seems to be the same in all of them, the discovery of the gene(s) responsible for this syndrome utilizing human patients is extremely improbable. Recently, mutations in the retinoic acid induced 1 gene (RAI1) have been identified as causative of SMS, however, the gene responsible for Dup(17)(p11.2p11.2) syndrome remains elusive. Human chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. By chromosome engineering we have generated a mouse model for Dup(17)(p11.2p11.2), Dp(11)17/+. Dp(11)17/+ mice are underweight and have hyperactivity and learning disabilities recapitulating the human phenotype. As Rai1 is a dosage sensitive gene present in this genomic interval we wanted to test the hypothesis that Rai1 is the gene responsible for the phenotypes observed in Dp(11)17/+. By mating Dp(11)17/+ with mice carrying a mutation in the Rai1 gene: Rai1+/-, we obtained compound heterozygote Dp(11)17/Rai- animals, in which the normal gene dosage of Rai1 is obtained despite the segmental duplication. In these mice a normal weight and learning behavior was observed, suggesting that Rai1 is the predominant responsible gene for the phenotypes observed in Dp(11)17/+ mice.

Strategies for detection of chromosome abnormalities in children with developmental delay: is it effective to use subtelomere FISH analysis as an initial screening test? *J.B. Ravnan[1], J.F. Stefanik[1,2], G. Avery[1], J.T. Mascarello[1].* 1) Genzyme Genetics, Santa Fe, NM; 2) University of Connecticut.

Clinical geneticists are faced with an array of choices for genetic testing of children with developmental delay or mental retardation. Without specific features to suggest a particular single gene disorder, most geneticists will pursue chromosome analysis followed by subtelomere FISH testing if the chromosome results are normal. Because subtelomere FISH testing can show abnormal results for large chromosome rearrangements as well as for cryptic rearrangements of the ends of the chromosomes, the question has been raised whether it might be effective to start with subtelomere FISH studies and then pursue chromosome analysis if needed. In order to find out what proportion of chromosome abnormalities detected by traditional G-banding could be detected by FISH with a subtelomere probe panel, five years of blood chromosome data from the Genzyme Genetics Santa Fe laboratory were reviewed. Abnormal chromosome results were reviewed and classified as detectable or undetectable by a subtelomere FISH panel. Preliminary review shows that approximately 80% of abnormal chromosome results overall would be detectable by subtelomere FISH, but only 50% of abnormal chromosome results found in children referred for developmental delay or mental retardation would be detectable by subtelomere FISH. Further discussion of these results will be presented and the efficacy of different testing strategies will be outlined.

Systematic screening for microduplications / microdeletions in patients with mental retardation using a simple QMPSF assay. *P. Saugier-Veber[1,2], A. Goldenberg[1], V. Drouin-Garraud[1], V. Layet[3], N. Drouot[1,2], G. Joly-Helas[4], C. de la Rochebrochard[4], H. Moirot[4], M. Tosi[2], T. Frebourg[1,2].* 1) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Inserm U614, Faculty of Medicine, 22 boulevard Gambetta, 76183 Rouen, France; 3) Department of Cytogenetics, Le Havre Hospital, 76083 Rouen, France; 4) Department of Cytogenetics, Rouen University Hospital, 76031 Rouen, France.

Microduplications, like microdeletions, result from illegitimate recombinations mediated by repeat elements, but their frequency and clinical presentation remain to be characterized. In order to evaluate the frequency of such microduplications, we developed a new one tube QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) assay covering loci either involved in microdeletion syndromes or known to be prone to genomic rearrangements. This microdeletion / duplication QMPSF assay includes 12 amplicons, corresponding to *WHSC1* (4p16.3), *SEMA5A* (5p15.2), *NSD1* (5q35), *ELN* (7q11), *EXT1* (8q24.13), *WT1* (11p13), *SNRPN* (15q11), *CREBBP* (16p13.3), *RAI1* (17p11.2), *LOXL1* (15q22), *PAFAH1B1* (17p13.3) and *TBX1* (22q11) and was used to screen 2 series of patients. In the first series, we screened 106 patients with mental retardation (MR) and facial dysmorphism associated with malformations, or growth anomalies, or familial history. Additional criteria were: cytogenetically normal chromosomes, no detectable FRAXA mutation, and no detectable subtelomeric rearrangement. A deletion affecting *NSD1* at 5q35 was identified in a patient with severe epilepsia, profound MR and, retrospectively, craniofacial features suggestive of Sotos syndrome. In the second series, we screened 101 patients with MR and behaviour disturbance who did not fulfil the de Vries criteria for subtelomeric deletion screening. We identified a 22q11 deletion in a patient with moderate MR, obesity and facial dysmorphism, and a 17p11 duplication in a patient with mild to moderate MR, behaviour disturbance, strabism and non specific facial features. Our results suggest that patients with MR should be screened for these rearrangements regardless of their inclusion or not in subtelomeric deletion screening.

Duplication of the commonly deleted Williams-Beuren syndrome region at 7q11.23 causes severe expressive language delay. *L.R. Osborne[1], C.B. Mervis[2], E.J. Young[1], E.J. Seo[3], M. del Campo[4], S. Bamforth[5], E. Peregrine[2], W. Loo[1], M. Lilley[5], C.A. Morris[6], L.A. Pérez-Jurado[4], S.W. Scherer[3], M.J. Somerville[5].* 1) Medicine, University of Toronto, Toronto, ON, Canada; 2) Psychological and Brain Sciences, University of Louisville, Louisville, KY; 3) Genetics & Genomic Biology, Sick Kids Hospital, Toronto, ON, Canada; 4) Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain; 5) Medical Genetics, University of Alberta, Edmonton, AB, Canada; 6) Pediatrics, University of Nevada School of Medicine, Las Vegas, NA.

The Williams-Beuren syndrome (WBS) locus at 7q11.23 is prone to recurrent rearrangements mediated by complex low copy repeats (LCRs) that flank the region. Deletions span a common 1.5 million base pair interval and result in WBS, a multi-system developmental disorder with characteristic cardiovascular, cognitive and behavioural features. It had been hypothesized that duplications of the WBS region should arise at equal frequency, although to date none have been identified. Here we present the first such case of reciprocal duplication of the WBS region. The most striking phenotype in the proband was severe developmental apraxia of speech, which is in sharp contrast to individuals with WBS who have normal articulation and fluent expressive language. The duplication breakpoints mapped within the same blocks of the LCR as those of common WBS deletion, indicating that this duplication is indeed the reciprocal of the deletion. Genes within the minimal critical interval for WBS showed increased expression in the proband, and reduced expression in individuals with WBS, compared to individuals with non-rearranged chromosomes. This is the first example of a novel syndrome due to duplication of the WBS region. WBS is characterized by relatively spared expressive language and severely impaired visuospatial abilities. In striking contrast, our patient shows the converse, suggesting that specific genes at 7q11.23 are exquisitely sensitive to dosage alterations, which can influence human language and visuospatial capabilities.

SIZN1 (Smad Interacting Zinc Finger Protein): a new gene implicated in X-linked mental retardation. *C.E. Schwartz[1], G. Cho[2], S.S. Bhat[1], Y. Lim[3], D. Zand[4], J. Gao[1], J. Collins[1], A.K. Srivastava[1], J.A. Golden[2,5].* 1) Greenwood Genetic Center, Greenwood, SC; 2) Dept Pathology, CHOP, Philadelphia, PA; 3) Dept Biology, Univ of Penn School of Med; Philadelphia, PA; 4) Dept Genetics, CHOP, Philadelphia, PA; 5) Dept Pathology, Univ of Penn School of Med, Philadelphia, PA.

SIZN1, a transcriptional co-activator located at Xq22.2, was recently identified by us. The gene derives its name as follows: Smad Interacting Zinc finger protein expressed in the Nervous system and encodes a 402 amino acids protein containing a CCHC domain and a putative nuclear localization sequence. *SIZN1* positively regulates BMP signaling in the nucleus through interaction with Smads that recruit CREB-Binding Protein (CBP). The expression pattern and location on the X chromosome indicated that *SIZN1* might be a candidate gene for X-linked mental retardation (XLMR). The coding region of *SIZN1* was screened in a cohort of 540 males with non-fragile X MR using IPS. All abnormal alleles were directly sequenced. Two distinct mutations were identified. Four brothers with MR had a c.1031C>T (p.T344I) mutation and the mother was heterozygous for this missense mutation. This allele was not observed in 430 control males. A second mutation, c.19C>T (p.R7C), was identified in 1.4% (4/290) of black males with mental retardation. The mutant allele was found in 2.9% (5/172) of black female newborn controls and 3.8% (5/131) of black female controls with normal intelligence. The mutation was not found in a screen of male controls with normal intelligence (95 African-Americans and 346 Caucasians), nor was it found in 462 male newborns (223 African-Americans and 239 Caucasians). A study of 250 Caucasian males with mental retardation and 405 Caucasian females with normal intelligence did not reveal the mutation. Thus, this mutation appears to be limited to the African-American population. However, based on the number of individuals studied it is unlikely that this represents a rare polymorphism. Additionally, reporter assay studies of the p.R7C mutation revealed a 40-60% reduction in SIZN1 function. All together these data suggest a possible role for *SIZN1* in brain development and human cognitive function.

The molecular basis of autosomal recessive nonsyndromic mental retardation (ARNSMR) is poorly understood due to the difficulty in grouping families for linkage analysis. Only two autosomal genes, PRSS12 on 4q26 and CRBN on 3p26, have been shown to cause ARNSMR, each gene in only one family. We have identified a protein-truncating mutation in the gene CC2D1A on chromosome 19p13.12 in nine consanguineous families with severe ARNSMR. CC2D1A is a member of a previously uncharacterized gene family that carries two conserved motifs, a C2 domain and a DM14 domain. The C2 domain is found in proteins which function in calcium-dependent phospholipid binding or in membrane trafficking. The DM14 domain is unique to the CC2D1A protein family, and its role is unknown. CC2D1A protein has many orthologues in mammals, as well as in other vertebrates and invertebrates. The gene was duplicated in vertebrates. CC2D1A is a putative signal transducer participating in regulation of I-B kinase/NF-B cascade. We demonstrated expression of CC2D1A mRNA in the embryonic ventricular zone and cortical plate in staged mouse embryos, persisting into adulthood with highest expression in the cerebral cortex and hippocampus. This suggests that previously unknown signal transduction pathway is important in human cognition.

Homozygous deletion of the very-low density lipoprotein receptor gene causes autosomal recessive cerebellar hypoplasia with cerebral gyral simplification. *K.M. Boycott[1], S. Flavelle[1], A. Bureau[1], H.C. Glass[2], T.M. Fujiwara[3], E. Wirrell[2], K. Davey[1], A.E. Chudley[4], J.N. Scott[5], D.R. McLeod[1], J.S. Parboosingh[1].* 1) Dept Med Genet, Alberta Children's Hospital, Calgary, AB, Canada; 2) Div Ped Neuro, ACH, Calgary, AB, Canada; 3) Dept Hum Genet Med, McGill University, Montreal, QC, Canada; 4) Sec Genet Metab, Children's Hospital, Winnipeg, MB, Canada; 5) Dep Rad, Foothills Hospital, Calgary, AB, Canada.

The Hutterites are an endogamous German-speaking people that originated from the Anabaptist movement during the 16th century. A syndrome of nonprogressive cerebellar ataxia with mental retardation was described in the Hutterite population in the 1980s and was referred to as Dysequilibrium syndrome (DES) (AJMG 1981;9:43; AJMG 1986;22:567). We recently reviewed the clinical features and neuroimaging of 12 Hutterite patients with Dysequilibrium syndrome (DES-H). DES-H is characterized by global developmental delay, moderate to severe mental retardation, late ambulation (after age six), truncal ataxia and a static clinical course. The neuroimaging is characterized by hypoplasia of the inferior portion of the cerebellar hemispheres and vermis and mild simplification of cortical gyri. An identity-by-descent mapping approach was used to localize the gene for DES-H. Multipoint linkage calculations provided statistical evidence of linkage to 9p24. Haplotype analysis identified familial and ancestral recombination events and refined the minimal region to a 2 Mb interval between D9S129 and D9S1871. A 199 kb homozygous deletion encompassing the entire very low density lipoprotein receptor (*VLDLR*) gene was present in all affected individuals. This deletion was characterized by a STS-walking strategy and an 8-bp direct repeat, GAAAACAA, was identified at each breakpoint. VLDLR is a receptor for Reelin and the Reelin pathway guides neuroblast migration in the cerebral cortex and cerebellum, thus providing an explanation for the cerebellar hypoplasia and mild cerebral gyral simplification characteristic of this syndrome. This condition represents the first lipoprotein receptor human malformation syndrome and the second human disease associated with a Reelin pathway defect.

***DOCK8* - A Candidate Mental Retardation Gene Located in Subtelomeric 9p.** *B.L. Griggs[1,2], S. Ladd[1], R.A. Saul[1], B.R. DuPont[1,2], A.K. Srivastava[1,2].* 1) Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC.

Submicroscopic aberrations in the subtelomeric regions of the autosomes have been found in 5-10% of patients with mental retardation and developmental disabilities (MR/DD). To facilitate autosomal MR gene identification, we have previously mapped a critical genomic region associated with MR in two unrelated patients and chromosomal rearrangement involving 9p subtelomere. In one patient, a male with MR, no speech, seizures, and some dysmorphic facial features, we mapped a genomic deletion of approximately 230 kb in subtelomeric 9p. In the second patient, a female with MR and ectodermal dysplasia and a balanced translocation t(X;9)(q13.1;p24), we mapped the 9p24 breakpoint to a region overlapping with the centromeric end of the 230 kb subtelomeric deletion. The ectodermal defects in the female patient are due to the disruption of the EDA gene at Xq13.1. Thus, the MR in the patient with the translocation is presumably associated with the 9p24 breakpoint.

In silico analysis of the gene content of the critical subtelomeric MR region revealed two known genes, *FOXD4* and *CBWD1*, and a putative partial gene, *DOCK8*. We assembled and characterized the novel *DOCK8* gene from the corresponding expressed sequences in the database. Several isoforms of the *DOCK8* gene have been identified. The longest isoform of the *DOCK8* gene was found to be disrupted in both patients. The gene was partially deleted at its 5 end in the patient with the subtelomeric 9p deletion and disrupted by the 9p24 translocation breakpoint in the second patient. The gene is expressed in several tissues including adult and fetal brain. All together these findings indicate that haploinsufficiency of DOCK8 is likely responsible for MR in the two patients with subtelomeric 9p aberrations and suggest a putative role for DOCK8 in brain development and function. Further analysis of the *DOCK8* gene in unrelated patients with MR, as well as functional analysis, should clarify a possible involvement of DOCK8 in the etiology of MR.

Analysis of the STK9/CDKL5 gene in patients with suspected Rett syndrome and X-linked infantile spasms syndrome/West syndrome. *A. Alkhateeb, K.L. Clift, K.S. Petras, W.B. Dobyns, S. Das.* Department of Human Genetics, University of Chicago, Chicago, IL.

The STK9 (or CDKL5) gene that codes for a putative kinase has recently been implicated in patients with a wide range of clinical presentations that include seizures, infantile spasms, developmental delay, mental retardation, hypotonia, absent speech, ataxia and stereotypic hand movements. The phenotypes observed in patients with STK9 mutations have included cryptogenic infantile spasms (ISS or West syndrome) and atypical Rett syndrome. Recent studies have demonstrated the interaction of STK9 with MECP2, implicating them in the same molecular pathway. While seizures appear to be a common feature in patients with STK9 mutations, no clear genotype-phenotype correlations have been reported. We set out to study involvement of the STK9 gene in a large group of patients that were refered to our molecular diagnostic laboratory, or our brain malformation research project, for testing of ARX or MECP2. We selected 95 patients with ISS (83% male) negative for mutations of ARX, and 127 patients with Rett syndrome-like features (69% female) negative for mutations and deletions of the MECP2 gene. Informed consent was obtained from the parents or guardians of all subjects. While limited clinical information was available for most patients, seizures were listed as an indication for testing in the majority of patients with ISS and in approximately 20% of patients referred for testing of MECP2 for possible Rett syndrome (likely to be higher). Mutation analysis of STK9 by full gene sequencing is in progress in these two cohorts. To date 15 patients in the MECP2 negative group and 10 patients in the ARX negative group have been analyzed and no obvious pathogenic mutations have been identified. This study is still in its preliminary stages and results of our completed study will be presented along with detailed clinical information of mutation positive cases. This study will aid in a better understanding of the genotype-phenotype correlation in patients with STK9 mutations as well as help to better determine the prevalence of mutations in this gene in a diagnostic setting.

Autosomal dominant mental retardation resulting from mutations in cell-adhesion molecules. *A.K. Srivastava[1], K. Bhalla[1], G.F. Guzauskas[1], T. Buchan[2], M.A. Beachem[1], S. Ladd[1], S.J. Bratcher[1], B.R. DuPont[1], R.J. Schroer[1], J. Balsamo[2], J. Lilien[2].* 1) Greenwood Genetic Center, Greenwood, South Carolina; 2) Department of Biological Sciences, University of Iowa, Iowa City, Iowa.

Mental retardation (MR) is the most common developmental disability, affecting cognitive function in about 1-3% of the human population. Genes that cause inherited MR are presumably distributed throughout the human genome. Several syndromic and nonsyndromic MR genes, especially on the X chromosome, have been cloned but success in identifying autosmal MR genes has been limited. Cell-adhesion molecules of the cadherin and immunoglobulin (Ig) superfamilies play critical roles in development of the brain, as well as maintaining synaptic structure, function and plasticity. We have identified defects of two genes encoding such cell-adhesion molecules, *CDH15* (cadherin superfamily) and *KIRREL3* (Ig superfamily) in autosomal dominant MR. Both genes are disrupted by a balanced translocation in a female patient with MR. In addition, among a group of 647 unrelated patients (552 females and 95 males) with unexplained MR, 5 female patients have missense mutations in *CDH15* and 5 other patients, one male and 4 females, have missense mutations in *KIRREL3*. All of the mutations in the expressed CDH15 protein are in the most distal EC1 repeat of the ectodomain and significantly reduce its ability to mediate cell-cell adhesion without affecting cell surface expression. Both genes are expressed in fetal and adult brain. These findings suggest a possible novel role for CDH15 and KIRREL3 in developing brain which is critical for the development and maintenance of human cognition.

Mutations in GLUT10/SLC2A10, a facilitative glucose transporter, cause arterial tortuosity syndrome. *PJ. Coucke[1], A. Willaert[1], B. Callewaert[1], MW. Wessels[2], GM. Mancini[2], J. De Backer[1], JE. Fox[3], M. Kambouris[4], R. Gardella[5], S. Barlati[5], M. Colombi[5], HC. Dietz[6], B. Loeys[6], PJ. Willems[7], A. De Paepe[1].* 1) Univ. Hospital Ghent, Belgium; 2) Erasmus Medical Centre, Rotterdam, The Netherlands; 3) Schneider Children's Hospital,A. Einstein College of Medicine, NY, USA; 4) Yale Univ., New Haven, USA; 5) Div. Biology and Genetics, Univ. Brescia, Italy; 6) McKusick-Nathans Institute, J. Hopkins, Baltimore, USA; 7) GENDIA, Antwerp, Belgium.

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive disorder characterized by tortuosity, elongation and aneurysm formation of the major arteries and pulmonary artery stenosis due to disruption of elastic fibres of the media. Homozygosity mapping in two consanguineous families, respectively from Morocco and Italy, identified a critical region of 4.1 Mb on chromosome 20q13.1. Haplotype sharing between 2 Moroccan families originating from the same region reduced the candidate interval to 1.2 Mb containing 7 genes (SLC13A3, TP53RK, SLC2A10, EYA2, PRKCBP1, NCOA3, SULF2) and 1 pseudogene (RPL35AP). Mutations in GLUT10/SLC2A10, a member of the facilitative glucose transporters (GLUTs), were identified in 6 ATS families: homozygous nonsense mutations or base pair deletions leading to premature stop codons in 4 families, and one identical missense mutation in 2 other families. Identification of a deficient glucose transporter as the underlying cause for arterial tortuosity is fascinating since glucose metabolism has not previously been involved in the elastic fibre network. Some evidence suggests that glucose influences TGFbeta signalling, a pathway associated with arterial tortuosity in the Loeys-Dietz syndrome, an aortic aneurysm syndrome caused by mutations in the TGFBR1 or TGFBR2 genes. Alternatively, GLUT10 could be involved in the transport of metabolites necessary for the synthesis or processing of glycoaminoglycans, important constituents of arterial walls. At present, other mechanisms explaining the role of GLUT10 cannot be excluded and research is ongoing to unravel the specific pathogenetic mechanisms underlying ATS.

Loss of function mutations in the *Growth differentiation factor - 1* (*GDF1*) are associated with congenital heart defects in humans. *J.D. Karkera[1], S.J. Lee[2], S. Banerjee-Basu[3], E. Roessler[1], M.V. Ouspenskaia[1], E. Goldmuntz[4], P. Bowers[5], J. Towbin[6], J. Blemont[6], A. Schier[2], A. Baxevanis[3], M. Muenke[1].* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Skirball Institute of Biomolecular Medicine and Department of Cell Biology, NYU School of Medicine, NY; 3) Genome Technology Branch, NHGRI/NIH, Bethesda, MD; 4) Divison of Cardiology, The Children's Hospital of Philadelphia, PA; 5) Department of Pediatrics, Yale University School of Medicine, New Haven, CT; 6) Divison of Cardiology, Department of Pediatrics, Baylor College of Medicine, Huston, TX.

Congenital heart defects (CHDs) originating from defects in early embryonic patterning collectively account for the largest number of birth defects in humans, with an incidence of ~8 per 1000 live births. Growth Differentiation Factor 1 (GDF1), encoding a TGF binding is essential for maintaining the Left-Right (L-R) axis asymmetry. Gdf1 murine mutants display a wide spectrum of L-R axis formation defects including visceral *situs inversus*, the abnormal positioning of the aorta and pulmonary artery (Transposition of the Great Vessels), atrial and ventricular septal defects. To determine whether GDF1 is a susceptibility gene for the CHDs, we screened a cohort of 375 unrelated individuals affected with wide spectrum of CHDs. We have identified one nonsense, seven missense mutations, and several single nucleotide common polymorphisms. Utilizing BMP7 crystal structure as the template a molecular model was generated of mature human GDF1. Here we report that all the missense mutations in the mature GDF1 domain appear to be clustered in the hydrophobic region predicting structural disruptions that might lead to loss of function. The functional effects of the identified variants using a highly conserved mature murine *Gdf1* as a chimera displayed Goosecoid expression as active readout for GDF1. All five of the human GDF1 missense mutations in the mature domain tested showed loss of function. Thus, molecular modeling and GDF1 over-expression in zebrafish suggests that the missense mutations in the mature GDF1 domain cause loss of function and contribute to disturbances of heart patterning in humans.

Transcript profiles of fat biopsies and two independent autopsy studies support the role of allelic variants of the *USF1*-gene in cardiovascular disease. *K. Komulainen[1], J. Naukkarinen[1], M. Gentile[1], P. Pajukanta[2], J. Saarela[1], M-R. Taskinen[3], P.J. Karhunen[4], M. Perola[1], L. Peltonen[1].* 1) Dept. of Molecular Medicine, KTL, Biomedicum, Helsinki, Finland; 2) Dept. of Hum. Gen., David Geffen School of Medicine at UCLA, CA, USA; 3) Dept. of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 4) School of Medicine, University of Tampere and Research Unit of Laboratory Center, Tampere University Hospital.

We recently reported an association of allelic variants of *USF1* with FCHL, a common dyslipidemia predisposing to cardiovascular disease (CVD). To investigate the functional relevance of different *USF1* alleles and the downstream targets of this transcription factor, expression studies were conducted in fat biopsies of FCHL family members. Further, the role of specific *USF1* alleles was addressed by quantitative analysis of arterial plaques in two human autopsy series.

The best associating SNP in the FCHL families is located in a 60 bp across species conserved sequence of intron 7 that we here established to bind nuclear proteins and regulate transcription in vitro. In analysis of transcript profiles from 19 fat-biopsies the putative *USF1* risk allele was associated with significant changes of transcript levels of 3 *USF1* target genes, namely *APOE*, *ABCA1* and *AGT*, highly relevant to the pathogenesis of CVD.

To further establish the role of different *USF1* alleles in quantitative changes of arterial atherosclerosis, we examined two autopsy series consisting of 700 males with sudden death in the Helsinki area during years 1981-82 and 1991-92. Detailed autopsy data included quantitative classification of atherosclerotic lesions in coronary arteries and abdominal aorta. Specific *USF1* alleles were associated with the size of fibrotic intimal lesions and the amount of calcification of the arteries and atherosclerosis of the brain (P=0.04 - <0.0001) as well as with death from ischemic heart disease (OR 5.0, 95% Cl 1.8-14.3, P=0.003). These results underline the importance of allelic variants of the *USF1* gene as a CVD risk factor at the population level and give more insight into the molecular pathogenesis of atherosclerosis.

Common Variants Influencing the QT-interval by Genome-wide Association Analysis. *D.E. Arking[1], A. Pfeufer[2,3], W. Post[1], W.H.L. Kao[1], M. Ikeda[1], C. Kashuk[1], S. Lin[1], D. Cutler[1], S. Perz[3], H.E. Wichmann[3], S. Kaab[4], P.M. Spooner[1], T. Meitinger[2,3], A. Chakravarti[1].* 1) Johns Hopkins Medical Institutes, Baltimore, MD; 2) Institute of Human Genetics, Technical University Munich, Germany; 3) GSF National Research Center, Germany; 4) Dept of Medicine I, University of Munich, Germany.

We performed a genome-wide SNP screen to identify genetic determinants of cardiac repolarization. The QT-interval is normally distributed in the general population and has moderate heritability (0.30). To minimize false positive findings, we took a 3 stage approach. In stage 1, we selected individuals from the extremes of the QT-interval (7.5th and 92.5th percentile), normalized for heart rate, age, and sex (QTc RAS), from 2,171 women enrolled in the population-based KORA S4 survey (age 25-75 yrs). Women were selected to avoid heterogeneity due to sex difference. 103 individuals from each extreme (mean QTc RAS: 385.77.7 ms vs. 444.83.6 ms) were genotyped for ~100,000 SNPs using Affymetrix Centurion arrays. While no single SNP reached genome-wide significance, several loci exhibited multiple SNPs with large differences in allele frequency between extremes of QT-interval (p0.0001). In stage 2, the 30 most significant SNPs (all p0.0003) from the whole-genome screen were genotyped in the next 200 females from each extreme. In stage 3, SNPs that were significant at p0.01 in the combined phase 1 and 2 datasets were then screened in all KORA S4 probands (n=3,966 after exclusion criteria: AF, pacer, and pregnancy). One SNP, in intron 1 of the CAPON gene, a regulator of nNOS which plays a key role in regulation of cardiac contractility, was significantly associated with QTc RAS ($p1.84x10^{-11}$), with ~5 ms difference in QTc RAS between the two homozygous genotype groups. When stratified by sex, this SNP was significant in both males ($p4.3x10^{-5}$) and females ($p4.7x10^{-8}$). The males serve as a validation cohort, as phases 1 and 2 used only female samples. Results of this study demonstrate the feasibility and the potential of genome-wide SNP association studies for identification of novel genes for complex traits.

Genotype-phenotype correlations in 7,000 Americans: *CRP* haplotypes are significantly associated with high plasma C-reactive protein levels in African- and Mexican-Americans. *D.C. Crawford, J.D. Smith, C. Shephard, M. Wong, L. Witrak, M.J. Rieder, D.A. Nickerson.* Dept Genome Sci, Univ Washington, Seattle, WA.

High levels of plasma C-reactive protein (CRP) are associated with an increased risk for heart disease. Given its clinical importance, it is important to understand *CRP* regulation so that novel prevention strategies can be developed. Here we explore the genetic factors that influence *CRP* regulation using two approaches. First, seven tagSNPs were selected based on linkage disequilibrium (using LDSelect; $r^2$0.64) from re-sequencing data on *CRP* designed to capture all common genetic variation (5% minor allele frequency) for European and African-Americans. Second, we re-sequenced an additional 950 chromosomes and identified two novel nonsynonymous SNPs predicted by PolyPhen as possibly damaging. These approaches encompass both the common variant/common disease and the rare variant/common disease models. Nine SNPs were then genotyped in 7,296 samples from the Centers for Disease Control and Preventions National Health and Nutrition Examination Survey (NHANES) III. NHANES III is population-based survey of American health and is one of the largest cross-sectional DNA collections of Americans (European, n=2,631; African, n=2,108; and Mexican, n=1,862) linked to extensive phenotyping. In NHANES III, we identified only two individuals heterozygous for one cSNP suggesting *CRP* cSNPs are rare in the general population. Classifying CRP levels as a dichotomous trait (1.0 mg/dl; 1.0 mg/dl), we performed univariate analyses for SNPs and haplotypes stratifying by sex and race/ethnicity. Three SNPs (790, p0.00001; 1440, p0.003; 3872, p0.002) were significantly associated in African-American females with high CRP levels. SNPs 1440 and 1421 (tagged by 790) are located in the promoter and are predicted to alter transcription factor binding. Haplotype analysis identified a strong association in Mexican-American females (p0.0001) and males (p=0.02) with high CRP levels compared with a weaker association in African-American females (p=0.04), demonstrating the possibility that a SNP-by-SNP analysis does not identify all significant associations between genetic variation and CRP plasma levels.

Contribution of Clinical Correlates and 13 C-Reactive Protein Gene Polymorphisms to Inter-Individual Variability in Serum C-Reactive Protein Level. *S. Kathiresan[1,2], C.Y. Guo[2], M.G. Larson[2,3], R.S. Vasan[2,3], P. Gona[2,3], P.A. Sutherland[2,3], J.F. Keaney[3], C. Newton-Cheh[1,2], S.L. Musone[1], A.L. Lochner[1], J.A. Drake[1], D. Levy[2], C.J. O'Donnell[1,2], J.N. Hirschhorn[1], E.J. Benjamin[2,3].* 1) Broad Institute, Cambridge, MA; 2) NHLBI's Framingham Heart Study, Framingham, MA; 3) Boston University, Boston, MA.

Background Serum level of C-reactive protein (CRP) is a heritable complex trait that predicts incident cardiovascular disease. We investigated the clinical and genetic sources of inter-individual variability in serum CRP level in the community. **Methods and Results** In a reference panel, we constructed a dense linkage disequilibrium (LD) map for common SNPs spanning the CRP locus (1 SNP every 830 bases, 26 kilobases). A single block of strong LD spanned the CRP locus and seven tag SNPs captured common genetic variation. We studied clinical correlates of serum CRP in 3301 Framingham Heart Study (FHS) participants (mean age 61 years, 53% women). Twelve clinical covariates explained 26% of variability in CRP level with body mass index alone explaining 15% ($P<0.0001$). Thirteen CRP SNPs (tag SNPs plus previously studied variants) were genotyped in 1640 unrelated FHS participants with measured CRP level. Adjusting for clinical covariates, nine of 13 SNPs were associated with serum CRP level ($P<0.05$). To account for correlation among SNPs, we conducted stepwise selection among all 13 SNPs and found that a triallelic SNP (rs3091244) or a two-SNP proxy for it (rs1205 and rs2808630) remained associated with CRP level (stepwise $P<0.0001$, <0.0001, and 0.003, respectively). The triallelic SNP (C>A>T, allele frequencies 62%, 31%, 6%), located in promoter sequence, explained 1.4% of variation in serum CRP. Eight common haplotypes differed with respect to mean CRP level (global $P <0.0001$). Haplotypes harboring the minor A and T alleles of the triallelic SNP were associated with higher CRP level (hap $P=0.0001$ and 0.004). **Conclusions** In our community-based sample, clinical covariates explained 26% of inter-individual variation in serum CRP levels; a common triallelic SNP in promoter sequence explained an additional 1.4% of the variation.

Admixture Mapping for Genomic Regions Linked to Hypertension in African Americans and Mexican Americans. *X. Zhu[1], J. Cohen[2], R.S. Cooper[1], H.H. Hobbs[2].* 1) Preventive Med & Epidemiology, Loyola Univ Medical Ctr, Maywood, IL; 2) Donald W. Reynolds Cardiovascular Clinical Research Center, Eugene McDermott Center For Growth and Development, University of Texas Southwestern Medical Center, Dallas, TX.

Migration patterns in modern societies have created the opportunity to use population admixture as a strategy to identify susceptibility genes. To implement this strategy, we genotyped a highly informative marker panel of 2270 single nucleotide polymorphisms in a random population sample of African Americans (N = 1743) and Mexican Americans (N = 631). We then examined the evidence for over-transmission of specific loci to cases from one of the two ancestral populations involved historically in the origin of these groups. Cases and controls were defined for hypertension based on standard clinical criteria; both case-only and case-control analyses were performed among African Americans, but only the case-control comparison was considered to be robust in the smaller Mexican American sample. Among the African Americans, the most significant results for hypertension were observed on chromosomes 1, 4, 6 and 16. These same loci were also associated with hypertension among the Mexican Americans in a case-control analysis. Significant linkage evidence was identified on chromosome 1, 6 and 16 when combining the results from the two samples. These data demonstrate the potential for admixture mapping among large cosmopolitan populations, provide incremental information about the location of susceptibility loci for complex traits. We also addressed the problems of admixture mapping due to the misspecified ancestral allele frequencies and background linkage disequilibrium.

Tobacco smoking, *estrogen receptor gene* variation, and small low-density lipoprotein particle level. *A.M. Shearman[1], S. Demissie[2], L.A. Cupples[2], I. Peter[3], C.H. Schmid[3], J.M. Ordovas[4], M.E. Mendelsohn[5], D.E. Housman[1].*
1) Center for Cancer Research,E17-536, MIT, Cambridge, MA; 2) Department of Biostatistics, Boston University School of Public Health, MA; 3) Biostatistics Research Center, Institute of Clinical Research and Health Policy Studies, Tufts-NEMC, Boston, MA; 4) Nutrition and Genomics Laboratory, USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA; 5) Molecular Cardiology Research Institute, Department of Medicine, NEMC, Boston, MA.

High levels of small low-density lipoprotein (LDL) particles are a major risk factor for cardiovascular morbidity and mortality. Both estrogens and smoking, with known anti-estrogenic effects, alter the atherogenic lipid profile. We tested for a role of interaction between smoking and *estrogen receptor alpha gene (ESR1)* variation in association with plasma concentration of atherogenic small LDL particles and LDL particle size. We studied 1727 unrelated men and women from the population based Framingham Heart Study. After covariate adjustment women who smoked and had the common *ESR1 c.454-397 TT* genotype (in 30% of women *T* was present on both chromosomes at position 397 prior to the start of exon 2) had > 1.7-fold higher levels of small LDL particles than women with the alternative genotypes (P for smoking-genotype interaction = 0.001). Similar results were obtained for three other *ESR1* variants, including *c.454-351A>G*, in the same linkage disequilibrium block. A similar substantial gender-specific result was also evident with a fifth variant, in a separate linkage disequilibrium block, in exon 4 (P = 0.003). Women who smoked and had specific, common *ESR1* genotypes had a substantially higher plasma concentration of atherogenic small LDL particles. Significant results revealed a dose dependent effect of smoking, and were evident in both pre- and postmenopausal women. The reported association has the potential to explain the risks associated with estrogen use in certain women and a recent report of association between an *ESR1* haplotype composed of *c.454-397 T* and *c.454-351 A* alleles with increased myocardial infarction, independent of the standard cardiovascular risk factors.

Association of common variation in AGTR1 with left ventricular mass in the Framingham Heart Study. *J.N. Hirschhorn*[1,2]. 1) for the Writing Group of the Cardiogenomics Program (an NHLBI Program for Genomics Applications), NHLBI's Framingham Heart Study and the Broad Institute of Harvard and MIT; 2) Genetics/Program in Genomics, Harvard Medical School/Childrens Hospital, Boston, MA.

Left ventricular (LV) mass and related structure/function measures are heritable intermediate phenotypes for cardiovascular diseases (CVD) such as hypertension and congestive heart failure. Because of human and animal data implicating the renin-angiotensin system (RAS) in cardiac hypertrophy and dilation, we performed comprehensive association tests of LV phenotypes with common variation in RAS genes, including angiotensin converting enzyme (*ACE*), angiotensin receptor types 1 (*AGTR1*) and 2 (*AGTR2*), renin (*REN*), and angiotensinogen (*AGT*).

To characterize common variation at these genes, we genotyped a dense set of SNPs in 12 CEPH pedigrees; 206 SNPs had frequencies >5%. We then selected 83 tag and missense SNPs that capture common variation in these genes, and genotyped these SNPs in 1234 unrelated men and women from the Framingham Heart Study (FHS), in whom LV mass (LVM), wall thickness, diastolic dimension, and fractional shortening were determined by M-mode echocardiography. Multivariable regression analysis was conducted for LV phenotypes, adjusted for sex, age, height, weight, smoking, BP, and hypertension therapy. General, additive, dominant and recessive genetic models were tested. SNPs with strong associations in the initial sample were genotyped in a validation sample of individuals from families in FHS.

Seven SNPs had at least one nominal p value <0.0001 or two nominal p values <0.001 in the initial sample, and were taken forward into the validation sample. A strong nominal association between SNP rs1800766 in *AGTR1* and LVM in men (p=0.00006 in the initial sample; age/sex adjusted, additive model) was convincingly validated in the second sample (p=0.0004 for this same phenotype and model). Initial associations with LVM under related genetic models, and for LVM with rs275649 (correlated with rs1800766; see www.cardiogenomics.org), were also validated. We conclude that variation in *AGTR1* influences LV mass in men, and is thus a good candidate for influencing CVD.

Identification of a novel locus for left main coronary artery disease. *L. Wang[1], ER. Hauser[1], SH. Svati[1], D. Seo[2], SG. Gregory[1], WE. Kraus[2], M. Pericak-Vance[1], PJ. Goldschmidt-Clermont[2], JM. Vance[1].* 1) Center for Human Genetics,; 2) Divison of Cardiology, Duke University Medical Center, Durham, NC.

Patients with left main coronary artery disease (LMD) have one of the worst prognoses for survival of coronary artery disease (CAD). We have identified a novel locus in the limbic system-associated membrane protein (LSAMP) gene associated with LMD risk, independent of classic CAD risk factors (cholesterol, diabetes, etc.). We began by using a DNA pooling technique to screen single nucleotide polymorphisms (SNPs) for association in our CAD linkage peak on chromosome 3q13. Subjects included 204 controls and 469 cases from patients who underwent cardiac catheterization (CATHGEN), which is an independent dataset from our early-onset CAD linkage probands (n=420). Allelotyping in DNA pools found a 12% allele frequency difference between older-onset CATHGEN cases and controls for SNP rs1875518 which was validated by individual genotyping. Similar associations were found in additional SNPs near rs1875518 and was confirmed in the linkage probands ($p<0.05$). Given the significant findings in both late and early-onset CAD datasets, we examined the data for association stratified by CAD index, a numerical summary of angiographic data that reflects severity of CAD. This analysis revealed a strong association with LMD ($p<0.001$), odds ratio 2.63 (95% CI: 1.43-4.83) for the marker rs1676232 in a recessive model. The associated SNPs reside within a large intron (1.6 Mb) lying between two alternative first exons (1a and 1b) of LSAMP gene, previously only described in mouse. *In silico* analysis suggested a similar exon structure for the human gene. Expression of LSAMP exon 1a was studied in 37 human aortas and found to be decreased 6.5 fold ($p<0.001$) in aortas with severe compared to mild atherosclerosis. In addition, the rs1676232 risk allele was associated with reduced expression of exon 1a ($p=0.05$) in the aortas. Given the pronounced risk associated with LMD, our findings could lead to a risk assessment tool facilitating early initiation of preventive and therapeutic strategies, and thereby reducing CAD morbidity and mortality.

Newborn screening reveals high incidence of later-onset Fabry disease: Implications for detection of later-onset, but treatable inherited disorders. *M. Spada[1], S. Pagliardini[1], M. Yasuda[2], G. Thiagarajan[2], A. Ponzone[1], R.J. Desnick[2].* 1) Pediatrics, Univ Torino, Torino, Italy; 2) Human Genetics, Mount Sinai School of Medicine, New York, NY.

Newborn screening for Fabry disease, an X-linked recessive lysosomal storage disease, was performed by assaying -galactosidase A (-Gal A) activity in blood spots obtained from 30,129 consecutive male infants born in the Piedmont region of Italy during the 20 months from July, 2003 through February, 2005. All 34 infants (0.11%) who had blood spot -Gal A activities <20% of the normal mean (7.7 nmol/h/ml blood) were retested. Of these, 10 infants had low -Gal A activities (range 0.0 to 0.2 nmol/h/ml blood or 0.3 to 1.1 nmol/h/ml plasma and DNA sequencing identified -Gal A missense mutations, including four newborns with novel mutations (M51I, E66G, A73V, and R118C) and six infants with three previously identified missense mutations (F113L, A143T and N215S) and one splicing defect ($IVS5^{+1GT}$). Surprisingly, the incidence of Fabry disease was ~1 in 3,000 males in this population, >15 times more frequent than the previously estimated 1 in ~50,000 males. Transient expression of the missense mutations revealed that all had residual -Gal A activities (~20-40% of wild type), which were enhanced by the -Gal A-specific pharmacologic chaperones, galactose and deoxygalactonojirmycin, findings consistent with the later-onset cardiac and renal variant phenotypes. The splicing defect was previously reported in a classically affected male. Thus, screening ~30,000 newborn males revealed a ratio of 1 classically affected to 9 later-onset variants with Fabry disease. These data suggest that the later-onset phenotype is under-diagnosed among adult male patients who will develop cardiac disease and/or renal insufficiency. Clearly, recognition of these patients would permit early intervention by enzyme replacement and/or enhancement therapy. However, the high incidence of the later-onset patients raises ethical issues related to when screening should be undertaken for this disease either in the neonate or in early maturity, perhaps in conjunction with screening for other treatable adult-onset disorders.

Perfect Sensitivity and Specificity of Plasma Catechol Measurements for Neonatal Diagnosis of Menkes Disease.

C.S. Holmes[1], S.G. Kaler[2]. 1) NINDS, NIH, Bethesda, MD; 2) Unit on Pediatric Genetics, Laboratory of Clinical Genomics, NICHD, Bethesda, MD.

Background: Menkes disease (MD) is an X-linked recessive neurodevelopmental disorder that features abnormal incorporation of copper into cuproenzymes, including dopamine--hydroxylase (DBH). Neonatal diagnosis and prompt treatment with copper injections can prevent the mortality and morbidity associated with MD, however early detection is hindered by inadequate sensitivity and specificity of commonly available biochemical tests. Abnormal plasma catechol levels, due to DBH deficiency, has been noted in MD. The present study evaluated prospectively the sensitivity and specificity of these measurements as a diagnostic test for Menkes disease in at-risk infants. Methods: Plasma specimens from 81 at-risk male infants referred by hospitals and medical centers throughout the US (31 states and the District of Columbia) and 5 foreign countries were analyzed between May, 1997 and April, 2005. Thirty-six were from asymptomatic newborns with a positive family history of Menkes disease. Plasma catechols were measured by high performance liquid chromatography with electrochemical detection. Results: Of 81 specimens, 46 had an abnormal plasma catechol pattern consistent with decreased DBH activity, and 35 did not have this pattern. Among the subgroup of newborns, 14 showed the abnormal pattern and 22 did not. Clinical and molecular follow-up confirmed 100% sensitivity and 100% specificity of the abnormal catechol pattern among the entire cohort. Thirty percent of asymptomatic affected infants identified and treated from a very early age with copper histidine injections had very favorable clinical outcomes. Conclusions: Plasma catechol measurements are sensitive and specific for diagnosing Menkes disease particularly in newborn infants for whom very early recognition is a prerequisite for successful therapeutic intervention in this otherwise lethal disorder.

Validation of pharmacogenetic data necessary to put personalized medicine into practice in rheumatoid arthritis.

A. Taniguchi[1], S. Furihata[2], W. Urano[1], M. Yamanaka[1], E. Tanaka[1], H. Yamanaka[1], N. Kamatani[1]. 1) Institute of Rheumatology, Tokyo Women's Medical Univ., Shinjuku-ku, Tokyo, Japan; 2) Genome Diversity Team, Japan Biological Information Research Center, Japan Biological Informatics Consortium, Koto-ku, Tokyo, Japan.

Aim: Methotrexate (MTX) and sulfasalazine (SSZ) are important drugs for the treatment of rheumatoid arthritis (RA). However, the outcome of the treatment with these drugs is known to vary among patients. We have previously reported an association between the C677T and A1298C polymorphisms of the 5,10-methylenetetrahydrofolate reductase (MTHFR) gene and MTX toxicity or efficacy (Pharmacogenetics 2002;12:2525). We also indicated that toxicity of SSZ is associated with diplotype configuration at N-acetyltransferase 2 (NAT2) gene (J Rheumatol 2002;29:2492). However, another reports have produced inconsistent results. The aim of this study was to validate our previous studies. Methods: 384 RA patients were randomly selected. Genotypes of C677T and A1298C polymorphisms of the MTHFR gene and the diplotype configuration at NAT2 gene were determined. Results: 227 patients had been administered MTX. The association between toxicity of MTX and MTHFR genotypes was examined in 156 patients who received a cumulative dose of MTX more than 300mg. MTX-related toxicity occurred in 43 patients before a total cumulative MTX dose of 300mg. For C677T, toxicity was more frequent in patients with 677T than in patients without the 677T (p=0.003). MTX had been administered at starting doses 2 to 6 mg/week in 159 patients, and whether different genotypes were associated with the level of MTX dose at a year after MTX was started was examined. Patients with the 1298C required significantly lower doses of MTX than patients without the 1298C (P=0.008). 94 patients had been treated with SSZ. 33 patients experienced any adverse effect, of whom 18% carried slow-acetylator diplotype, while among the 61 patients who were free of adverse effects 5% were slow-acetylator diplotype carriers (P=0.04). Conclusion: This work confirms our previous results. The application of phamacogenetics may reduce toxicities and enhance the desirable effects of MTX and SSZ.

A novel genome-wide approach to finding determinants of chemotherapeutic susceptibility. *S.J. Shukla[1], J.A. Badner[2], X. Wu[3], W. Zhang[1], C. Cheng[4], W.K. Bleibel[3], M.E. Dolan[3].* 1) Human Genetics, U Chicago, Chicago, IL; 2) Psychiatry, U Chicago; 3) Medicine, U Chicago; 4) Biostatistics, St. Judes, Memphis, TN.

Little is known about heritable factors that influence chemotherapeutic-associated toxicity. Our goal is to better understand the genetic basis of drug toxicity by utilizing a genome-wide approach with no a priori assumptions about candidate genes, in order to identify previously unknown genetic variation in germline DNA. Our approach combines information from linkage, expression, bioinformatics, and association analyses. Cell growth inhibition of lymphoblastoid cell lines (LCLs), derived from members of CEPH pedigrees, was quantified following treatment with a range of chemotherapeutic agents. 10 to 17 families were evaluated for linkage and heritability (H2) analyses for cisplatin, carboplatin, etoposide, daunorubicin, and vincristine. H2, using SOLAR, revealed significant values ranging from 0.24-0.73 ($p<0.0001$) for all 5 drugs. Moderate linkage peaks (lod >2) were found at chromosomes 1, 9, and 12. The 8 most resistant and 8 sensitive LCLs following cisplatin treatment were used to evaluate expression differences at baseline and across time. 829 probe sets were identified as different at baseline using ANOVA ($p<0.05$). Linear regression was used to correlate the IC_{50} (dose inhibiting 50% of cell growth) of cisplatin and publicly available baseline LCL expression data. JARID1B, a DNA binding protein, was common to linkage, baseline microarray, and linear regression analyses. Clusters of probesets that had similar patterns of expression over 0,2,5,8 hours were identified ($p<0.05$). Oct-1 emerged as a common transcription factor among a group of highly correlated probesets within a cluster, which may be important in their regulation. Pathway analysis using Ingenuity software revealed CDKN2A and MYC as central hubs of gene interactions, based on 89 genes common to linkage and microarray analyses. Phenotyped LCLs with HapMap data will be used for association. Our approach could lead to the discovery of genes that were previously unknown or unrecognized as important determinants of drug response.

A predictive bar-code for cancer therapy based on kinase inhibitors. *A. Killian[1], R. Sesboue[1], G. Raux[1], J-M. Flaman[1], F. Le Pessot[2], F. Di Fiore[1,3], B. Paillot[3], P. Michel[3], T. Frebourg[1].* 1) Inserm U614, IFRMP, Faculty of Medicine, Rouen, France; 2) Department of Pathology, Rouen University Hospital, France; 3) Department of Gastroenterology, Rouen University Hospital, France.

The recent development of selective anticancer therapies, based on kinase inhibitors, represents one of the most important improvements in cancer treatment and recent studies have revealed that the clinical response depends on the presence of activating alterations. In solid tumours, these predictive alterations correspond to point mutations or deletions within the kinase domain but systematic screenings of tumours suggest that such alterations are infrequent. Gain of copies / amplification of genes encoding kinases appear more frequent and have also been shown to be associated with a clinical response. Therefore detection of gain of copies and of amplifications of genes encoding kinases may be required in the future for patient targeted therapies. Thus, we have developed a predictive bar-code for kinase inhibitors, called the kinogram, which is based on the QMPSF (Quantitative Multiplex PCR of Short fluorescent Fragments) method. In this single tube assay, 15 short genomic sequences (<250 pb), corresponding to genes encoding kinases against which inhibitors have been developed, and 2 control amplicons are simultaneously amplified under quantitative conditions using dye-labelled primers. For each patient, the QMPSF profile generated from the tumour is superimposed to that generated from the adjacent non tumoral tissue, using control amplicons. This predictive QMPSF bar-code was used to analyse 52 primary colorectal cancers. This preliminary study revealed that more than half of the tumours exhibited gain of copies of target genes. Furthermore, gain of copies of several targets were often detected within the same tumour. This is particularly important in the context of acquired resistance to kinase inhibitors. Indeed, as highlighted by clinical trials, the genetic instability of tumour cells represents a pitfall for targeted anti-cancer treatment. Our results suggest that in cancer, like in bacterial or viral diseases, combined targeted treatment should be of interest.

Sequential morphology (phenotype)/ FISH (genotype) assessment by targeting plasma cells greatly improves residual disease detection in multiple myeloma. *M.L. Slovak, V. Bedell, K. Pagel, L. Weiss, G. Somlo.* City of Hope Natl Medical Ctr, Duarte, CA.

Clonal abnormities of -13/del(13q), 14q32/IGH, del(17p), and hyperdiploidy (+5, +9, +15) have been reported in >80% of newly diagnosed multiple myeloma (MM) cases. Detection of these same abnormalities post treatment by conventional cytogenetics (CC) or standard FISH, however, has proven to be very difficult in samples with less than 20% bone marrow (BM) involvement, correlating poorly with pathology assessment. In this study, we investigated 102 post treatment samples collected from 82 MM patients (17 pts with multiple studies), all with less than 20% BM involvement, using a combined May-Grünwald Giemsa (MGG) (morphology)/FISH approach to determine the plasma cell genotype (target or T-FISH). Cytospin slides were made using 200 l of BM and stained with MGG for morphologic classification on a Duet Image Analyzer (Bioview Ltd., Rehovot, Israel). After identifying and mapping the plasma cells, the slides were destained and hybridized with one of four FISH probe strategies corresponding to the chromosome aberrations listed above. The T-FISH results were correlated with CC and the BM pathology report, which quantified the percentage of plasma cells in the BM aspirate. Target FISH identified MM aberrations in 88/102 (86.3%)samples. The aberrations observed were IGH in 49 samples, -13/del(13q) in 32, hyperdiploidy in 27, hypodiploidy in 6, and del(17p) in 2, with 25 samples showing more than one abnormality. Only 7 samples showed clonal karyotypic aberrations by CC; an additional 3 samples showed a presumed stemline with only one abnormal cell (9.8%). A comparison with % of plasma cells in the BM smears showed T-FISH detected residual disease in all 36 samples with 6 % plasma cells, 7 of 8 hemodilute samples, one smoldering MM sample and 75% (43/57) of the samples with 1-5% plasma cells. Our data indicate target FISH is a quick and reliable genotype/phenotype molecular cytogenetics technique that greatly improves residual disease detection and provides an exceptionally sensitive strategy for investigating low mitotic malignancies such as multiple myeloma.

Incomplete processing of mutant lamin A in HGPS leads to nuclear abnormalities, which are prevented by farnesyl-transferase inhibition. *M.W. Glynn, T.W. Glover.* Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

Hutchinson-Gilford progeria syndrome (HGPS) is commonly caused by mutations in codon 608 (G608G) of the *LMNA* gene, which activates a cryptic splice site resulting in the in-frame loss of 150 nucleotides between the cryptic splice site in exon 11 and the beginning of exon 12. The deleted region includes a protein cleavage site that normally removes the C-terminal 15 amino acids, including a CAAX box farnesylation site from lamin A. It has been assumed, but not proven, that the mutant protein remains farnesylated. We have investigated the processing of the C-terminus of the mutant protein, progerin, and have found that it does not undergo this cleavage event and, indeed, remains farnesylated. The retention of the farnesyl group may have numerous consequences as farnesyl groups increase lipophilicity and are involved in membrane association and protein interactions, and is thus likely to be an important factor in the HGPS phenotype. To further investigate this, we studied the effects of farnesylation inhibition on nuclear phenotypes in cells expressing the progerin protein. Expression of an N-terminal GFP-progerin fusion protein in normal fibroblasts caused a high incidence of nuclear abnormalities, as seen in HGPS fibroblasts, and abnormal nuclear distribution of the GFP-progerin in comparison to the localization pattern of GFP-lamin A. Expression of a GFP-lamin A fusion containing a mutation (L647R) that prevents the final cleavage step, causing the protein to remain farnesylated, was found to give rise to identical localization patterns and nuclear abnormalities as in HGPS cells and in normal cells expressing GFP-progerin. Exposure to a farnesyl transferase inhibitor, PD169541, caused redistribution of GFP-lamin A and GFP-progerin localization in normal fibroblasts and a significant improvement in the nuclear morphology of cells expressing GFP-progerin. We also observed a significant improvement in the nuclear morphology of HGPS fibroblasts exposed to this FTI. These results implicate the abnormal farnesylation of progerin in the cellular phenotypes in HGPS cells and suggest that FTIs may represent a therapeutic option for patients with HGPS.

TGF-induced failure of satellite cell performance and muscle regeneration in mouse models of Marfan syndrome and other myopathic states. *R.D. Cohn[1], J. Pardo[1], B.L. Loeys[1], T.M. Holm[1], D.P. Judge[2], H.C. Dietz[1].* 1) Johns Hopkins Hospital, McKusick-Nathans Institute of Genetic Medicine, Howard Hughes Medical Institute, Baltimore, MD; 2) Division of Cardiology, Baltimore MD.

A large subset of patients with Marfan syndrome (MFS), an autosomal dominant connective tissue disorder caused by mutations in the fibrillin-1 gene, exhibit significant muscle hypoplasia and myopathy. Recent evidence suggests that the pathogenesis of MFS does not simply manifest loss of structural tissue integrity, but rather involves excessive activation of and signaling by the transforming growth factor- (TGF)superfamily of cytokines. TGF has been shown to be a potent inhibitor of terminal differentiation of cultured myoblasts, however the functional impact of TGF signaling on myogenesis in vivo remains obscure. We find for the first time that excessive TGF bioactivity in vivo leads to significant myopathic alterations. Mice homozygous for a missense mutation (C1039G) in fibrillin-1 exhibited significant muscle hypoplasia and muscle hypotrophy in association with nuclear enrichment of pSmad2/3, indicative of excessive TGF signaling. Heterozygote C1039G/+ mice demonstrated myopathic alterations at 3 months of age with a reduction and marked variation in fiber size, and endomysial fibrosis. Identical myopathic changes were observed in patients with MFS. Analysis of skeletal muscle after cardiotoxin injection revealed failed muscle regeneration in C1039G/+ mice secondary to perturbed satellite cell proliferation and differentiation, as evidenced by decreased M-cadherin and myogenin expression, respectively. Systemic administration of TGF neutralizing antibody fully normalized muscle architecture, satellite cell performance and muscle regeneration in response to injury. Additional data suggest that excessive TGF signaling contributes to pathogenesis in the dystrophin-deficient mdx mouse model of Duchenne muscular dystrophy. These data provide the first and compelling evidence for a primary role of dysregulated TGF signaling in myopathic states and impaired muscle repair and thus provide both rationale and motivation to explore the therapeutic utility of TGF antagonism in vivo.

AT1 blockade rescues multisystem manifestations of Marfan syndrome independent of hemodynamic effects. *J.P. Habashi[1], T. Holm[1], B.L. Loeys[1], D. Bedja[1], E.R. Neptune[1], D.P. Judge[1], H.C. Dietz[1,2].* 1) Johns Hopkins Univ Sch Med, Baltimore, MD; 2) HHMI, Bethesda, MD.

Marfan syndrome (MFS) is an autosomal dominant condition associated with aortic aneurysm and dissection. Murine models indicate that many manifestations, including myxomatous mitral valve disease and impaired pulmonary alveolar septation, are mediated by excess activation and signaling of the TGF family of cytokines. We observed increased TGF signaling in the aortic wall of patients and mouse models of MFS. We hypothesized that treatment with losartan, an angiotensin II type I (AT1) receptor antagonist that can achieve a clinically relevant inhibition of TGF in other disease states, would provide protection from aneurysm both by decreasing hemodynamic stress and attenuating TGF-initiated pathogenetic events. Mice heterozygous for a fibrillin-1 missense mutation (C1039G/+) were randomized at 7 weeks of age to placebo(n=9), losartan(50 mg/kg,n=8) or propranolol(30 mg/kg,n=7) and compared to wild-type. The dose in each treatment arm was titrated to achieve comparable effects on heart rate and blood pressure. Three echo measurements of the aortic root were obtained from a long axis view in systole at 3 time points (baseline, 2 and 4 months of treatment). All analyses were performed blinded to genotype and treatment arm. Aortic growth during the 4 months of treatment was significantly reduced in the losartan (0.060.07mm;$p<0.0001$) and propranolol (0.220.08mm;$p<0.0001$) groups, compared to placebo (0.430.09mm). The growth in the losartan group was less than that seen with propranolol($p<0.004$) and indistinguishable from that seen in wild-type mice(0.090.05mm). Propranolol treatment did not improve elastic matrix architecture while histologic parameters were normalized in losartan-treated mice. Preliminary studies show that administration of TGF-neutralizing antibody provided similar protection ($p<0.02$). We demonstrated that losartan also rescued other aspects of the phenotype including alveolar septation. This represents the first therapy for MFS that derives from interrogation of disease pathogenesis and the first possibility for primary prevention of disease manifestations.

Dietary methyl donors modify the phenotype of a Rett syndrome mouse model. *P. Moretti[1,2], C.P. Schaaf[1], R. Teague[1], C. Pedroza[5], O. Smith[1], H. Zoghbi[1,3,4].* 1) Dept of Mol and Human Genetics; 2) Neurology; 3) Pediatrics; 4) Howard Hughes Medical Institute Baylor College of Medicine, Houston, TX 77030; 5) University of Texas School of Public Health, Houston, TX 77030.

Mice engineered to express a truncated allele of *MECP2* (*Mecp2*$^{308/Y}$) recapitulate many neurologic features of Rett syndrome (RTT) and provide an excellent model for studying the biological basis of RTT and for testing treatment interventions. MeCP2 is involved in the regulation of methylation-dependent gene expression. Methyl donors such as folate, betaine, methionine, and choline are available as nutritional supplements and have been shown to modify DNA methylation levels in vivo and in vitro and to affect gene expression. We hypothesized that dietary methyl donors modify the neurologic deficits of *Mecp2*$^{308/Y}$ mice by modulating the level of DNA methylation of MeCP2-regulated genes. We performed a controlled randomized trial in which wild-type and mutant animals were exposed prenatally and postnatally to diets containing low or high concentrations of methyl donors. The behavioral and morphologic phenotypes of all animals were studied from weaning until death. *Mecp2*$^{308/Y}$ mice exposed pre- and postnatally to a low methyl donor diet showed significant modification of key phenotypes including decreased motor deterioration and increased life span. The health and behavior of wild-type mice were not influenced by these dietary manipulations. These data indicate that reducing dietary methyl donors improves the neurologic deficits and general health of *Mecp2*$^{308/Y}$ mice. The results raise important questions about the effects of nutrition on the epigenetic regulation of neuronal gene expression. Future work will determine whether dietary methyl donors affect DNA methylation and gene expression in *Mecp2*$^{308/Y}$ mice.

eQTL mapping in the mammalian eye: Application to the identification of human disease genes. *K.A. Kim[1], T.E. Scheetz[1], R. Swiderski[1], A.R. Philp[1], T.L. Casavant[1], J. Huang[1], E.M. Stone[1,2], V.C. Sheffield[1,2].* 1) University of Iowa, Iowa City, IA; 2) HHMI, Iowa City, IA.

Recent advances in microarray technology and bioinformatics have made it possible to perform experiments that examine the expression of thousands of genes in related individuals and to use these data to identify the chromosomal locations of the genetic elements that are responsible for gene expression variation among individuals. This technique is known as expression quantitative trait locus (eQTL) mapping. In order to gain a broad perspective of mechanisms of gene regulation in the mammalian eye, and to use this perspective to find new genes that cause human eye disease, we performed eQTL mapping in the mammalian eye. Two inbred strains of laboratory rats were crossed and the resultant F_1 animals were used to generate 120 healthy F_2 male animals. The F_2 animals were euthanized at 12 weeks of age, and tissues were harvested. RNA was harvested from the whole eyes and ocular gene expression of each animal was determined using Affymetrix microarrays containing approximately 31,000 probes. DNA was obtained from the liver of each animal and used for genotyping with microsatellite markers across the whole rat genome. Two types of analyses were performed with the data. First, genetic analysis was performed to look for relationships between marker locus and expression. Second, pair-wise analysis of each gene with all other genes was performed to identify correlated variations in gene expression. Of the ~31,000 probes on the array, ~18,000 exhibited sufficient signal and variation in expression among the 120 F_2 animals for reliable analysis. Significant linkage to at least one genetic marker was detected for thousands of probes. In all, more than 4,000 marker-probe linkages were detected at an of 0.001. Both cis- and trans-acting loci were identified. The pair-wise correlated expression analysis make it possible to infer gene expression networks. In a novel application of these data, we used predicted expression networks to prioritize candidate genes within a linkage interval to aid in the identification of a gene that causes a human retinal degeneration syndrome.

Susceptibility genes for age related maculopathy (ARM) on chromosome 10q26. *J. Jakobsdottir[1], Y.P. Conley[2,3], D.E. Weeks[1,2], T.S. Mah[4], R.E. Ferrell[2], M.B. Gorin[2,4].* 1) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA; 3) Department of Health Promotion and Development, School of Nursing, University of Pittsburgh, PA; 4) UPMC Eye Center, Department of Ophthalmology, School of Medicine, University of Pittsburgh, PA.

We discovered susceptibility genes for ARM of comparable impact to Complement factor H (CFH) which several groups reported during the past year. We performed a SNP genotyping on 594 ARM families and 179 controls on chromosome 10q26. The linkage analysis gave a wide (10 cM) multipoint S_{all} peak and indicated two regions; GRK5 with the highest multipoint S_{all} LOD score (3.07) and PLEKHA1 with two-point S_{all} of 3.34 and the highest two-point HLOD (2.66). Association analysis allowing for related cases showed a strong signal over PLEKHA1 (p-value < 0.00001). We extended this finding by genotyping all known non-synonymous SNPs in the region of three tightly linked genes PLEKHA1, LOC387715 and PRSS11. We also tested for the presence of their proteins in the eye using RT-PCR of human retinal RNA. The follow-up analysis also yielded a strong signal in PLEKHA1 and LOC387715; due to high linkage disequilibrium it is hard to statistically distinguish between those genes. Both PLEKHA1 and LOC387715 are expressed in the eye; PLEKHA1 in the retina and central macula but the expression of LOC387715 appears to be limited to the placenta. The genotype-IBD sharing test suggests that PLEKHA1 (p-value 0.006) is more likely to account for the linkage signal then LOC387715 (p-value 0.018). The association with PLEKHA1/LOC387715 is very similar to the association found between CFH and ARM. In our data PLEKHA1/LOC387715 and CFH account for a dominant odds ratio of 5.0 (3.2-7.9) and 5.3 (3.4-8.4) and attributable risk of 57% and 68%, respectively. Biologically PLEKHA1 and LOC387715 are relevant candidates to contribute to risk of ARM; though more is known about the expression of PLEKHA1 in the eye and its potential role in cellular responses to inflammatory cytokines.

Mutations in *TCF8* cause posterior polymorphous corneal dystrophy and ectopic expression of epithelial characteristics by corneal endothelial cells. *C.M. Krafchak[1,2], H. Pawar[1], S.E. Moroi[1], A. Sugar[1], P.R. Lichter[1], D.A. Mackey[3,4], S. Mian[1], T. Nairus[1], V. Elner[1], C.A. Downs[1,5], T. Guckian Kijek[1], J.M. Johnson[1], E.H. Trager[1], F. Rozsa[1], M.N. Mandal[1], M.P. Epstein[6], D. Vollrath[7], R. Ayyagari[1], M. Boehnke[8], J.E. Richards[1,2].* 1) Department of Ophthalmology, University of Michigan; 2) Department of Epidemiology, University of Michigan; 3) Department of Ophthalmology, University of Melbourne, Australia; 4) School of Medicine, University of Tasmania, Australia; 5) Department of Otolaryngology, University of Michigan; 6) Department of Human Genetics, Emory University; 7) Department of Genetics, Stanford University; 8) Department of Biostatistics, University of Michigan.

Posterior polymorphous corneal dystrophy (PPCD) is a rare disease involving metaplasia and overgrowth of corneal endothelial cells. In PPCD patients, these cells manifest epithelial morphology and gene expression patterns, produce an aberrant basement membrane and sometimes spread over nearby structures increasing the risk of glaucoma. Within the previously mapped PPCD locus *PPCD3*, we report a heterozygous frameshift mutation in *TCF8*, a gene encoding a two-handed zinc-finger homeodomain transcription factor, that co-segregates with PPCD in the *PPCD3* family, and four different heterozygous nonsense and frameshift mutations in *TCF8* in other probands. Findings of inguinal hernia, hydrocele and possible bone anomalies in affected individuals suggest that those with *TCF8* mutations should be examined for non-ocular anomalies. We detect transcripts of all three identified PPCD genes (*VSX1, COL8A2*, and *TCF8*) in the cornea. We show the presence of a complex (core plus secondary) binding site for TCF8 in the promoter of Alport syndrome gene *COL4A3*, and present immunohistochemical evidence of ectopic expression of COL4A3 in the corneal endothelium of the proband of the *PPCD3* family. Identification of *TCF8* as the *PPCD3* gene provides a valuable tool to study gene regulation events in PPCD pathology and suggests a role for *TCF8* mutations in altering the structure and function of cells lining body cavities other than the anterior chamber of the eye.

Heterozygous and homozygous mutations in PITX3 in a large Lebanese family with posterior polar cataracts and neurodevelopmental abnormalities. *C. Bidinost[1], M. Matsumoto[2], D. Chung[3], N. Salem[3], K. Zhang[4], D.W. Stockton[5], A. Khoury[3], A. Megarbane[3], B.A. Bejjani[1,6], E.I. Traboulsi[2].* 1) Health Research and Education Center, Washington State University, Spokane; 2) Center for Genetic Eye Diseases, Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH; 3) Medical Genetics Unit, Faculty of Medicine, Saint Joseph University, Beirut, Lebanon; 4) Department of Ophthalmology and Visual Sciences, University of Utah Health Sciences Center, Salt Lake City, UT; 5) Departments of Molecular and Human Genetics, Medicine and Ophthalmology, Baylor College of Medicine, Houston, TX; 6) Sacred Heart Medical Center, Spokane, WA.

The *PITX3* gene that codes for a homeobox bicoid-like transcription factor is responsible for dominant cataract and anterior segment mesenchymal dysgenesis in humans. We performed a linkage study in a large Lebanese family with autosomal-dominant posterior polar cataract (PPC) and found a Lod score of 6.56 (=0.00) to chromosome 10q25. Haplotype and sequencing analysis revealed a *PITX3* mutation that co-segregates with the disease. We also describe two siblings who are homozygous for the *PITX3* mutation who have microphthalmia and significant neurologic disorder characterized by mental retardation, choreiform movements, and paraplegia with increased muscle tone and decreased deep tendon reflexes. This is the first report of homozygous *PITX3* mutations in human. The phenotype in these individuals highlights the role of *PITX3* in ocular and CNS development.

Genetic association analysis of bitter-taste sensitivity in chimpanzees: convergent evolution at *TAS2R38*. *S. Wooding[1], B. Bufe[2], A. Stone[3], C. Grassi[4], M. Howard[1], D. Dunn[1], W. Meyerhof[2], R. Weiss[1], M. Bamshad[1].* 1) Dept Human Genetics, Univ Utah, SLC, UT; 2) German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany; 3) Arizona State University, Tempe, AZ; 4) Southwest Foundation for Biomedical Research, SA, TX.

In humans, sensitivity to the bitter compound, phenylthiocarbamide (PTC), is largely explained by the presence of taster and non-taster alleles at the *TAS2R38* locus. In 1939, Fisher *et al.* reported that chimpanzees also vary in sensitivity to PTC. Like humans, chimpanzees harbor PTC taster and non-taster alleles at roughly 50:50 frequencies. Fisher *et al.* argued that the best explanation for this finding is that humans and chimpanzees share taster and nontaster alleles that originated prior to the human-chimpanzee species divergence. To test this hypothesis, we analyzed patterns of DNA sequence variation in *TAS2R38* in 37 wild-born and 40 captive chimpanzees. Sequences from the wild-born chimpanzees revealed seven haplotypes, which did not differ at any of the nucleotide or amino acid positions distinguishing the seven *TAS2R38* alleles identified to date in humans. Like humans, chimpanzees had two common haplotypes; however, unlike the human taster and non-taster haplotypes, which differ by three amino acids, the chimpanzee common haplotypes differed by a single nucleotide substitution that is predicted to cause a null allele. *In vitro* translation experiments revealed that the putative null allele produces a severely truncated protein that is probably non-functional. Further, expression of the chimpanzee alleles in human embryonic kidney cells revealed that while the chimpanzee wild-type allele had a PTC dose/response curve similar to that of the human taster allele, the null allele showed no response to PTC. Finally, an association analysis in the captive chimpanzees confirmed that the null allele is negatively correlated with PTC sensitivity *in vivo* ($p < 0.001$). These findings suggest that PTC sensitivity in both humans and chimpanzees is determined by taster and non-taster alleles of *TAS2R38*; however, these alleles operate through different molecular mechanisms that are the result of convergent evolution.

Estimating Age Related Changes in the Causes of Deafness by Sentinel Phenotype Analysis. *W.E. Nance[1], A. Pandya[1], K.S. Arnos[2], B.G. Lim[3], C.C. Morton[4].* 1) Human Genetics, Virginia Commonwealth Univ., Richmond, VA; 2) Gallaudet Univ, Washington, DC; 3) Pediatrix Corp, Sunrise FL; 4) Harvard Medcal School, Boston MA.

A major limitation of existing audiologic newborn hearing screening programs is that they cannot detect late onset prelingual losses if testing is confined to the newborn period. Few if any studies have compared age related changes in the incidence and prevalence of more than one form of deafness in a large population based sample of deaf children identified by newborn hearing screening. We have combined data from England and the US to estimate the overall frequency prelingual hearing loss at birth (186/100,000) and 4 years of age (270/100,000) in the US. Using frequencies of connexin deafness in simplex and multiplex probands with non-syndromic deafness, the proportion of genetic deafness in simplex probands is GS=CS/CM where GS is the proportion, CS is the frequency of connexin deafness in that group and CM the frequency of connexin deafness in multiplex probands. Applying this formula to data from a Nationwide Repository of DNA samples from deaf probands where CS was 0.136, and CM was 0.323, giving 0.421 for Cs. We used this result to estimate that the total proportion of genetic deafness at birth was 68% and 55% at age 4. Using available data we estimated the frequencies of CMV deafness at birth and age 4 as well as Pendred syndrome, non-syndromic EVA, connexin deafness and A1555G mediated aminogycoside ototoxicity. Finally we used race specific frequencies of hearing loss and the racial distribution of births in the US in 2003 to adjust our estimates to reflect the US population. Congenital CMV infections and connexin deafness are the two major causes of deafness at birth in the US, and syndromic and non-syndromic forms of enlarged vestibular aqueduct with hearing loss along with congenital CMV infections are the two major postnatal causes of deafness that begin by the age of four. We estimate that nearly 60% of the infants who develop late onset pre-lingual hearing loss could be identified at birth by screening newborn blood spots for four causes of deafness by molecular genetic techniques.

Additional Clinical Manifestations in Children with Sensorineural Hearing Loss and Biallelic *GJB2* Mutations: Who Should Be Tested for *GJB2* Mutations? *D.M. Yaeger[1], M.A. Kenna[2,3], A. Frangulov[2], J. McCallum[1], I.D. Krantz[1], H.L. Rehm[4].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia and The University of Pennsylvania, Philadelphia, PA; 2) Department of Otolaryngology, The Childrens Hospital Boston; 3) Department of Otology and Laryngology, Harvard Medical School; 4) Department of Pathology, Brigham and Womens Hospital, Harvard Medical School, Boston, MA.

Sensorineural hearing loss (SNHL) is the most common sensory deficit, occurring in 3 out of every 1000 live births. Worldwide, mutations in the *GJB2* (*gap junction beta 2*) gene, encoding the connexin 26 (Cx26) protein, are the most common genetic cause of hearing loss and are responsible for approximately 30% of all cases of childhood SNHL. *GJB2* mutations are primarily associated with autosomal recessive nonsyndromic bilateral SNHL, although there are rare syndromic forms, most commonly associated with dermatologic manifestations. In general, children with bilateral SNHL and associated non-dermatologic structural or developmental abnormalities are often overlooked as candidates for *GJB2* testing. In a cohort of 139 probands with biallelic *GJB2* mutations, we identified 30 (22%) with additional physical and/or developmental findings. In 21 of these individuals there were sufficient clinical and developmental anomalies to suggest a syndromic etiology for their hearing loss. In the remaining 9 probands, SNHL was seen in combination with a single additional clinical manifestation. Given the high prevalence of *GJB2*-related SNHL, individuals with SNHL and additional findings, which are not definitively explained by a syndromic etiology, should be considered for *GJB2* mutation analysis. While *GJB2* mutations may not be directly responsible for the additional findings, identifying a cause for the SNHL may help to clarify the etiology of the additional findings as well as aid in recurrence risk counseling for families.

Genomic approaches for pathway identification in regenerating sensory epithelia of the inner ear. *D. Alvarado, K. Powder, D. Hawkins, S. Bashiardes, V. Bhonagiri, R. Veile, M. Warchol, M. Lovett.* Dept Genetics, Washington Univ, St Louis, MO.

Loss of sensory hair cells in the cochlea and vestibular organs of the inner ear is the leading cause of hearing and balance deficits in humans. In mammals, sensory hair cells are formed during embryonic development and if damaged, lack the capacity for regeneration. However, in birds, sensory hair cells can regenerate in response to injury. We have recently completed the first large-scale gene expression profile of regenerating avian hair cells on a custom transcription factor (TF) gene microarray. The sensory epithelia (SE) from avian cochlea and utricle were separately profiled at various recovery time points following damage by either laser or chemical ablation. This study involved hundreds of microarray comparisons and numerous biological samples. Expression profiles for all timecourses were compared to identify common differentially expressed TFs. Many of these identified genes can be placed into known signaling cascades such as the *Ap1* pathway, *Tgf* pathway, sonic hedgehog signaling and the *Pax-Eya-Six-Dach* pathway. To assess the necessity of these TFs for SE proliferation and to identify downstream targets, 20 of these TFs were targeted with siRNAs using a 96-well SE cell proliferation assay. We also employed various pharmacological inhibitors and inducers of defined pathways. Targeted knockdowns of *Pax2*, *JunD* and *Cebpg* significantly inhibited SE proliferation. Inhibition of the Jun kinase (JunK) pathway also inhibited SE proliferation. Additionally, TF gene expression profiles for targeted knockdowns or chemical agents were compared to identify potential epistatic relationships. In this way we have placed many TF genes into previously undescribed interactive relationships. One example of an implicated pathway involves the JunK signaling cascade. Our siRNA and profiling data indicate that *JunD* lies upstream of *Cebpg* and that five additional genes lie downstream of *Cebpg*: *IRX4*, *LRP5*, *TAF-172*, *RARA*, and *ZNF44*. Knockdowns of these genes indicate that *IRX4*, *LRP5* and *TAF-172* all inhibit proliferation and that this cascade may intersect with *Wnt* signaling.

Prevalence, impact and genetics of slight/mild sensorineural hearing loss in school age children. *H.-H. Dahl, M. Wake, S. Tobin, Z. Poulakis, F. Rickards, B. Cone-Wesson, & the Hearing In Schools Study team.* Murdoch Childrens Res. Inst., Melbourne, AUSTRALIA.

Existing research suggests slight/mild childhood sensorineural hearing loss (SNHL) has important consequences, but this evidence is mainly from clinic or population samples with low (<50%) response rates. Our aim is to determine, from an unbiased population sample, the impact of slight/mild SNHL on language, reading, behaviour and health-related quality of life (HRQoL) in elementary school children and assess the genetic contribution to the slight/mild SNHL. We have completed a cross-sectional observational study of a random cluster sample of 6587 children (85% response; 3367 Year 1, 3214 Year 5) in 89 schools in Melbourne, Australia. All parents reported on childrens HRQoL and behaviour prior to child audiometric assessment. Slight/mild SNHL was defined as low-frequency pure tone average (LPTA) across 0.5, 1, 2 kHz and/or high-frequency PTA (HPTA), across 3, 4, 6 kHz of 16-40 dB HL in the better ear, with air-bone conduction gaps <10dB. Normal hearing was defined as LPTA and HPTA 15dB HL in both ears. Each child with slight/mild SNHL (matched to 2 normally-hearing children on school, year level, age and gender) completed standardised measures of language, reading, phonological skills, non-verbal IQ, and HRQoL. 55 children (0.83%) had slight/mild SNHL; 48 participated in further assessment, along with 96 normally-hearing children. Affected children showed poorer phonological skills, but language, reading, behaviour and HRQoL scores were not significantly different from those of the control group. Four of 48 children with slight/mild SNHL were homozygous for the connexin 26 (Cx26) V37I mutation, 2 were carriers of the V37I mutation. All were of Asian background. Two children in the control group were carriers of known Cx26 mutations (235delC and 35delG). We conclude that the prevalence of slight/mild SNHL is lower than commonly reported, that mutations in the connexin 26 gene is the underlying cause in ~8% of young Australians with a slight/mild SNHL and that the V37I change is a common cause of slight/mild SNHL in children of Asian ethnicity.

The severity of hearing impairment due to connexin 26 mutations strongly depends on the nature of the mutations: a multi-center study. *G. Van Camp, The connexin 26 genotype phenotype consortium.* Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium.

Hearing impairment (HI) affects 1 in 650 newborns, making it the most common congenital sensory impairment. Despite extraordinary genetic heterogeneity, mutations in one gene, GJB2, are found in up to 50% of patients with autosomal recessive non-syndromic hearing loss. Because of the high frequency of GJB2 mutations, mutation analysis of this gene is widely available as a diagnostic test. We performed a cross-sectional analysis of GJB2 genotype and audiometric data from 1531 persons from 16 different countries with autosomal recessive, mild-to-profound, nonsyndromic hearing impairment. The median age of all participants was 8 years; 90% of persons within the age range of 0-26 years (total age range, 0-70 years). Of the 83 different mutations identified, 47 were classified as non-truncating and 36 as truncating. A total of 177 different genotypes was found, of which 64 were homozygous truncating (T/T), 42 were homozygous non-truncating (NT/NT) and 71 were compound heterozygous truncating / non-truncating (T/NT). The degree of HI associated with biallelic truncating mutations was significantly more severe than the HI associated with biallelic non-truncating mutations ($p < 0.0001$). Forty-seven different genotypes showed less severe HI compared to 35delG homozygotes. Several common mutations (M34T, V37I, L90P) were associated with mild-to-moderate HI (median 25-40 dB; range 10-60 dB for genotypes involving M34T and/or V37I, range 10-110 dB for those involving L90P). Two genotypes (35delG/R143W (median = 105 dB; range = 105-115 dB) and 35delG/del(GJB6-D13S1830) (median = 108 dB; range = 70-120 dB) had significantly more severe HI compared to 35delG homozygotes. The results of this large multicenter study show that the probability of having a severe to profound hearing impaired child strongly depends on the mutations carried by the parents and that the phenotype of future children can be predicted on the basis of these mutations with a certain probability. This has important consequences for genetic counselling for this frequent form of hereditary hearing impairment.

Pur alpha overexpression suppresses neurodegeneration in the *Drosophila* FXTAS Model. *P. Jin, R. Duan, F. Hassouna, T.C. Rosser, S.T. Warren.* Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA.

Fragile X syndrome premutation carriers have FMR1 alleles containing 55 - 200 CGG repeats. Fragile X-Associated Tremor/Ataxia Syndrome (FXTAS) is a neurodegenerative disorder, with neuronal inclusions, that has been recognized in some premutation carriers. We have developed a *Drosophila* model of FXTAS and demonstrated that transcribed premutation repeats alone are sufficient to cause neurodegeneration. It has been proposed that rCGG-Repeat-Binding Proteins (rCGGBPs) may be sequestered from their normal function by binding to lengthy rCGG repeats similar to the myotonic dystrophy mechanism. Using rCGG oligoribonucleotides to capture rCGGBPs from mammalian brain lysate followed by mass spectrometry, we identified Pur alpha as a rCGGBP. In mammals, Pur alpha is a conserved RNA-binding protein that is expressed in neuronal cytoplasm and involved in dendritic mRNA transport. We found that Pur alpha and rCGG repeat interaction is conserved between mammals and *Drosophila*, and is sequence-specific. As our hypothesis predicts, over-expression of Pur alpha in *Drosophila* could suppress rCGG-mediated neurodegeneration in a dose dependent manner. Further, Pur alpha was found to be part of inclusions induced by rCGG repeats in this model. These data support the disease mechanism of the fragile X premutation rCGG repeat sequestering specific rCGGBPs leading to neuronal cell death and suggest that Pur alpha could play a role in the pathogenesis of FXTAS.

A first generation drug screen for fragile X syndrome. *S. Chang, P. Jin, S.T. Warren.* Human Genetics, Emory University, Atlanta, GA.

Fragile X syndrome is an inherited form of mental retardation that results from the loss of the fragile X mental retardation 1 protein (FMRP). Currently there are only modest palliative treatments for only some of the behavioral aspects of the disorder. FMRP is a translational suppressor of a subset of mRNAs and is found within dendritic spines. Recent data has linked FMRP action with the postsynaptic metabotropic glutamate receptor 5 (mGluR5), whose downstream actions on learning and memory require new protein synthesis. Thus FMRP may act to balance the translational stimulation of mGluR5 activity. Indeed, in the absence of FMRP, the protein encoded by the MAP1B mRNA, a known FMRP ligand is over expressed in neurons. Thus mGluR5 antagonists, such as MPEP, may attenuate this consequence of FMRP loss. We found *Drosophila* with *dFmr1* null mutation exhibits early developmental blockade and lethality before pupae stage on a commercial food source (JAZMIX), which was not apparent with homemade food. Placing ~40 *dFmr1* null embryos in vials of homemade food led to an average of 38 pupae/vial while on JAZMIX only an average of 0.5 pupae/vial (1.3 % false positive). Supplementing JAZMIX with 86 ?M MPEP led to the recovery of 21 pupae/vial. These observations led to the development of a novel drug screen for pharmacological agents that suppress this *dFmr1* null phenotype. A collection of 2,000 FDA-approved, biologically active and structurally diverse compounds was tested. Only 43 drug-treated vials showed evidence of pupae formation (~2.1 %). 9 drugs showed at least 15% pupae recovery or the emergence of *dFmr1* deficient adults. Some of these identified drugs are known to influence the serotonin, dopamine, and mGluR pathways. This screen identified multiple structurally unrelated pharmacological agents, for follow-up studies in *Drosophila* and mice that may modulate the consequence of FMRP loss.

A conserved function for two *Drosophila* homologs of *Chx10*, a human micropthalmia gene, in the control of proliferation and interneuron differentiation of the visual system. *T. Erclik[1,2], V. Hartenstein[3], H. Lipshitz[1,2], R. McInnes[1,2].* 1) Prog in Dev Biol, Hosp for Sick Children, Toronto; 2) Dept of Mol and Medical Genetics, Univ of Toronto; 3) Dept of Mol, Cell and Dev Biol, UCLA.

Chx10 encodes a homeodomain (HD) and CVC domain protein that is an essential component of a genetic pathway which regulates mammalian eye development. In vertebrates, including human, *Chx10* loss of function is associated with poor proliferation of retinal progenitors, microphthalmia and blindness. Because regulators of eye development are often highly conserved between invertebrates and mammals (e.g.*Pax6*) we are using the powerful genetics of *Drosophila* to facilitate the dissection of the *Chx10* regulatory pathway. We have identified two *Drosophila* homologs of *Chx10*, *dChx1* and *dChx2*, which are >80% identical to *Chx10* in the HD and CVC domains. We report that, remarkably, *dChx1* is expressed in the proliferating progenitors of the fly optic lobe and that a loss of *dChx1* function leads to a great reduction in the size of the optic lobe. This finding suggests that *dChx1* may play a role in the proliferation of optic lobe progenitors of invertebrates that is orthologous to that of *Chx10* in the neuroretinal progenitors of vertebrates. In later stages of *Drosophila* development both *dChx* genes are expressed in the medulla of the mature optic lobe. The medulla contains a class of interneurons that synapse with the photoreceptors required for colour and UV light detection. The expression of the *dChx* genes in the medulla suggests that *dChx*-expressing mature optic lobe interneurons in the fly and *Chx10*-dependent bipolar interneurons in mammals are orthologous populations of visual interneurons. We propose, based on the expression data and mutant phenotypes, that the neuroretina of vertebrates and the optic lobe of flies are evolutionarily conserved structures whose development is regulated by the orthologous homeobox genes, *Chx10* and *dChx1* and *dChx2*. These findings extend the evidence for striking evolutionary conservation of the genetic control of eye development to include the genes that regulate the development of the major interneurons of visual systems.

Dissection of epistasis in an oligogenic disorder. *J.L. Badano[1], C.C. Leitch[1], S.J. Ansley[1], H. May-Simera[2], R.A. Lewis[3], P.L. Beales[2], H.C. Dietz[1,4], S. Fisher[1,5], N. Katsanis[1,6].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Molecular Medicine Unit, Institute of Child Health, University College London, London WC1N 1EH, UK; 3) Departments of Molecular and Human Genetics, Ophthalmology, Pediatrics, and Medicine, Baylor College of Medicine, Houston, TX; 4) Howard Hughes Medical Institute; 5) Department of Cell Biology, Johns Hopkins University, Baltimore, MD; 6) Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD.

Epistatic interactions are though to play a significant role in phenotypic variation, yet the genetic dissection of such phenomena remains challenging. Through a combination of computational and experimental approaches, we have identified a novel locus, *BBSIP1*, which contributes epistatic alleles to Bardet-Biedl syndrome (BBS), a pleiotropic, oligogenic disorder. *BBSIP1* encodes a pericentriolar protein that interacts and co-localizes with the BBS proteins. Sequencing of two independent BBS cohorts revealed a significant enrichment of a heterozygous 430T mutation in patients and TDT analysis showed strong over-transmission of this variant. This mutation results in the utilization of a cryptic splice acceptor due to the aberrant potentiation of an exonic splice enhancer, deletion of five nucleotides and a moderate reduction of steady-state *BBSIP1* mRNA. Finally, recapitulation of the human genotypes in zebrafish shows that modest suppression of *bbsIP1* in early embryos exerts an epistatic effect on the expressivity of the developmental phenotype of BBS morphants. Our data demonstrate how the combined use of biochemical, genetic and in vivo tools can facilitate the dissection of epistatic phenomena and enhance our appreciation of the genetic basis of phenotypic variability.

Bardet-Biedl Syndrome genes are involved in a common pathway affecting intracellular trafficking and cilia maintenance. *M. Tayeh[1, 3], H.-J Yen[1, 3], R. Mullins[4], C. Searby[1, 3], T. Westfal[2], E. Stone[3, 4], D. Slusarski[2], V. Sheffield[1,3].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Biology, Univ Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, Bethesda, MD; 4) Dept Ophthalmology, Univ Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is characterized by obesity, retinopathy, polydactyly, cognitive impairment, renal and cardiac anomalies, hypertension and diabetes. The eight known BBS genes do belong to the same functional category; yet mutation of these genes results in a similar phenotype. While the precise functions of the BBS proteins are unknown, data support a role in ciliated organisms and study of individual BBS proteins indicate involvement in basal body biology. To gain insight into the biological processes controlled by BBS genes, we embarked on studies of six BBS orthologues from zebrafish. Knockdown of zebrafish bbs2, 4, 5, 6, 7 or 8, using antisense morpholinos (MO), results in a specific defect in a non-ciliated cell type altering retrograde organelle (melanosome) transport and a progressive loss of ciliated cells within a developmental structure known as Kupffers vesicle (KV). KV is a ciliated organ thought to play a role in left-right patterning. Our data demonstrate abnormal KVs in MO-treated embryos and subsequent alterations to organ laterality, including heart and brain laterality defects.To confirm the specificity of the generated phenotypes, we rescued with in vitro transcribed wild-type RNA. We further demonstrate that RNA with putative human BBS mutations do not rescue the phenotypes. We also embarked on using zebrafish as a model system to investigate genetic interactions between the zebrafish bbs2, bbs6 and bbs7 genes using co-injection of combinations of MOs targeting the zebrafish bbs genes. Double knockdown data show an additive effect of the phenotype severity. In summary, our data demonstrating overlapping cellular phenotypes of the individual BBS knockdowns and additive effects of the double knockdown suggest that mutated BBS genes affect a common pathway involved in general organelle trafficking and cilia maintenance and that BBS genes can potentially modify each others phenotype.

Organ laterality: cilia direct a wave of asymmetric gene expression that establishes the left and right sides of developing organs. *J.D. Amack, X.H. Wang, H.J. Yost.* Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT.

Reversed organ laterality (*situs inversus*) in patients affected with a subtype of primary ciliary dyskinesia, known as Kartagener syndrome, provides a link between cilia function and organ laterality that has been recognized for many years. Recently, work in mouse and zebrafish embryos has established a model that explains the role of cilia in left-right (LR) patterning of asymmetric organs such as the heart, brain and gastro-intestinal tract. In this model, motile cilia generate a leftward fluid flow that is required for asymmetric expression of a conserved battery of genes on the left side of the embryo, including members of the *nodal* and *pitx2* gene families. In zebrafish embryos, these specialized cilia reside in a transient organ called Kupffers vesicle (KV). We have previously demonstrated that KV cilia create a directional fluid flow, and that perturbation of KV form or function alters LR patterning. Here, we show that expression of the zebrafish nodal family member *southpaw* (*spaw*), which is initiated in left lateral plate mesoderm (LPM) lateral to KV in the tail, progresses as a dynamic posterior-to-anterior (P-A) wave to generate molecular asymmetry in the developing heart, brain and gut. By analyzing mutant embryos in which KV is abnormal, we show that normal KV morphology is not necessary for initiation of *spaw* in LPM, but is required to direct this initiation to the left side. Spatio-temporal analysis of *spaw* expression using *myod* as a somite stage marker indicated that the anterior boundary of *spaw* moved anteriorly at a speed of 3 somite lengths per somite generation time between the 12-20 somite stages. *spaw* expression then rapidly diminished in a P-A fashion between the 20-24 somite stages. Further expression analyses revealed that two additional genes involved in LR patterning*pitx2* and *lefty1*show a similar P-A wave that appears coordinated with *spaw*. Cell labeling experiments indicate the P-A wave is not a result of cell migration, suggesting cell-to-cell signaling as a likely mechanism. These results suggest that a wave of asymmetric gene expression transfers LR pattern information generated by cilia to developing organ primordia.

Fishing for functional DNA: Efficient functional examination of noncoding sequences in transgenic zebrafish. *A. McCallion[1,2], S. Fisher[1], E.A. Grice[1], R. Vinton[1].* 1) McKusick-Nathans Inst Gen Med, Johns Hopkins Univ, Baltimore, MD; 2) Department of Comparative Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA.

Evolutionary sequence conservation is recognized as a reliable indicator of functional sequences (coding and noncoding). With accessible transparent embryos, the zebrafish Danio rerio is an attractive model system to test noncoding putative regulatory elements during development. However, significant problems with mosaicism have hindered the use of transgenic zebrafish to assay for functional noncoding sequences. We have overcome these limitations with a novel transgenic strategy, using the recently described Tol2 transposon. Tol2-based vectors provide a high frequency of plasmid integration and 5 fold higher germline transmission frequencies (mean>=25%) than established protocols. This permits rapid examination of the ability of non-coding sequences to direct tissue-specific GFP expression in live G0 zebrafish. We are systematically testing the hypothesis that conserved non-coding sequences will frequently play a role in regulating expression of their neighboring genes. We have begun by analyzing conserved sequences at the *RET* gene encoding a critical receptor tyrosine kinase in the genesis of the multiple organ systems, and one in which regulatory mutations have already been implicated in human disease (Hirschsprung Disease). To date we have studied 27 amplicons containing 42 conserved non-coding sequence elements, associated with the human and zebrafish *RET* genes, examining their ability to drive consistent reporter expression in live G0 embryos. The majority (24/27) recapitulate endogenous RET expression (CNS, PNS, kidney), including amplicons encompassing >=22 human sequences that display no overt sequence conservation with the teleost genome (>=100bp, >=75%). We are extending these analyses to other critical genes in nervous system development and osteogenesis. This system will facilitate the rapid functional analysis of conserved sequences from multiple vertebrate genomes, and will aid in the refinement of computational approaches to identify fundamental aspects of sequence conservation.

Genetic backgrounds susceptible to genomic deletions: *Alu*-mediated mutations of BRCA1 as a model. *K.M. Chisholm[1], P.L. Welcsh[2], K.P. Freese[2], M.-C. King[1,2].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

At the BRCA1 gene, large genomic deletions frequently occur as somatic loss of heterozygosity in breast tumors and as inherited mutations in families. These genomic deletions appear to be the result of aberrant homologous recombination between *Alu* elements, which are densely packed at the BRCA1 genomic locus. My hypothesis is that loss of function of a still unknown mutator gene(s) leads to increased frequency of homologous recombination and thereby increased frequency of large genomic deletions at susceptible loci. The purpose of my project is to identify such mutator gene(s) using BRCA1 as a model. I have created a construct incorporating BRCA1 exon 17 and flanking *Alu* sequences; these *Alu* repeats are often rearranged in inherited breast tumors. I have inserted this construct, as well as a URA3 selection gene, into a yeast transformation plasmid. This plasmid has successfully been screened for genomic deletions in 99% of the Saccharomyces Genome Project collection of yeast strains comprised of all viable individual gene knockouts. The resulting 80 putative mutator strains include kinases, DNA repair proteins, and proteins involved in meiotic recombination between homologous chromatids. The assay also identified mutator genes found to cause gross chromosomal rearrangements in previous studies, as well as genes such as *msh5* and *pms1*, suggesting that the screen was effective. The potential mutator strains are being analyzed to determine the kinds of mutations they cause and at what rate. Human homologs have been identified thus far for 47 of the 80 genes; mutations in these human genes will be screened for in high-risk breast cancer families who are wildtype for all known breast cancer genes and in sporadic breast tumors. Though the primary aim of this research proposal is to identify mutator genes involved in breast carcinogenesis, these same genes may be involved in other cancers as well. Thus, identifying mutator genes may not only help in understanding breast cancer, but also other cancers.

Yeast model system reveals the mechanism of palindrome-mediated chromosomal translocation. *T. Ohye[1], H. Inagaki[1], H. Kogo[1], B.S. Emanuel[2], H. Kurahashi[1].* 1) Div Molecular Genetics, Fujita Health Univ, Toyoake Aichi, Japan; 2) Div Human Genetics, Children'fs Hosp Philadelphia, Philadelphia PA.

The constitutional t(11;22)(q23;q11) is the most frequently occurring non-Robertsonian translocation in humans. The breakpoints of the t(11;22) were identified within palindromic AT-rich repeats (PATRRs) on chromosomes 11 (PATRR11) and 22 (PATRR22), suggesting that cruciform structures mediate double-strand-breaks (DSBs) leading to this recurrent translocation. The breakpoints of a variety of translocations involving PATRR22 have been reported, which demonstrated similar palindromic sequences on partner chromosomes, such as 17q11, 4q35.1, and 1p21.2. To investigate why the partner of a PATRR-mediated translocation is preferentially a PATRR located on another chromosome, we analyzed the mechanism of PATRR-mediated chromosomal translocation using yeast model. Previously, we created a diploid yeast harboring the 445bp PATRR11 at the TRP1 locus on chromosome IV and the 595bp PATRR22 at the LEU2 locus on chromosome III. We successfully recapitulated PATRR-mediated chromosomal translocations. We introduced a recognition sequence for a restriction enzyme, I-SceI, into the yeast genome instead of the PATRR22. This would induce mandatory 3'f-overhang DSBs through transient expression of I-SceI. However, we did not detect any translocation-specific PCR products between the PATRR and the I-SceI recognition site. Next, we determined the 5'f and 3'f end of DSBs at the PATRR by ligation-mediated PCR and tailing-mediated PCR, respectively. The majority of the 3'f ends of both proximal and distal sides of the DSB appear to cluster at the starting point of the PATRR. However, the 5'f ends of both sides are distributed throughout the PATRR, and further extend beyond the center of the palindrome. Finally, sequence analysis of the junction fragments indicates that the translocations always occur at a region with microhomology between PATRR11 and PATRR22, and that some breakpoints traverse beyond the tip of the PATRR. We propose that the unusual 5'f overhang DSBs at both PATRRs followed by single-strand annealing is the mechanism that mediates the recurrent chromosomal rearrangement.

Human inversion polymorphisms identified through studies of inversion events in recent primate evolution. *L. Feuk, J. MacDonald, A.R. Carson, T. Tang, S.W. Scherer.* Dept Genetics & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada.

The aim of this study was to investigate inversions that have occurred during recent primate evolution, including the most recent inversions that are polymorphic in the human population. We initially identified all inverted sequences from the net alignments between the human and chimpanzee genome assemblies (human NCBI Build 35 and chimpanzee NCBI Build 1). Segmental duplications were identified as the major source of non-syntenic alignments and these regions were therefore excluded. After this filtering, a total of 2868 regions larger than 20bp remained. Thirteen of the inversions between human and chimpanzee are larger than 100kb and not previously described in literature. We chose 30 regions for experimental validation. Using fluorescence in situ hybridization or PCR, 23 regions were confirmed to be inverted between human and chimpanzee. Using gorilla as an outgroup, 14 inversions were shown to have arisen in the human lineage. Upon examination of 20 human control samples, two of these regions were found to be polymorphic inversions. Three individuals were heterozygous for a 700kb inversion region flanked by segmental duplications. The second region found to be polymorphic involves an 18kb region, of which 13kb are inverted and 5kb are deleted. The allele frequency of the inversion/deletion allele is 70% in control individuals. These results indicate that inversions have been a common rearrangement in recent primate evolution. Encouraged by these findings, we have expanded our analysis to include an alignment between the human R27C assembly from Celera and NCBI Build 35 in order to identify further candidate polymorphic regions. A total of 590 intra-scaffold regions of inverted orientation were identified from this alignment. These regions are now being evaluated experimentally and preliminary results indicate that this dataset includes both assembly errors and inversion polymorphisms.

A fine-scale map of recombination rates and hotspots across the human genome. *G. McVean, S. Myers, C. Freeman, L. Bottolo, P. Donnelly.* Department of Statistics, University of Oxford, United Kingdom.

Genetic maps, which document the way in which recombination rates change with physical position over a genome, are an essential tool for many genetic analyses. Here we present a high resolution genetic map of the human genome, based on statistical analyses of genetic variation data. The new map details extensive recombination rate variation over kilobase scales, around three orders of magnitude finer than existing pedigree-based human genetic maps, and will facilitate more powerful genetic association and fine-mapping studies, in addition to population genomic analyses. We identify more than 25,000 recombination hotspots, an average of one per 108kb, and no regions larger than 200kb that are devoid of recombination. Recombination rate variation over centimorgan scales, such as the marked differences between telomeres and centromeres, results from changes in both the density and intensity of hotspots. While much of the rate variation over these large scales can be explained by DNA sequence and structural features, the same features fail to predict the precise location of individual hotspots. We also show that recombination rates over large scales appear to be slow-evolving, in contrast to recent evidence that the local recombination landscape is evolving rapidly. This suggests a two stage model for recombination in which hotspots are stochastic features within a framework in which large-scale rates are constrained.

Genome-wide distribution of genes and sequence features in the context of linkage disequilibrium values. *A.V. Smith[1,2], D.J. Thomas[3], H.M. Munro[4], G.R. Abecasis[4].* 1) Cold Spring Harbor Laboratory, 1 Bungtown Road, Cold Spring Harbor, NY; 2) Genthor ehf., Gardastraeti 11, Reykjavik, Iceland; 3) Biomolecular Engineering Department, Baskin School of Engineering, University of California at Santa Cruz, 1156 High Street, Santa Cruz, CA; 4) Center for Statistical Genetics, School of Public Health, University of Michigan, 1420 Washington Heights, Ann Arbor, MI.

The current availability of large-scale datasets providing information on linkage disequilibrium for >1 million markers will greatly aid in the design and interpretation of genome-wide association studies and facilitate the identification of alleles underlying susceptibility to complex disease. In addition to facilitating disease association studies, these datasets also provide us with the best opportunity yet to explore the relationship between local sequence variation and patterns of linkage disequilibrium (LD). Using data from the International HapMap Consortium, we characterize the relationship between local sequence variation and patterns of LD in the genome in three different populations. Our results show remarkable consistency across populations and suggest that GC content, DNA polymorphism, and repeat content are strongly associated with the local extent of LD. We find that genes and coding sequences are enriched in regions of very high and very low disequilibrium, compared to the rest of the genome. Interestingly, when we used the Gene Ontology database to aggregate genes according to their functional roles, we found different types of genes locate preferentially to the high LD and low LD regions. Genes contained involved in the cell cycle control and DNA metabolism are more often found in regions of high LD. In contrast, genes found with a role in immune responses are more often found in regions of lower LD, as they might benefit from increased allele and haplotype diversity. These results suggest that genes within in regions of lower LD might be involved in pathways that benefit from greater diversity, whereas genes in regions of high LD might be involved in more evolutionary conserved processes.

Annotation of the protein-coding genes in the ENCODE regions. *A. Reymond[1,2], F. Denoeud[3], J. Harrow[4], C. Ucla[2], E. Eyras[3], C. Wyss[2], J. Lagarde[3], E. Birney[5], T. Hubbard[4], R. Guigo[3], S.E. Antonarakis[2], ENCODE consortium members.* 1) Center of Integrative Genomics, University Lausanne, Switzerland; 2) Genetic Medicine, University of Geneva, Switzerland; 3) IMIM, Barcelona, Spain; 4) Wellcome Trust Sanger Institute, Cambridge, UK; 5) EBI, Cambridge, UK.

The aim of the ENCODE project (http://genome.gov/10005107) is to identify all the functional elements of the human genome. In its pilot phase, ENCODE focuses on 44 regions of the human genome corresponding to 1% of its sequence. Within this pilot phase, the GENCODE subgroup (http://genome.imim.es/gencode/) has produced a detailed reference annotation. First, all the 426 known genes mapping to the ENCODE regions were subjected to 5 RACE in 12 tissues. These experiments showed that many known genes are not fully annotated at their 5 as 10-15 % of the RACEs products exhibit yet undescribed exons at their 5end. Second, the genes categorized as putative or novel, were experimentally verified by RT-PCR in 24 different human adult and fetal tissues. Full-length structure of the confirmed genes was obtained by bi-directional RACE. Third, all the 1255 computational predictions from ab initio and EST-based programs that fell outside of our reference annotation were tested experimentally. Only about 3% (32/1215) of them could be verified, suggesting that not many standard protein coding genes are missed from the current set of human genes. The reference annotation of the 44 regions was released in June, 2005. The annotation revealed the complex transcript structure of the human genome with multiple overlapping transcription units through the genome, challenging the traditional view of genes encoded as discrete entities. Alternative splicing is widespread: all multi-exonic genes have more than one splice form. The second phase of the GENCODE project will target specifically those genes and exonic variants likely to be underrepresented in the current catalog of human genes: short and intronless genes, genes undergoing non-canonical splicing, selenoprotein genes, genes with unusual codon composition that may be expressed at very low levels or with a very restricted pattern, and human specific genes, among others.

Islands of euchromatic-like sequence and expressed genes within the heterochromatic regions: lessons from the initial sequence analysis of 21p. *P. Prandini[1], R. Lyle[1], K. Osoegawa[2], B. ten Hallers[2], S. Humphray[4], B. Zhu[2], E. Eyras[2], R. Castelo[3], C. Bird[4], M. Cruts[5], S. Dahoun[1], X. She[6], C. Van Broeckhoven[5], E. Eichler[6], S.Y Wang[7], R. Guigo[3], J. Rogers[4], P. de Jong[2], A. Reymond[1], S.E. Antonarakis[1].* 1) Univ. Geneva, CH; 2) Children's Hospital Oakland Res. Inst, USA; 3) Ctr Genomic Regulation, Spain; 4) Sanger Institute, Cambridge, UK; 5) Univ. Antwerp, Belgium; 6) Univ. Washington, Seattle, USA; 7) Shangai Genome Ctr, China.

Although the sequence of the euchromatic portion of the human genome is essentially complete, the heterochromatic regions (5-10% of the genome) remain to be sequenced. These regions include the short arms of the acrocentric chromosomes, which are involved in many translocations associated with disease phenotypes. Chromosome 21 has special significance because of its involvement in Down Syndrome and we have thus initiated an international collaboration to determine the sequence of 21p. We have constructed a BAC library from the human-mouse somatic hybrid cell line WAV17, which contains sequence from a single Hsa21. We present here data on 1.3Mb of new sequence from 21p (estimated to be 10-15% of the total) generated from 8 BAC clones isolated with STSs mapping to 21p. Unexpectedly, 21p contains islands of sequence showing euchromatic-like features with an interspersed repeat content very similar to the 21q. Gene predictions by EST and in silico based methods identified 29 gene models, 30% of which were validated by RT-PCR in 24 human tissues. In addition, we mapped the 5 ends of each transcript by RACE. Thus far we have identified an expressed sequence approximately every 100kb, each of which are highly conserved in the chimp genome. Analysis of these transcripts from different individuals and monochromosomal cell hybrids shows extensive variability and suggests that multiple inter- and intrachromosomal copies exist. Quantification of their copy number by qPCR indicates that many are present in 20-50 copies in the human genome. This study is an important step in the characterization of these unexplored regions of the genome and toward the real completion of the human genome project.

A minority of Conserved Non-Genic sequences (CNGs) of chromosome 21q show properties of transcription regulators. *C. Attanasio[1], J.A. Stamatoyannopoulos[2], R. Lyle[1], M. Dorschner[2], R. Humbert[2], E.T. Dermitzakis[3], A. Reymond[1,4], S.E. Antonarakis[1].* 1) Dept Genetic Medicine & Development, University of Geneva, Switzerland; 2) Dept Molecular Biology, Regulome, Seattle, USA; 3) The Wellcome Trust Sanger Institute, Cambridge, UK; 4) Center for Integrative Genomics, University of Lausanne, Switzerland.

Comparative genome analysis across mammals has revealed a large number of highly conserved non-genic sequences (CNGs). We had studied CNGs from 21q and found that their evolutionary features strongly suggested functional importance. However the function of the majority of these sequences is unknown. A possible role of a subset of CNGs is transcriptional regulation. Indeed sequences involved in transcription regulation are often conserved. In vitro luciferase expression assays on 100 CNGs versus 20 control sequences (single-copy, non-conserved, same GC content), was carried out in two different human cell lines (293T & Huh7). Only 9% of these CNGs displayed a 2-fold increase in luciferase activity compatible with enhancer function. Overall, however, there was no statistically significant difference between CNGs and control sequences in this assay. Since DNaseI hypersensitivity (HS) is a known property of classical cis-regulatory elements (promoters, enhancers, insulators, silencers), we used this characteristic to explore the chromatin structure of a set of 192 CNGs in 8 different human cell types representing derivatives of the 3 embryonic layers. 13% of the CNGs were HS in one or more cell lines. Interestingly, the majority of HS CNGs displayed a cell-type specific DNaseI hypersensitivity, consistent with a tissue-specific role. Finally, as a functional link between the assays used here and gene expression variation in vivo, we assayed expression of 128 genes on Hsa21 by qRT-PCR in 7 cell lines. We are currently investigating a potential correlation between the presence / absence of a cell-type specific HS CNG with cell-specific gene expression. Taken together, the results indicate that only a minority of CNGs have properties of transcriptional regulators.

Multiple Mammalian Genomes. *R. Gibbs, J. McPherson, J. Belmont, D. Wheeler, G. Weinstock, I. Yakub, A. Goldman, C. Davis, D. Burgess, J. Noebels.* Hum Genome Seq Ctr, Baylor Col Medicine, Houston, TX.

Multiple mammalian genomes have been sequenced and analyzed and we are now turning our efforts back to the understanding of the biology of individual diseases by discovery of specific alleles that underlie different human disease conditions. To accomplish this we established a pipeline at the Baylor College of Medicine Human Genome Sequencing Center (BCM-HGSC) that allows sequencing of PCR products from thousands of exons and samples, thereby simultaneously screening large numbers of candidate disease genes in several affected populations for both putative functional mutations and associated polymorphisms. The pipeline is also being used to re-sequence several genes and regions, including behavioral disorder candidates, and West Nile Virus susceptibility regions. We are also searching for causative mutations in patients with Idiopathic Generalized Epilepsy by systematic re-sequencing of the exons and 5 regions of all ~300 ion channel genes. Over 100 patient samples have been collected and a total of 500 will be banked. In the first few genes and patients we are already finding multiple coding changes that may be associated with disease. To attribute functional significance to the changes we are both studying marker frequencies in matched controls and systematically reconstructing the mutant proteins in order to perform patch clamp assays. The ion channels are likely involved in other neurobehavioral disorders including autism, and the survey will be expanded into these by the third quarter of 2005.

Overcoming a Technical Hurdle in Identifying Variation and Mutations in Large Genomic Regions: Direct Genomic Selection (DiGS). *R. Veile, A.M. Bowcock, M. Lovett.* Division of Human Genetics, Department of Genetics, Washington University School of Medicine, St Louis, MO.

The search for DNA sequence variants that underly many genetic diseases increasingly requires the resequencing of very large genomic regions, including intragenic and intergenic intervals. We recently describe modifications to direct selection that provide a rapid route to the targeted resequencing of large genomic regions (>100kb) and the identification of novel variants, in patient genomic DNAs. This method employs biotinylated BAC DNAs in a hybridization-selection scheme with PCR-linkered total genomic DNAs from patients. This resulted in enrichments of 10,000-fold, in which 50% of the sequence-ready clones were from the targeted region. In a resequencing project of psoriasis patient DNAs covering 150kb of the human RAPTOR gene, we detected 69 known SNPs and ~100 new variants (including several small insertion/deletions). We have now implemented this scheme on several additional genomic intervals and have made the following four modifications: (1) the use of larger BAC contigs of >500kb; (2) we have addressed the issue of contig coverage and completion in the final resequenced interval, by employing random shearing, repair and linker ligation of the target genomic DNAs to derive more even clone coverage; (3) to reduce the number of false positive SNPs (introduced by Pfu polymerase in the large number of PCR cycles), we have optimized the number of PCR cycles and cloning efficiencies, and; (4) to adapt this scheme for cross-species genomic selections we have used a chicken BAC (from which this reference avian genome was derived) to select the orthologous contigs from 50 different diverse bird species. This type of cross-species genomic selection should speed up targeted sequencing (and comparative genomics) of many different species for which BAC libraries and genomic DNA sequences are currently unavailable.

Genome-wide Mapping of DNaseI Hypersensitive Sites by Massively Parallel Signature Sequencing (MPSS) and DNase-chip Technologies. *G. Crawford[1], S. Davis[1], P. Scacheri[1], I. Holt[1], J. Whittle[1], E. Margulies[1], B. Webb[1], J. Bernat[2], D. Ginsburg[2], S. Luo[3], D. Zhou[3], T. Vasicek[3], R. Green[4], T. Wolfsberg[1], F. Collins[1].* 1) NHGRI, NIH, Bethesda, MD; 2) University of Michigan, Ann Arbor, MI; 3) Solexa, Inc., Hayward, CA; 4) Nimblegen Systems, Inc., Madison, WI.

A major goal in genomics is to understand how genes are regulated in different tissues, stages of development, diseases, and species. Mapping DNaseI hypersensitive (HS) sites within nuclear chromatin is a powerful and well-established method of identifying many different types of regulatory elements, but in the past has been limited to analysis of single loci. We have developed two methods to identify DNase HS sites on a genome-wide scale. First, we report high throughput analysis, using massively parallel signature sequencing (MPSS), of 500,000 tags from DNase libraries generated from quiescent and activated human CD4+ T cells. Of the tags that uniquely map to the genome, we identified 26,000 clusters of sequences that group within close proximity to each other. Using a real-time PCR strategy, we determined that the majority of these clusters represent valid DNase HS sites. Approximately 80% of these DNase HS sites uniquely map within one or more annotated regions of the genome believed to contain regulatory elements, including regions 2kb upstream of genes, CpG islands, and highly conserved sequences. Genes with a DNase HS site nearby had higher expression levels than average, indicating that many of these sites correlate with activation of transcription. Interestingly, 10% of the DNase HS sites are exclusive to lymphocytes, suggesting that this procedure can identify gene regulatory elements that control cell type specificity. We have also developed a second technology, called DNase-chip, which hybridizes genome-wide captured DNase HS sites to custom tiled oligonucleotide microarrays. This method is highly reproducible and can be used to identify DNase HS sites around a single gene or across the entire genome. These strategies, which can be applied to any cell line or tissue from any sequenced organism, will enable a better understanding of how chromatin structure dictates cell function and fate.

A Survey of Copy-Number Polymorphisms using a set of twenty high density SNP Genotyping Arrays. *H. Matsuzaki, X. Di, G. Liu, H. Loi, J. Law, T. Berntsen, M. Chadha, B. Nguyen, G. Yang, T. Webster, P.S. Walsh, R. Mei.*
Affymetrix, Santa Clara, CA.

Recently, hundreds of Copy-Number Polymorphisms (CNPs) have been observed in normal individuals. CNP regions are on the order of hundreds of kilobases and are distributed across the genome, often in close proximity to segmental duplications. The vast majority of CNPs were identified in comparative genome hybridization studies using DNA microarrays. Here, we used a set of twenty high density oligonucleotide arrays originally designed to genotype SNPs, to instead identify CNP regions. The set of arrays contains probes for ~ 2.2 million SNP sites, and has a resolution of one probe set every ~1.5 kb across the genome. Hybridization intensities from probes for the two SNP alleles were combined, and then normalized across individuals using Quantile Normalization. We assayed 48 unrelated individuals belonging to four ethnic groups. Probe intensities from the 48 individuals were clustered in sliding windows of 25 SNPs; and regions where adjacent windows showed significant clustering were identified as possible CNP regions. The regions identified in our survey totaled ~ 4% of the genome, and overlapped with 39% (137 of 352) of CNPs currently reported in the Database of Genomic Variants (The Centre for Applied Genomics). The known CNPs have an average length of ~ 200 kb, while the regions identified in our survey tended to be shorter, with an average length of ~50 kb. Consequently, in many of the overlapping regions there was a many-to-one relationship between our regions and the known CNP regions. The identified regions, on average, spanned ~ 21.5 SNP sites. For ~ 600,000 of the ~ 2.2 million SNP sites surveyed, we determined SNP genotypes in the 48 individuals, which enabled us to investigate possible associations between genotypes/haplotypes and individual variations in the CNP regions.

Q62R Substitution in KLF11 Gene Is Associated with Type 2 Diabetes and Related Traits in Pima Indians. *L. Ma, R.L. Hanson, L.N. Que, P.W. Franks, J. Baer, A.M. Infante, S. Kobes, C. Bogardus, L.J. Baier.* NIDDK/PECRB, NIH, Phoenix, AZ.

The TGF-¦Â signal pathway is important for normal pancreatic development. Since KLF11 is a TGF-¦Â inducible transcription factor, we analyzed this gene as a candidate gene for type 2 diabetes in Pima Indians, who have the highest reported prevalence of this disease in the world. Sequencing of the 4 exons, exon-intron boundary regions, 5' and 3' untranslated regions, and 2kb of the 5' (putative promoter) region of KLF11 in 24 non-first-degree related Pimas identified 9 variants, one of which was a non-synonymous amino acid substitutions (Q62R). These variants and other SNPs available in public databases were genotyped for association analysis in 1300 Pima Indians from 332 nuclear families. The Q62R was associated with young onset type 2 diabetes (onset-age under 45 years) (P=0.017, odds ratio=2.44, CI=1.17-5.08, additive model; P=0.005, odds ratio=3.05, CI=1.40-6.64, recessive model defined as QQ vs QR+RR) after adjusting for sex, nuclear family membership and Pima heritage. The risk allele Q had a frequency of 0.956. When analyzed using a within-family model in the same group of subjects, the Q62R was again associated with young onset type 2 diabetes (P=0.023, odds ratio=4.19, CI=1.22-14.45, additive model; P=0.005, odds ratio=6.49, CI=1.74-24.2, recessive model) after adjusting for sex, nuclear family membership and Pima heritage. In a subgroup of 261 non-diabetic full-heritage Pimas who have undergone detailed metabolic testing including measurements of body composition, oral glucose tolerance (OGTT), hyperinsulinemic-euglycemic clamp, and indirect calorimetry, the risk allele Q was associated with a higher plasma glucose concentration at 0', 30', and 120' (P=0.038-0.002; recessive model), lower plasma insulin concentration at 30' (P=0.0005, recessive model) during OGTT, and lower post-absorptive glucose oxidation rate (P=0.01, recessive model) after adjusting for age, sex, percentage of body fat, and family membership. These findings suggest that the Q allele at Q62R is associated with increased risk of type 2 diabetes as a result of impaired insulin secretion in Pimas.

Mutations in NOTCH2 cuase Alagille syndrome (a heterogenous disorder). *D. Warthen, R. McDaniell, A. Pai, J.J.D. Morrissette, B.M. Kamath, D.A. Piccoli, I.D. Krantz, N.B. Spinner.* Dept Path and Lab Med and Human Gen, Abramson Res Bldg, Children's Hosp, Philadelphia, PA.

Alagille Syndrome (AGS) is a dominant, multi-system disorder consisting of cholestasis, cardiac defects, butterfly vertebrae, posterior embryotoxon, and characteristic facies. We find that >90% of patients with a diagnosis of AGS have mutations in Jagged1 (JAG1), a ligand in the developmentally critical Notch Signaling Pathway. There are 4 human Notch receptors (Notch 1,2,3,4) that can potentially interact with JAG1. The mouse model for a heterozygous Jag1 mutation is not like AGS, but encompasses eye defects only. However, the Jag1/Notch2 double heterozygote has the liver, cardiac, eye, and renal defects found in patients with AGS, suggesting that Notch2 is the receptor important in these tissues. We studied 248 patients with a diagnosis of AGS and found JAG1 mutations in 227 (91.5%). Twenty-one patients did not have mutations, and we screened them for mutations in NOTCH2 by sequencing all 34 exons. We identified 2 mutations predicted to impact the function of the NOTCH2 protein. In both cases, the probands inherited a single mutation from their affected mother, indicating an autosomal-dominant form of inheritance. The probands have classic features of this disease. The first mutation is an AG>AA alteration at the splice acceptor site of exon 33, which resides in the intracellular domain of the protein. Through cDNA analysis, we determined that this mutation leads to the excision of exon 33 from the mature mRNA transcript, causing a frameshift across the last exon, and a premature stop codon. This is predicted to result in a NOTCH2 protein with loss of 2 of 6 evolutionarily conserved ankyrin repeats and the PEST sequence. The second is a C444Y missense mutation. This causes a loss of a cysteine residue from one of the extra-cellular EGF repeats, which are essential for ligand-receptor binding. Similar mutations in the EGF repeats of JAG1, NOTCH3, DLL3, and FBN1 have all been associated with human disease. This is the first report of disease causing mutations in the NOTCH2 gene, and the first demonstration that Alagille syndrome is a heterogenous disorder.

Risk haplotype for dyslexia on chromosome 6p22 is associated with a reduced expression of the KIAA0319 gene.
S. Paracchini, B.J. Keating, R. Wade-Martins, M. Dennis, T. Caffrey, C. Franks, J.C. Knight, A.P. Monaco. Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Dyslexia has an incidence of 5-10%; in school-aged children and is caused in large part by genetic factors. We have recently shown that a haplotype on chromosome 6p22 is significantly associated to dyslexia (Francks et al., 2004). This haplotype spans a 77 kb region of strong inter-marker linkage disequilibrium, encompassing the first four exons of *KIAA0319*, the entire *TTRAP* gene and the first exon of *THEM2*. Mutation screening by DHPLC of all exons and predicted promoters did not detect obvious variants that would disrupt any of the three gene functions. We then hypothesised that the risk haplotype might influence gene transcription regulation. To test this hypothesis we used the MassARRAY (Sequenom) platform to determine quantitatively relative differences in allele-specific transcription in cell lines that were heterozygous for the risk haplotype. We identified three lymphoblastoid and three neuroblastoma cell lines, which carry one copy of the risk haplotype and were heterozygous for at least one marker within the transcript of each of the three genes. Heterozygous markers in proximity of the promoters were also analysed in immuno-precipitated chromatin (haploChIP assay) from the three lymphoblastoid cell lines. Antibodies against phosphorylated RNA polymerase II allowed us to isolate and to use for allele-specific quantitative analysis those chromatin fragments where transcription initiates. The markers analysed for *TTRAP* and *THEM2* showed no quantitative differences between transcripts generated either on the risk or non-risk haplotypes. Conversely, all the markers used for *KIAA0319* showed consistently a transcription reduction of about 40% associated to the risk haplotype. These data show, for the first time, a relation between a genetic background and a biological mechanism that might be involved in the development of dyslexia. We are now working on the identification of the aetiological variant responsible for the reduced expression of the *KIAA0319* gene using different strategies, including gene reporter and EMSA assays.

A Deletion in DCDC2 on 6p22 is Associated with Reading Disability. *H. Meng[1], S.D. Smith[2], K. Hager[3], M. Held[1], J. Liu[4], R.K. Olson[5], B.F. Pennington[6], J.C. DeFries[5], J. Gelernter[7], T. OReilly-Pol[1], S. Somlo[8], P. Skudlarski[1], S. Shaywitz[1], B. Shaywitz[1], K. Marchione[1], G.P. Page[9], J.R. Gruen[1].* 1) Dept Pediatrics, Yale Univ, New Haven; 2) Munroe Meyer Inst, Univ of Nebraska, Omaha; 3) WM Keck Foundation Biotech Resource Lab, Yale Univ, New Haven; 4) SoftGenetics, State College; 5) Univ of Colorado, Boulder; 6) Univ of Denver, Denver; 7) Dept of Psychiatry, Yale Univ, New Haven; 8) Depy of Internal Medicine, Yale Univ, New Haven; 9) Dept of Biostatistics, Univ of Alabama, Birmingham.

DYX2 on 6p22 is the most replicated reading disability locus. We previously confined DYX2 to a 1.5Mb region surrounding a STR marker, JA04. We now report a peak of single-marker transmission disequilibrium with quantitative traits of reading performance in intron 6 of the DCDC2 (doublecortin domain containing 2) gene (P = 0.0003), identified by saturating this region with 147 SNPs markers. We also characterize short haplotypes with clusters of consecutive markers confined to DCDC2 that show significant transmission disequilibrium with several quantitative assessments of reading performance in the context of preserved IQ. Within human brain, DCDC2 is most strongly expressed in temporal lobe, prefrontal cortex, and posterior cingulate gyrus, regions that, in part, have been implicated in the reading process. We hypothesize that based on amino acid sequence homology to doublecortin domains, DCDC2 could direct subcortical neuron migration; differences in DCDC2 expression could therefore disrupt normal brain circuitry connecting these reading centers. Within the deletion, there is a 168bp purine-rich region (98% AG) containing a compound STR encoding multiple copies of putative PEA3 and NF-ATp binding sites. PEA3 and NF-ATp are transcription factors that are active in brain. Loss of this entire regulatory region, as would happen with the common large deletion we found in dyslexics, would likely affect DCDC2 function. Furthermore, polymorphisms of the compound STR, disrupting the PEA3 and NF-ATp sites, are strongly associated with reading performance (P = 0.00002) and may account for variation in reading ability in subjects without the common deletion, or in compound heterozygotes.

Mutations in Ionotropic AMPA Receptor 3 (GluR3) in Males with X-linked Mental Retardation. *Y. Wu[1], Y. Jiang[1], L. Zhang[1], M. Splaine[1], R. Huganir[2,4], C. Schwartz[3], D. Valle[1,4], T. Wang[1].* 1) Inst. of Genet. Med., Johns Hopkins Univ., MD; 2) Dept. Neurosci. Johns Hopkins Univ., MD; 3) Greenwood Genet. Center, Clemson Univ. SC; 4) Howard Hughes Med. Inst.

Glutamate receptors are the predominant excitatory neurotransmitter receptors in CNS and are essential for the induction and maintenance of long-term potentiation (LTP) and long-term depression (LTD), two cellular models of learning and memory. Ionotropic AMPA receptors (GluR1-4) mediate basal excitatory synaptic transmission and are a major determinant in the strength of synaptic response. Using an X-chromosome cDNA microarray, we identified a significant reduction of GluR3 transcript in a lymphoblast cell line of an XLMR male, which was confirmed by real-time PCR. By screening of an additional 150 unrelated XLMR males, we identified three missense mutations, R450Q, within the ligand-binding domain; R631S, near the channel-lining core; G833R in the transmembrane domain 4 of GluR3. Amino acid residues at all three positions are conserved in evolution from human to zebra fish. None of these mutations were found in a screening of 540 normal control males. GluR3-G833R protein was reduced to <50% of the normal control in transfected HEK293 cells on Western blot. We rescued the mutant protein to near normal levels when we cultured the cells at 30 oC or inhibited proteosome function by lactacystin, suggesting that G833R results in mis-folding and increased degradation of the mutant protein. Using biotin-based membrane protein-pull down, we showed a significant reduction of GluR3-G833R protein on the plasma membrane (~30% of normal control). Using an AMPA-induced receptor endocytosis assay, we found an 80-90% increase in receptor endocytosis for GluR3-R450Q as reflected by the increased amount of internalized GluR3, suggesting a potential change in the binding property of AMPA to GluR3-R450Q. This finding was further supported by the results of a binding kinetic study using 3H-labeled AMPA and GluR3-R450Q in transfected HEK293 cells. Our results indicate that mutations in GluR3 represent a newly recognized cause of X-linked mental retardation.

Identification of CUL7 mutations in the 3 M syndrome. *C. Huber[1], D. Dias-Santagata[2], A. Glaser[3], J. O'Sullivan[4], K. Wu[2], X. Xu[2], K. Pearce[3], R. Wang[2], G.C.M. Black[4], P.E. Clayton[4], A. Read[4], M. Le Merrer[1], A. Munnich[1], Z.-Q. Pan[2], R. Winter[3], V. Cormier-Daire[1], and the clinical consortium on 3 M syndrome.* 1) Department of Medical Genetics, Hopital Necker, Paris, France; 2) Department of Oncological Sciences and of Human Genetics, the Mount Sinai School of Medicine, New York, USA; 3) Genes, Development and Disease Theme, Institute of Child Health, London, UK; 4) Department of Clinical Genetics, St Mary's Hospital, Manchester, UK.

First described by Miller, McKusick and Malvaux, the 3-M syndrome (OMIM 273750) is an autosomal recessive condition characterized by severe pre- and post-natal growth retardation, facial dysmorphism, large head circumference, normal intelligence and endocrine function. Skeletal changes include long slender tubular bones and tall vertebral bodies. Studying 29 families with 3-M, we first mapped the disease gene to chromosome 6p21.1. We then considered Cullin 7 (CUL7) as a good candidate based on the cul7 gene targeted mouse model characterized by intrauterine growth retardation (IUGR) at late gestational age, with a placenta of reduced size and early death of respiratory distress. By direct sequencing of the CUL7 gene, we identified 25 mutations including 19 non sense and 6 missense mutations. Northern blot and RT-PCR analyses detected expression of CUL7 in fetal and adult tissues including fetal brain and kidney, placenta, trophoblast, osteoblats, chondrocytes and fibroblasts. CUL7 belongs to the cullin family, which is involved in cell cycle regulation, signal transduction, oxygen regulation and DNA repair. CUL7 assembles an E3 ubiquitin ligase complex containing Skp1, Fbx29/Fbw8, and ROC1 and promotes ubiquitination. Using deletion analysis, we show that CUL7 utilizes its central region to interact with the Skp1-Fbx29 heterodimer. Functional studies indicated that the CUL7 nonsense and missense mutations R1445X and H1464P respectively, render CUL7 deficient in recruiting ROC1. This study provides the first evidence of a cullin gene mutation in a human disease and suggests that impaired ubiquitination may play a role in the pathogenesis of IUGR in humans.

Interferon Regulatory Factor 6 (Irf6), the mouse ortholog of the gene mutated in Van der Woude Syndrome, is essential for craniofacial, skin, and limb development. *C.R. Ingraham[1,2], R. Richardson[3], B. Yang[1], J. Dixon[3], K.J. Trout[1], M.I. Malik[1], M.J. Dixon[3], B.C. Schutte[1].* 1) Departments of Pediatrics and Obstetrics/Gynecology, University of Iowa, Iowa City, IA; 2) New York University School of Medicine, New York, NY; 3) Faculty of Life Sciences, University of Manchester, Manchester, UK.

Mutations in IRF6 cause Van der Woude Syndrome (VWS) and genetic variation in IRF6 confers risk for non-syndromic cleft lip and palate, the most common form of orofacial clefting. To further study IRF6s role in clefting disorders and to create an experimental model for VWS, two independent mutant alleles for Irf6 were created in mouse: one by gene targeting and one by gene trapping. In both strains, Irf6+/- embryos appear normal, but Irf6-/- embryos die within a few hours of birth. Observations were thus made before embryonic day 17.5 (E17.5). E17.5 Irf6-/- mutants had taut skin lacking normal ridges or wrinkles, smaller heads, absent ears, shortened snouts, shortened forelimbs lacking visible digits, and the hindlimbs and tail were fused into one caudal projection. Fused bones were present in all feet. The skin showed abnormal differentiation, with a normal basalis layer, expanded spinosum, and absent granulosum and corneum layers. Irf6 is expressed exclusively in the spinosum layer of wild-type mice and is absent in mutants. We conclude that Irf6 is essential for craniofacial, skin, and limb development in mouse. Further phenotypic analysis revealed cleft palate in all Irf6-/- mice (n=61). Given the abnormal differentiation of skin epithelium and the high expression of Irf6 in the medial edge epithelium of the palate shelves, we hypothesized that palate shelves excised from mutant mice would fail to fuse in vitro. Surprisingly, similar rates of fusion were observed between mutants (n=3) and wild-types (n=5). Thus, the cleft palate in Irf6-/- mice does not appear to be due to a defect in growth or fusion of the palate shelves. Rather, there is a problem with elevation of the palate shelves, and further studies are needed to determine if this is a primary defect, or secondary to the skin defect causing crowding of craniofacial structures.

The common Bardet-Biedl syndrome type 1 (BBS1) M390R mutation is a hypomorphic allele that protects against embryonic lethality and cardiovascular defects. *R.E. Davis[1], H. Yen[1], M. Tayeh[1], R.F. Mullins[1], M.A. Fath[1,2], C.C. Searby[1,2], D.Y. Nishimura[1,2], B. Yang[1], D. Slusarski[1], V.C. Sheffield[1,2].* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute.

Bardet-Biedl syndrome (BBS) is an autosomal recessive disorder resulting in obesity, retinopathy, polydactyly, cognitive impairment, congenital heart defects, and renal abnormalities. Patients with this disorder display variable expressivity. To date, eight BBS genes have been reported. *BBS1* is the most commonly mutated gene and a single mutation (M390R) is involved in ~80% of cases. Our laboratory developed mouse models with a *Bbs1* null allele, as well as a knock-in model with the *Bbs1* M390R allele. Homozygosity for the null allele resulted in embryonic lethality, while homozygous knock-in mice were produced at the expected Mendelian ratio. M390R *Bbs1* mice recapitulate primary aspects of the human phenotype including obesity, photoreceptor cell death, and male infertility. *Bbs1* knock-in mice also have diminished olfaction and leptin resistance. These data indicate that the M390R allele has partial functional activity, as mice with this allele are rescued from the embryonic lethality observed in *Bbs1* null mice.

To further evaluate developmental aspects of *BBS1* deficiency, we analyzed the phenotype resulting from antisense morpholino (MO) knockdown of zebrafish *bbs1* expression. Zebrafish *bbs1* knockdown results in cilia and organelle transport defects, as well as cardiac abnormalities resulting in enlarged ventricles and atria, and pericardial edema. The morphants do not survive past 5 days post-fertilization. Normal *bbs1* RNA rescues all aspects of the MO knockdown phenotype. However, RNA containing the M390R mutation rescues the cardiac phenotype but not the ciliated organ defect or the organelle transport defect. Our combined data demonstrate that the *BBS1* M390R missense mutation is a hypomorphic allele that protects against embryonic death and defects in cardiac development compared to *BBS1* null alleles.

Identification of the first gene causing Meckel syndrome, MKS 1. *M.M. Kyttälä[1,2,3], J.E. Tallila[1], R. Salonen[4], M. Kestilä[1], L. Peltonen[1,2,3].* 1) Department of Molecular Medicine, Biomedicum, NPHI, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Department of Human Genetics, University of California Los Angeles, USA; 4) Department of Medical Genetics, Väestöliittö, Finland.

Meckel syndrome (MKS) is an autosomal recessive developmental disorder, diagnosed in most populations. It is characterized by three primary defects: cystic and fibrotic changes of liver and kidney, occipital meningo encephalocele and polydactyly. MKS affects 1:9000 births in the Finnish population and was mapped in Finnish families to chr17q23 (MKS1, MIM 249000). Two other loci for MKS have been identified on chr11q13 (MKS2, MIM 603194) and on 8q24 (MKS3, MIM 607361) in families representing different ethnic backgrounds. We report here the identification of the first MKS gene, MKS1, representing a previously unknown transcript of a 14 kb gene on 17q. The coding region shows across species homology and the structure of mouse gene is identical to that of human gene with 18 exons. The Finnish MKS1 major mutation causes a defective splicing and leads to a transcript missing one exon and the frameshift after the exon deletion. This altered splicing can be seen also in mRNA extracted from different tissues of Finnish MKS patients. All Finnish patients are homozygous for the mutation and we found this same mutation in a homozygous form in three non-Finnish patients from different Caucasian populations. We have also identified two additional mutations in this gene: one splice site mutation and one five bp insertion in exon 1 in a German MKS family. In situ hybridization established low level ubiquitous expression of the Mks1-gene in mouse embryonic tissues. Higher expression was observed in limb buds, brain, kidney and liver: organs showing characteristic malformations for MKS. The expression array analyses accompanied by bioinformatics studies should provide clues of the metabolic pathways associated with the novel MKS gene and disturbed in this lethal malformation syndrome. Further characterization of the MKS gene should reveal a pathway or signalling cascade, crucial for the normal embryonic development.

Mutations in *UBR1*, encoding an E3 ubiquitin ligase of the N-end rule pathway, cause Johanson-Blizzard syndrome. *M. Zenker[1], J. Mayerle[2], A. Tagariello[1], K. Zerres[3], P.R. Durie[4], G. Huelskamp[5], C. Guzman[6], H. Rehder[7], F.A. Beemer[7], B. Hamel[7], P. Vanlieferinghen[7], R. Gershoni-Baruch[7], M.W. Vieira[7], Y.T. Kwon[8], A. Varshavsky[9], M.M. Lerch[2], A. Reis[1].* 1) Inst of Human Genetics, Univ Erlangen, Germany; 2) Dept of Gastroenterology, Univ Greifswald, Germany; 3) Inst of Human Genetics, Univ Aachen, Germany; 4) Dept of Pediatrics, Univ Toronto, Canada; 5) Dept of Pediatrics, Univ Muenster, Germany; 6) National Children's Hospital, Univ Costa Rica, San Jose, Costa Rica; 7) Depts of Genetics, Univ Vienna, Austria; Univ Utrecht and Nijmegen, The Netherlands; CHU Clermont-Ferrand, France; Rambam Medical Center, Haifa, Israel; and Univ Sao Paolo, Brasil; 8) Center of Pharmacogenetics, School of Pharmacy, Univ Pittsburgh, USA; 9) Div of Biology, California Inst of Technology, Pasadena, USA.

Johanson-Blizzard syndrome (JBS; OMIM 243800), an autosomal recessive multisystem disorder, is characterized by the combination of congenital exocrine pancreatic insufficiency and aplasia of the alae nasi, as well as multiple facultative features, including scalp defects, imperforate anus, deafness, hypothyroidism, dental anomalies, genitourinary malformations, and mental retardation. To determine the molecular basis of JBS, we mapped this disease to 15q14-21.1, using a genome-wide linkage scan. We identified truncating mutations in the gene *UBR1* in 12 unrelated JBS families. *UBR1* encodes one of several E3 ubiquitin ligases of the N-end rule pathway, a ubiquitin-dependent proteolytic pathway whose substrates include proteins with destabilizing N-terminal residues. This pathway is present in both prokaryotes and eukaryotes. Its known functions include the regulation of peptide import, apoptosis, chromosome segregation, meiosis, cardiovascular development, and leaf senescence in plants. We show that *ubr1*(-/-) mice, whose previously reported phenotypes include reduced weight and behavioural abnormalities, have an exocrine pancreatic insufficiency with impaired stimulus-secretion coupling and increased susceptibility to pancreatic injury. Our results indicate that the perturbation of UBR1-dependent ubiquitylation is the primary cause of JBS.

Trps1 is a repressor of the gene for the cartilage matrix component Perlecan, *Hspg2*. *H.-J. Luedecke, P. Brega, F. Kaiser, B. Horsthemke.* Institut für Humangenetik, Universitätsklinikum, Essen, Germany.

Heterozygous mutations of the *TRPS1* gene cause the tricho-rhino-phalangeal syndrome (TRPS), which is characterized by craniofacial and skeletal abnormalities. Mice carrying a targeted deletion of the GATA zinc finger encoding exon (*Trps1*$^{+/-}$) develop mild signs of this disease, whereas homozygous mutant mice (*Trps1*$^{-/-}$) die of neonatal respiratory failure resulting from spine and rib abnormalities. To identify target genes of the TRPS1 transcription repressor, we compared the expression profiles of limbs from three wild-type and two *Trps1*$^{+/-}$ E11.5 embryos from the same litter using Affymetrix MOE430A oligonucleotide arrays. The gene for the core protein of the heparan sulfate proteoglycan Perlecan, *Hspg2*, was among the genes found to be differentially expressed. In agreement with Perlecan's previously published developmental expression pattern, the *Hspg2* transcript was absent in E11.5 wild-type embryos but present in significant amounts in heterozygotes. This result was confirmed by quantitative real-time PCR analysis of limbs from two wild-type and eight *Trps1*$^{+/-}$ embryos from three additional litters. To examine whether *HSPG2* is a direct target of TRPS1, we used 1,711 bp from the upstream promoter region of the human *HSPG2* gene, which contains nine GATA1 motifs, to control the expression of an SV40-promoter driven luciferase reporter gene. We observed a TRPS1 dosage-dependent repression of the luciferase activity in HeLa cells co-transfected with the reporter and a TRPS1 encoding plasmid. Perlecan is a component of the extracellular matrix of many organs and tissues. Increased as well as decreased deposition of Perlecan is associated with defects in several tissues such as the nasal septum, oral epithelia, the growth plates of the developing bone, and the articular surface of the bone, which are affected in TRPS. Our results suggest that up-regulation of *HSPG2* expression may explain some of the clinical signs of TRPS like bulbous tip of the nose, cleft palate, cone-shaped epiphyses or early-onset osteoarthritis.

Patterns of BDNF/NTRK2 variants and BDNF protein blood levels in the susceptibility to eating disorders. *X. Estivill[1,2,3], M. Ribasés[1], J.M. Mercader[1], H.C. Howard[1], B. Puchau[1], F. Fernández-Aranda[4], M. Bayés[1,2], M. Gratacòs[1,2].* 1) Genes and Disease Program, Center for Genomic Regulation (CRG), Barcelona, CATALUNYA, Spain; 2) CeGen - Spanish Genotyping Network, Barcelona, CATALUNYA, Spain; 3) Pompeu Fabra University (UPF) Barcelona, CATALUNYA, Spain; 4) Psychiatric Service, Ciutat Sanitaria Bellvitge, LHospitalet, CATALUNYA, Spain.

Eating disorders (ED), such as anorexia nervosa (AN) and bulimia nervosa (BN), predominantly affect women and adolescents, and have a high prevalence and mortality rate in European populations. Although environmental factors play an essential role in the aetiology of ED, there are strong evidences of a genetic participation in the predisposition and development of AN and BN. Experiments on murine models and pharmacological studies in rats indicate the potential role of BDNF in the regulation of food intake and body weight as an anorexigenic factor. We have performed several case-control studies finding a consistent association between the -270C/T BDNF SNP and bulimia nervosa (BN), and the Val66Met variant to both AN and BN in different European populations. Furthermore, haplotype relative risk analysis and the transmission disequilibrium test (TDT) in ED trios for BDNF alleles have been confirmed in a large sample of trios from different European countries. We have analyzed SNPs with a minor allele frequency higher than 0.10, covering the entire BDNF gene using the SNPlex technology in 174 ED patients and 174 sex-matched unrelated controls, permitting a dense and targeted genetic characterization of the variability of BDNF in ED. We have also screened the entire NTRK2 gene in patients with ED and found evidence of association of a specific NTRK2 haplotype with binge-eating/purging AN, and a reduced frequency of another haplotype in BN patients. Finally, we have assessed BDNF plasma levels in 50 discordant sib pairs with ED and found that BDNF levels were significantly higher in ED patients than in their unaffected sibs, irrespectively of the Val66Met genotype. The data strongly indicate that BDNF participates in the genetic susceptibility to ED and strongly argue for a role of BDNF signaling in eating behavior and body weight regulation.

Disentangling depression and apolipoprotein E. *M.A. Slifer[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Apolipoprotein E isoforms play an important role in many neuropsychiatric disorders including Alzheimer disease, Parkinson disease, cerebrovascular ischemic disease, and traumatic brain injury recovery. Geriatric depression is a highly prevalent neuropsychiatric mood disorder thought to be related to neurologic injury in the elderly. Geriatric depression is clinically paramount as an independent risk factor, across co-morbidities, for poor outcomes including mortality. Importantly geriatric depression is under-recognized, but when recognized, it is amenable to treatment. Several reports have linked Apolipoprotein E isoforms (ApoE) with geriatric depression (Caselli 2004, Flicker 2004, Laveretsky, Muller-Thomsen 2002, Nebes 2001, Stewart 2001). Others reports failed to identify an association (Liu 2002, Mauricio 2000, Harwood 1999, Papassotiropoulos 1999, Levy 1999, Forsell 1997, Lyketsos 1997). In this study, we present results from the largest study to date of ApoE and depression. Unlike previous studies, we assess mood symptoms, cognitive symptoms and ApoE genotype for our analyses. In the overall Collaborative Alzheimer Disease case-control data set (n=999), ApoE-4 is associated with depression as reported in 30.7% of ApoE-4 carriers versus 20.7% of ApoE-4 non-carriers ($p<0.01$). However, the presence of dementia completely explains the observed effect. When stratifying on dementia, there is no significant difference in depression by ApoE genotype in either the Alzheimer cases (n=491) or controls (n=508). This suggests that the inconsistent results among prior studies may be due to unrecognized confounding. Furthermore, this study demonstrates the importance of accounting for co-morbid dementia in the assessment of mood symptoms in the elderly.

A Scan of Chromosome 10 Identifies Novel Candidate Genes Showing Strong Association to Late-Onset Alzheimer's Disease. *J.S.K. Kauwe III[1], A. Grupe[2], Y. Li[2], C. Rowland[2], P. Nowotny[1], A.L. Hinrichs[1], S. Smemo[1], L. Doil[2], K. Tacey[2], P. Holmans[3], J. Hardy[5], M. O'Donovan[3], S. Lovestone[6], L. Jones[3], J. Morris[1], L. Thal[4], M. Owen[3], J. Williams[3], A. Goate[1].* 1) Washington Univ Sch of Med, St Louis, MO; 2) Celera Diagnostics, Alameda, CA; 3) Cardiff Univ, Wales College of Med, Cardiff, UK; 4) Univ of California, San Diego, La Jolla, CA; 5) National Institute on Aging, Bethesda, MD; 6) King's College London, London, UK.

Evidence of linkage to late-onset Alzheimers disease (LOAD) has been observed on chromosome 10, implicating a wide region and at least one disease susceptibility locus. Although significant associations with several biological candidate genes on chromosome 10 have been reported, these findings have not been consistently replicated and remain controversial. We performed a chromosome 10 specific association study with 1,430 single nucleotide polymorphisms (SNPs, allele frequency 2%). The scan covered 728 genes with one or more markers per gene. Initial tests were performed in a Caucasian case-control sample from the St. Louis area with 419 LOAD cases and 377 aged-matched controls. Markers that showed significant association in the exploratory analysis were followed up in two other Caucasian case-control sample sets to confirm the initial association. The replication case-control sets included a total of 670 LOAD cases and 819 controls, collected in the San Diego area and in the UK. Of the 1,398 markers tested in the exploratory sample, 69 reached significance (P=<0.05). Of these, 5 markers were replicated at P<0.05. One marker, rs498055, located in a gene homologous to RPS3A, was significantly associated with AD in each of the three case-control series, with an allelic P-value of 0.00004 (OR=1.3) in the meta-analysis. This marker was also tested in a case-control sample derived from our linkage sample (P=0.0165 OR=1.257). These results indicate that variants in the RPS3A homolog and haplotypes in the RPS3A homolog region are associated with LOAD and implicate this gene, adjacent genes or other functional variants (e.g. non-coding RNAs) in the pathogenesis of this disorder.

Polymorphisms in paraoxonase are associated with Alzheimer Disease in African Americans and Caucasians.

P.M. Erlich[1], K.L. Lunetta[2], L.A. Cupples[2], M. Huyck[1], R.C. Green[1,2], C.T. Baldwin[1], L.A. Farrer[1,2]. 1) Boston Univ Sch Med; 2) Boston Univ Sch Pub Health.

Epidemiological and autopsy studies suggest an involvement of cerebrovascular atherosclerosis in the etiology of Alzheimer disease (AD). The serum enzyme paraoxonase, encoded by 3 PON genes on chromosome 7q21 has been implicated in several vascular disorders and recently in AD. We conducted a high density SNP association study to investigate the association between the PON gene cluster and AD in African American and Caucasian subgroups of the MIRAGE Study. The sample included 243 African American and 277 Caucasian AD cases, their non-demented sibling controls (N=143, N=329), and unrelated spouse/neighborhood controls (N=81, N=124). We used family-based tests (FBAT) in the sib pairs and a generalized estimating equation approach in the full data set to test for association. Of the 29 PON SNPs genotyped, 7 SNPs were associated with AD (0.0002p0.03) in the full African American sample and 2 SNPs were associated with AD in the Caucasian sibships 0.01p0.04). In the combined family sample, single-SNP FBAT analysis revealed significant evidence of association for 4 SNPs (0.007p0.03), and haplotype FBAT analysis using sliding windows of 2-5 SNPs identified AD associated haplotypes throughout the PON gene cluster (0.00009p0.04). The strongest association was found in the region spanning the PON1 proximal promoter, where a common haplotype (20% frequency) was transmitted disproportionately to AD probands. These data suggest that a genetic variant in the PON1 promoter influences AD risk in both Caucasians and African Americans. Association was observed also in transcribed regions of PON1, PON2 and PON3. The multiplicity of sites within the PON locus associated with AD may be due to extensive LD across the region or the existence of multiple functional variants affecting AD risk. These findings are likely to be robust and replicable because the observations were made in two independent and ethnically diverse populations. Given the well established role of paraoxonase in atherosclerosis, these results suggest that atherosclerosis may be a part of the etiology of AD.

Dose effect of Apolipoprotein A-II (TG) repeat on age-at-onset in APOE-4(+) late-onset Alzheimer disease by splicing modification. *K. Kamino[1], T. Kida[1], T. Tanaka[1], T. Kudo[1], M. Yamamoto[1], R. Kimura[1], H. Akatsu[2], T. Uema[3], H. Yoneda[4], T. Miki[5], H. Hattori[6], M. Imagawa[7], Y. Ihara[8], S. Ohta[9], M. Takeda[1].* 1) Post-Genomics & Diseases, Osaka Univ Grad Sch Med, Suita, Japan; 2) Choju Medical Institute, Fukushimura Hosp, Toyohashi, Japan; 3) Psychiatry, Osaka General Medical Center, Osaka, Japan; 4) Neuropsychiatry, Osaka Medical College, Takatsuki, Japan; 5) Geriatric Medicine, Ehime Univ Sch Med, Toon, Japan; 6) Psychiatry, National Hosp for Geriat Med, Ohbu, Japan; 7) Imagawa Clinic, Osaka, Japan; 8) Neruopathology, Fac Med, Univ Tokyo, Tokyo, Japan; 9) Biochemistry and Cell Biology, Institute of Gerontology, Nippon Medical School, Kawasaki, Japan.

It has been noted that patients with late-onset Alzheimer disease (LOAD) show decreased plasma apolipoprotein A-II (apoA-II) levels, but it remains undetermined whether this decrease reflects a preventive effect of apoA-II or the resultant outcome of nutrition and the physical condition. The apolipoprotein A-II (APOA2) gene showed 9 major haplotypes, which can be grouped into 4 haplotype groups in Japanese subjects. Haplotype-based alleles were in Hardy-Weinberg equilibrium in both 564 sporadic LOAD and 746 age-matched control subjects. No haplotype-based alleles were associated with LOAD, and age-at-onset, in normal distribution, tended to correlate with the dose of the apolipoprotein E (APOE)-4 allele in all LOAD subjects. Nonetheless, in 234 patients with APOE-4(+) LOAD, the age-at-onset significantly showed an inverse correlation with the (TG) dose of intron 2 microsatellite of the APOA2 gene ($p<0.005$), and haplotype-basd allele dose did not contradict to the effect of the (TG) dose. In vitro transfection in COS-7 cells of minigene vectors harboring exon 3 and its nearby sequence of the APOA2 gene revealed that the (TG) number was correlated with the amount of the transcript lacking exon 3, and the same effect was also found by genomic APOA2 expression vectors. These results indicate that the APOA2 gene modifies age-at-onset in APOE-4(+) LOAD, explained by altered splicing of the APOA2 exon 3, and suggest that impaired splicing efficiency is involved in the occurrence of LOAD.

Metabolic stress induces cell death in Parkinson disease cybrids and fibroblasts. *J. van der Walt[1], M. Noureddine[1], P. Trimmer[2], J. Bennett[2], J. Stajich[1], B. Scott[1], M. Stacey[1], W.K. Scott[1], E.R. Martin[1], Y. Li[1], M. Hauser[1], M.A. Pericak-Vance[1], J.M. Vance[1].* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Center for the Study of Neurodegenerative Diseases and Department of Neurology, University of Virginia, School of Medicine, Charlottesville, VA.

Substantial evidence suggests that mitochondrial (mt) impairment may be involved in Parkinson disease (PD) pathogenesis. Complex I is the major site of reactive oxygen species (ROS) generation within the mitochondrion during metabolism leading to damage of DNA, lipids and proteins. Biochemical analyses using cybrids have demonstrated impairment of complex I in PD cases indicating that mtDNA may cause the deficit in energy production. For the purpose of this study, we created two cell models to examine mt function. Cybrids were created by fusing donor platelets with SH-SY5Y cells and fibroblast cultures were created from skin biopsies. In order to test mt function in cells derived from PD patients and controls, we induced metabolic stress in cell culture and observed cell growth. Galactose media was used to force cells into utilizing mt oxidative phosphorylation (OXPHOS) to generate ATP rather than glycolysis. We observed six out of nine PD cybrid lines and 2 out of five age-matched control cybrid lines that were unable to sustain growth in the galactose media after 48-96 hours. Western blot analysis of OXPHOS complexes demonstrated that COX2 and ND6 were either absent or found at low levels in cybrids lines that died under galactose culture. All other cybrids that survived in galactose showed normal levels of mt protein. We also incorporated a mtDNA resequencing kit (MitoChip) to detect mutations within one PD cybrid. Through this method, we were able to detect one heteroplasmic mutation within the ND1 gene. Similarly, cell growth of PD fibroblast lines (14/14) under galactose were arrested after 9 days while all control lines (4/4) proliferated. These preliminary results suggest that mt impairment affects cell growth in cell culture models of PD. Further investigation is needed to elucidate whether cell death is caused by decreased ATP production, increased oxidative stress or a combination of both mechanisms.

High-resolution Whole-genome Association Study of Parkinson's Disease. *D.M. Maraganore[1], M. de Andrade[2], T.G. Lesnick[2], K.J. Strain[2], M.J. Farrer[3], W.A. Rocca[1,2], K. Pant[4], K.A. Frazer[4], D.R. Cox[4], D. Ballinger[4].* 1) Department of Neurology, Mayo Clinic College of Medicine, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN; 3) Department of Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL; 4) Perlegen Sciences, Inc., Mountain View, CA.

We performed a two-tiered, whole-genome association study of Parkinsons disease (PD [MIM 168600]). For tier 1, we individually genotyped 248,535 uniformly spaced single nucleotide polymorphisms (SNPs) in 443 sibling pairs discordant for PD. For tier 2a, we individually genotyped 1,518 PD-associated SNPs ($p < 0.01$ in tier 1) and 311 genomic control SNPs in 332 matched case-unrelated control pairs. We identified 25 SNPs that were associated with PD ($p < 0.01$) in both tier 1 and tier 2 samples. For these 25 SNPs, we combined data from the case-unaffected sibling pair (tier 1) and case-unrelated control pair (tier 2) samples and employed a liberalization of the sibling transmission disequilibrium test to calculate odds ratios, 95% confidence intervals, and p-values. Eleven of the 25 SNPs were associated with PD in the combined data and had the same direction of the effect in tier 1 and tier 2a. A SNP within a semaphorin-related gene had the lowest combined p-value ($p = 7.62 \times 10\text{-}6$). Proteins encoded by this class of genes play important roles in neurogenesis and neuronal apoptosis, consistent with existing hypotheses regarding PD pathogenesis. A second SNP tagged the PARK11 late onset PD susceptibility locus ($p = 1.70 \times 10\text{-}5$). We also selected for genotyping in tier 2b additional SNPs that in tier 1 were borderline significant ($p < 0.05$) but which tested a priori biological and genetic hypotheses regarding susceptibility to PD (n = 1,312 SNPs). In analysis of the combined tier 1 and tier 2b data, one of these SNPs tagged the PARK10 late onset PD susceptibility locus ($p = 9.07 \times 10\text{-}6$). Independent replication across populations will clarify the role of the genomic loci tagged by these SNPs in conferring PD susceptibility.

A frameshift mutation in Disrupted in Schizophrenia 1 in an American family with schizophrenia and schizoaffective disorder. *N.A. Sachs[1], S.E. Holmes[1], P. Sklar[2], S. Waggoner[2], M.T. Pato[3], C.N. Pato[3], D.B. Wildenauer[4], S.G. Schwab[4], F. Dickerson[5], R.H. Yolken[1], F.J. Leister[1], V.L. Nimgaonkar[6], A. Sawa[1], C.A. Ross[1], L.E. DeLisi[7], R.L. Margolis[1].* 1) Johns Hopkins University Sch of Med, Baltimore; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Department of Psychiatry, State University of New York, Syracuse, NY; 4) School of Psychiatry and Clinical Neurosciences, University of Western Australia, Perth, Australia; 5) Stanley Research Center, Sheppard Pratt Health System, Baltimore; 6) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 7) Department of Psychiatry, New York University, NY, NY.

In a large Scottish pedigree, a balanced translocation t(1:11)(q42.1q14.3) segregates with major mental illness, including schizophrenia, bipolar disorder, and recurrent major depression. The translocation is predicted to lead to loss of the C-terminal region of the protein product of Disrupted In Schizophrenia 1 (DISC1), a gene located on 1q42.1. DISC1 has been functionally implicated in several processes, including neurodevelopment. We sequenced portions of DISC1 in 28 unrelated probands with schizophrenia and six unrelated probands with schizoaffective disorder. We detected a 4 bp deletion at the extreme 3 end of exon 12 in a proband with schizophrenia. The mutation has been detected in a sib with schizophrenia, a sib with schizoaffective disorder, and the father with possible major depression, while the mutation has not been detected in 2035 cases or 2182 controls. The mutant transcript is detectable, but at a reduced level, in lymphoblastoid cell lines from three of four mutation carriers. The mutation is predicted to cause a frameshift and encode a truncated protein with nine abnormal C-terminal amino acids. While previous research demonstrates that DISC1 interacts with NUDEL, transient transfection and immunoprecipitation demonstrated that the mutated form of DISC1 does not interact with NUDEL. These findings are consistent with the possibility that mutations in the DISC1 gene may increase the risk for schizophrenia and related disorders.

Increased expression in dorsolateral prefrontal cortex of CAPON in schizophrenia and bipolar disorder. *L.M. Brzustowicz[1,4], B. Xu[1], N. Wratten[1], E.I. Charych[2], S. Buyske[1,3], B.L. Firestein[2].* 1) Departments of Genetics; 2) Cell Biology and Neuroscience, and; 3) Statistics, Rutgers University, Piscataway, NJ; 4) Department of Psychiatry, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, NJ.

We have previously reported linkage of markers from chromosome 1q22 to schizophrenia, a finding supported by several independent studies. Within this linkage region, we have identified significant linkage disequilibrium (LD) between schizophrenia and markers within the gene for carboxyl-terminal PDZ ligand of neuronal nitric oxide synthase (CAPON). Prior sequencing of the 10 exons of CAPON failed to reveal a coding mutation associated with illness. We have screened a human fetal brain cDNA library and identified a new isoform of CAPON, which consists of only the terminal two exons of the gene, and have verified the expression of the predicted protein in human dorsolateral prefrontal cortex. We have examined the expression levels of both the 10-exon CAPON transcript and the new isoform in post-mortem brain samples from the Stanley Array Collection. Quantitative real-time PCR analysis of RNA from the dorsolateral prefrontal cortex in 105 subjects, 35 each with schizophrenia, bipolar disorder, and psychiatrically normal controls, revealed significantly ($p<0.005$) increased expression of the new isoform in both schizophrenia and bipolar disorder. Furthermore, this increased expression was significantly associated ($p<0.05$) with genotype at the three SNPs previously identified as being in LD with schizophrenia. Based on the known interactions between CAPON, neuronal nitric oxide synthase (nNOS), and proteins associated with the N-methyl-D-aspartate receptor (NMDAR) complex, over-expression of either CAPON isoform would be expected to disrupt the association between nNOS and the NMDAR, leading to changes consistent with the NMDAR hypofunctioning hypothesis of schizophrenia. This study adds support to the role of CAPON in schizophrenia, produces new evidence implicating this gene in the etiology of bipolar disorder, and provides insight into the potential mechanism of action of CAPON in psychiatric illness.

Association of *GABRA4* and *GABRB1* in African American autism families. *A.L. Collins[1], D.Q. Ma[1], P.L. Whitehead[1], E.R. Martin[1], H.H. Wright[2], R.K. Abramson[2], J.P. Hussman[3], J.R. Gilbert[1], M.L. Cuccaro[1], M.A. Pericak-Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) The Hussman Foundation, Ellicott City, MD.

Autism is a neurodevelopmental disorder characterized by impairment in social interaction and communication as well as repetitive behavior. It is thought to be a complex genetic disorder, caused by many interacting genes. While many candidates exist, to date no single gene has consistently been identified as a major player in the disorder. Multiple lines of data including alterations in levels of GABA and the GABA receptors in autistic patients indicate that the GABAergic system, which is responsible for synaptic inhibition in the adult brain, may be involved in autism. Previous studies in our lab have indicated association of non-coding single nucleotide polymorphisms (SNPs) with a GABA receptor subunit gene on chromosome 4, *GABRA4*, as well as interaction between SNPs in *GABRA4* and *GABRB1* (also on chromosome 4), within caucasian autism patients. Studies of genetic variation in African American (AA) autism families are rare despite data supporting similar involvement of this racial group. We screened SNPs in the *GABRA4* (N=7) and *GABRB1* (N=5) in our AA dataset of 48 families and have found rs2280073 and rs13151759 (r^2=0.51;*GABRA4*) and hcv2119841 ($r^2$0.016;*GABRB1*) all show significant allelic association with autism in the AA families, p=0.0035, 0.034 and 0.041, respectively. Interestingly, rs13151759 is located in the region homologous to the minimal promoter region in mouse, suggesting a potential functional change. These results confirm our earlier findings implicating *GABRA4* and *GABRB1* as genes contributing to autism susceptibility and extend autism genetic studies beyond a single racial-ethnic group.

Using haplotype maps to improve power of whole genome association studies with fixed sets of markers. *I. Pe'er[1,2], P.I.W. deBakker[1,2], J. Maller[1,2], K. Jones[3], D.M. Altshuler[1,2], M.J. Daly[1,2].* 1) Broad Institute, MIT & Harvard, Cambridge, MA; 2) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 3) Affymetrix Inc., Santa Clara, CA.

Whole genome association studies are an increasingly practical strategy for dissecting the heritable causes of common complex disease. With the goal of scanning the lions share of the 107 polymorphic sites in the Human genome for association, challenges involve both practical throughput as well as statostocs. Practically, the economically-feasible scale of SNP genotyping allows directly typing only a small fraction of these sites, with technology and economy imposing this fraction to be a fixed set of markers in a whole-genome genotyping product. Statistically, the true association signal is hidden by many random ones. Recent data resources of genomewide variation patterns allows tackling these obstacles, in order to empower association studies performed using a fixed set of markers. We developed theoretical framework, software implementation, and data summaries to thereby improve association testing in several respects: (i) We list linkage-disequilibrium-based correlations between typed and untyped SNP alleles. These imply a small fraction of SNPs actually captures a much larger set of variants; (ii) We list and apply predictors for each untyped allele based on several typed ones, This increases the extent of variation tested for association with the same set of typed SNPs; and (iii) We weigh different association tests according to a Bayesian prior. We develop a neutral such prior, uniform over all SNPs, that dictates promotion of tests that examine more correlated alleles, i.e of variants that are in denser bins of linkage disequilibrium. We examine these approaches and their contribution to improved statistical power when applied to the Affymetrix 100k and 500k mapping arrays.

Coverage and Power in Genome-wide Association Studies. *E. Jorgenson, J. Witte.* Epidemiology & Biostatistics, University of California, San Francisco, San Francisco, CA.

Large sets of SNPs are becoming available for genome-wide association studies. The extent to which these SNP sets provide information about unobserved SNPs (coverage) is currently unknown. We can use information from resequencing efforts focused on specific regions of the genome and groups of genes as a gold standard for determining the coverage that large genome-wide SNP sets provide. Since less than complete linkage disequilibrium between the causal locus and observed SNPs will result in a reduction in power, quantifying sequence coverage will provide a metric for the reduction in power to be expected when using a particular SNP set to perform genome-wide association studies. We compare average and cumulative distribution measures of sequence coverage, using real SNP data, to determine the reduction in power. Measures based on the cumulative distribution reveal that power is lower than expected under commonly used average metrics. This has important implications for genome-wide association studies, as average metrics, including the average maximum r^2, can inflate power estimates and lead to a higher than expected false negative rate.

Statistical power provided by random SNP subsets in whole genome case-control association studies. *R. Lazarus[1], W. Qiu[1], B.A. Raby[1], E.K. Silverman[1], P. Kraft[2], C. Rakovski[2], N. Laird[2], S.T. Weiss[1].* 1) Channing Laboratory, Boston, MA; 2) Harvard School of Public Health, Boston, MA.

Whole genome association experiments in which hundreds of thousands of random SNPs are genotyped using extremely high-throughput technologies are now feasible and attractive for complex disease research. Where a large sample has been completely sequenced, adequate power can be obtained using small, carefully chosen sets of tag SNPs, but the statistical power for genome wide case-control association studies using randomly chosen subsets of SNPs is not well understood. We simulated a very large number of case-control studies under alternative hypotheses to obtain empirical estimates of statistical power. Samples were drawn from 14400 diplotypes implied by random mating of 120 CEPH parental HapMap chromosomes, to ensure that realistic LD patterns and haplotype distributions were preserved. Only SNPs with minor allele frequency (MAF) >= 0.05 (n=7461) were considered. Over a range of alternative hypothesis odds ratios (OR), samples of cases and controls were drawn for every possible disease susceptibility locus (DSL). The smallest p-value from testing every genotyped SNP over a range of random SNP subset sizes was recorded, and compared to a Bonferroni adjusted threshold (0.05/n where n=number of tests) to control familywise error. The entire procedure was repeated over each of the 10 ENCODE regions. Power estimates were averaged over repeated simulations at each combination of factors to improve precision, because we noted that random subsets, particularly at low densities, provide highly variable power. For DSL with MAF > 0.2, on average, in 500 cases and 500 controls, 80% statistical power is obtained from a random SNP subset of 1.5% for OR=2.0, and 3% for OR=1.75. Assuming about 5 million SNPs >= 0.05 MAF in the human genome, a 3% (n=150,000) sample of randomly selected SNPs can be expected to provide adequate power for DSL SNPs > 0.2 MAF with true OR=1.75 or greater. The situation for SNPs below 0.2 MAF is more problematic. For DSL SNPs between 0.05 and 0.1 MAF, a 10% random SNP density is required to provide 80% power to detect a true OR=3.0.

Forget replication: Joint analysis is more efficient for whole genome association studies. *A.D. Skol, L.J. Scott, G.R. Abecasis, M. Boehnke.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Whole genome association is a promising approach to identify common genetic variants that predispose to human diseases. Because of the high cost of genotyping hundreds of thousands of markers on thousands of subjects, whole genome association studies will often follow a staged design in which a proportion of the available samples are genotyped on a large number of markers in stage 1, and a small proportion of these markers are followed up by genotyping them in the remaining samples in stage 2. The standard strategy for analyzing such two-stage data is to view stage 2 as a replication study, and to focus on findings that reach statistical significance when stage 2 data are considered alone. An alternative strategy for two-stage data is to analyze all available data jointly. We compare the power of replication-based and joint analysis for two-stage designs. We find that regardless of the two-stage design used, and despite the need to use more stringent significance levels, analyzing the data from both stages jointly is always more powerful than treating stage 2 as a replication study for stage 1, and that in many cases joint analysis results in substantially greater power. Consistent with previous work by Satagopan and colleagues (2002, 2004), we further demonstrate that joint analysis of two-stage data can attain nearly identical power to that of the one-stage design in which all markers are genotyped on all samples, while requiring only a fraction of the genotyping effort. For example, a one-stage design which genotypes 1000 cases and 1000 controls on 300k markers (600 million genotypes) has 75% power to find a disease predisposing variant with a multiplicative genotype relative risk of 1.4, prevalence .10, and risk allele frequency .50 in the controls. Nearly identical power (74%) can be achieved by joint analysis when genotyping 40% of the sample in stage 1 and following up 5% of the markers in stage 2. Analyzing these same two-stage data using a replication-based analysis achieves only 51% power. We suggest that for two-stage whole genome association studies, we should forget replication, and use joint analysis as the standard analysis strategy.

Logistic regression protects against population structure in genetic association studies. *D. Balding[1], E. Setakis[1], H. Stirnadel[2].* 1) Dept Epidemiology/Public Hlth, Imperial Col Sch Medicine, London, United Kingdom; 2) Worldwide Epidemiology, GlaxoSmithKline, Harlow, United Kingdom.

Although there has been much interest in the effects of population structure on genetic association studies, and in the relative merits of different prophylactic statistical methods, there is as yet no extensive simulation study to address these questions. We conduct such a study, including two computationally demanding structured association methods, as well as the simple and popular genomic control approach. We find that all these methods perform reasonably well although each has limitations that we illuminate. However our most important finding is that simple and computationally fast statistical procedures based on logistic regression - readily available in many statistical software packages - is superior to the tailor-made software that we consider. This is surprising since logistic regression does not explicitly model the population structure. It seems that including unlinked markers as predictors in a logistic regression analysis automatically adjusts for population structure: each marker soaks up some of the spurious association due to population stratification. Our conclusion is that even very large well-designed association studies can be conducted without fear of substantial numbers of false positives due to population structure, using only well-known and routinely-available statistical analysis methods.

False Discovery or Missed Discovery? Using Linkage to Improve Power of Association Tests. *K. Roeder[1], L. Wasserman[1], S-A. Bacanu[2], B. Devlin[2].* 1) Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA; 2) Dept Psychiatry, Univ. of Pittsburgh, PA.

To scan the genome for association between markers and complex disease typically requires testing hundreds of thousands of genetic polymorphisms. Testing such a large number of hypotheses exacerbates the tradeoff between power to detect meaningful associations and the chance of making false discoveries. Although the full genome is scanned, investigators typically favor certain regions of the genome based on the results of prior investigations. The remaining regions of the genome are investigated simultaneously because genotyping is relatively inexpensive compared to the cost of recruiting participants in a genetic study, and because prior evidence is rarely sufficient to rule out these regions as harboring liability genes. Moreover technological advances permit inexpensive testing of a predetermined set of markers. However, this broad genomic investigation diminishes power to detect association, even for genes falling in regions of the genome favored a priori. Multiple testing problems of this nature are well suited for application of the false discovery rate (FDR) principle, which can improve power. To further enhance power, a new FDR approach is investigated that involves weighting the hypotheses based on prior data. We present a method for using linkage data to weight the association p-values. Our investigations reveal that if the linkage study is informative, the procedure improves power considerably. Remarkably, the loss in power is small even when the linkage study is uninformative. For the space of genetic models likely to underlie complex phenotypes, we calculate the sample size required to obtain useful prior information from a linkage study. Next we find the sample size required to obtain sufficient power to warrant a genome scan association study, assuming various levels of prior information obtained from a previously conducted linkage study. This inquiry reveals that among genetic models that are seemingly equal in genetic information, some are much more promising than others for this mode of analysis.

The power of genome-wide association studies. *R.J. Klein, J. Ott.* Laboratory of Statistical Genetics, Rockefeller University, New York, NY.

Recent technological advances have made the high-throughput genotyping of a large number of SNPs possible. This has opened the door to genome-wide association studies, in which a collection of SNPs spanning the genome are typed to find those variants associated with a disease. These studies do not genotype all potentially causative SNPs. Instead, they aim to genotype a subset of marker SNPs that, because of linkage disequilibrium (LD), will allow detection of a causative variant that is not genotyped. Several products are or will soon be on the market for genotyping large numbers of SNPs simultaneously. One question that has not been answered is how one can estimate the power of a genome-wide association study. Given genotype frequencies in cases and controls and the number of cases and controls, calculation of the power of an association study is straightforward. This is true even for a large number of genotyped SNPs, assuming the causative SNP is in the set that is genotyped, because the significance level can be adjusted by the Bonferroni correction. To account for an ungenotyped functional mutation in LD, we need to know the extent of LD in the population between the ungenotyped mutation and the marker variant. Then, the power of detecting an association at the ungenotyped mutation using the marker can be computed. The overall power is then simply the average power over all the possible SNPs. Using this approach and data from the International HapMap project, we show that for the Affymetrix 100K genotyping platform and reasonable effect and sample sizes, power is highest if a study is performed in a population from Utah of northern and western European ancestry. Studies of Han Chinese from Beijing or Japanese from Tokyo would have intermediate and equal power, while studies of Yoruba in Ibadan, Nigeria would have the least power. For a risk allele with a population frequency of around 6% and a two-fold relative risk, approximately 3000 cases and 3000 controls would be needed to get a power of over 50%. In contrast, higher power was achieved using a set of only 44,000 SNPs selected to maximize the power of the study. This suggests that SNP selection is key to the power of a genome-wide association study.

Combining correlated p-values in trait-SNP association studies. *K.N. Conneely, M. Boehnke.* Dept Biostatistics, University of Michigan, Ann Arbor, MI.

Whole-genome association studies will yield an abundance of data for localizing and identifying genetic variants that predispose to complex human diseases. For many such studies, each SNP marker will be tested for multiple phenotypes, resulting in a large array of tests. Since this creates vast amounts of information to process, it may be convenient to combine the information from these multiple correlated tests into a single overall test for each SNP or group of SNPs. Assessing overall significance is difficult in this situation due to the correlation between tests, since markers may be in linkage disequilibrium (LD) and traits may be correlated. Most corrections for multiple testing are only valid for independent tests. For example, Fishers (1932) method, which compares the summed log p-values to a chi-square distribution to obtain a global p-value, is anti-conservative when tests are correlated. A common solution is to use methods such as Fishers, but to rely on permutation tests rather than analytical distributions to estimate a global p-value. If permutation maintains the original correlation structure, such tests are unbiased but often not very powerful. A potentially more powerful approach, suggested by Zaykin et al. (2002), is to decorrelate the p-values by pre-multiplying a normalized vector of p-values by the Cholesky factor of the vectors correlation matrix. This approach produces a set of independent p-values which may then be combined using Fishers method or other similar methods. Decorrelating the p-values requires knowledge of the correlation matrix of the test statistics. We propose a method (and software in R) for estimating this matrix from the data using the residuals and slope estimates from the trait association test and the LD between the markers. We simulate data under a variety of models to assess the validity and power of this method to detect association between SNPs in LD and correlated traits. Decorrelating the p-values generally increases power substantially relative to 1) ignoring the correlation and 2) other procedures for handling multiple correlated tests. Our results suggest that this method is a powerful and computationally highly efficient tool for analyzing the wealth of whole-genome data.

Quantifying the relationship between linkage disequilibrium (LD) and association tests: how correlated are test statistics if LD between SNPs is high? *D. Nielsen.* Statistics, North Carolina State Univ, Raleigh, NC.

One of the goals of the HapMap project is to provide information that will allow investigators to select a small subset of SNPs from a larger set so that genotyping costs of association mapping studies can be reduced, presumably without a substantial loss of power. Many different selection methods have been proposed to accomplish this. These include strategies that utilze information on haplotype blocks as well as methods that rely instead on patterns of linkage disequilibrium (LD) that do not assume strict block boundaries. The assumption behind these SNP selection strategies is that there is an advantageous relationship connecting LD between SNPs to the power to detect association with these SNPs. We have examined this relationship directly. Haplotypes were simulated for pairs of SNPs in a way that reflected patterns of LD estimated from real data. These haplotypes, together with a phenotype, were assigned to individuals so that no association between the two was expected. Each SNP in a pair was then evaluated using a standard case-control association test. This was repeated 10,000 times for each SNP pair, and the results used to estimate the degree of correlation between the two tests. Using this approach, estimates of the correlation between the tests could be compared with estimates of LD between the two SNPs. By plotting these two estimates for each of the more than 35,000 SNP pairs that were examined, a tight connection between the correlation of the tests and LD becomes evident. This relationship is, however, not linear. Instead, LD must get quite high before correlation between the tests becomes substantial. For example, correlation between the tests reached about 0.3 only when LD correlation coefficient, r^2, reaches about 0.8. We extend these analyses to family based association tests and to tests of quantitative traits. We also consider relationships between tests when associations between the SNPs and the phenotype exist.

Long tracts of homozygosity in the HAPMAP data. *J. Gibson, N.E. Morton, A.R. Collins.* Human Genetics, University of Southampton. SO16 6YD. UK.

An individual is homozygous for a marker if the two alleles at that marker are identical. In some individuals long tracts of homozygosity can be found where homozygous markers occur in an uninterrupted sequence. The most obvious explanation for such tracts is autozygosity, where the same chromosomal segment has been passed to a child from parents who both inherited it from a common ancestor. Assuming recombination breaks up long chromosome segments over time, the length of a homozygous segment should be related to the time since the last common ancestor of the parents. In an inbred population we would expect to see longer segments of homozygosity than in outbred populations. However, using SNP genotypes from the apparently outbred populations in the HAPMAP data we have found segments of several megabases that appear to be identical by descent. Long segments of homozygosity have been recorded in the CEPH population (Broman & Weber, 1999), but this was in part due to an identifiable relationship between some pedigrees. The dense SNP typing of the HAPMAP project provides a unique opportunity to establish the distribution of size and location of these segments and their relationship to linkage disequilibrium patterns. The longest homozygous tracts we have determined to date span 11Mb in a Yoruban individual and 6.5Mb in a CEPH individual. Many factors may influence their length, abundance and location including SNP mutation rate, population structure, uniparental disomy, natural selection, recombination, and linkage disequilibrium patterns. We have examined the relationship between the location and size of tracts of homozygosity and the linkage disequilibrium structure as represented in linkage disequilibrium unit (LDU) maps. The correlation between the regional LDU/Mb and tract length is -0.17 (.0001), suggesting that the longer tracts are found in regions of strong LD. Our preliminary studies show that homozygous segments are surprisingly common and long in unrelated individuals from the outbred populations represented in HAPMAP. Their presence is likely to be associated with both autozygosity and regions of extensive LD, and have substantial impact on association mapping studies. Am. J. Hum.Genet. 65:1493-1500, 1999.

Potassium channels and neurodegeneration: mutations in KCNC3 cause Spinocerebellar ataxia type 13 (SCA13).

M. Waters[1,2], N. Minassian[2], G. Stevanin[3], K. Figueroa[1], D. Nolte[4], J. Bannister[2], A. Mock[2], V. Evidente[5], D. Fee[6], U. Müller[4], A. Dürr[3], A. Brice[3], D. Papazian[2], S. Pulst[1,2]. 1) Cedars-Sinai Medical Center; 2) UCLA; 3) Hôpital de la Salpêtrière; 4) Justus-Liebig-Universität; 5) Mayo Clinic; 6) Univ of Kentucky.

Potassium channel mutations have been described in episodic neurological diseases, though not late-onset degenerative disorders. We identified a Filipino pedigree with adult onset gait/limb ataxia, dysmetria, hypotonia, dysarthria, and nystagmus. Linkage analysis mapped the causative mutation to a ~4cM region of 19q13. This partially overlapped with the previously mapped 11.4cM SCA13 locus described in a French pedigree with childhood onset mental retardation, and relatively pure cerebellar ataxia. Both pedigrees show marked cerebellar atrophy on MR imaging. Using STR markers we narrowed the candidate region to a ~900kb region which contained the KCNC3 channel. Sequence analysis of KCNC3 revealed two missense mutations in exon 2: 1554GA (R420H) in the Filipino pedigree and 1639CA (F488L) in the French pedigree. No other sequence variants were observed. KCNC3 (Kv3.3) is a fast-rectifying voltage-gated Shaw subtype potassium channel with enriched expression in the cerebellum. The mutations occur in functionally critical regions of the protein and alter highly conserved residues. Screening of two hundred alleles from normal individuals revealed no polymorphisms at either site. We expressed wildtype and the R420H mutant KCNC3 in X. laevis oocytes. Expression of the wildtype channel resulted in currents with fast activation kinetics and a depolarized range of activation, as expected. In contrast, the 1554GA mutant showed no detectable channel activity. Co-expression of wildtype and mutant KCNC3 resulted in decreased current amplitude consistent with a dominant negative effect of the mutant allele. Identification of KCNC3 mutations contributes a new class of genes to causative etiologies of progressive degenerative ataxias. These findings highlight the importance of voltage-gated potassium channels in both neuronal function and cell survival and should lead to their investigation in other neurodegenerative diseases.

A mutation in the COL9A1 gene in a family with a new autosomal recessively inherited form of Stickler syndrome. *S. Usami[1], R. Snoeckx[2], J. Van den Ende[2], F. Declau[3], E. Smets[4], F. Vanhoenacker[5], P. Van de Heyning[3], G. Van Camp[2].* 1) Dept Otorhinolaryngology, Shinshu Univ, Matsumoto, Naga, Japan; 2) Dept. of Medical Genetics, University of Antwerp; 3) Dept. of Otorhinolaryngology, University of Antwerp; 4) Dept. of Ophthalmology, University of Antwerp; 5) Dept. of Radiology, University of Antwerp.

Stickler syndrome is characterized by ophthalmic, articular, orofacial and auditory manifestations. It has an autosomal dominant inheritance pattern and is caused by mutations in COL2A1 (MIM 108300), COL11A1 (MIM 604841) and COL11A2 (MIM 184840). We describe family of Moroccan origin, comprising 4 children with Stickler syndrome, 6 unaffected children and 2 unaffected parents that were distant relatives (fifth degree). Four children showed symptoms characteristic of Stickler syndrome, including moderate to severe sensorineural hearing loss, high myopia with vitreoretinopathy and epiphyseal dysplasia. We considered the COL9A1 gene as a candidate gene on the basis of the structural association with type II and XI collagen and because of the high expression in the human eye and inner ear indicated by cDNA microarray. In addition, COL9A1 shows an expression pattern in cartilage, eye and cochlea that is very similar to type II, IX and XI collagens. Mutation analysis of the coding region of the COL9A1 gene showed a homozygous R295X mutation in the 4 affected children. The parents and 4 children were heterozygous carrier of the R295X mutation. Two children were homozygous for the wildtype allele. None of the family members except for the homozyogous R295X carriers had any signs pointing to Stickler syndrome. COL9A1 is the fourth gene that can cause Stickler syndrome. In contrast to the three previous Stickler-causing genes, this form of Stickler syndrome has an autosomal recessive inheritance pattern. This finding has a major impact on the genetic counselling of Stickler syndrome patients and on the understanding of the pathophysiology of collagens. Mutation analysis of this gene is recommended in Stickler patients with unaffected parents or Stickler patients that have no mutations in COL2A1, COL11A1 and COL11A2.

A novel class of PAR1 deletions excluding *SHOX* is associated with Léri-Weill dyschondrosteosis (LWD). *K.E. Heath[1], S. Benito-Sanz[1], N.S Thomas[2], C. Huber[3], D. Gorbenko del Blanco[1], M. Aza-Carmona[1], J. Crolla[2], V. Maloney[2], V. Cormier-Daire[3], A. Campos-Barros[1], J. Argente[1].* 1) Dept. Endocrinology, Hospital Infantil Universitario Niño Jesús, Universidad Autónoma de Madrid, Madrid, Spain; 2) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, UK; 3) Dept. of Genetics and INSERM U393, Hospital Necker Enfants Malades, Paris, France.

Léri-Weill dyschondrosteosis (LWD) is a pseudoautosomal dominant skeletal dysplasia characterized by disproportionate short stature and Madelung deformity. Mutations in *SHOX*, located in the pseudoautosomal region 1 (PAR1) of the X and Y chromosomes have been associated with LWD, Langer mesomelic dysplasia (LMD) and idiopathic short stature (ISS). Defects in *SHOX* have been identified in 60% of LWD cases while in the remaining 40% the molecular basis is unknown. This suggests genetic heterogeneity or the presence of mutations in unanalyzed *SHOX* regions such as the upstream, intragenic or downstream regulatory sequences.

Therefore, using a novel panel of microsatellites and SNPs, we analyzed the PAR1 sequences flanking *SHOX*, in 80 LWD patients in whom no *SHOX* deletion/mutation had been detected.

We identified the presence of a novel class of PAR1 deletions that exclude the *SHOX* locus, in 12 LWD patients (i.e. 15% of LWD probands). The deletions were of variable size and mapped between 30-530kb 3'downstream of *SHOX*. All shared a common deleted region of 29kb. Cosegregation with the phenotype was observed in all cases. Deletions were confirmed by FISH in 4 analyzed families. The presence of PAR1 deletions downstream of *SHOX* in LWD patients suggest two alternative hypotheses: a position effect due to distal regulatory elements of *SHOX* transcription in PAR1 or, alternatively, the existence of an additional locus apparently involved in the pathogenesis of LWD. Deletion analysis of this newly identified region should be included in the mutation screening of LWD, LMD and ISS patients. (kheath71@yahoo.com).

Mutation in Non-Classic Region of the *p63* Gene causes Hay-Wells Syndrome. *T.A. Maher[1], G. Zhao[1], J.M. Milunsky[1,2,3].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Hay-Wells syndrome or Ankyloblepharon-ectodermal defects-cleft lip/palate (AEC syndrome) (OMIM 106260) is a rare autosomal dominant disorder with variable expressivity. Clinical features include congenital filiform eyelid fusion, ectodermal dysplasia, cleft lip/palate, hypoplastic maxilla and deafness. Several features overlap other ectodermal dysplasia syndromes including ectrodactyly,ectodermal dysplasia, and facial clefting (EEC;OMIM 604292), split hand-split foot malformation (SHFM;OMIM 183600), limb-mammary syndrome (LMS;OMIM 603543), acro-dermato-ungual-lacrimal-tooth syndrome (ADULT;OMIM 103285) and cleft lip/palate, ectodermal dysplasia syndrome (CLPED1;OMIM 225060). Mutations have been described in the *p63* gene for these ectodermal dysplasias and genotype-phenotype correlations have been recognized for EEC and AEC syndromes. The vast majority of mutations resulting in AEC have been reported to be found in the sterile alpha motif (SAM) domain of the *p63* gene (mostly exon 13). We report a 30 year old Puerto Rican male with classic findings of AEC syndrome. Bidirectional sequencing of the *p63* gene using an ABI 3100 detected a missense mutation (T193K) in exon 4. The mutation was confirmed using restriction digestion and is in the DNA binding domain of the *p63* gene, typically associated with ADULT, EEC, and SHFM phenotypes. Hence, mutation screening in individuals with classic AEC should start with sequencing of the exons coding for the SAM domain and continue if negative to the entire gene. To our knowledge, this is the first report of a mutation in the DNA binding domain of the *p63* gene causing AEC.

LADD syndrome is caused by *FGF10* mutations and is allelic to autosomal dominant Aplasia/Hypoplasia of Lacrimal and Salivary Glands. *J.M. Milunsky[1,2,3], G. Zhao[1], T.A. Maher[1], D.B. Everman[4].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA; 4) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC.

Lacrimo-auriculo-dental-digital syndrome (LADD;OMIM 149730) is an autosomal dominant MCA disorder characterized by aplasias, atresias or hypoplasias of the lacrimal/salivary system, cup-shaped ears and hearing loss, in addition to dental and digital anomalies. Loss of function mutations in the *FGF10* gene were recently described (Entesarian et al, 2005; Milunsky et al, 2005) resulting in aplasia of lacrimal and salivary glands (ALSG; OMIM 180920 and 103420). Due to the significant phenotypic overlap and variable expressivity, we hypothesized that the LADD syndrome may be an allelic disorder. Our proband is a three year old female with nasolacrimal fistulae, dacryostenosis, bilateral atresia of the lacrimal system, hypoplastic biphalangeal thumbs, dental anomalies, right esotropia, and small prominent ears in whom a diagnosis of LADD syndrome was made following an extensive negative work-up. Parents are non-consanguineous and unaffected. Bidirectional sequencing of the coding regions of the *FGF10* gene using an ABI 3100 in our proband demonstrated a single nucleotide substitution in exon 3 (I156R) resulting in a non-conservative amino acid change from isoleucine to arginine. This missense mutation was confirmed by restriction enzyme digestion and was not found in 250 normal controls. Parental studies are anticipated in the near future. Expression studies of *FGF10* have previously demonstrated its presence and when disrupted, its effects in all of the systems with anomalies in LADD syndrome including lacrimal, inner ear, dental, limb, midface and genitourinary. Further studies are ongoing to determine if genotype/phenotype correlations exist. We have now shown that haploinsufficiency of the *FGF10* gene leads to ALSG and a missense mutation results in LADD syndrome, providing evidence that ALSG and LADD syndrome are allelic disorders.

Freeman-Sheldon syndrome is caused by defects of myosin. *R. Toydemir[1], D. Stevenson[2], L.B. Jorde[1], J. Carey[2], M. Bamshad[1,2].* 1) Dept Human Genetics, Univ Utah, Salt Lake City, UT; 2) Dept Pediatrics, Univ Utah, Salt Lake City, UT.

Several years ago, we discovered that missense mutations in *TPM2* encoding tropomyosin cause distal arthrogryposis type 1, while missense mutations in either *TNNI2* or *TNNT3*, encoding isoforms of troponin I (TnI) and troponin T (TnT) respectively, cause Sheldon-Hall syndrome (SHS). Tropomyosin, TnI, and TnT are components of the troponin-tropomyosin complex of fast-twitch myofibers and are expressed primarily in the peripheral muscles of the limbs. Based on these observations we hypothesized that other DAs were caused by mutations in genes encoding other structural components of the contractile apparatus of fast-twitch myofibers. We have now screened several additional genes encoding proteins of the contractile machinery of fast-twitch myofibers and identified new mutations causing other distal arthrogryposis syndromes, most notably classical Freeman-Sheldon syndrome (FSS).

FSS is a rare, multiple congenital contracture syndrome that is nonetheless, relatively well known because affected children have a striking appearance-it was historically called whistling-face syndrome because of involvement of the facial muscles. We screened 20 probands with FSS and found 4 different mutations a myosin heavy chain gene (*MYH*) in 19 cases (95%). Most *MYH* mutations caused non-synonymous amino acid substitutions, and one specific codon was mutated in 14 (70%) of cases. Mutations in *MYH* were also found in 9 cases (~25%) of SHS. None of these mutations were found in unaffected family members or 450 control chromosomes from an ethnically matched population. Each of the affected codons is strongly conserved among *MYH* orthologs and paralogs. No substantial relationship between the location of a mutation and the clinical characteristics of either FSS or SHS was observed. Additionally, three mutations in *MYH* were shared between FSS and SHS cases suggesting that the phenotype of both disorders is influenced by other genetic factors and/or environmental factors. Studies are underway to explore the mechanism by which mutations in *MYH* cause congenital contractures in FSS and SHS.

Familial Soft Tissue Cavernous Hemangioma (FSTCH): A new autosomal dominant disorder. *T.C. Falik-Zaccai[1,2], E. Blechman[3], M. Khayat[1], M. Genser[1,2], L. Even[2,3], I. Cohen[4], N. Heno[2,3].* 1) Inst. of Medical Genetics, Western Galilee Hosp, Nahariya, Israel; 2) Rappaport faculty of Medicine, Technion, Haifa, Israel; 3) Dep. of Pediatrics, Western Galilee Hosp, Nahariya, Israel; 4) Dep. of Pathology, Western Galilee Hosp, Nahariya, Israel.

Cavernous hemangioma is a benign vascular tumor of dilated blood vessels mostly capillaries or veins filled with blood. A familial form of cavernous hemangioma of the CNS has been well described. We report here a new phenotype of FSTCH that occur in different organs and systems such as skin, subcutaneous tissues, muscles, and oral or lingual mucus membranes without infiltration into the CNS or viscera. FSTCH was diagnosed in fifty two affected individuals out of 250 members of a large 7 generations Druze kindred related to a single ancestor. The lesions start to appear within a few months after birth and their number increase with age. The lesions cause pain, discomfort and significant self esteem problems but do not affect mortality. Surgery of lesions is of limited benefit due to recurrent growth. The pedigree structure and statistical analysis support autosomal dominant inheritance of FSTCH in this family. Linkage analysis to five loci, mapped to chromosomes 3, 5 and 7, that are known to be involved in familial cerebral cavernous hemangioma / malformation was performed. Linkage to these loci was ruled out, thus, indicating that a novel locus is involved in FSTCH in the present family. The structure of the pedigree and number of individuals in this family enable us to map and identify the FSTCH causative gene. Studies are in progress. This is the first report of a new (non CNS) cavernous hemangioma disoder. Identification of the causative gene and its protein product might shed light on important new pathways playing a significant role in the normal biology of angiogenesis.

***RAI1* mutation in Smith-Magenis syndrome.** *S. Girirajan[1], D.J. Bunyan[3], S.H. Elsea[1, 2].* 1) Dept. of Human Genetics; 2) Dept. of Pediatrics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA; 3) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, Wiltshire, United Kingdom.

Smith-Magenis syndrome (SMS) (OMIM #182290) is a mental retardation syndrome characterized by distinctive craniofacial features, delayed milestones, cognitive impairment and mild to severe mental retardation. Behavioral abnormalities include significant sleep disturbance and maladaptive and self-injurious behaviors. SMS is caused by either deletion or mutation of the *RAI1* gene located in the Smith-Magenis syndrome region on 17p11.2. We have analyzed 60 putative SMS patients referred to us for molecular evaluation of 17p11.2. FISH using an *RAI1*-specific probe revealed a heterozygous 17p11.2 deletion in 23/60 patients. The remaining 37 patients were further evaluated for mutations in the coding region of *RAI1* using a PCR-based sequencing strategy. In this study, we identified novel mutations in *RAI1* in 9/37 (24%) individuals. Mutations include small and large intragenic deletions and missense mutations. We also identified several polymorphisms that are new and unclassified, as well as those that are reported in the NCBI SNP database. Clinical analyses of these patients suggest certain differences between the 17p11.2 deletion patients and those with mutations in *RAI1*; however, the neurobehavioral anomalies unique to SMS are consistent between the two groups. Notable are absence of visceral abnormalities, failure to thrive, iris anomalies, and cleft lip and palate. Further, these individuals show decreased incidence of short stature, hearing loss, motor delay and hypotonia compared to those with 17p11.2 deletions. These data suggest that mutations in *RAI1* contribute a substantial portion to the causation of SMS; thus, putative SMS patients with no deletion of 17p11.2 should be evaluated for mutations in *RAI1*.

Williams Syndrome: Gene expression is related parental origin and regional coordinate control. *J.C. Collette[1], K. Tea[1], U. Bellugi[2], A. Galaburda[3], D.L. Mills[4], A.L. Reiss[5], J.R. Korenberg[1].* 1) Neurogenetics, Cedars-Sinai Med Ctr, Los Angeles, CA; 2) Salk Inst for Biological Sciences, La Jolla, CA; 3) Beth Israel Deaconess Med Ctr, Boston, MA; 4) Univ of California, San Diego, CA; 5) Stanford Univ School of Medicine, Stanford, CA.

Williams syndrome is a neurodevelopmental disorder caused by a deletion of chromosome 7q11.23 including about 24 genes. We have shown that the deletion of genes encoded by GTF2I and GTF2IRD1 was related to WS features and now provide evidence that WS gene expression from the non-deleted 7 is related to parental origin of the deletion and regional transcriptional control. We hypothesize that this variation contributes to WS features, full scale IQ, visual spatial deficits, social-emotional, linguistic and neuroanatomic variations. To elucidate the underlying genetic and neural mechanisms, we have examined WS gene expression in a cohort of 99 individuals with WS (41 males aged 28.1 10.9 years, 58 females aged 26.5 12.2 years) and 48 controls (24 females, 24 males). We established the regions deleted and gene expression in lymphoblastoid cell lines using TaqMan-based quantitative real-time PCR and probes for TBL2, GTF2IRD1, GTF2I, NCF1 (gene and pseudogenes) and WBSCR16, and controls from the non -WS regions of chromosome 7. Using b actin as a control, we found: 1. GTF2I expression was decreased in WS versus controls, ($p < 0.0001$); 2. GTF2I and TBL2 expression was higher in WS subjects with deletions derived from the father than in those whose deletions derived from the mother ($p < 0.05$; $p < 0.05$), in contrast to NCF1 expression of which was higher in subjects with maternal than in paternal deletions ($p < 0.05$); 3. Expression GTF2I was directly proportional to TBL2; more in WS versus controls ($p < 0.0001$ in WS, $p < 0.002$ in controls), and to GTF2IRD1 ($p < 0.002$) as well as to WBSCR16 ($p < 0.0001$) and to NCF1 ($p < 0.0001$). These data support the hypothesis that gene expression and possibly phenotype in WS are predicted by parental origin of the deletion and local transcriptional control. The use of WS to parse the contribution of genetic mechanisms to human behavior links these to the elusive systems neurobiology of humans.

The 9q subtelomere deletion syndrome: Further delineation of the common breakpoint and critical region and analysis of Eu-HMTase1 as a candidate gene for congenital heart disease. *C. DeScipio[1], M.T. Saung[1], M. Kaur[1], D.R. Stewart[2], E. Goldmuntz[1], N.B. Spinner[1], H. Riethman[3], I.D. Krantz[1].* 1) Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA. and The University of Pennsylvania School of Medicine, Philadelphia, PA; 2) NHGR/NIH, Bethesda, MD; 3) Wistar Institute, The University of Pennsylvania School of Medicine, Philadelphia, PA.

The 9q subtelomere deletion syndrome consists of several common phenotypic findings including mental retardation, distinct facial features, and congenital heart defects (primarily conotruncal defects). Molecular characterization of the breakpoint in a cohort of twelve individuals defined an ~1.2 Mb commonly deleted region containing 14 genes. In the majority of individuals, the proximal breakpoint clustered to within a 400kb interval, suggesting either a genomic predisposition to rearrangement or proximal genes that may result in embryonic lethality. Kleefstra et al. (J Med Genet 2005) recently reported an individual with features of the 9q subtelomere deletion syndrome and a balanced de novo t(X;9)(p11.23;q34.3) which was shown to disrupt a gene (euchromatin histone methyl transferase1, Eu-HMTase1), that maps to within our defined minimal commonly deleted region. This identified Eu-HMTase1 as a candidate gene for some or all of the features of the 9q subtelomere deletion syndrome. Since congenital heart defects are present in ~50% of individuals with the 9q subtelomere deletion syndrome, as well as in the patient described by Kleefstra et al., the Eu-HMTase1gene, which is expressed developmentally in the heart, may have a role in cardiac development. Using conformation sensitive gel electrophorsis (CSGE), we are completing mutational analysis in 150 individuals with isolated congenital heart defects (50 with ventricular septal defects (VSD), 50 with atrial septal defects (ASD), and 50 with Tetralogy of Fallot (TOF)). All individuals in this cohort had a normal karyotype and 22q11 fluorescence in situ analysis (FISH). Further genomic characterization of the common breakpoint region and results of mutational analysis of Eu-HMTase1 will be presented.

Enzyme replacement therapy (ERT) with recombinant human arylsulfatase B (rhASB) for MPS VI (Maroteaux-Lamy): 96 week follow-up. *P. Harmatz[1], D. Ketteridge[2], J. Hopwood[2], R. Giugliani[3], I. Schwartz[3], N. Guffon[4], C. Sa Miranda[5], E. Teles[5], J.E. Wraith[6], M. Beck[7], M. Scarpa[8], Z-F. Yu*[9], J. Wittes*[9], S.J. Swiedler**[9].* 1) Children's Hospital, Oakland, CA; 2) LDRU, Adelaide; 3) Med Genet Serv HCPA, Brazil; 4) Hosp Edouardo Herriot Pavillon, Lyon, France; 5) Hosp de Sao Joao and IBMC, Porto, Portugal; 6) RMCH, Manchester, UK; 7) Children's Hosp, U of Mainz, Germany; 8) Pediatrics, U of Padova, Italy; 9) *Statistics Collaborative, Inc, Washington, D.C.; **BioMarin Pharmaceutical Inc, Novato, CA.

MPS VI is a rare, life-threatening lysosomal storage disease. ERT has shown positive results in 3 clinical studies and received FDA approval as galsulfase (Naglazyme). Efficacy and safety are reported through 96 wks. Patients were enrolled in 1 of 3 studies: Phase 1 / 2 (2 dose, blinded x 6 mo, then open-label at 1mg/kg), Phase 2 (open-label, 1mg/kg), or Phase 3 (randomized, double-blind, placebo-cont x 6 mo at 1 mg/kg, then open-label). Endpoints included 6 or 12 min walk tests (6MWT or 12MWT), 3 min stair climb (3MSC), urine glycosaminoglycans (GAGs), adverse event monitoring, safety labs, and anti-rhASB antibody. Fifty-five patients were enrolled; 53 continue to receive ERT. Data are reported for Phase 1 / 2(n=5) and Phase 2(n=10) through 96 wks. Phase 3 data through 96 wks will be presented at the meeting. Phase 1 /2 patients receiving rhASB for 96 wks improved 99m in the 6MWT (mean, p=0.046, Wilcoxon Signed-Rank), Phase 2 patients improved 246m in the 12MWT (mean,p=0.005). Similar improvements in 3MSC were noted with Phase 2 patients increasing from 50 to 114 stairs (mean,p=0.005). All patients had rapid, persistent decline in urinary GAGs by mean 75%. Improvement in height (mean 3.9 cm, p=0.004) and forced vital capacity (FVC, mean 0.1 L, 17%, p=0.001) occurred in most patients. Infusions were generally well tolerated. All but one patient developed anti-rhASB antibody, but these antibodies were not associated with infusion-associated reactions or lack of clinical benefit. In conclusion, rhASB maintains improvement in physical mobility, endurance, and urine GAGs over 96 wks, and has an acceptable safety profile.

Ramaswami[9], M. Calikoglu[1], S. Vijayaraghavan[2], A. Puga[4], B. Ulbrich[9], M. Shinawi[6], M. Cleary[7], S. Wendt[3].* 1) Univ North Carolina, Chapel Hill, NC; 2) Royal Manchester Childrens Hospital, Manchester, UK; 3) Univ of Mainz, Mainz, Germany; 4) Medical Genetics Service, HCPA/UFRGS, Brazil; 5) Children's Hospital, Oakland, CA; 6) Baylor College of Medicine, Houston, TX; 7) Great Ormond Street Hospital, London, UK; 8) St. Louis Childrens Hospital, St Louis, MO; 9) Cambridge Univ Teaching Hospitals, Cambridge, UK.

MPS II (Hunter syndrome) is caused by a deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S). Currently there is no effective therapy for MPS II. ERT with I2S was evaluated in a multicenter clinical trial in MPS II patients. The main objective of this trial was to determine the efficacy of I2S (0.5 mg/kg) given weekly or biweekly versus placebo over 1 year. The primary efficacy endpoint was the change from baseline to wk 53 in a 2-component composite score using forced vital capacity (FVC) and distance walked in 6 min. Of the 96 enrolled patients, 94 completed the study and all have elected to participate in an open-label extension study. Treatment with I2S was well-tolerated and the most common adverse events observed were associated with the clinical manifestations of the disease. Of the adverse events considered possibly related to I2S, infusion related reactions were the most common and generally mild. The mean improvement from baseline to wk 53 in % predicted FVC was 3.4% in patients receiving I2S compared to 0.8% for placebo patients. The mean increase from baseline to wk 53 in the distance walked by I2S treated patients was 44 meters as compared to 7 meters by the placebo group. Patients who received I2S showed a statistically significant improvement in the composite primary efficacy endpoint (p=0.0049) compared to placebo. Additional supportive efficacy data includes liver and spleen size, urine GAG and joint range of motion. These results indicate that I2S can be safely administered and is a promising treatment for MPS II.

Enzyme Replacement Therapy (ERT) with Recombinant Human Acid Alpha Glucosidase (rhGAA) in Infantile-onset Pompe Disease: Interim Results from a Pivotal Trial. *P. Kishnani[1], B. Byrne[2], M. Nicolino[3], H. Mandel[4], N. Leslie[5], W.L. Hwu[6], E. Wraith[7].* 1) Department of Pediatrics, Duke University Medical Center, Durham, NC; 2) Shands Hospital at the University of Florida, Gainesville, FL; 3) Pediatrique Hopital Debrousse, Lyon, France; 4) Ramban Medical Center, Haifa, Israel; 5) Cincinnati Children's Hospital, Cincinnati, OH; 6) National Taiwan University Hospital; 7) Royal Manchester Hospital, Manchester, UK.

Introduction. Pompe disease is caused by a deficiency of the lysosomal enzyme acid alpha glucosidase (GAA). IOPD is characterized by severe, progressive cardiomyopathy, muscle weakness, respiratory insufficiency, and death usually by one year of age. **Methods.** This is an open-label, randomized, dose-ranging, multinational, multicenter study. 18 patients <6 months of age, with cardiomyopathy, and residual GAA activity of <1% in skin fibroblasts were enrolled. rhGAA derived from CHO cell culture is administered IV at 20 or 40 mg/kg qow. Efficacy end-points include survival, ventilator-free survival, decrease in LVMI, and changes in growth parameters and motor development scores. **Results.** 11 males and 7 females were enrolled; 7 patients (39%) are Caucasian, 4 (22%) Black, 3 (17%) Asian, 2 (11%) Hispanic, and 2 (11%) of Other ethnicity. Median age at first symptoms was 1.0 month (range: 0-5.5 months). Median age at first infusion was 5.3 months (range: 1.2-6.1). After 6 months of ERT, 18 patients (100%) are alive and 17 patients (94%) are free of invasive-ventilator support. 15 patients (83%) developed anti-rhGAA antibodies. 8 patients (44%) had infusion associated reactions, mostly mild to moderate in severity and managed symptomatically. **Conclusions.** rhGAA has been generally well tolerated. After 6 months of ERT, patients age ranges from 7.2 to 13.3 months. Data analyses of all above described end points are ongoing and will be presented. Results of earlier clinical trials of ERT administration to a small number of patients with IOPD have been promising. This trial provides additional information on the safety and efficacy of rhGAA to a larger cohort of IOPD patients at two different doses.

Adult Hypophosphatasia Treated with Teriparatide. *C. Deal[1], S. Mumm[2,3], M.P. Whyte[2,3].* 1) Cleveland Clinic, Cleveland, OH; 2) Div Bone and Mineral Dis, Wash Univer Schl Med and; 3) Research Center, Shriners Hospital; St. Louis, MO.

We report the first case of hypophosphatasia (HPP) treated with the parathyroid hormone sequence, teriparatide (rhPTH 1-34, TPTD). HPP features low serum alkaline phosphatase (ALP) activity from deactivating mutation of the gene for the tissue nonspecific isoenzyme of ALP (TNSALP). Extracellular accumulation of inorganic pyrophosphate (PPi) impairs skeletal mineralization causing rickets in children and osteomalacia in adults. There is no established therapy. Adult HPP typically presents with poorly-healing metatarsal stress fractures (MTSF) and unhealing femoral pseudofractures (FPF). At age 54, our patient had a painful MTSF with delayed healing. Two non-healing MTSFs occurred 2 yrs later. A FPF ensued. Pain occurred at all fractures. Serum ALP ranged from 10-24 IU/L (40-150 nl), and bone-specific ALP was 6 IU/L (12-31 nl). Other biochemistries were unremarkable except for two further features of HPP: elevated serum phosphate (Pi) of 5.1 mg/dl and vitamin B6 concentration of 603 ug/L (18-175 nl). DXA of the spine and hip showed Z-scores of +2.9 and +1.5, respectively. Treatment began at age 56 with 20 mcg TPTD daily. After 2 mo, pain improved in the thigh and foot. After 4 mo, no fracture site was painful. X-rays showed significant healing after 4 mo in 2 MTSFs and delayed healing with exuberant callus in 1 MTSF (no callus was present 9 mo after MTSF prior to TPTD treatment). The FPF appeared completely healed after 9 mo. A marked reduction in chondrocalcinosis in the symphysis pubis was seen after 9 mo of TPTD. Sequential biochemistries showed improved serum ALP activity (max. 43 IU/L) and sustained increments in NTX and OC. Ours is the first report of HPP treated with TPTD. Complete pain relief at fracture sites occurred after 2 mo; MTSP and FPF healed. Increased ALP, NTX, and OC suggested improved bone remodeling. Little change in circulating vitamin B6 levels indicated a focal (skeletal) effect of TPTD treatment. TPTD may improve adult HPP by enhancing osteoblast production of TNSALP and/or causing phosphaturia (lowering, at mineralization sites, extracellular Pi levels which acts as a competitive inhibitor of TNSALP).

AAV1-mediated Gene Therapy For LPL Deficiency. *C. Ross[1], J. Twisk[2], J. Rip[3], M. Nierman[3], P. Dijkhuizen[2], W. Hermens[3], J. Meulenberg[3], J. Kastelein[2], J. Kuivenhoven[2], M. Hayden[1].* 1) UBC, Vancouver, Canada; 2) AMT, Amsterdam, Netherlands; 3) AMC, Amsterdam, Netherlands.

Lipoprotein lipase (LPL) deficiency results in excessive plasma triglycerides (TG 1,000 mg/dl), abdominal pain, and occasionally life-threatening pancreatitis, but there is no adequate treatment for LPL deficiency. A single intramuscular (IM) administration of AAV1 vector, encoding the human LPL-S447X variant, results in complete, long-term normalization of dyslipidemia in LPL -/- mice. To determine the conditions for clinical application, varied doses of AAV1-LPL-S447X (1x10(11)-1x10(12) genome copies (gc)/kg) and varied numbers of IM injection sites (2-50) were tested in the large feline model of LPL deficiency. RESULTS: Administration of 5x1011 gc/kg completely resolved the visible plasma lipemia within 3-7 days, and plasma TG were reduced 99.9 percent to normal levels (8-19 mg/dl). Intermediate efficacy was achieved at 1x10(11) gc/kg. By varying the dose per site, linear LPL expression was demonstrated over a wide range of local doses in muscle (4x10(10)-1x10(12) gc/site). In LPL -/- cats, efficacy was transient, due to inhibitory anti-LPL antibodies blunting LPL expression. The level and duration of efficacy were improved with cyclophosphamide immunosuppression. The cause of the anti-hLPL response is related to species differences between human and feline LPL (88 percent identical), since LPL -/- cats treated with AAV1-LPL-S447X also develop antibodies. Efficacy and safety studies in other species have now permitted the initiation of a clinical trial in LPL deficient patients. Eight patients have been characterized for enrollment. TG levels varied greatly per patient (1,000-4,000 mg/dl), even on a stringent low-fat diet, and episodes of pancreatitis were observed. All patients had no LPL catalytic activity, but LPL protein levels of 19-103 percent of normal were present, thus reducing the risk of immune responses towards transgenic LPL. Patient myoblasts, isolated from muscle biopsies, secreted catalytically active LPL after infection with AAV1-LPL-S447X. These data supported the initiation of a clinical trial, for whic regulatory approval has now been granted.

Pseudo-ochronosis due to a common SNP in the organic anion transporter MRP4 / ABCC4: Pharmacogenomic implications. *R. Kleta[1,2], C. Klein[1], P. Suwannarat[1], H. Stanescu[1], A. Jeong[1], H.A. Austin[3], G. Burckhardt[4], W.A. Gahl[1].* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) Office of Rare Diseases, OD, NIH; 3) NIDDK, NIH; 4) Vegegative Physiologie und Pathophysiologie, Goettingen, Germany.

Alkaptonuria is a disorder of tyrosine catabolism in which homogentisic acid (HGA) accumulates and destroys connective tissue, causing darkened cartilage (ochronosis), joint and cardiac valve deterioration. In our investigation of 73 alkaptonuria patients, we identified 4 young women with an ochronotic phenotype but normal HGA excretion. All had been treated with the tetracycline derivative minocycline. Tetracyclines are secreted into the urine by proximal tubular organic anion transporters. These transporters recognize a variety of drugs / xenobiotics, including p-aminohippurate (PAH), which serves as a reference ligand and whose clearance provides a measure of tubular anion secretion. We sequenced all coding exons of OAT1, OAT3, OAT4, and MRP4 in two of our 4 pseudo-ochronotic patients. Both exhibited a homozygous intronic acceptor splice site mutation in MRP4, IVS2-5T>C. cDNA generated from leucocyte RNA showed that this splice site mutation leads to partial skipping of exon 3, comprised of 121 bp. This out-of-frame deletion produces a premature stop codon (c.186-306del; p.G62fsX67). PAH clearance was abnormally low in the one patient we studied, proving the deleterious effect of this mutation on organic anion transport. The two other patients were homozygous or heterozygous for this mutation. We generated a restriction site in MRP4 to screen for IVS2-5T>C. In 136 Caucasian alleles we found 70% wildtype and 30 % mutated alleles. This common MRP4 SNP, IVS2-5T>C, essentially defines MRP4 as a luminal PAH exit mechanism. It can also influence drug metabolism. First, it possibly can impair secretion of minocycline and create a pseudo-ochronotic state mimicking alkaptonuria. Second, it could modulate the clinical severity of alkaptonuria, since HGA secretion depends upon intact organic anion transport. Examination of normal individuals for this common SNP could provide guidance for the appropriate use of a host of antibiotic and chemotherapeutic agents.

Search for additional genetic determinants of warfarin dose and bleeding side effect. *R. McGinnis[1], M. Wadelius[2], L. Chen[1], A. Rane[3], P. Deloukas[1].* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Medical Sciences, Clinical Pharmacology, University Hospital, Uppsala, Sweden; 3) Clinical Pharmacology, Karolinska Institute, Campus Huddinge, Stockholm, Sweden.

Warfarin is an anticoagulant that is the most widely prescribed therapy for reducing thromboembolic events that often give rise to stroke, deep vein thrombosis, pulmonary embolism or serious coronary malfunctions. Clinical use of warfarin is made difficult by the wide interindividual variation in dose required to achieve the usual magnitude of anticoagulant effect (2.0-3.0 PT INR) and by a serious side effect (severe bleeding) in a minority of patients. Following the recent identification of the gene that encodes the warfarin drug target (vitamin K epoxide reductase complex 1 or VKORC1), we analysed a sample of 200 warfarin-prescribed Swedish patients and reported that SNPs in VKORC1 are highly associated ($p<0.0001$) with warfarin dose (Wadelius et al, Pharmacogenomics J. May 2005). Each of the three most predictive SNPs (rs9923231, rs9934438, rs2359612) accounts for approximately 30% of the variance in warfarin dose and, when considered together with the only other confirmed genetic factor (cytochrome P450 CYP2C9) and with non-genetic factors (weight, age, diagnosis, other medications), accounts for more than 50% of the variance in dose. To extend these VKORC1 results and identify additional genetic factors that influence warfarin dose or cause the severe bleeding side effect, we are typing the original sample and 1300 additional warfarin-prescribed Swedish patients (WARG study) for VKORC1 SNPs as well as 270 tagSNPs selected in 25 additional candidate genes located in metabolic (e.g. CYP 450) and blood clotting factor pathways. Based on multiple regression and case-control analyses, we will present results of testing individual SNPs and haplotypes for association with warfarin dose or cause of severe bleeding.

Defective *in vivo* Hedgehog signaling in NSDHL deficient mice, a model for cholesterol biosynthesis disorders. *F. Jiang[1], D. Cunningham[1], G. Herman[1,2].* 1) Center for Human and Molecular Genetics, Columbus Children's Research Institute, Columbus, OH; 2) Department of Pediatrics, The Ohio State University.

The X-linked *Nsdhl* gene encodes a sterol dehydrogenase involved in cholesterol synthesis. Mutations in this gene cause the male lethal phenotypes in human CHILD syndrome and bare patches (*Bpa*) mice. Affected male mouse embryos for several *Bpa* alleles die in mid-gestation with a thinner, less vascularized fetal placental labyrinth. Due to preferential inactivation of the paternal X in most extraembryonic lineages in female mouse embryos, the primary defect resulting in male lethality must lie in cells of extraembryonic mesoderm that demonstrate random X-inactivation. We hypothesized that NSDHL deficiency is disturbing one or more signaling pathways primarily in extraembryonic mesoderm in the developing placenta. We initially examined the Hedgehog (HH) signaling pathway since (1) HH proteins are modified by cholesterol during their processing and (2) other researchers have demonstrated abnormal HH signaling in cells cultured from patients with selected other disorders of cholesterol synthesis. *Patched (Ptch)*, encoding the HH receptor, is upregulated by HH signals and thus acts as a sensitive indicator of HH signaling. Although expression of a HH protein in the mouse placenta has not been reported, we have now demonstrated clear expression of PTCH in allantoic mesoderm of wild type placentas using X-gal staining of transgenic mice carrying a *Ptch-lacZ* reporter. In RT-PCR and *in situ* hybridization experiments, we demonstrate that the signaling molecule is Indian hedgehog (IHH), produced by yolk sac endoderm cells that migrate into allantoic mesoderm around 10dpc. There is no expression of Sonic or Desert hedgehog in the early fetal placenta. Affected placentas from mutant *Bpa* male embryos demonstrate markedly decreased Ptch-lacZ staining and migration of *Ihh* expressing cells. These data strongly implicate the HH signaling pathway in the pathogenesis of the placental defects in NSDHL deficiency and further provide the first evidence for a role for HH signaling in the development of a functional mammalian placenta.

The second family with AGAT deficiency (creatine biosynthesis defect): diagnosis, treatment and the first prenatal diagnosis. *K. Johnston[1], L. Plawner[1], L. Cooper[1], G.S. Salomons[2], N.M. Verhoeven[2], C. Jakobs[2], A.J. Barkovich[3].* 1) Kaiser Permanente, San Francisco, CA; 2) VU University Medical Center, Amsterdam, The Netherlands; 3) Department of Radiology, University of California, San Francisco, CA.

Deficiency of arginine:glycine amidinotransferase (AGAT), the first step in creatine biosynthesis, has been described in three related individuals. We describe a new unrelated 3-year-old girl. She showed delayed motor milestones from 4 months of age. At 14 months she had moderate hypotonia, developmental delay and failure to thrive. After demonstrating moderate generalized organic aciduria, she was found to have extremely low levels of guanidinoacetic acid in urine (<0.3 mmol/mol creatinine) and plasma (<0.05 uM/l), with low plasma creatine (2.3 uM/l). Single voxel proton magnetic resonance spectroscopy (MRS) of the brain showed absence of creatine. AGAT activity was not detectable in lymphoblasts. DNA sequence analysis of the AGAT gene revealed a homozygous mutation (IVS3+1G>T), which results in the skipping of exon 3 (r.289_484del196). The parents are carriers of this mutation. In a subsequent pregnancy of the family, DNA isolated from CVS was found to be homozygous for the IVS3+1G>T mutation. At age 16 months, Bayley Infant Development Scale (BIDS) showed functioning at 7 month level (43% of chronologic age). Oral creatine supplementation (400 mg/kg/d) was begun. Growth rate accelerated to the normal range. BIDS at 18 months showed developmental age of 10 months, a clear increase in developmental trajectory. Creatine dose was increased to 600 mg/kg/d at 20 months, and reduced to 400 mg/kg/d at 27 months. BIDS at 29 months showed Mental Scale at 23 months and Motor Scale at 25 months (80% and 86% of chronologic age). Partial recovery of cerebral creatine levels was demonstrated on MRS at 25 months of age. Brain MRS at 33 months of age revealed creatine/NAA ratio about 50-60% of normal, compared with age-matched contols. Presenting symptoms of AGAT deficiency (developmental delay and hypotonia) are non-specific. Early identification and treatment of AGAT deficiency may lead to improvement of developmental outcome.

Structural, biochemical, and functional characterization of the OPA3 gene, defective in Type III 3-methylglutaconic aciduria. *M. Huizing[1], L. Ly[1], H. Dorward[1], I. Nouvel[1], R. Kleta[1], B. Feldman[1], W.A. Gahl[1], Y. Anikster[2].* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) Sheba Medical Center, Israel.

Type III 3-methylglutaconic aciduria is a neuro-ophthalmologic syndrome of early-onset bilateral optic atrophy and later-onset spasticity, and extrapyramidal dysfunction. Urinary excretion of 3-methylglutaconic acid (3MGA) and of 3-methylglutaric acid is markedly increased. In 2001, we identified the causative gene, *OPA3*, consisting of two exons coding for a 179-amino acid protein. Here we report that *OPA3* also produces a novel transcript consisting of the common exon 1 spliced directly to a 3rd exon, skipping exon 2 altogether. This transcript is conserved in other species, and exon 3 closely resembles exon 2, suggesting a common evolutionary origin. Molecular analysis of 11 patients with unexplained optic atrophy and increased urinary 3MGA did not reveal exon 3 mutations. The OPA3 protein, whose function remains unknown, contains an N-terminal mitochondrial leader sequence and targeting signal and a putative C-terminal peroxisomal targeting signal. Since increased 3MGA levels can result from defects in either the mitochondrion (e.g., leucine degradation) or the peroxisome (e.g., mevalonate shunting), we investigated intracellular localization of OPA3. Normal fibroblasts were electroporated with Green Fluorescent Protein tagged OPA3 fusion proteins (ex 1-2 and ex 1-3 transcripts) with or without mutated mitochondrial and/or peroxisomal targeting signals. Confocal microscopy clearly demonstrated a mitochondrial localization for both OPA3 transcripts (ex 1-2 and ex 1-3). However, only the ex 1-2 transcript also localized to peroxisomes. This rare dual localization could help elucidate the biochemical function of OPA3. To further explore OPA3 function, we created zebrafish models using antisense morpholinos. The mutant fish showed unique features, including small eyes with severely affected optic nerves, delayed development, kinked tails and spastic movements - all related to the human symptoms. These zebrafish models promise to further elucidate the biochemical function of OPA3 and assist in the development of possible therapies for this devastating disorder.

Frequent recent inter-chromosomal sequence transfers and segmental duplications in human subtelomeres. *E.V. Linardopoulou[1,2], E.M. Williams[1], Y. Fan[3], C. Friedman[1], J.M. Young[1], B.J. Trask[1,2,4].* 1) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Bioengineering, University of Washington, Seattle, WA; 3) Department of Laboratory Medicine and Medicine, University of Washington, Seattle, WA; 4) Department of Genome Sciences, University of Washington, Seattle, WA.

Human subtelomeres form the transition zones between chromosome-specific sequence and the arrays of telomeric repeats capping each chromosomal end. These zones are composed of sequences duplicated on different sets of chromosomes and are highly polymorphic in content. We wish to understand human subtelomere organization, evolution, variation, and function, as well as to learn more about the origin and consequences of segmental duplications in general. Based on our analyses of patterns and breakpoints of subtelomeric homologies, we conclude that these patchworks were created by a series of chromosome translocations involving the very tips of chromosomes. We find that non-homologous end-joining appears to be the primary mechanism of DNA repair leading to the formation of subtelomeric duplications. Once duplications arise on different chromosomes, they undergo continued homology-based sequence transfers, which are apparent from the incongruent phylogenetic relationships of neighboring sections. Ectopic repair of subtelomeres is a potent force for recent change. Our cytogenetic analyses reveal that subtelomeric sequence moved or changed copy number at the unprecedented rate of ~0.09 times per basepair per million years during human-chimpanzee divergence. From sequence comparisons, we estimate that ~50% of known subtelomeric sequence, including ~40 new gene copies, formed through human-specific duplications or sequence transfers. Thus, subtelomeric dynamics could have both advantageous and pathological consequences in human biology. Our study suggests the existence of an evolutionary cycle between segmental polymorphisms and genome rearrangements. More generally, the translocation-based model used to explain subtelomeric duplications may be broadly applicable to other inter-chromosomal segmental duplications in the genome.

Cloning of interstitial deletion breakpoints in monosomy 1p36. *M. Gajecka[1], C.D. Glotzbach[1], K.A. Bailey[1], L.G. Shaffer[1,2].* 1) Health Research and Education Center, Washington State University, Spokane; 2) Signature Genomic Laboratories, LLC, Spokane, WA.

Although terminal deletions of 1p36 are relatively common, interstitial deletions of 1p occur in only ~7% of cases. Little is known about the mechanism of formation of these deletions. Of the 114 monosomy 1p36 subjects ascertained to date, eight cases have one interstitial deletion and three cases have complex rearrangements with at least two interstitial deletions. Here we present the mapping and cloning of the breakpoint junctions in these subjects. To determine the sizes of the 1p36 interstitial deletions, we performed array CGH with cell lines derived from each of the three subjects using the SignatureChip^{TM} with contains BAC clones spanning the most distal 10.5 Mb of 1p36. Array CGH and metaphase FISH analyses showed that the 1p36 interstitial deletions varied in size. To identify the breakpoints, we generated somatic cell hybrids from each subject containing the derivative chromosomes 1 segregated from the normal chromosomes 1 and performed PCR and STS marker walking. After narrowing the regions containing the junctions, we used the TOPO Walker protocol (Invitrogen) to amplify across the interstitial deletion breakpoints. Junctions were identified and analysis of the DNA surrounding each breakpoint was performed. Our results indicate that the breakpoint locations, as characteristic for monosomy 1p36 syndrome, are variable in the subjects, with no common breakpoint and no common deletion size. In one subject previously identified to have two interstitial deletions, a complex rearrangement consisting of an inversion and a third, cryptic interstitial deletion, was found. Deletion breakpoints were found in unique sequences and repetitive elements in the subjects; thus, no consistent sequence motif was identified among subjects. Alignment of the deletion junctions revealed the lack of sequence similarity between the breakpoints implicating involvement of NHEJ in stabilizing these broken chromosomes.

Delineation of chromosome 9p deletions: A model of phenotype and chromosomal mechanisms for terminal deletions. *S. Schwartz[1,2], S. Biton[2], L. Christ[2], M. Eichenmiller[2], M. Graf[3], H. Vance[4], C. Crowe[5].* 1) Univ of Chicago, Chicago, IL; 2) Case Western Reserve Univer, Cleveland, OH; 3) TGen, Phoenix, AZ; 4) Roswell Park Cancer Institute, Buffalo, NY; 5) MetroHealth Hospital, Cleveland, OH.

Over the past decade our knowledge of the phenotypic abnormalities seen in chromosomal abnormalities and mechanisms responsible for these abnormalities has increased. However, there is still little information concerning terminal deletions. We have studied 113 chromosomal abnormalities involving the deletion of a portion of chromosome 9 of which 85% of the abnormalities were de novo, and 20% of these more complex than simple deletions. Breakpoints from 65 individuals have been mapped by BAC studies and a total of 50 different breakpoints in a 9 Mb region have been identified; only in 11 breakpoints do 2 or more individuals share the same breakpoint. Breakpoints studied in greater detail have been isolated to LINE or SINE elements. A 0.5-1 Mb region has been implicated as a critical region for the characteristic facial phenotype in this syndrome; however any deletion in the 9 Mb region leads to both hypotonia and mental retardation. A deletion of only the subtelomeric region does not appear to lead to phenotypic consequences. Paternal origin of the deletions was significantly more frequent than maternal; however, there appeared to be preferential parental breakpoint regions. Results from these studies are interesting and reveal important information including that: (1) An area of increased breakage in 9p22/p23 has been identified; (2) Over 88% of the breakpoints identified are unique; most do not share the same breakpoint; (3) Although the majority of abnormalities are simple deletions a larger proportion than expected are more complex abnormalities; (4) Low-copy repeats are not implicated as a mechanism leading to these abnormalities, but other repetitive elements are important; (5) As this chromosome arm is gene poor, much of the phenotype seems similar regardless of the location of the break with the exception of the characteristic facial features; (6) The pattern of preferential regions of breakage is suggestive of a relationship with recombination differences in males and females.

Clinical diagnosis of genomic disorders, their reciprocal products, and atypical-sized deletions and duplications by array CGH. *B.C. Ballif, C.D. Kashork, E.A. Rorem, K. Sundin, V.M. Schmitz, B.A. Bejjani, L.G. Shaffer.* Signatuare Genomic Laboratories, LLC, Spokane, WA, USA.

Genomic architectural features, such as low copy repeats (LCRs), provide recombination substrates that mediate recurrent chromosomal rearrangements that, in most instances, result in characteristic, common-sized microdeletions or microduplications. These genomic disorders alter the copy number of dosage sensitive genes resulting in genetic disease. Although the reciprocal products of these canonical microdeletions or microduplications are predicted to occur with equal frequencies, they are, nevertheless, infrequently identified. This is most likely due to the inability of conventional diagnostic methodologies to identify such rearrangements and ascertainment bias in that the reciprocal chromosomal aberrations may not be compatible with life or may produce mild, uncharacteristic, or variable phenotypes. With this in mind, the SignatureChip targeted BAC microarray was constructed with contigs of 3-6 overlapping clones for 126 clinical loci including all of the known microdeletion and microduplication syndromes. In addition, the array contains 104 control regions including contigs located 1 Mb outside of the LCRs which flank the common microdeletion and microduplication loci thus enabling the detection of typical and atypical-sized deletions and duplications. The utility of array CGH and this array format in clinical diagnostics is evident in that out of 1300 cases submitted to our laboratory we have detected the common-sized aberrations for seven genomic disorders (Sotos, Williams, AS/PWS, SMS, HNPP, NPHP1, and DGS/VCFS). Furthermore, we have identified the reciprocal products of five genomic disorders (AS/PWS, SMS, NPHP1, STS, and DGS/VCFS) and detected atypical-sized deletions or duplications in four genomic disorders (Williams, AS/PWS, SMS, and dup 17p11.2). We anticipate that array CGH will not only expand our understanding of known genomic disorders but will also facilitate the identification of variability within known syndromes by identifying reciprocal and atypical genomic rearrangements.

Polymorphism of the palindromic sequence at the 11q23 breakpoint region affects de novo t(11;22) translocation frequency. *T. Kato[1,2], H. Inagaki[1], K. Yamada[1], H. Kogo[1], T. Ohye[1], B.S. Emanuel[3], H. Kurahashi[1,2].* 1) Div Molecular Genetics, Fujita Health Univ, Aichi, Japan; 2) Development Center for Targeted and Minimally Invasive Diagnosis and Treatment, Fujita Health Univ, Aichi, Japan; 3) Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

Chromosomal translocation is one of the most frequent chromosomal aberrations. Balanced carriers of a constitutional translocation usually manifest no phenotype unless an essential gene is disrupted. However, they often have problems in reproduction, such as infertility, recurrent abortion, and the birth of offspring with chromosomal imbalance. The recurrent constitutional t(11;22) is a good model for studying translocations in humans. We previously demonstrated de novo t(11;22)s in sperm samples from normal healthy males using translocation-specific PCR. In this study, we show that polymorphism of the palindromic AT-rich repeat (PATRR) identified at the t(11;22) breakpoint cluster region on chromosome 11 affects the frequency of de novo occurrence of the translocation. The typical chromosome 11 allele harbors a 450bp PATRR which comprises a nearly perfect palindrome, whereas variant alleles bear partially deleted or duplicated derivatives. Most of these variant alleles comprise asymmetric palindromes. We examined the frequency of de novo t(11;22)s in sperm from individuals with various genotypes. The typical PATRR produces de novo t(11;22)s at a frequency of ~10-5, while a short symmetrical PATRR produces them at a lower frequency. Of note, PATRRs with asymmetric centers do not produce any de novo t(11;22)s at all. We conclude that the size and symmetry of the PATRR11 are the important factors that determine the frequency of de novo t(11;22)s. It can be reasonably imagined that all symmetric PATRRs will be converted into asymmetric PATRRs in the course of human genome evolution. If this is indeed the case, our results imply that this t(11;22) translocation will rarely occur de novo in humans in the future. Palindromic regions appear to be subject to deletion to maintain genomic integrity, which is likely to protect the reproductive fitness of humans.

Novel t(5;9)(q33;q22) fuses Itk to Syk in unspecified peripheral T-cell lymphoma. *B. Streubel[1], U. Vinatzer[2], M. Raderer[3], A. Chott[1].* 1) Department of Pathology, Medical University of Vienna, Vienna, Austria; 2) Department of Gynecology, Medical University of Vienna, Vienna, Austria; 3) Department of Internal Medicine I, Medical University of Vienna, Vienna, Austria.

Among peripheral T-cell lymphomas the heterogenous category of unspecified peripheral T-cell lymphomas represents the most common subtype. Nevertheless, recurrent chromosomal translocations are not known to occur in this aggressive type of lymphomas. Here we describe a novel t(5;9)(q33;q22) in unspecified peripheral T-cell lymphoma. Molecular analyses delineated the breakpoints to Itk and Syk resulting in a previously undescribed activation of the Syk tyrosine kinase by Itk. Itk-Syk transcripts were detected in 5 of 30 (17%) unspecified peripheral T-cell lymphomas, but not in cases of angioimmunoblastic T-cell lymphoma (n=9) and ALK-negative anaplastic large cell lymphoma (n=7). In all 5 translocation-positive cases the breakpoints were identical fusing the N-terminal pleckstrin homology domain and proline-rich region of Itk to the tyrosine kinase domain of Syk. Three of the five t(5;9)(q33;q22)+ unspecified peripheral T-cell lymphomas shared a very similar histological pattern with predominant involvement of lymphoid follicles and the same CD3+CD5+CD4+bcl-6+CD10+ immunophenotype. These results demonstrate the presence of a recurrent t(5;9)(q33;q22) in a substantial minority of unspecified peripheral T-cell lymphomas which may represent a novel distinct subgroup of peripheral T-cell lymphomas.

Epigenetic Regulation of Pericentromeric Heterochromatin during Mammalian Meiosis. *A. Khalil, D. Driscoll.*
Pediatrics and Center for Mammalian Genetics, University of Florida College of Medicine, Gainesville.

Mammalian meiosis is an elegant process that allows diploid progenitor germ cells to produce haploid gametes after proceeding through two rounds of cell divisions. The first division (MI) is unique and results in the separation of homologous chromosomes, while the second division (MII) leads to the separation of sister chromatids similar to a somatic cell division. However, the mechanisms by which meiotic cells regulate their two very different cell divisions are not well understood. We postulated a role for epigenetic chromatin modifications in regulating these processes. Therefore, we examined male germ cells with antibodies to various histone modifications. We found prior to the onset of MI that pericentromeric heterochromatic regions, which are enriched with histone H3 lysine 9 (H3-K9) dimethylation throughout meiosis, become enriched at late pachytene with H3 serine (S) 10 phosphorylation and at diplotene with H4-K5 and H4-K16 acetylation, but remain underacetylated at other sites examined. RNA polymerase II, which is clearly excluded from pericentromeric heterochromatin at pachytene, becomes exclusively associated with these regions from diplotene to MI. By contrast, pericentromeric heterochromatic regions at MII are not engaged by RNA pol II nor enriched with H3-S10 phosphorylation. Furthermore, we postulate that DNA sequences transcribed from pericentromeric heterochromatin during MI could participate in RNAi pathways as we found both DICER and RISC to be present during meiosis. These results are significant since they suggest: 1) that distinct chromatin modifications differentiate the two meiotic divisions; 2) a role for repetitive DNA sequences and RNAi in meiosis; 3) H3-K9 dimethylation is not sufficient to block RNA pol II elongation through heterochromatin; and 4) H3-S10 phosphorylation provides a binary switch to activate transcription in heterochromatin.

Variation in meiotic recombination frequency for individual chromosomes. *R. Martin[1,2], F. Sun[1,2], M. Oliver-Bonet[1,2], T. Liehr[3], H. Stark[3], P. Turek[4], E. Ko[2], A. Rademaker[5].* 1) Medical Genetics, University of Calgary, Calgary, Canada; 2) Genetics, Alberta Children's Hospital, Calgary, Canada; 3) Institute of Human Genetics and Anthropology, Jena, Germany; 4) Urology, Obstetrics and Gynecology and Reproductive Sciences, University of California, San Francisco, USA; 5) Cancer Center, Northwestern University Medical School, Chicago, USA.

Meiotic recombination is essential for the segregation of homologous chromosomes and the formation of normal haploid gametes. This process is subject to stringent genetic control. Variation in the overall mean recombination frequencies per cell has been reported among human males. Here, we report variation in each individual chromosome among 8 normal human males (3 cancer patients with normal spermatogenesis and 5 vasectomy reversals) for the first time. An immunocytogenetic approach allowed analysis of pachytene cells by using antibodies to detect the bivalent synaptonemal complex (SCP1/SCP3), the centromere (CREST) and sites of recombination (MLH1). Individual bivalents were identified with centromere-specific multicolour FISH (cenM-FISH). The mean number of overall MLH1 foci per bivalent among donors was: chromosome 1 (3.75, range 3.33-4.11), 2 (3.40, 3.01-3.68), 3 (3.04, 2.70-3.33), 4 (2.67, 2.70-3.33), 5 (2.67, 2.42-2.98), 6 (2.50, 2.22-2.63), 7 (2.54, 2.20-2.73), 8 (2.23, 2.14-2.31), 9 (2.30, 2.10-2.41), 10 (2.39, 2.20-2.62), 11 (2.25, 2.08- 2.51), 12 (2.40, 2.18- 2.63), 13 (1.91, 1.80-2.00), 14 (1.89, 1.82-2.07), 15 (1.90, 1.83-1.97), 16 (1.96, 1.89-2.13), 17 (2.00, 1.90-2.13), 18 (1.78, 1.62-1.88), 19 (1.93, 1.80-2.03), 20 (1.84, 1.68-1.89), 21 (1.00, 0.98-1.00) and 22 (1.22, 1.07-1.88). There was significant heterogeneity in recombination frequencies across donors for chromosomes 1-7, 10-12 ($p<0.0001$, one-way ANOVA). Smaller chromosomes have 1 to 2 recombination sites and thus have less opportunity for variation since a minimum of one site is required for proper chromosome segregation. There was significant heterogeneity among males for the total mean recombination frequency ($p<0.0001$, two-factor ANOVA), but there was no significant difference between cancer patients and vasectomy patients ($p=0.68$, nested ANOVA).

Natural variation in human meiotic recombination. *V.G. Cheung[1], D.A. Hirschmann[2], J. Burdick[1], M. Morley[1].* 1) Depts of Pediatrics & Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Combined Degree Program, School of Veterinary Medicine, Univ Pennsylvania, Philadelphia, PA.

The focus of this project is to characterize natural variation in human meiotic recombination. Using genotypes of over 6,000 SNP markers on members of the CEPH pedigrees, we examined the pattern of recombination between individuals and across the genome. In each family, we used SNP genotypes to determine the segments of the genome shared identical-by-descent between a child and his/her grandparents, and to identify the sites of recombination during paternal and maternal meiosis.

We found more than 20,000 recombination events from 619 meioses (314 maternal and 305 paternal). On average, there are 41 recombinations per female meiosis, compared to only 25 in male meiosis, a ratio of 1.7 which agrees with results from previous studies (Broman et al, 1998; Kong et al, 2002). We also found significantly different number of recombination events among women ($P < 10^{-14}$) and also among men ($P < 10^{-10}$). Previous linkage-based studies (Broman et al, 1998; Kong et al, 2002) demonstrated variation in recombination events only in female meiosis. We now provide linkage-based support for the cytological observations (Lynn et al, 2002) that recombination also varies among men.

Besides inter-individual variation, we also observed variation in recombination across the genome. We found previously known and new genomic regions with increased recombination frequency. There are genomic regions that are recombination jungles in both male and female meioses but also ones that appear to be gender specific.

In this presentation, we will describe the landscape of human meiotic recombination based on information from 43 CEPH families.

Direct analysis of meiotic recombination in the human female. *E. Cheng[1], D. Piperna[1], R. Vallenta[2], T. Hassold[2].* 1) Dept OB/GYN, Univ Washington, Seattle, WA; 2) School Molecular Biosciences, Washington State Univ, Pullman, WA.

Until recently, almost all studies of meiotic recombination have been based on genetic linkage analyses. However, the application of immunofluorescence methodology now allows us to directly visualize meiotic exchanges; i.e., by analyzing cross-over associated proteins (e.g., MLH1) in pachytene stage spermatocytes and oocytes, we can determine the number and distribution of exchanges in individual gametes. This makes it possible to conduct studies that were previously impractical or impossible: e.g., detailed comparisons of exchanges among individuals; analyses of chromosome-specific variation in exchange distribution; studies to determine whether MLH1 foci localize to specific chromosomal sites; and direct analyses of interference. Accordingly, we recently initiated studies of human female meiosis and to date, have collected tissue from 11 fetal ovarian samples (with gestational ages ranging from 13-30 weeks). Our preliminary analyses indicate an average of 65-70 MLH1 foci per cell, consistent with expectations from CEPH genotype data. Several other expectations have also been met: in general, we observe at least one exchange on all chromosome arms (except the p arms of acrocentrics); exchanges are located more interstitially than in human male; and evidence for crossover interference is observed both in the number of exchange events per chromosome and in their relative spacing along the chromosome. However, other observations have been more surprising. Most importantly, the recombination process appears extremely sloppy when compared to our previous observations on human males and mouse males and females. Specifically, a large proportion of human oocytes have severe synaptic defects, a high frequency of bivalents have no MLH1 foci (exchanges), and non-homologous associations are common. These observations suggest that the high rate of human nondisjunction may well be set-up by abnormalities in the fetal ovary. If so, we would predict that errors of synapsis and/or recombination would be more common for chromosomes thought to be prone to nondisjunction (e.g., chromosome 16) than for others, and we are presently testing this hypothesis.

A high-resolution survey of deletion polymorphism in the human genome. *D.F. Conrad, J.K. Pritchard.* Department of Human Genetics, The University of Chicago, Chicago, IL.

Recent work has shown that copy number polymorphism represents an important class of genetic variation in human genomes. However, previous studies have either had limited resolution to detect medium-sized polymorphisms, or have examined very few genomes. Here we report a new method that uses SNP genotype data from parent-offspring trios to identify polymorphic deletions. The method is applied to data from the CEPH and Yoruba samples from the International HapMap Project to provide the first high-resolution population surveys of deletion polymorphism. Our analysis identifies a total of 576 distinct regions that harbor deletion polymorphisms in one or more of the families. Rather strikingly, we estimate that typical individuals are hemizygous for around 25-50 deletions larger than 5 kb, totaling at least 500-700 kb of euchromatic sequence across their genomes. The detected deletions span a total of 149 known and predicted genes. However, overall the deleted regions are relatively gene-poor, consistent with the action of purifying selection against deletions. Deletion polymorphisms may well play an important role in the genetics of complex traits, however they go undetected in most current gene mapping studies. Our new method will permit the identification of deletion polymorphisms in high density SNP surveys of trio or other family data.

A genome-wide haplotype map of 50 inbred strains of mice. *A.N. Kirby[1], C.M. Wade[1], I. Pe'er[1], E.J. Kulbokas[2], B. Blumenstiel[2], K. Lindblad-Toh[2], M. Zody[2], S. Gabriel[2], G. Liu[3], K. Jones[3], D. Hinds[4], D. Cox[4], K. Frazer[4], M.J. Daly[1,2].* 1) Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Affymetrix, Inc., Santa Clara, CA; 4) Perlegen Sciences, Inc., Mountain View, CA.

We present a haplotype map of the mouse with a density of >1 SNP per 20 kb on 50 commonly used classical and wild-derived strains of mice. The vast majority of the data is collected with a newly developed genotyping chip from Affymetrix, the accuracy of which is determined through inclusion of strains used in the original SNP discovery process.

We describe the analysis of genome-wide patterns focusing on the application of the map to the study of complex trait genetics including the acceleration of positional cloning efforts following on successful QTL identification, the integration of these variation patterns with gene expression data, and the comparison of inbred strains to putative ancestral strains to search for unlinked regions that may be not be compatible with each other in different homozygous states

We describe also progress and initial results from resequencing of 15 mouse strains being performed at Perlegen Sciences. This more complete view of variation enables deeper analyses and is compared with (and used to evaluate) the patterns observed in the haplotype map in the strains for which this data is available. The integration of these two emerging variation resources will provide a thorough catalog of variation and a better understanding for increasing the effectiveness of mapping complex phenotypes in mice.

Common Deletions and SNPs are in Linkage Disequilibrium in the Human Genome. *K. Frazer, A. Kloek, X. Chen, M. Jen, J. Au-Young, D. Hinds.* Perlegen Sciences, Mountain View, CA.

Genomic DNA rearrangements, insertions and deletions, have recently been identified as frequent genetic differences between individuals. It is currently unknown whether these DNA rearrangements are largely rare variants (each found in a limited number of individuals) or common variants (minor allele frequency 10%) in the human population. If DNA rearrangements are common variants it is reasonable to assume that they are likely to contribute to phenotypic variation in complex traits. Since current analyses of complex human traits are primarily based on well characterized SNP data, it is important to not only determine if DNA rearrangements are common variants but whether or not they are in linkage disequilibrium (LD) with common SNPs, and thus are assessed indirectly through SNP-based association studies. To address these questions, we used a panel of 24 ethnically diverse individuals previously utilized for SNP discovery to identify over 100 human deletion polymorphisms ranging in size from 70 bp to 7 kb. We then examined these deletion polymorphisms in a second, independent set of 71 individuals used previously to construct a LD map of 1.6 million common human SNPs. Approximately 84% of the deletions identified in the discovery panel were also observed in the second larger set of individuals, suggesting that the majority are common variants. We then examined the allele frequencies of common deletions and common SNPs with similar ascertainment demonstrating that the allele frequency distributions of these two types of variants are almost identical. Further, we find that common deletions and SNPs are in strong LD with each other indicating a shared evolutionary history and suggesting that most common deletions are effectively assayed by proxy in SNP-based association studies.

Power and phase based selection of single nucleotide polymorphisms for disease association mapping. *N.L. Saccone[1], S.F. Saccone[2], J.P. Rice[2].* 1) Department of Genetics, Division of Human Genetics, Washington University, St. Louis, MO; 2) Department of Psychiatry, Washington University, St. Louis, MO.

A thorough understanding of linkage disequilibrium (LD) patterns in the human genome is important for the design of whole-genome association studies of complex human disease. To reduce genotyping costs, it is of interest to select subsets of single nucleotide polymorphisms (SNPs) that capture the key LD information in a region. We have developed a tag SNP selection method that incorporates power calculations to identify SNPs that can best retain power to detect disease association when genotyped and used to represent untyped variants. The power calculations specify the threshold of LD strength, measured by either D' or r, used to define LD blocks from which SNPs are selected for genotyping; all markers not in blocks are added to complete the set of tag SNPs. A key, novel aspect of our SNP selection process is that it uses information about the phase of LD observed among markers to retain markers whose minor alleles are likely to be in coupling with an underlying disease allele. Coupling phase corresponds to higher power than the repulsion phase scenario; thus, this method provides improved power compared to a phase-blind approach. We have applied this method to genotype data from the International HapMap Project. Analysis of 28,937 SNPs on chromosome 7 having minor allele frequency (MAF) at least 10% was carried out with a range of LD thresholds and power requirements. With the most stringent threshold of |D'| = 1, our algorithm identified LD blocks covering 48% of the chromosome. From these blocks, phase-sensitive tag SNP selection resulted in 14,679 SNPs for a 49% reduction in numbers of SNPs required for genotyping. Relaxing the |D'| threshold to 0.8 improves reduction to 63%. Associated power calculations illustrate the advantages of this approach. We also demonstrate that these tag SNPs effectively represent underlying variants not included in the LD analysis and SNP selection, using a leave-one-out test to show that most (90%) of the untyped variants lying in blocks are in LD with a tag SNP and detectable in a screen that uses only the tags.

An efficient comprehensive search algorithm for tagSNP selection using linkage disequilibrium criteria. *Z. Qin*[1], *S. Gopalakrishnan*[2], *G. Abecasis*[1]. 1) Center for Statistical Genetics, Department of Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Department of Electrical Engineering and Computer Science, Univ Michigan, Ann Arbor, MI.

Selecting SNP markers for genome wide association studies is an important and challenging task. The goal is to minimize the number of markers selected for genotyping in a particular platform and therefore reduce genotyping cost while simultaneously representing information provided by all other markers. Depending on the platform, it is also important to select sets that are robust against occasional genotyping failure. An array of methods has been proposed to effectively select these tag SNPs using various criteria. In this study, we devised an improved algorithm for tagSNP selection using the pairwise r2 criteria. We first break down large marker sets into many disjoint pieces, where more exhaustive searches can replace the greedy algorithm for tagSNP selection. These exhaustive searches lead to smaller tagSNP sets being generated for any given threshold. In addition, we evaluated multiple solutions that are equivalent according to the LD criteria to accommodate additional constraints such as platform specific SNP assay characteristics. We have written a computer program named FESTA (Fragmented Exhaustive Search for TAgging SNPs) based on this algorithm, and evaluated its performance using HapMap data from all Chromosomes and the ENCODE regions. We found that in densely typed regions, using a moderate pairwise r2 of 0.5 as the threshold for defining tagSNP sets, about 10% of all markers are selected as tags. At a more stringent threshold (r2>=0.8), about 20% of all markers are selected as tags. Simulation studies under various settings confirmed that our method performs well at selecting tagSNPs for association studies.

Portability of the HapMap: Linkage Disequilibrium sharing between the continental populations and the Samoans of Polynesia. *R. Deka[1], W. Huang[2], Y. He[3], H. Wang[2], Y. Wang[3], Y. Wang[2], H. Li[3], D.E. Weeks[4], S.T. McGarvey[5], L. Jin[1,2,3].* 1) Center for Genome Information, Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Chinese National Human Genome Center at Shanghai, China; 3) Fudan University, Shanghai, China; 4) Dept of Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 5) International Health Institute, Brown University, Providence, RI.

Genome-wide association mapping has become a reality in understanding the genetic basis of common diseases. While the HapMap project would provide high-density single nucleotide polymorphism (SNP) data useful to assess the magnitude of the sharing of linkage disequilibrium (LD) among the three major continental populations, the utility of such data in association studies remain to be evaluated in other global populations, particularly in isolated populations with recent evolutionary histories. We have investigated the sharing of LD between the Samoan, a Polynesian population of relatively recent founding, and three continental HapMap populations (African, Chinese and European) based on ~8,000 SNPs covering half of the chromosome 21 with a mean density of ~1 SNP/1.9kb. Our results indicate LD extends much further in Samoans compared to the other three populations, and interestingly, we observe substantial sharing of LD between the Samoan and the Chinese. We also show that the tag SNPs identified (based on r^2) in the Chinese capture 90% of the information on genetic variation in the Samoans. Portability of genome-wide datasets among populations, particularly among those of recent shared ancestry, would tremendously impact on the utility of such data in association studies. This work is supported by the Chinese Human Genome Center at Shanghai and NIH grants DK59642 and ES06096.

Testing tag SNP transferability across different population samples. *P.I.W. de Bakker[1,2], N. Burtt[2], R.R. Graham[1,2], J.N. Hirschhorn[2], L.C. Groop[3], C.A. Haiman[4], B.E. Henderson[4], M.J. Daly[1,2], D. Altshuler[1,2].* 1) Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Lund University, Malmo, Sweden; 4) University of Southern California, Los Angeles, CA.

Linkage disequilibrium between single-nucleotide polymorphisms (SNPs) makes it possible to increase dramatically the cost-effectiveness of association studies to test common variants for a role in disease. The International HapMap Project will very soon complete the construction of a dense SNP map across the entire human genome in 270 individuals from four ethnic groups. A major outstanding question is how tag SNPs chosen in one population (e.g. DNA samples used in the HapMap project) can capture the common genetic variation in another.

We genotyped more than 3,000 SNPs across 30 loci (in total spanning >3 Mbp) in almost 800 samples to evaluate the transferability of tag SNPs selected from the HapMap. Thus, in addition to the HapMap samples, we collected genotypes in samples from a range of ongoing disease studies: two Caucasian samples, three East Asian samples, one West African sample, two African American samples, a Latino sample, and a native Hawaiian sample. We find that tag SNPs picked from the HapMap samples appear to provide very good coverage of common (>5%) variants with only modest loss of power. These insights offer compelling experimental validation of an LD-based approach for association studies.

Distribution of Genome-wide Linkage Disequilibrium among Multiple Populations. *H.J. Tsai[1,2], N. Battle[1,2], J. Kho[1,2], S. Choudhry[1,2], T.P. Speed[3], E.G. Burchard[1,2].* 1) University of California, San Francisco, CA; 2) Lung Biology Center, San Francisco General Hospital, SF, CA; 3) University of California, Berkeley, CA.

Genome-wide screen based on linkage disequilibrium (LD) patterns has been proposed as a plausible tool for gene mapping in complex traits. In this study, we genotyped 116,204 single nucleotide polymorphisms (SNPs) randomly distributed across the genome and examined genome-wide LD patterns in four different populations, consisting of Africans, Europeans, Native Americans and Puerto Ricans. We computed LD by using three different measures: D', r^2 and the log odds ratio, . The LD quantity, , has been proposed, but not commonly applied to measure LD (ref). We compared LD patterns obtained from these three measures. The results demonstrate that r^2 and provide better measures for capturing genome-wide LD patterns. In addition, the distributions of LD patterns across genome among four various populations show that there is significant variation in LD among populations. In a genome-wide average, Native Americans have the highest LD, Africans have the lowest LD, and Puerto Ricans, an admixed population, are intermediate. Our results provide evidence that is an excellent quantity for the measurement of LD. In addition, our results indicate the importance of investigating diverse populations for gene mapping in complex diseases. Reference: Edwards, A.W.F. (1963) J.Roy. statist. Soc. A, 126, 109-14.

AN EVALUATION OF THE POTENTIAL OF THE HAPMAP FOR WHOLE GENOME ASSOCIATION IN A POPULATION ISOLATE. *P. Bonnen[1], I. Pe'er[2], J. Breslow[1], M. Daly[2,3], M. Stoffell[1], D. Altschuler[3,4], J. Friedman[1,5].* 1) Rockefeller Univ, New York, NY; 2) Whitehead Institute for Biomedical Research, Cambridge MA; 3) Broad Institute of Harvard and MIT, Cambridge MA; 4) Department of Genetics and Medicine, Harvard Medical School, Boston, MA; 5) Howard Hughes Medical Institute.

The availability of an emerging haplotype map of the human genome will facilitate genetic analyses by enabling whole genome association studies in advance of being able to score all of the available human SNPs. While such studies are predicted to be most powerful in isolated populations where increased linkage disequilibrium (LD) and decreased allelic diversity, the relative advantages of studying genetic isolates has not yet been formally evaluated using the HapMap data. In this report we used Affymetrix Centurion SNP arrays to compare the haplotype maps from 30 trios of the Pacific Island of Kosrae to the HapMap samples; 30 CEPH trios, 30 Yoruban trios, 88 unrelated Japanese, and 90 unrelated Han Chinese. A whole genome haplotype map was assembled from 113,240 SNPs typed in 30 unrelated Kosraen trios. On average, LD extended nearly two times (or more) farther in Kosrae compared to the other populations; 46 Kb in Kosrae vs. 28 Kb in the EUR samples and 14 Kb in the YRI samples. Haplotype diversity was also significantly reduced as assessed by counting of haplotypes over defined intervals with an average of 35 haplotypes accounting for 95% of chromosomes. In contrast 35 haplotypes accounted for only 50% of the total in the EUR population and 40% for the YRI population. We further analyzed these data to evaluate the effectiveness of the Affymetrix panel of 110,000 SNPs to detect a potentially causative allele, by hiding one SNP and evaluating its best correlate on the array. In Kosrae, one can capture 60% the SNPs in the genome with correlation of $r2 > 0.75$, reflecting practical sample size requirements, compared to an r2 cutoff of 0.25-0.55 in HapMap populations to capture the same fraction of SNPs. These data confirm that many fewer markers will be needed to conduct a whole genome association study in the Kosraen cohort (and perhaps other isolated populations).

Chromosome-Scale Linkage Disequilibrium Properties Characterized by the Genotype Correlation. *J. Belmont[1], M. Strivens[1], S. Leal[1], A. Milosavljevic[1], R. Gibbs[1], N. Kaplan[2].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) National Institute of Environmental Health Science, Research Triangle Park, NC.

Linkage disequilibrium (LD) among closely-spaced polymorphic loci might be used to identify disease genes via indirect association. The International HapMap project has produced a database of genotypes from >1M SNP markers in 269 reference samples (Release 16). We have used the standardized composite linkage disequilibrium (cld - also called the genotype correlation) to investigate the LD patterns in the major populations of the HapMap database. We have organized the pairwise genotype correlations using spectral decomposition as a method for dimension reduction and annotated the results in the GENBOREE genome browser. About 70% of SNPs could be uniquely assigned to mutually exclusive subsets ranging in complexity from only 2 members to >50. Some SNP (~10%) exhibited LD with markers in multiple subsets (non-unique LD), while the remaining markers did not exhibit strong LD with any neighboring loci. The allele frequency distributions among markers in these groups showed that there is a strong tendency for markers with non-unique LD patterns to have higher minor allele frequencies whereas markers which are part of small subsets (2 - 6 markers) are skewed to low minor allele frequency i.e lower frequency alleles generally have fewer surrogates. Using the number of marker subsets per genomic interval as a diversity metric, we found that there are large magnitude variations in LD along chromosomes, among chromosomes, and among populations. For example, a pattern of increased long-range LD at the pericentromeric regions was observed for chromosome 3-6 and 10-13, but chromosomes 9, 14, 15, and 22 have reduced LD at the centromeres. These patterns were consistent in all HapMap populations indicating that they correspond to stable features of the chromosomes across the sample. This form of LD map has an extremely low computational overhead and provides convenient summary tools that will aid in association study design and analysis.

The BRCA1 interacting helicase BACH1/BRIP1 is deficient in Fanconi anemia. *A.D. Auerbach[1], O. Levran[1], C. Attwooll[2], R.T. Henry[1], K.L. Milton[1], S. Barral[1], J. Ott[1], J. Petrini[2], H. Hanenberg[3], D. Schindler[4].* 1) The Rockefeller Univ., New York, NY; 2) Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Childrens Hospital, Heinrich Heine University, Duesseldorf, Germany; 4) Institute of Hum. Genetics, University of Wuerzburg, Germany.

Fanconi anemia (FA) exhibits extensive genetic heterogeneity. Seven of the FA proteins (FANCA/B/C/E/F/G/L) form a nuclear FA core complex that activates the monoubiquitination of FANCD2, while two complementation groups (FA-D1/BRCA2 and FA-J) are downstream of FANCD2. Here we identified the FA-J gene. Five patients from four families (two Hispanic and two Inuit) in the IFAR were selected for a genome-wide scan using the GeneChip Human Mapping 50K Array 240 Xba (Affymetrix Inc. Santa Clara, CA). Patients were selected because of the following criteria: a, unassigned complementation group; b, normal expression of the two isoforms of FANCD2; and c, suspected homozygosity by descent. A shared 6 Mb region of homozygosity on chromosome 17q23 was found. From this interval we chose BRIP1/BACH1 as a candidate gene based on its biological functions. Sequencing BRIP1 revealed a c.2533C>T nonsense mutation in exon 17 (R798X). Surprisingly, all five patients were homozygous for this mutation, which is predicted to create a truncated protein lacking the BRCA1-binding domain. Consistent with this, the mutated lymphoblastoid cell lines (LCLs) showed no expression of wild type BACH1 protein by WB with an antibody that recognizes the C-terminal part of BACH1. Haplotype analysis indicates that the Inuit patients share the same haplotype, while each of the Hispanic patients presents a unique haplotype. Next we screened for the c.2533C>T mutation in DNA from an additional 18 IFAR patients for whom known FA genes had been excluded. Of these, 3 more patients were homozygous and 3 were compound heterozygotes, each with a unique mutation as the second abnormal allele. Our data from functional studies of BACH1 deficient IFAR cells suggest that DNA double strand breaks are the lesions that underly the pathology of FA-J and that the FA pathway converges on BRCA1 and the BACH1 as mediators of chromosome maintenance downstream of FANCD2.

Fanconi anemia proteins and BLM, the Bloom syndrome DNA helicase, are involved in ALT telomere maintenance. *H. Root[1], D.J. Stavropoulos[1,2], M.S. Meyn[1,2].* 1) Genetics & Genomic Biology, Hospital for Sick Children, Toronto, ON; 2) Molecular & Medical Genetics, Univ of Toronto, Toronto, ON.

Fanconi anemia and BLM proteins have been implicated in genetic recombination, a process thought to be involved in ALT (Alternative Lengthening of Telomeres) telomere maintenance. We now report data supporting interactive roles for the FA and BLM proteins in ALT.

We find that the FA proteins FANCD2, BRCA2 (FANCD1), FANCA and FANCG localize to telomeric foci in ALT human fibroblasts, but not in telomerase-positive or primary fibroblasts. Colocalization of FANCD2 and telomeres primarily occurs within PML bodies in late S/G2. Association of FANCD2 with ALT telomeres may depend on BLM, as ~90% of FANDCD2 foci that colocalize with TRF1 also co-localize with BLM. It has been proposed that ALT cells harbor dysfunctional telomeres that trigger a DNA damage response, as H2AX, a marker of double strand breaks, localizes to some ALT telomeric foci. FANCD2 is almost always present in those foci. BRCA2 localization to ALT telomeres occurs primarily in the presence of FANCD2, consistent with a role for FANCD2 in BRCA2 damage-induced foci formation.

Co-IP experiments indicate ALT-specific in vivo interactions between FANCD2, BLM, and the telomeric protein TRF2 in late S/G2. In support of a functional role for FA and BLM proteins in ALT, we can stably suppress FANCD2 expression with shRNA in telomerase positive cells but not in ALT cells. We also find that transient reductions in FANCD2 expression strongly impairs growth of ALT fibroblast cultures while transient reductions in BLM expression cause ALT-specific increases in dicentric formation and end to end fusions.

Our results indicate that the presence of FA, BLM and other recombination proteins at ALT telomeres is dynamic, with FA and BLM proteins spatially and temporally poised to assist in replication and maintenance of telomeres. Our data indicate a critical role for FANCD2 in ALT telomere maintenance and support a model in which a normal function of the FA pathway is to help cells deal with dysfunctional telomeres.

Analysis of homology-directed DNA double-strand break repair in Fancd2-deficient mouse embryonic stem cells.
H. van de Vrugt, S. Komaki, M. Grompe. Molecular & Medical Genetics, OHSU, Portland, OR.

Fanconi anemia (FA) is a genomic instability disorder, characterized by cancer predisposition and bone marrow failure. Including FANCD2 and BRCA2, nine FA genes have been identified, the products of which operate in a genomic caretaker pathway. The FANCA,-B,-C,-E,-F,-G and -L proteins are all required for the activation of the FANCD2 protein by monoubiquitination, which occurs in S-phase and in response to DNA damage. Activated FANCD2 relocates to nuclear foci that also contain BRCA1 and BRCA2. Despite extensive characterization of the FA pathway and the associated proteins, the fundamental molecular defect in FA cells remains unknown. Previously, it has been reported that ES cells with a truncated Brca2 protein display an increase in error-prone homology-directed repair of DNA double-strand breaks (Tutt et al. 2001). Considering the convergence of the FA and BRCA genomic caretaker pathways we set out to determine whether Fancd2-deficient ES cells display a similar homology-directed DSB repair response as Brca2-truncated ES cells. Fancd2-deficient and corrected ES cells were established carrying a single copy of a direct repeat reporter construct. These cells were transfected with I-SceI to induce a DSB in a partial Bsd reporter gene. Recombination between the homologous repeats, i.e. two inactive Bsd selection markers, generates a functional selection marker and homology-directed DSB repair events were identified by selecting for blasticidin resistant ES cell clones. Our preliminary results indicate that Fancd2-deficient and corrected ES cells have similar blasticidin survival frequencies after I-SceI DSB induction, suggesting the efficiency of homology-directed repair of induced DSBs is not compromised in absence of Fancd2. Analysis of the reporter construct after DSB repair to characterize the nature of the recombination event is in progress. Moreover, the blasticidin-mediated selection of recombinant ES cell clones allows us to analyze spontaneous and DNA damage-induced recombination events within the reporter construct. SNM1 acts in a BRCA1-dependent pathway non-epistatic to Fanconi anemia for genome stability. *A.W. Hemphill, Y. Akkari, J. Hejna, S. Olson, R.E. Moses.* Dept Molecular & Medical Gen, Oregon Health & Science Univ, Portland, OR.

The gene encoded by SNM1 in *Saccharomyces cerevisiae* has been shown to act specifically in the repair of DNA interstrand crosslinks (ICLs). There are five mammalian homologs of *SNM1*, including Artemis. Artemis is involved in V(D)J recombination, and mice deficient in Artemis develop severe combined immunodeficiency syndrome (SCID). Mice with a mutation in *Snm1* are sensitive to the ICL agent Mitomycin C (MMC). To explore the role of SNM1 and its homologs in ICL repair in human cells, we used siRNA to deplete SNM1, SNM1B, and Artemis in human fibroblasts, with cell survival and chromosome radials as the end points for cellular sensitivity and genome stability. Depletion of either SNM1 or SNM1B increases sensitivity to ICLs as detected by both end points, while depletion of Artemis does not. Thus SNM1 is active in maintenance of genome stability following ICL formation. To study the epistatic relationship between SNM1 and other ICL repair pathways, we used siRNAs to deplete SNM1 in a Fanconi anemia (FA) cell line. FA is a recessive disorder characterized by sensitivity to ICL agents, including MMC, manifest by increased cell death and genome instability. We find that depletion of SNM1 in an FA cell line produces additive sensitivity to MMC. We have previously shown that BRCA1 acts in the FA pathway for ICL repair, plus at least one other. Upon depletion of both SNM1 and BRCA1 in a normal cell line, we saw no increase in sensitivity above that of BRCA1 alone. We conclude that SNM1 represents a second BRCA1-dependent pathway for ICL repair, distinct from the FA pathway.

GENOME WIDE ANALYSIS OF ALLELIC IMBALANCE IN TUMOR EPITHELIUM AND STROMAL IN PATIENTS WITH BRCA1 AND BRCA2 MUTATION POSITIVE HEREDITARY BREAST CANCER. *F. Weber[1], L. Shen[2], K. Sweet[1], K. Cooper[1], C.D. Morrison[3], T. Caldes[4], C. Eng[1].* 1) CCC,HCG,MVIMG; 2) Div of Epidemiology and Biometrics; 3) Dep of Pathology, The Ohio State University; 4) Laboratory of Molecular Oncology, San Carlos University Hospital.

Distinct molecular and clinical features different from those found in sporadic breast cancer characterize BRCA1/2 mutation carriers. The dynamic interaction between epithelial and mesenchymal cells altered by genetic alterations might promote these differences. We investigated the pattern of genomic alterations in the tumor epithelium and stroma of patients with hereditary breast cancer.51 samples were subjected to laser capture microdissection and DNA extraction from the tumor epithelium and stroma. Of these, 29 are BRCA1 and 20 are BRCA2 mutation positive. Genotyping was performed with 371 microsatellite markers using fluorescence detection method.

19375 informative markers could be evaluated for loss of heterozygosity (LOH). The proportion of LOH was 60% in the stroma and 67% in the epithelium. Hirachical cluster analysis showed a strong cluster of BRCA1 mutation positive cases. We also found for 15 out of 51 subjects the epithelium and stroma group immediately together, 10 of which are BRCA1 mutation positive. Several regions could be identified as LOH hot spot in epithelium or stroma and correlated to clinical data.The high frequency of LOH manifests the functional effect of BRCA1/2 mutations; disruption of the DNA repair mechanism. The subsequent genetic events can alter the mammary gland architecture as a determining factor for cancer susceptibility. The disproportional representation of BRCA1 mutation positive cases for which epithelium and stroma cluster directly together lend evidence for an epithelial to mesenchymal transition. Our data indicate that BRCA1/2 deleterious mutation and variants show similar high degree of genomic instability. This is also reflected in a patient with BRCA1 mutation who received prophylactic surgery. Our data underscore the interplay of tumor epithelium and its stroma in the development of hereditary breast cancer.

Most somatic mutations in cancer occur in a novel nine-nucleotide purine-rich (NNUPURI) motif. *N. Makridakis*[1], *L. Ferraz*[1,2], *J. Reichardt*[1,3]. 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Current address: University of Campinas, São Paulo, Brazil; 3) Current address: Plunkett Chair of Molecular Biology (Medicine), University of Sydney, Sydney, Australia.

Somatic mutations are hallmarks of cancer progression. We screened 26 matched human prostate tumor and constitutional DNA samples for somatic alterations in the SRD5A2 (steroid 5?-reductase type II), HPRT (hypoxanthine-guanine phosphoribosyltransferase), and HSD3B2 (3?-hydroxysteroid dehydrogenase type II) genes, by direct sequencing of specific PCR products. We identified a total of 71 somatic substitutions in these genes. All patients analyzed had somatic alterations in at least one of these loci. Interestingly, 77.5% (55/71) of all somatic substitutions occur at a nine-nucleotide purine-rich (NNUPURI) motif with up to one nucleotide mismatch (out of nine). We also found this motif in 88.5% (23/26) of the H-ras gene somatic mutations formed in the SENCAR mouse skin model, after induction of error-prone DNA repair following mutagenic treatment. Transitions account for 92% of the H-ras somatic mutations detected in the SENCAR model and 93% of the somatic substitutions that we found in all three genes analyzed. Moreover, examination of the published literature revealed that the NNUPURI motif accounts for 66.1% (37/56) of all somatic prostate cancer mutations found in the human genes analyzed (H-ras, N-ras, Ki-ras, PTEN, p53 and the androgen receptor (AR) gene), and for 73.8% (90/122) of all somatic breast cancer mutations found in the 11 genes analyzed. The high prevalence of the NNUPURI motif in each case mentioned above cannot be explained by chance ($p < 1.32 \times 10^{-9}$). These data suggest that most somatic nucleotide substitutions in human cancer may occur in sites that conform to the NNUPURI motif. These mutations may be the result of a specific molecular mechanism, such as error-prone DNA repair.

Loss of p21 permits carcinogenesis from chronically damaged liver and kidney epithelial cells despite unchecked apoptosis. *H. Willenbring[1], A. Vogel[1], A. Rothfuss[1], S. Eftekhari[1], M. Al-Dhalimy[1], M. Finegold[2], M. Grompe[1].* 1) Dept. of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR; 2) Dept. of Pathology, Texas Children's Hospital, Houston, TX.

In tyrosinemia type I accumulation of toxic metabolites due to fumarylacetoacetate hydrolase (Fah) deficiency results in chronic DNA damage and consequently the highest risk for hepatocellular carcinomas (HCCs) of any human disease. Here we show that *Fah*$^{-/-}$ hepatocytes exhibit a profound cell cycle arrest which causes mortality due to impaired liver regeneration despite the apoptosis resistance inherent to Fah deficiency. Using microarray analysis we found that Fah deficiency led to induction of proliferative as well as antiproliferative genes, foremost the cyclin-dependent kinase inhibitor p21. To test the role of p21 in the formation of HCCs we generated mice deficient in both Fah and p21. Remarkably, loss of p21 resulted in massive proliferation of hepatocytes and renal tubular epithelium in *Fah*$^{-/-}$ mice. This response was sufficient to compensate for cell loss due to unchecked apoptosis and hence facilitated survival. However, p21 deficiency caused HCCs, renal cysts and renal carcinomas in these animals. Thus, p21s antiproliferative function is indispensable for the suppression of carcinogenesis from chronically injured liver and renal epithelial cells and cannot be compensated for by induced apoptosis. Our results highlight the essential role of cell cycle control in both intrinsic suppression and targeted therapy of cancer.

The human telomere maintenance proteins TRF2 and TRF1 are involved in an early DNA damage response. *P.S. Bradshaw[1,2], J.D. Stavropoulos[1,2], H. Tanaka[3], D. Gilley[3], M.S. Meyn[1,2,4].* 1) Genetics & Genomic Biology, Hospital for Sick Children, Toronto, ON; 2) Molecular & Medical Genetics, Univ of Toronto, Toronto, ON; 3) Medical & Molecular Genetics, Univ of Indiana, Indianapolis, IN; 4) Paediatrics, Univ of Toronto, Toronto, ON.

Human cells protect their genomes by using DNA damage surveillance networks that can activate DNA repair, cell cycle checkpoints and apoptosis in response to 4 double-strand breaks (DSBs)/genome. These same networks tolerate telomeres, in part because the TRF2 protein prevents recognition of telomeric ends as DSBs. We recently reported that TRF2 unexpectedly associates with induced DSBs (Nat Genet 37:193). We now present evidence that TRF2 and the telomeric protein TRF1 are involved in a novel cellular response to DSBs.

TRF1 forms transient foci with TRF2 that colocalize with laser microbeam-induced DSBs in human fibroblast nuclei. TRF1 and TRF2 are detectable at DSBs <3 seconds post-irradiation, earlier than ATM, a kinase that controls the major DSB surveillance network. Like many DNA damage response proteins, TRF2 is phosphoyrlated after DSB induction. Phospho-Thr188 TRF2 associates with induced DSBs but not undamaged telomeres. Multiple lines of evidence suggest that TRF2 and ATM functionally interact at DSB sites: the two proteins colocalize at DSBs, -ray induced phosphorylation of TRF2 is ATM-dependent, and over-expression of TRF2 impairs DSB-induced ATM autophosphoyration as well as ATM-dependent phosphorylation of H2AX and p53.

Our results provide evidence that TRF2 and TRF1 interact with DSB-containing chromatin, TRF2 competes with or attenuate ATM responses to DSBs and DSB-induced modifications to TRF2 may shift TRF2 from telomere maintenance to DSB repair. Our findings also indicate that human cells practice a strategic economy in using the same proteins in telomere maintenance and DSB repair.

Detection of Hereditary Nonpolyposis Colorectal Cancer (HNPCC) among newly diagnosed endometrial cancer patients. *H. Hampel[1], J. Panescu[1], K. Sotamaa[1], D. Fix[1], W. Frankel[2], I. Comeras[1], P. Penzone[3], J. Lombardi[5], P. Dunn[5], D. Cohn[3], L. Copeland[3], L. Eaton[3], J. Fowler[3], G. Lewandowski[4], L. Vaccarello[4], J. Bell[5], G. Reid[5], A. de la Chapelle[1].* 1) Human Cancer Genetics Program, The Ohio State University, Columbus, OH; 2) Dept of Pathology, The Ohio State University; 3) Div of Gynecologic Oncology, The Ohio State University; 4) Gynecologic Oncology & Pelvic Surgery Assoc, Mount Carmel Health System, Columbus, OH; 5) Central Ohio Gyn Oncology, Riverside Methodist Hospital, Columbus, OH.

All newly diagnosed endometrial cancer patients in Columbus, Ohio were offered participation in a study to determine the frequency of HNPCC. All tumors underwent microsatellite instability (MSI) testing using a modified Bethesda panel of markers. Patients with MSI positive (high or low) tumors, underwent genetic testing for germline mutations in *MLH1*, *MSH2*, and *MSH6* using a variety of methods including immunohistochemical staining (IHC) for mismatch repair proteins, genomic sequencing, and multiplex ligation-dependent probe amplification. Those patients identified as having HNPCC received genetic counseling and their at-risk family members were offered counseling and predictive testing. Enrollment included 566 endometrial cancer patients. To date, 540 tumors have had MSI testing. Of these, 122 are MSI positive (22.6%; 100 MSI-high and 22 MSI-low) and 418 are MSI negative. All 122 patients with MSI positive tumors have had genetic testing and six patients have been identified with germline mutations (1 *MLH1*, 2 *MSH2* (both large deletions), 3 *MSH6*). In addition, one case with an MSI negative tumor had abnormal MSH6 IHC and was subsequently found to have a mutation in *MSH6*. IHC was consistent with the mutation result in all 7 mutation positive cases while MSI failed to identify HNPCC in 1 of 7 cases. Thus, in central Ohio 1.3% (7/540) of newly diagnosed endometrial cancer patients have been found to have HNPCC. Of the seven HNPCC patients, two meet Amsterdam criteria, two meet the Bethesda guidelines, and three do not meet any published criteria for HNPCC. Four of the patients with HNPCC were diagnosed at age 50 or later.

Molecular analysis in patients with colorectal cancer and associated tumors in the Netherlands: MSH6 founder effects and a large proportion of MSH6 mutations conferring a phenotype which differs from classical HNPCC.

D. Dooijes, R. Olmer, R.M. van der Helm, A. de Snoo, D.J.J. Halley, A. Wagner. Department of Clinical Genetics, Erasmus MC, Rotterdam, the Netherlands.

Hereditary nonpolyposis colorectal cancer (HNPCC) is the most common autosomal dominant susceptibility syndrome, predisposing to colorectal and endometrial cancer. Germline mutations in the mismatch repair (MMR) genes MLH1, MSH2 and, to a lesser extent, MSH6 have been shown to cause HNPCC in families fulfilling the diagnostic Amsterdam-criteria (AC). Preliminary data suggest that phenotypic expression of MSH6 gene defects may differ from classical HNPCC AC-positive expression caused by mutations in the MLH1 and MSH2 genes. We analysed 130 families, not-strictly complying with the Amsterdam criteria, for HNPCC associated mutations in the MMR genes MLH1, MSH2 and MSH6. Remarkably, in addition to families with germline pathogenic MLH1 (7/22) and MSH2 (3/22) mutations, half of the families carried a pathogenic mutation in the MSH6 gene (11/22). Moreover, two out of eight different MSH6 mutations were observed more than once in apparently unrelated families. Extended haplotype analysis subsequently demonstrated these two MSH6 mutations to be founder mutations present in the Dutch population. Clinical findings in the mutation carriers from the MSH6 positive pedigrees were in agreement with an later age at onset of HNPCC associated tumors compared to MLH1 and MSH2 mutation carriers, but a similar cumulative risk at age 65. MSH6 mutation carriers showed a lower lifetime cumulative risk for colorectal cancer compared to MLH1 and MSH2 mutation carriers. Cumulative risk for endometrial cancer was significantly higher in MSH6 mutation carriers compared to carriers of an MLH1 or MSH2 mutation and almost twice as high at age 65+. Our data suggest that MSH6 mutations are underdiagnosed and represent a separate clinical entity compared to classical AC-positive HNPCC, as expressed in most MLH1 and MSH2 families, including a later age at onset and a broader range of malignant abnormalities. Initial MSH6 gene mutation analysis is suggested in Amsterdam-negative or atypical HNPCC families with an MSH6 phenotype.

The effect of study design on the inference of human population structure. *N.A. Rosenberg[1], S. Mahajan[2], J.K. Pritchard[3], M.W. Feldman[4].* 1) Bioinformatics Program, Univ of Michigan, Ann Arbor, MI; 2) Dept of Biological Sciences, Univ of Southern California, Los Angeles, CA; 3) Dept of Human Genetics, Univ of Chicago, Chicago, IL; 4) Dept of Biological Sciences, Stanford Univ, Stanford, CA.

Previously (Science 298:2381-2385, 2002), we observed that without using prior information about individual sampling locations, a clustering algorithm applied to 1056 individual multilocus genotypes from 52 worldwide human populations produced genetic clusters largely coincident with major geographic regions. Reanalyzing our data, Serre and Pääbo (Genome Res 14:1679-1685, 2004) argued that the degree of clustering is diminished by use of samples with greater uniformity in geographic distribution. However, because the study design differed between their analyses and ours, it is difficult to assess the extent to which differences in outcomes arose from differences in the geographic dispersion of the samples, or from differences in sample size, number of loci, number of clusters, or assumptions about allele frequency correlations across populations. Expanding our earlier data set to 993 markers, we systematically examine the influence of these variables on the clusteredness of individuals. Among the variables considered, the number of loci and the assumptions regarding allele frequency correlation are observed to have the greatest impact. With all other variables held constant, geographic dispersion is seen to have little effect on the degree of clustering. Thus, the discrepancy from our results discussed by Serre and Pääbo is likely attributable to other factors, in particular, their use of a smaller sample size and their assumption that allele frequencies are uncorrelated across populations. As correlation coefficients 0.6 between allele frequencies on separate continents belie this assumption, our analysis of the 993 loci accounting for such correlations corroborates our earlier results: if enough markers are used with a large enough worldwide sample, individuals can be divided into genetic clusters that match major geographic subdivisions of the globe, with individuals from intermediate geographic locations having mixed membership in the clusters that correspond to neighboring regions.

Genetic Structure of Asian Indian Populations: Genome-wide analysis of variation at 1200 DNA markers. *P.I. Patel[1, 3], S. Mahajan[2], C. Gonzales[1], L. Nino-Rosales[3], V. Ninis[3], P. Das[3], M. Hegde[4], L. Molinari[4], G. Zapata[4], J.L. Weber[5], J.W. Belmont[4], N.A. Rosenberg[6].* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Department of Biological Sciences, University of Southern California, Los Angeles, CA; 3) Department of Neurology, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Marshfield Clinic Research Foundation, Marshfield, WI; 6) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Although India comprises over one-sixth of the world's human population, individuals from India have generally not been included in large genomic surveys of genetic variation. We studied 672 individuals from 17 Indian populations at a collection of 1200 autosomal microsatellite and insertion/deletion polymorphisms, of which 925 overlap with markers genotyped in the HGDP-CEPH Human Genome Diversity Panel. When performing cluster analysis of individual multilocus genotypes, combining the Indian genotypes with the diversity panel data, we found that populations from India, and those from South Asia more generally, constituted one of the major human ancestry subgroups. In the combined analysis, the six main genetic clusters correspond to Africa, Europe and the Middle East, South Asia, East Asia, Oceania, and the Americas, with South Asia displacing an isolated population previously identified as the sixth cluster. Surprisingly, despite the cultural, geographic, and linguistic diversity of the 17 sampled Indian groups, genetic differentiation within India is smaller than that within comparable regional subdivisions of the human population, with $F_{st}<0.01$ across Indian populations.

Taken together, these results suggest both that many of the common genetic variants in India will not be identified without incorporating Indian groups into genome-wide investigations, but that most of these variants will be found if at least one population from India is included. Consequently, we recommend that a sample from India be incorporated alongside better-studied populations in future genomic surveys.

European Population Structure: Ability to distinguish North and South. *M.F. Seldin[1], R. Shigeta[1], P. Villoslada[2], C. Selmi[1], L. Klareskog[3], P.K. Gregersen[4].* 1) UC Davis, Davis, CA; 2) Cent Applied Med Res, Pamplone, Spain; 3) Karolinska Univ Hosp, Stockholm, Sweden; 4) North Shore-LIJ Res Inst, Manhasset, NY.

Population structure is potentially important in clinical epidemiologic studies and in conducting association tests. This study examines population structure in a diverse group of Europeans and European Americans. After exclusion of subjects with evidence of non-European origin using ancestry informative markers, the remaining 932 subjects of nearly exclusive European ancestry were examined with a genome-wide SNP linkage typing panel. Using 2756 SNPs chosen to reduce or eliminate LD (minimum separation of 500 kb between markers), analyses were performed with both STRUCTURE and GENECLASS2 (Mountain-Rannala algorithm). The ability to distinguish populations based only on SNP typing as being derived from southern European countries or regions compared with northern European countries or regions was consistently observed and reproducible under assumptions of k (number of populations)ranging from 2 to 8 or using leave-one out cross-validation studies e.g. for k=2: 78/87 Italian and 51/78 Spanish subjects had >90% membership in the south population, where as 84/90 Swedish subjects had > 90% membership in the north population. Groups of European Americans who reported specific grandparental European origin provided additional support for this major division in European population structure: 143/162 subjects with reported Western European heritage had >90% membership in the north population. Similar results were found for Eastern Europe, whereas self identification with southeastern European origin (Italian, Spanish and Portuguese)showed predominant membership in the south population group. Finally, small groups of subjects including 1)Sephardic Jewish Americans (3/3 >90% south European); 2)Portuguese (2/3 >90% south) and 3)the only Basque subject within the Spanish collection (>85% north) provided additional support for this division. These results and identification of smaller sets of the most informative markers suggest that this major partition in European population structure may be applicable to a variety of clinical and genetic studies.

From a still small voice - the recent evolution of a new gene VOC1 within a new locus regulating vocal development. *R.A. Clarke, C.E. de Brock, Z.M. Fang.* St George Hosp, Sch Medicine, Univ of NSW, Kogarah, Australia.

The human voice has evolved through a coordinated interplay of anatomical and neurological developments. Here we report the first voice gene (VOC1) disrupted within a family with a congenital (anatomical and neurological) vocal defect. Heterozygous individuals present with limited vocal range often reduced to a whisper. VOC1 is a new gene that has recently evolved within a new locus implicated in vocal development. The recently evolved VOC1 gene is present within all primates tested and absent from mouse and rat. VOC1 evolution is not the result of gene conversion nor does VOC1 share any significant degree of homology elsewhere within the genome. VOC1 evolved during a relatively recent rearrangement between two adjacent syntenic blocks of the genome. VOC1 mRNA transcripts are expressed across a wide range of tissue types. VOC1 represents a genuine 'new gene' that has evolved in recent evolutionary history. The new status of the VOC1 gene may prove timely in human development when consideration is given to the dependence of human speech and language on parallel vocal development. The first two speech/language genes described recently 1) FOXP2 is a transcription factor involved in a range of developmental processes in addition to the regulation of some cognitive aspects of normal speech development 2) ATP13A4 appears to be a more ubiquitously expressed cation transporting ATPase. As expected, FOXP2 and ATP13A4 have close homologues in other species including mouse suggesting their likely recruitment to speech developmental processes within the brain rather than a driving force. The very recent emergence of the VOC1 gene within a recently rearranged locus is compelling evidence for the emergence of a new vocal genotype in parallel with the evolution of human voice/speech.

Evolutionary genetics of normal variation in human skin pigmentation. *H.L. Norton[1], E.J. Parra[2], R.A. Kittles[3], M.D. Shriver[1].* 1) Department of Anthropology,Penn State University; 2) Department of Anthropology, University of Toronto at Mississagua; 3) Human Cancer Genetics. Ohio State University.

Human pigmentation is dramatically variable among the populations of the world. Although much is known regarding the genetics of rare Mendelian hypopigmentation disorders, normal variation has been less well studied. Given the variation among world populations, two analytical methods stand out as ideally suited to study the evolutionary genetics of skin pigmentation: admixture mapping and differentiation-based screens for selection. We have surveyed several pigmentation candidate genes (TYR, OCA2, ASIP, MATP and MC1R) for signatures of selection across representative populations from six global regions: West Africa, Europe, South Asia, East Asia, Meso America, and Island Melanesia and have used admixture mapping in African-American and African-Caribbean population samples to test for admixture linkage. With the exception of MC1R, these genes all show significantly high locus-specific pairwise Fst relative to empirical distributions. These four genes also show evidence for admixture linkage in this and other studies. We next assayed the HGDP-CEPH collection of 52 populations for these SNPs. Two of these genes (OCA2 and ASIP) support a common origin for some of the variants leading to dark skin, while the other two genes (TYR and MATP) show evidence for independent origins of some of the genes underlying light skin in Europeans and East Asians.

Non-synonymous coding SNPs from multiple populations reveal extensive gene-gene interactions in the human genome. *Z. Bochdanovits, P. Heutink.* Dept Medical Genomics, VU Univ Med Ctr, Amsterdam, Netherlands.

The existence of non-additive (epistatic) gene-gene interactions is widely accepted but how important their contribution is to phenotypic variation in humans is yet to be determined. To address this issue we performed a search for functional gene-gene interactions in the human genome. When SNP genotypes are available form multiple populations genetic differentiation at individual loci can be calculated; values that are larger than can be expected from neutral processes alone are indicative of directional selection. We extended this approach to calculate genetic distances (detect signatures of selection) at pairs of loci. Each individual possesses one out of four possible combinations of any two SNPs; i.e. is homozygous for both, heterozygous for both or homozygous for one and heterozygous for the other (2x). If selection favors one of these configurations (haplotypes) above the others, than genetic divergence at the level of haplotypes is indicative of functional epistatic interaction between the SNPs. Based on SNP genotype data from three human populations (Asian, African-American and Caucasian; dbSNP Build 124) we estimated haplotype frequencies for 12,875,275 combinations of 5075 non-synonymous coding SNPs (NSCS) using the EM-algorithm. The distribution of Fst values derived from the NSCS haplotypes were significantly different (right skewed) from the distribution based on 5075 randomly chosen neutral SNPs (NS). Because random (demographic) processes are expected to have a similar effect on all SNPs, a difference between these two classes should be the result of selection on functional interaction between NSCS. The average number of interactions per SNP was significantly larger in NSCS vs NS; the excess represents true functional gene-gene interactions. Interestingly, the magnitude of the (proportional) excess in the number of interactions, was largest at an intermediate level of genetic differentiation. Apparently, gene-gene interactions that cause a mild phenotypic change subject to intermediate levels of selection have the largest contribution to the evolved genetic divergence between human populations.

Functional importance of evolutionarily conserved noncoding regions in humans demonstrated using HapMap data. *J. Nemesh[1,2], J.A. Drake[1,2], C. Newton-Cheh[2,3], J.N. Hirschhorn[1,2].* 1) Program in Genomics/Genetics, Children's Hospital/Harvard Medical School, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Cardiology, Massachusetts General Hospital, Boston, MA.

Evolutionarily conserved noncoding regions (ECRs) are hypothesized to be enriched for functional regulatory variants, but alternatively they could largely consist of regions with lower mutation rates during mammalian evolution. It is possible to distinguish between these alternatives: if noncoding ECRs are functionally constrained in humans, then new (derived) alleles arising within ECRs should often be subject to negative selection, and derived alleles within noncoding ECRs will be rarer than those in the remainder of the genome; by contrast, regions of low mutation rate would not alter the allele frequency distribution.

We now directly demonstrate that ECRs are functionally constrained in humans by using data from the HapMap (www.hapmap.org) to compare the derived allele frequency distributions of single nucleotide polymorphisms (SNPs) within and outside of ECRs. Specifically, we identified ECRs using the ECR browser (ecrbrowser.dcode.org), with a threshold of 80% identity with the mouse genome and 90% identity with the dog genome across 200+ bp. We compared the frequencies of derived alleles of 16,279 SNPs within ECRs and 518,705 SNPs outside of ECRs. We observed a highly statistically significant shift towards rare derived alleles for SNPs within ECRs ($p<0.0001$ by Kolmagorov-Smirnoff test; 24% vs. 22% of alleles had frequency <10%; $^2 = 72$, 1 df). We also found that the enrichment of rare alleles is unlikely to be due to ascertainment bias in HapMap, and is less dramatic in ECRs that are distant from genes. The shift towards rare alleles in ECRs is similar to that for missense vs silent variants, once ascertainment is corrected for.

We conclude that ECRs are functionally constrained in humans and are thus a potentially fertile hunting ground for disease-causing variants. Allele frequency analysis may help define classes of ECRs or parts of ECRs that are enriched for functional elements in humans.

Genetic architecture of the extended MHC in multiple populations based on a high resolution SNP map. *M. Miretti, MHC consortium.* Wellcome Trust Sanger Institute, Hinxton-Cambridge, UK.

We constructed a genetic variation map across a 7.8Mb segment of chr 6p which harbours the extended major histocompatibility complex (MHC), in multiple populations. The 6338 SNP-based map allows to look at patterns of linkage disequilibrium (LD) which fluctuate markedly across the region. We also used the population data to estimate the recombination rates at high resolution. The distribution of the inferred recombination hotspots perfectly matched with previous sperm genotyping over the class II sub-region. Recombination rate varies across the region and is significantly lower in the the extended MHC class I sub-region containing the olfactory receptor and histone gene clusters. Between populations, recombination rates differed mainly in intensity at hotspot, which were similarly distributed. We observed multiple long-range haplotypes several of which extended over adjacent recombination hotspots. Given their population frequencies, such haplotypes can either result from population history or from selective sweeps. We are using this map to look for signatures of selection associated to ancestral HLA haplotype blocks and to select tagSNP lists representing key haplotypes. Finally, we have explored the relationship between classical HLA typing and patterns of diversity and recombination in the underlying haplotype structure. This resource will contribute to our understanding of generation and maintenance of MHC variation and aid disease association studies.

Interparalog gene conversion pattern and evolutionary dynamics of HBII-52 C/D box snoRNAs cluster at 15q11-q12. *M. Ogorelkova[1], A. Navarro[2], X. Estivill[1].* 1) Gene & Disease Prog, Ctr Genomic Regulation, Barcelona, Catalonia, Spain; 2) Experimental and Health Sciences Department, Pompeu Fabra University, Barcelona, Catalonia, Spain.

Brain expressed, paternally imprinted C/D box HBII-52 snoRNAs are organized in a ~100 Kb cluster of 47 copies on chromosome 15q11-q12. They are suggested to post-transcritionally modify the 5HT2C transcripts by affecting the editing and/or alternative splicing. The HBII-52 copies share high homology with each other (>97%), and over half of them are expected to be functionally active. Due to high level of sequence identity, gene conversion is anticipated to be the main event shaping the DNA variability of the cluster. We have analysed the DNA variability of 25 presumably functional copies in 70 Spanish individuals. In 6.6 Kb of sequence, 34 SNPs and rare variants have been identified, 23 of which are novel. Two third of the variants have minor allele frequency less than 5%. Six variants are predicted to lead to non-functional snoRNA copies. Twenty six substitutions correspond to paralogous sequence variants (PSVs) in other copies and occur at potential gene conversion sites with tract of >5 bp. We detected 4 gene conversion events involving more than one PSV, with potential tracts between 6 and 31 bp. The overall nucleotide diversity of the cluster (4.2x10 -4) is higher than the genome average, and several snoRNA copies display very high nucleotide diversity of up to 1x10 -3. Interparalog gene conversion is expected to generate excess of sequence diversity, with excess of variants with low MAF. The spectrum of variability at HBII-52 snoRNAs cluster is strongly suggestive of frequent and recurrent gene conversion events between paralogous copies, and multiple gene conversion hot spots. Multiple SNPs are found at the proximal and distal parts of the snoRNAs cluster while central copies are devoid of variants. A recent positive selection event, possibly a fixation of human-specific copy 38, might have removed the variability within the central copies, as confirmed by tests of neutrality on preliminary data. Alternatively, some snoRNA paralogs might represent gene conversion receiver hot spots.

Systematic sequencing analysis discloses the pattern of nucleotide polymorphisms in human microRNA genes. *A. Tajima, Y. Sakamoto, R. Mitsumori, I. Inoue.* Div Genetic Diagnosis, IMS, Univ Tokyo, Minato-ku, Tokyo, Japan.

MicroRNAs (miRNAs) are a family of small noncoding RNAs in a wide variety of organisms including humans. Recent experimental and bioinformatics studies have disclosed that over 200 distinct miRNAs are encoded in human genome. The small RNAs are enzymatically processed from hairpin-shaped precursor transcripts (pre-miRNAs), and can work as post-transcriptional repressors of target-gene expression by base-paring with the target mRNAs, implying possible associations between miRNA dysregulation and human diseases. Although miRNA biogenesis and miRNA-mediated regulation of gene expression are thought to be highly controlled in a sequence-dependent manner, there has been little attempt to characterize miRNA diversities within human populations at the nucleotide level. Here we show the genetic basis for the extent and pattern of DNA polymorphisms in human miRNA genes. We identified a total of 103 SNPs on 30,967-bp comparisons excluding indel polymorphisms by sequencing 10 selected genomic regions, which are composed of 20 distinct miRNA genes and their flanking regions, in 30 subjects (10 each from African American, European American and Japanese populations). Among the 103 polymorphic sites, three SNPs ('precursor SNPs') were observed in three pre-miRNA sequences, but none in mature ones. Within-diversity estimate for concatenated sequences of 20 pre-miRNA regions was comparable to those of the adjacent surroundings such as 5'- and 3'-flanking regions, whereas between-species comparison revealed that the 20 orthologues were highly evolutionarily conserved between humans and chimpanzees. F_{ST}-based analysis indicated that all the precursor SNPs exhibited low levels of genetic differentiation between three human populations. Considered together with additional results regarding the suppressive effect of a particular precursor SNP on *in vitro* miRNA processing and the SNP locations in hairpin structures of pre-miRNAs, the present findings suggest that purifying and/or balancing selection has shaped the pattern of nucleotide polymorphisms in human miRNA genes.

Concordance of blastomeres in preimplantation aneuploid screening. *E. Pergament[1], C.B. Coulam[2], M. Fiddler[3], R.S. Jeyendran[4].* 1) Northwestern Reproductive Genetics, Inc; 2) Rinehart Center for Reproductive Medicine; 3) DePaul University; 4) Andrology Laboratory Services, Inc., Chicago, IL.

The testing of preimplantation embryos for aneuploidy - known as aneuploid screening - appears to be a rational yet questionable approach to enhance the initiation and outcome of pregnancies undertaken through *in vitro* fertilization (IVF). Fluorescent in situ hybridization (FISH) analyses for as few as 9 chromosomes demonstrate that the majority of human preimplantation embryos are not only aneuploid but mosaic; however, in many IVF programs transfer of embryos following aneuploid screening is based on FISH analyses of a single blastomere derived from each embryo. There have been no prospective, randomized, multicenter trials with external oversight addressing the efficacy of aneuploid screening of embryos by multicolor FISH. We report on the rates of concordance and discordance for eight chromosomes (13, 15, 16, 18, 21, 22, X and Y) between two blastomeres derived from each embryo as part of a standard IVF program in which FISH was performed by a national laboratory offering preimplantation genetic services. The study population consisted of 24 women who underwent 28 IVF cycles in which 167 of 287 (58%) embryos were successfully biopsied for two blastomeres and FISH probes were successfully applied to both blastomeres in 108 cases. In only 21% was there complete concordance for the eight chromosomes. Twenty-four percent of the embryos were discordant for one chromosome, 22% for two, 11% for three, 12% for four, 3.7% for five and six, and 1% for seven and eight chromosomes. The rate of discordance for individual chromosomes ranged from a low of 13.9% of embryos for the Y chromosome to a high of 33.3% of embryos for chromosome 15 (mean, 26.3%) There were 10 embryos (9.3%) which if transfer were based on their diploid blastomere had the potential for a trisomic conception of clinical significance. This data indicates that aneuploid screening based on FISH analyses of preimplantation embryos is unlikely to be effective in enhancing the initiation and outcome of pregnancies undertaken by IVF.

Uniparental disomies in human preimplantation development. *A. Kuliev, S. Rechitsky, Y. Verlinsky.* Reproductive Genetics Inst, Chicago, IL.

More than half of patients undergoing IVF are 35 years or older, increasing the risk for producing gametes with age-related aneuploidies. The embryos resulting from such prezygotic errors may be predisposed to further mitotic errors, with potential of resulting in uniparental disomies through the trisomy rescue mechanism, providing one of possible explanations for imprinting disorders associated with assisted reproductive technologies (ART). To identify uniparental disomies in preimplantation embryos, we biopsied single blasomeres from the 8-cell embryos in cases of preimplantation diagnosis for age related aneuploidies, and cases of preimplantation HLA typing in patients of advanced reproductive age, using a DNA fingerprinting based on the patterns of alleles that uniquely identify an individual, relying on a multiplex fluorescent PCR of low template DNA. Using short tandem repeats (STR) with a high heterozygosity, we performed single cell DNA fingerprinting for detection of aneuploidies for chromosomes 6, 13, 16, 18, 21, 22 and X. Overall, 655 embryos were tested, showing aneuploidy prevalence of 44%, including comparable rates of trisomies, monosomies and complex errors. Uniparental disomies were detected in 15 (2.3%) cases, involving all tested chromosomes except chromosome 13. All but one uniparental disomies (uniparental disomy 16) were of maternal origin, in agreement with the predominant female meiosis origin of aneuploidies. Therefore, testing for aneuploidies in oocyte and embryos may allow not only avoiding the transfer of aneuploid embryos, but also detecting and avoiding the transfer of embryos with uniparental disomies, one of the possible contributors to imprinting disorders associated with ART.

Spatial organization of the Prader-Willi/Angelman Syndrome region is dependent on the parent of origin. *A.D. Heggestad[1], T.R. Dennis[2], S. Rodriguez-Jato[1], B.A. Gray[2], R.T. Zori[2], D.J. Driscoll[2], T.P. Yang[1,2].* 1) Dept. Biochemistry and Molecular Biology; 2) Dept. Pediatrics, Univ. of Florida, Gainesville, FL.

The Prader-Willi and Angelman Syndrome (PWS/AS) region on chromosome 15 is composed of at least eight imprinted genes that are coordinately regulated by a bipartite imprinting center (IC). We have hypothesized that the PWS-IC acts as a positive regulator of genes expressed on the paternal chromosome via long-range intrachromosomal interactions and formation of an active chromatin hub (ACH). We now have used FISH to examine association of the PWS-IC with the distal imprinted *MKRN3*, *MAGEL2*, and *NDN* genes on the maternal and paternal chromosomes. In normal human cells, we found differential FISH patterns on the two chromosomes in which a majority of the cells showed one *MKRN3* or *MAGEL2/NDN* FISH signal that co-localized with one of the PWS-IC FISH signals, and one *MKRN3* or *MAGEL2/NDN* FISH signal that did not co-localize with the other PWS-IC FISH signal. To determine the parental origin of each FISH pattern, we used cells from AS patients with uniparental disomy (UPD) to examine the paternal chromosome, and PWS UPD cells to analyze the maternal chromosome. AS UPD cells showed preferential association of both PWS-IC FISH signals with the *MKRN3* or *MAGEL2/NDN* FISH probes, consistent with association of these distal genes with the PWS-IC on the paternal chromosome. In contrast, neither of the *MKRN3* or *MAGEL2/NDN* FISH signals associated with either of the PWS-IC FISH signals in the majority of PWS UPD cells, suggesting that these genes do not associate with the PWS-IC on the maternal chromosome. These data are consistent with a spatial organization of the AS/PWS domain in which the PWS-IC interacts with the chromosomal region containing *MKRN3*, *MAGEL2*, and *NDN* and forms an ACH specifically on the paternal chromosome. We postulate that these long-range interactions contribute to imprinting by facilitating activation of transcription of genes specifically on the paternal chromosome. We are currently investigating parent-of-origin long-range intrachromosomal interactions in this region by chromosome conformation capture.

MLPA screening reveals subtelomeric rearrangements in holoprosencephaly. *V. David[1,2], C. Bendavid[1,2], I. Gicquel[1], M.R. Durou[2], L. Pasquier[3], S. Jaillard[4], C. Henry[4], S. Odent[3], C. Dubourg[1,2].* 1) Faculte de Medecine, Rennes1, UMR 6061 CNRS, Rennes, Cedex, France; 2) Laboratoire de Genetique Moleculaire, CHU Pontchaillou, Rennes, France; 3) Genetique Medicale, Hopital Sud, Rennes, France; 4) Laboratoire de Cytogenetique, CHU Pontchaillou, Rennes, France.

Holoprosencephaly (HPE) is the most common developmental brain anomaly in humans, usually associated with facial features. The clinical spectrum is wide, ranging from cyclopia and alobar HPE to microforms like single central median incisor. The etiology is extremely heterogeneous with environmental and genetic factors. Out of twelve redundant loci reported until 1998 in karyotype anomalies in HPE, eight were subtelomeric. Furthermore, out of the four major genes previously identified among these twelve loci, two were subtelomeric : SHH and TGIF. Therefore, we hypothesized that a subtelomeric screening in HPE patients with normal karyotypes could reveal microrearrangements in chromosomal telomeres; this could aid in refining the six remaining previously described minimal critical regions, as well as identifying new candidate loci for HPE genes. In this study we screened a cohort of 70 fetuses and 100 newborn HPE samples with normal karyotypes, even if they were already known to have mutations or microdeletions in HPE genes (SHH, TGIF, SIX3,ZIC2). We used the SALSA MLPA kit P036B human telomers from MRC Holland. Based on our results, we demonstrated that subtelomeric rearrangements, duplications or deletions, are present in HPE patients. They were associated with SHH and TGIF microdeletions in 7q and 18p respectively, but were also found in some of the other six subtelomeric loci (1q, 20p, 21q) previously described. We also pointed out that other subtelomeres defects could be involved in 1p, 5q, 8p, 9q, 16p, 17q, 18q, 22q and in 15q subcentromeric. A few cases consisted of an association between a duplication and a deletion in two chromosomal subtelomeres like 7p del and 7q dup. If confirmed, these findings will reinforce the multigenic and multihit origin usually evocated for HPE and will also offer another explanation for the wide phenotypic spectrum described in this developmental disorder.

Novel Mutations in Human NODAL are Potentially Associated with Heterotaxy Syndrome. *B. Mohapatra[1], H. Li[1], S. Ware[3], S. Fernbach[2], T. Ho-Dawson[2], L. Molinari[2], B. Casey[4], J. Belmont[2], J. Towbin[1].* 1) Pediatrics(Cardiology), Baylor College of Medicine, Houston, TX; 2) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 3) Children's Hospital Medical center, Cincinati, OH; 4) Childrens & Womens health center, Vancouver BC V 6H 3V.

Heterotaxy is a complex congenital disorder, characterized by abnormal left-right asymmetry, involving heart and variety of visceral organs (e.g., gut, liver, lungs and spleen). The TGF- family member NODAL is known to play a critical role in vertebrate embryonic development by inducing mesoderm formation and determining left-right axis. We hypothesize that mutations in NODAL gene are associated with human heterotaxy syndrome. We have screened 300 unrelated probands with heterotaxy phenotype using PCR-based DHPLC analysis followed by DNA sequencing method and identified four missence (E203K, R275C, G260R & V284F) and a 24 base deletion with a 9 base insertion in the NODAL gene. With an exception of 1 control for G260R, all other changes are not found at least in 596 control chromosomes.All these variants except E203K are conserved across the species. Phenotype analysis of the patients carrying these heterozygous mutations revealed a high incidence of TGA, reversed heart looping and abnormal organ situs. In order to evaluate the functional roles of the identified sequence variants on the Nodal signaling pathway we have introduced these variants into the full length NODAL cDNA in pcDNA 3.1-V5-6His mammalian expression vector. A luciferase reporter assay in P19 embryonic cells by using p(AR3)-lux, p(SBE)4-lux and p(CAGA)12-lux plasmids containing down stream target promoters tagged with luciferase reporter gene demonstrated a significant inhibition of down stream target promoter activity(40-50%)with the mutants. Further analysis of Smad2 phosphorylation, an important measure of Nodal signaling, by Western blot and immunofluorescence studies using phospho-specific antibodies, also exhibited a significant reduction of Smad2/3 phosphorylation. The genotype-phenotype analysis as well as the in vitro studies, together suggests that the sequence variants observed in the NODAL are causative mutations for heterotaxy syndrome.

Non invasive screening and rapid QF-PCR assay could reduce the need of conventional cytogenetic analyses in prenatal diagnosis. *V. Cirigliano[1], G. Voglino[2], M. Adinolfi[3].* 1) Dept Molecular Genetics, General Lab, Barcelona, Spain; 2) Molecular Genetics and Cytogenetics Lab Promea Turin, Italy; 3) The Galton Laboratory, University College London, London, U.K.

Recently it has been shown that rapid prenatal diagnosis by Quantitative Fluorescent PCR (QF-PCR) can detect the great majority of chromosome abnormalities, despite being deliberately targeted to disorders affecting three autosomes (21,18 and 13) and the sex chromosomes. Main advantages of the assay are low cost, speed and automation allowing its large scale application. We developed a QF-PCR assay that was applied on 28.000 consecutive prenatal samples with results issued in 24 hours. Most common referral indications were: raised biochemical risk (32%), advanced maternal age (30%), parental anxiety (22%) abnormal ultrasound (7 %) and increased nuchal translucency (6%). All samples were also tested by conventional cytogenetic analysis. In 26755 cases a normal chromosome complement was correctly assessed by QF-PCR without false positive results. All 1030 non mosaic aneuploidies involving chromosomes 21, 18, 13, X and Y were identified with 100% specificity. The assay also proved efficient in detecting 9/17 cases of partial trisomies and 18/36 cases of mosaicism. QF-PCR showed 100% sensitivity in detecting clinically relevant chromosome abnormalities in samples referred for advanced maternal age and increased biochemical risk. In fetuses with abnormal ultrasound the sensitivity was 95%. QF-PCR proved efficient and reliable allowing termination of affected pregnancies without waiting for cytogenetic analysis. Our results raise the possibility of reducing the load of prenatal cytogenetics if all pregnancies are also monitored by careful application of biochemical and ultrasound tests. Women with positive results are offered amniocentesis or CVS and rapid QF-PCR should be performed on all samples. In case of positive QF-PCR results further cytogenetic analyses are not necessary and, in our experience, parents have opted for early termination in all cases of autosomal trisomies. In cases of negative QF-PCR results cytogenetic analyses might only be performed for fetuses with abnormal ultrasound.

Evidence that a deletion at the Xist locus destabilizes the DNA of the inactive X chromosome. *Y. Marahrens[1], S. Diaz-Perez[1], D. Ferguson[3], S-C. Tsai[1], Y. Ouyang[1], V. Perez[1], S. Kim[1], S. Nahas[2], R. Gatti[2].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 3) Department of Pathology, University of Michigan, Ann Arbor, MI.

The inactive X chromosome of female mammals displays several properties of heterochromatin including late replication in S phase, hypoacetylation of histone H4, hypomethylation at lysine-4 of histone H3, and DNA methylation at CpG islands. Here we show that Cre-Lox mediated excision of 21-kb from both *Xist* alleles in female mouse embryonic fibroblasts led to the appearance of histone modifications normally associated with euchromatin, histone H4 acetylation and histone H3 lysine 4 methylation, throughout the inactive X chromosome. Despite the appearance of euchromatic histone modifications, the excision of 21-kb from both *Xist* alleles did not abolish Brca1 and Mecp2 localization to the inactive X chromosome and caused the inactive X chromosome to replicate even later in S phase than it does in wild type female cells. Homozygosity for the 21-kb deletion also caused the regions of the active X chromosome associated with very high concentrations of LINE-1 elements to be replicated very late in S phase. Extreme late replication is a property of fragile sites and the 21-kb deletions destabilized the DNA of both X chromosomes leading to deletions and translocations. X chromosome instability was accompanied by the phosphorylation of p53 at serine-15, a signaling event that occurs in response to DNA damage and chromatin defects. The deletions at the Xist locus also resulted in histone ?-H2AX, a histone variant that associates with double strand breaks and other DNA damage, concentrating on the inactive X chromosome. Element(s) at the *Xist* locus therefore serve to maintain the stability of the X chromosome.

Familial and Genetic Susceptibility to Major Neonatal Morbidities in Preterm Twins. *M.J. Bizzarro[1], V. Bhandari[1], A. Shetty[1], R.A. Ehrenkranz[1], L.M. Ernst[1], B.R. Vohr[2], N. Desai[3], H.S. Bada[3], N. Hussain[4], X. Zhong[1], R. Feng[1], I. Gross[1], G.P. Page[5], H. Zhang[1], L.R. Ment[1], J.R. Gruen[1].* 1) Yale Univ, New Haven, CT; 2) Brown Univ, Providence, RI; 3) Univ of Kentucky, Lexington, KY; 4) Univ of Connecticut, Farmington, CT; 5) Univ of Alabama at Birmingham, AL.

BACKGROUND: Intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD) remain significant causes of morbidity and mortality in preterm newborns. OBJECTIVES: To assess the familial and genetic susceptibility to IVH, NEC, and BPD. METHODS: Mixed effects logistic regression and latent variable probit model analysis were used to assess the contribution of several covariates in a multicenter retrospective study of 348 twin pairs born at 32 weeks of gestation. To determine the genetic contribution, concordance rates in a subset of 160 MZ and DZ twin pairs were compared.

RESULTS: The study population had a mean gestational age (GA) of 29 weeks and birthweight (BW) of 1262 grams. Respiratory distress syndrome (RDS) ($p<0.001$), treating institution (INST) ($p<0.001$), and GA ($p<0.001$) were significant independent variables for IVH. GA ($p=0.03$) was the significant independent variable for NEC. Male gender ($p=0.01$), GA ($p=0.05$) RDS ($p<0.001$), and INST ($p<0.001$) were significant independent variables for BPD. After controlling for effects of covariates, the twin data showed that 41.1% ($p<0.001$), 37.4% ($p=0.001$), and 45.0% ($p<0.001$) of the variances in liability for IVH, NEC, and BPD respectively, could be accounted for by shared genetic and environmental factors. Amongst the 39 MZ twin pairs the observed concordance for BPD was significantly higher than the expected concordance ($p<0.001$). Without adjusting for covariates, the heritability of BPD was 48.7%. After controlling for covariates, genetic factors accounted for 58.4% ($p=0.005$) of the variance in liability for BPD.

CONCLUSIONS: Twin analyses show that IVH, NEC, and BPD are familial in origin. There is also a significant genetic susceptibility for the development of BPD in preterm newborns.

Multilocus interactions at maternal TNF-, IL-6 and IL-6R genes predict spontaneous preterm labor in Caucasian Women. *S. Williams[1], D. Velez[1], R. Menon[2], H. Simhan[3], K. Ryckman[1], L. Jiang[1], P. Thorsen[4], I. Vogel[4], B. Jacobsson[4], S. Fortunato[2].* 1) Ctr Hum Genet Res, Vanderbilt Univ, Nashville, TN; 2) Perinatal Research Ctr, Nashville, TN; 3) Magee Women's Hosp, Pittsburgh, PA; 4) University of Aarhus, Denmark.

Preterm birth(PTB)has been shown to have a genetic component with heritability estimated to be 0.20 to 0.40. Previous studies show association of SNPs in TNF- and IL-6 with PTB. These studies have however only documented the effects of single variants or genes. Since it is probable that PTB is a multigenic phenotype, we used multifactor dimensionality reduction (MDR) to assess interactions between multiple SNPs in TNF-, IL-6 and their receptors in susceptibility to PTB. 102 Caucasian PTB mothers (<36 weeks gestation) and 325 Caucasian controls (>36 weeks gestation) were recruited. All women were between the 18 and 40 with singleton births and no preeclampsia, gestational diabetes, fetal anomalies nor placental insufficiencies. A total of 27 SNPs in the TNF-* and IL-6 pathway genes were assessed (6 in TNF-*, 6 in TNFR1, 7 in TNFR2, 5 in IL-6, 3 in IL-6R). Only 3 marginally significant allelic and genotypic associations were detected between cases and controls. Single locus analysis documented independent association of SNPs at -7294 (allele and genotype) of TNFRI and 24660 (genotype) of TNFRII loci with PTD. A multilocus model using MDR revealed a significant three site interaction between SNPs at -3448 (TNF-*), -7227 (IL-6) and 33314 (IL-6R). This interactive model predicted pheotype correctly 65.6% of the time ($p<0.001$). The high risk genotypes had an odds ratio of 3.15(95% CI 2.28-4.36, $p<0.001$). This report documents a significnat multilocus interaction that predicts PTB. Although putatively significant associations with PTD were seen at sites in TNFRI and TNFRII, they were not as predictive as the three-locus model produced by MDR, suggesting the utility of multilocus analyses in premature birth. Outcome of high-risk pregnancies may hinge on epistasis at TNF-*, IL-6 and its receptors loci. Our data suggest that interactions at these loci can be used as a screening tool for high-risk status in Caucasians.

Complex Genetic Architecture of Birth Weight in Mexican Americans Revealed by Oligogenic Linkage Analysis.

R. Arya[1], S. Fowler[1], J. Schneider[2], S. Puppala[2], V. Farook[2], R. Granato[1], T.D. Dyer[2], C.P. Jenkinson[1], L. Almasy[2], A.G. Comuzzie[2], B. Bradshaw[3], R.A. DeFronzo[1], J.W. MacCluer[2], M.P. Stern[1], J. Blangero[2], R. Duggirala[2]. 1) Univ of Texas Health Sci Ctr, San Antonio, TX; 2) Southwest Found for Biomed Res, San Antonio, TX; 3) Univ of Texas Health Sci Ctr-Houston, San Antonio, TX.

Birth weight is a complex phenotype with clinical and public health implications. Several studies have shown that birth weight is associated with metabolic diseases such as obesity and diabetes in adulthood. However, the genetic architecture of birth weight and its association with diseases that occur in later life is not clear. Therefore, the purpose of this study was to examine the genetics of birth weight (BW) in Mexican Americans using data from San Antonio Family Birth Weight Study subjects, all of whom had previously participated in the San Antonio Family Diabetes/Gallbladder Study, the San Antonio Family Heart Study, and the VA Genetic Epidemiology Study. For this study, both BW data and genotypic information (~10 cM map) are available for a subset of 840 individuals. Heritability of BW was 72% (p 0.0001). Using the combined map and multipoint variance components linkage analysis (SOLAR), we found the strongest evidence for linkage of BW (LOD = 3.7) at the markers D6S1053 and D6S1031 on chromosome 6q, which was replicated (LOD = 2.4) in an independent European population (Demerath et al. unpublished). Since multiple linkage peaks with some evidence for linkage (LOD 1.2) were observed on chromosomes 1q, 2q, 4q, 9p, 19p, and 19q, oligogenic models were considered that incorporated multiple loci simultaneously, and loci were added to the model sequentially until no locus met a conditional LOD score of 0.59. The joint four-locus model (LOD = 10.2) suggested that variation in BW is influenced by four QTLs: the primary QTL on chromosome 6q (D6S1053), and three others on chromosomes 2q (D2S1776), 1q (D1S518), and 9p (GATA187D09-D9S925). Some of these chromosomal regions overlap with those shown to be linked with metabolic diseases in adulthood. Thus, we found multiple loci significantly influencing variation in BW in Mexican Americans.

A germline mutation in BLOC1S3/reduced pigmentation causes a novel variant of Hermansky Pudlak syndrome (HPS8). *N.V. Morgan[1], S. Pasha[1], J.R. Ainsworth[2], R.A.J. Eady[3], C. McKeown[4], R.C. Trembath[5], J. Wilde[6], C.A. Johnson[1], E.R. Maher[1, 4].* 1) Section of Medical & Molecular Genetics, University of Birmingham, Birmingham, United Kingdom; 2) Birmingham Midlands Eye Hospital and Birmingham Childrens Hospital, Birmingham, UK; 3) Genetic Skin Disease Group, St John's Institute of Dermatology, St Thomas' Hospital. London, UK; 4) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Birmingham UK; 5) Division of Medical Genetics, Departments of Medicine and Genetics, University of Leicester, Leicester, UK; 6) Haemophilia Centre, Queen Elizabeth University Hospital, Edgbaston, Birmingham. UK.

Hermansky-Pudlak syndrome (HPS) is genetically heterogeneous and previously mutations in seven genes have been reported to cause HPS. Autozygosity mapping studies were undertaken in a large consanguineous family with HPS. Affected individuals displayed features of incomplete oculocutaneous albinism and platelet dysfunction. Skin biopsy demonstrated aggregates of abnormally small, but fully melanized, melanosomes. A homozygous germline frameshift mutation in BLOC1S3 (p.Gln150ArgfsX75) was identified in all affected individuals. BLOC1S3 mutations have not been reported previously in HPS patients, but BLOC1S3 encodes a subunit of the biogenesis of lysosome-related organelles complex 1 (BLOC-1). Mutations in other BLOC-1 subunits have been associated with a HPS phenotype in humans and/or mouse and a frameshift mutation in the murine orthologue of BLOC1S3 causes the reduced pigmentation (rp) model of HPS. Interestingly eye pigment formation is reported to be normal in rp but we found visual defects (iris transilluminacy, reduced visual acuity and evidence of optic pathway misrouting) in affected individuals. These findings define a novel form of human HPS (HPS8) and extend genotype-phenotype correlations in HPS.

Loss-of-function mutations in transglutaminase 5 cause acral peeling skin syndrome. *W.H.I. McLean[1], M.A.M. van Steensel[2], E. Sprecher[3], P.M. Steijlen[2], J. van der Velden[2], S.M. Morley[1], A. Terrinoni[4], E. Candi[4], A.J. Cassidy[1].* 1) Human Genetics Unit, Univ Dundee, Dundee, United Kingdom; 2) Dermatology, Univ Maastricht, Netherlands; 3) Rambam Medical Center, Haifa, Israel; 4) Univ Rome "Tor Vergata", Rome, Italy.

Peeling skin syndrome (PSS) is an autosomal recessive disorder characterized by erythema and shedding of the outer epidermis. We studied three families where peeling was limited to the acral regions. Ultrastructural analysis revealed blister formation at the junction between the stratum granulosum and stratum corneum. By genetic linkage in an extended Dutch family, we localised the gene to a ~1 Mb region on chromosome 15q15.2, giving a significant two-point lod score of 5.7. TGM5, the gene encoding transglutaminase 5 (TG5), is located centrally in the locus. TG5 is expressed in the upper layers of the epidermis where it cross-links a variety of proteins during the cornification process. DNA sequencing revealed two homozygous missense mutations, M109T and G113C, in exon 3 of TGM5 in affected persons from the Dutch family and an unrelated Scottish kindred. Shared haplotypes suggested that this may be an ancestral mutant allele in Europe. Expression constructs were made for wild-type and mutant TG5 and were used to measure normal or mutant enzyme activity using a biochemical assay. This revealed that M109T does not significantly reduce TG5 activity and probably represents a rare polymorphism, however, G113C completely abolished TG5 activity. The atomic structure of TG5 was modelled on the published structure of TG2. This showed that the G113C mutation is located near a hinge region connecting the N-terminal domain to the active site. Perturbation of this critical region is consistent with loss of enzyme activity. In an Israeli kindred, affected persons were compound heterozygous for mutations c.255delC and c.1002+1delTG, which are predicted to result in loss of TG5 expression. This study identifies a gene for acral PSS and shows the importance of TG5 in maintaining the structural integrity of the outer differentiating layers of the epidermis.

***CACNA1F* mutations in CSNB2 patients and characterization of a mouse model for X-linked CSNB.** *N.C. Orton[1], F.C. Mansergh[2], R. Tobias[1], T. Rosenberg[4], D.E. Rancourt[2], W.K. Stell[3], N.T. Bech-Hansen[1].* 1) Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Biochemistry & Molecular Biology, University of Calgary; 3) Cell Biology & Anatomy, University of Calgary; 4) National Eye Clinic, Denmark.

Mutations in *CACNA1F* cause type 2 (incomplete) congenital stationary night bliness. This variable X-linked disorder is characterized by abnormal electrophysiological response, night blindness, impaired visual acuity, myopia, nystagmus, and strabismus. DNA sequencing of *CACNA1F* in 82 patients identified 52 unique mutations (16 single base pair missense, 5 in-frame INDELS, 11 nonsense, 13 frameshift INDELS and 7 splice site). These *CACNA1F* mutations were identified among 73 patients originally diagnosed with CSNB2, Aland Eye Disease (AED), or Aland Island eye disease-like (AIED-like) suggesting that they represent the same clinical entity. The high success rate of detecting mutations in *CACNA1F* in this patient set with negative ERGs suggests that the encoded protein $Ca_v1.4$ ($_{1F}$) is important for retinal neurotransmission.

To investigate the functional effect of mutant *CACNA1F*, we created a mouse model of CSNB2 by targeted gene disruption. In characterizing this model, we observed pronounced morphological changes in second-order neurons of the adult mutant retina: ON-bipolar and horizontal cell processes extended distally from the outer plexiform layer (OPL), deep into the outer nuclear layer (ONL). Key pre-and post-synaptic components were greatly reduced in the outer plexiform layer. The dramatic reduction and disorder of photoreceptor synapses and the structural abnormalities of horizontal and bipolar cell dendrites in adult mutant *Cacna1f* mice indicate a probable role for $Ca_v1.4$ in the maintenance of photoreceptor synapses, and provides evidence for understanding the consequence of *CACNA1F* mutations in CSNB2 patients.

Mutations in *GRM6* cause autosomal recessive congenital stationary night blindness (CSNB) with a distinctive scotopic 15 Hz flicker electroretinogram (ERG). *C. Zeitz[1], M. van Genderen[2], J. Neidhardt[1], U. Luhmann[1], F. Hoeben[2], U. Forster[1], K. Wycisk[1], G. Mátyás[1], C. Hoyng[3], F. Riemslag[2], F. Meire[2], F. Cremers[4], W. Berger[1].* 1) Division of Medical Molecular Genetics and Gene Diagnostics, Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland; 2) Institute for the Visually Handicapped "Bartimeus", Zeist, The Netherlands; 3) Department of Ophthalmology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

CSNB is a group of non-progressive retinal disorders characterized by impaired night vision, presumably due to a defect in signal transmission from the photoreceptor cells to the adjacent second order neurons. The mode of inheritance is autosomal dominant, recessive or X-linked. Autosomal recessive (ar) CSNB seems to be rare and so far, knowledge about the molecular basis is very limited. Here we have used a candidate gene approach and identified the underlying gene defect in families with arCSNB. Since mice lacking the metabotropic glutamate receptor 6 (*GRM6*) fail to transmit signals from the photoreceptors to ON-bipolar cells, we screened this gene for mutations in individuals of five families. Affected individuals in three of the five families carried either compound heterozygous or homozygous mutations in *GRM6*. With the standard ERG, arCSNB and X-linked CSNB1 patients could not be distinguished. Strikingly, here we show that all arCSNB patients with *GRM6* mutations displayed a distinctive abnormality of the rod pathway signals as measured with the scotopic 15 Hz flicker ERG. This novel profile suggests the existence of more than two rod pathways. The distinctive ERG feature has been observed neither in patients with X-linked CSNB1 nor CSNB patients with unknown molecular defect. Our observations will help to discriminate autosomal recessive from X-linked recessive cases by means of ERG and by molecular genetic analysis.

SOX9 is a potent transcriptional repressor for RUNX2 during skeletogenesis. *G. Zhou[1], Q. Zheng[1], E. Munivez[2], F. Elgin[1], P. Fonseca[1], Y. Chen[2], E. Sebald[3], D. Krakow[3], B. Lee[1,2].* 1) Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Medical Genetics Institute,Cedars-Sinai Medical Center and David Geffen School of Medicine at UCLA, Los Angeles, CA.

Runt-domain transcription factor RUNX2 is essential for osteoblast differentiation and chondrocyte hypertrophy. However, during mouse embryonic development it is also expressed early in mesenchymal condensations. Hence, antagonism of Runx2 is required to down regulate its expression and function in those condensates that are destined to differentiate into chondrocytes instead of osteoblasts. But how this is achieved is still poorly understood. SOX9 is a transcriptional activator essential for chondrocyte condensation and cartilage formation. *SOX9* heterozygous mutations in humans cause the severe skeletal malformation syndrome campomelic dysplasia. Since *Sox9* is expressed highly in chondrogenic mesenchymal cell condensations but absent in hypertrophic chondrocytes, we hypothesize that SOX9 also acts as a transcriptional repressor for osteoblast differentiation and chondrocyte hypertrophy via inhibition of RUNX2 activity. In this study, we demonstrate that SOX9 and RUNX2 directly interact with each other through their DNA binding domains. SOX9 decreased RUNX2 binding to its target sequence and severely repressed RUNX2 transactivation of its reporter constructs. We have also generated transgenic mice expressing *SOX9* in osteoblasts by utilizing a 2.3-kb *Col1a1* promoter. The *Col1a1-SOX9*transgenic mice displayed generalized dwarfism and osteoblasts from transgenic mice were less active compared with wild-type mice. Expressions of osteoblast-related markers including *Runx2*, *Col1a1*, and *osteocalcin* were also downregulated in the long bones of transgenic mice. Furthermore, we correlated this observation in humans with campomelic dysplasia. Here, haplonisufficiency of *SOX9* resulted in upregulation of *COL10A1*, a known transcriptional target of RUNX2 during chondrocyte hypertrophy. In summary, our results suggest that an important aspect of regulating chondrogenesis is the dominant effect of SOX9 over RUNX2.

Cranio-Lenticulo-Sutural dysplasia is caused by a SEC23A mutation resulting in abnormal COPII-mediated intracellular trafficking. *S.A. Boyadjiev Boyd[1], D. Hur[1], G. Zhang[1], W. Eyaid[2].* 1) McKusick Nathans Inst Gen Med, Baltimore, MD; 2) Department of Pediatrics, King Fahad Hospital, Riyadh, Saudi Arabia.

We described Cranio-Lenticulo-Sutural Dysplasia (CLSD, OMIM 607812) as a novel autosomal recessive dysmorphic syndrome with mild generalized skeletal dysplasia. Five males and one female in a consanguineous Saudi Arabian family have similar craniofacial features, including wide-open calvarial sutures with large and late-closing anterior fontanels, frontal bossing, hyperpigmentation of the forehead, hypertelorism, a broad and prominent nose, and Y-shaped sutural cataracts. The skeletal features also include vertebral and pelvic anomalies. A genome-wide scan detected linkage to chromosome 14q13-q21. All affected individuals were found to be homozygous for a missence mutation in SEC23A, a member of the COPII intracellular trafficking pathway. A distinct cellular phenotype of grossly dilated endoplasmic reticulum (ER) was observed in primary fibroblasts of an affected patient and unaffected carrier of CLSD. Mutations in SEDL, another member of the ER-to-Golgi trafficking pathway, have been described in patients with X-linked Spondiloepiphyseal Dysplasia Tarda (SEDT), who have a similar cellular phenotype of dilated ER. We suggest that mutations in other members of the COPII pathway may produce genetic syndromes with skeletal involvement.

***CRTAP* is required for fibrillar collagen prolyl 3-hydroxylation and is down-regulated in osteogenesis imperfecta type VII.** *R. Morello[1], T. Bertin[1], Y. Chen[1], P. Castagnola[2], F.H. Glorieux[3], D.R. Eyre[4], B.F. Boyce[5], B. Lee[1,6].* 1) Baylor College of Medicine, Houston, TX; 2) National Institute for Cancer Research, Genoa, ITALY; 3) Shriners Hospital for Children, Montreal, CANADA; 4) University of Washington, Seattle, WA; 5) University of Rochester Medical Center, Rochester, NY; 6) Howard Hughes Medical Institute, Houston, TX.

About 10% of patients affected with Osteogenesis Imperfecta (OI) do not have type I collagen mutations or alterations, suggesting that other genes are involved in the pathogenesis of OI. The *Crtap* gene is expressed in chondrocytes, osteoblasts and osteoclasts during mouse development and after birth. To understand its function, we generated mutant mice by homologous recombination. The null mice are born viable and, although smaller, they show no obvious abnormalities at birth. However, by 3-4 months of age they develop a moderate kyphosis that becomes pronounced at 6 months of age. Radiographic analyses revealed generalized low bone mass. Histological analysis confirmed severe osteoporosis and abnormal growth plate. Bone histomorphometry demonstrated approximately 50% decrease of axial and appendicular bone volume compared to wild type mice, normal osteoblast and osteoclast numbers, but low apposition and bone formation rates. Importantly, Crtap null mice have defective osteoid formation. Moreover, because Vranka JA et. al (2004) showed that Crtap co-purifies with prolyl 3-hydroxylase, we analyzed tryptic digested, cyanogens bromide derived peptides from types I and II collagen isolated from *Crtap* null mice tissues using tandem mass spectrometry. Interestingly, the single prolyl 3-hydroxylation modification known to exist in these collagen chains was completely absent. This altered post-translation modification together with defective osteoid formation suggest a critical role of prolyl 3-hydroxylation for proper bone matrix formation. Moreover, *CRTAP* maps on 3p22, within the critical interval of OI type VII, a rare, rhyzomelic, recessive form of OI. Primary fibroblasts derived from a patient affected with OI type VII showed >10 fold decreased CRTAP mRNA and protein levels, suggesting that *CRTAP* is the gene responsible for OI type VII.

Heterozygous mutations in *EFNA4* , the gene encoding ephrin-A4, are associated with unicoronal craniosynostosis. *E.G. Bochukova[1], A.E. Merrill[2], M. Ishii[2], D.T. Pilz[3], S.A. Wall[4], R.E. Maxson, Jr.[2], A.O.M. Wilkie[1,4].* 1) Weatherall Institute of Molecular Medicine, Oxford University, Oxford, UK; 2) USC Keck School of Medicine, Los Angeles, CA; 3) University Hospital of Wales, Cardiff, UK; 4) Craniofacial Unit, Oxford, UK.

Craniosynostosis (CRS), the premature fusion of the cranial sutures, is a common developmental anomaly affecting about 1 in 2,500 children. About 25% of CRS cases are caused by single gene defects involving *FGFR1*, *FGFR2*, *FGFR3*, *TWIST1*, *MSX2* or *EFNB1*, but the remainder arise from unidentified genetic and/or environmental insults. The recent discovery that heterozygous loss of function mutations in ephrin-B1 (*EFNB1*) cause X-linked craniofrontonasal syndrome in females, but that hemizygous males exhibit a paradoxically milder phenotype, suggested functional redundancy in the ephrin-Eph receptor signalling pathway. The observation of an altered protein distribution of two further members of the ephrin family, ephrin-A2 and -A4, in the defective coronal sutures of *Twist1*$^{+/-}$ mutant mice, prompted us to investigate the contribution of mutations in the human orthologues to craniosynostosis. We found no mutations in *EFNA2*, but identified three different heterozygous mutations in *EFNA4* in a panel of 81 individuals with non-syndromic coronal synostosis of unknown cause. By contrast, no *EFNA4* alterations were identified in 151 patients with other forms of CRS, or in 370 controls. Two *EFNA4* mutations (encoding H60Y and P117T) are predicted to affect ligand-receptor interaction, the third (471_472delCCinsA) introduces a frameshift into an alternative spliceform. Further analysis of the *Twist1*$^{+/-}$ mice indicates a role for ephrins in specifying the boundary between neural crest and cephalic mesoderm. Our findings identify a new genetic predisposition to nonsyndromic CRS and confirm a key role for ephrin-Eph signalling in the developing coronal suture.

Zebrafish dax1 is required for development of the interrenal organ, the teleost adrenal cortical equivalent. *Y. Zhao[1], Z. Yang[2], J.K. Phelan[3], D.A. Wheeler[4], S. Lin[2], E.R.B. McCabe[1,3].* 1) Human Genetics, UCLA Geffen Sch of Med; 2) Molecular, Cell and Developmental Biology,UCLA; 3) Pediatrics, UCLA Geffen Sch of Med; 4) Molecular and Human Genetics, Baylor Coll of Med, Hoston, TX.

Mutations in human *DAX1*, an unusual orphan nuclear receptor, cause X-linked adrenal hypoplasia congenita (AHC). *DAX1* is expressed throughout the hypothalamic-pituitary-adrenal-gonadal (HPAG) axis in mammals. Previously we reported the cloning of a DAX1 homologue in the zebrafish embryo. Like other non-mammalian DAX1s, the putative zebrafish dax1 contained the conserved C-terminal ligand-binding-like motif; but the N-terminal region lacked the unusual repeat motif of the DNA-binding-like domain in mammals. Whole mount *in situ* hybridization (ISH) revealed the expression of this gene in the hypothalamus, the interrenal organ and a novel bilateral symmetrical structure in the trunk during early embryogenesis. To define further the expression profile of the zebrafish *dax1*, we performed two-color ISH of *dax1* and markers for the fin bud, otic vesicle and kidney, respectively. The novel bilateral *dax1*-expressing structure was located immediately above the yolk sac, between the otic vesicle and the pectoral fin buds. We also examined the expression of *dax1* at later developmental stages. Interestingly, this gene was expressed in the liver after 3 days post fertilization (dpf) in the zebrafish larvae. To investigate the potential role of dax1 in zebrafish interrenal gland development, we used antisense *dax1* morpholino oligonucleotides (MO) to knockdown dax1 expression during early embryogenesis. Injection of *dax1* MO led to severe phenotypes similar to *ff1b* (SF1) MO injected embryos consistent with disturbance of salt metabolism, a normal function of the interrenal organ. The disruption of dax1 function was also shown to downregulate expression of steroidogenic proteins, *cyp11a* and *star*. Based on the conserved gene structure, significant protein homology, shared expression profile, and striking MO phenotypes, we propose that dax1 is the ortholog to mammalian DAX1, and is required for the normal development and function of the interrenal organ in zebrafish.

Disruption of the microRNA pathway by the targeted loss of Eif2c2 results in aberrant primitive streak formation.*Eif2c2*. *R.S. Alisch, M. Nakamoto, T. Caspary, P. Jin, S.T. Warren.* Department Human Genetics, Emory University School of Medicine, Atlanta, GA.

MicroRNAs are a class of noncoding RNAs that play critical roles in a diverse collection of physiological and developmental processes. MicroRNAs regulate the expression of a wide variety of genes at both the transcriptional and post-transcriptional levels. MicroRNA function requires the formation of an RNA-induced silencing complex (RISC). The Argonaute family of proteins are highly conserved members of the RISC. One family member, AGO1, and its mammalian ortholog, EIF2C2, have recently been shown to interact with the fragile X mental retardation protein, whose deficiency causes fragile X syndrome. To more fully understand the function of the microRNA pathway in mammals, we disrupted the Eif2c2 locus in mice. Homozygous embryos were recovered at e7.5, but not at e8.5, in appropriate genetic ratios, indicating the loss of EIF2C2 function results in developmental arrest during gastrulation. As an initial characterization of this phenotype, we monitored the expression pattern of a primitive streak marker, Brachyury (T), in e7.5 embryos. In Eif2c2-/- embryos, T expression was expanded compared to wild-type, suggesting the microRNA pathway regulates primitive streak formation. Using gene chip microarray expression analysis on Eif2c2-/- embryos, we discovered sex-specific expression patterns for 137 genes. Because e7.5 is prior to gonadal differentiation in mice, these data suggest the microRNA pathway also may play a role in regulating chromosomal sex-specific gene expression. Interestingly, a sex-specific quantitative trait locus that modifies T expression was mapped within 2 centimorgans of Eif2c2. Together, these data suggest that EIF2C2 regulates fundamental processes during mammalian development by modifying T expression in a sex-dependent manner.

Dissecting the genetic basis of gene expression variation in the human genome. *B.E. Stranger[1], M.S. Forrest[1], S. Tavaré[2], A.G. Clark[3], S. Deutsch[4], R. Lyle[4], S. Antonarakis[4], P. Deloukas[1], E.T. Dermitzakis[1].* 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Centre for Mathematical Sciences, University of Cambridge, Cambridge, UK; 3) Department of Molecular Biology and Genetics, Cornell University, NY; 4) Department of Genetic Medicine, University of Geneva Medical School, Geneva, Switzerland.

The goal of this work is to identify and characterize functionally variable genomic regions that are likely to contribute to complex phenotypes and disorders in human populations through effects on regulation of gene expression. Gene expression level was quantified for ~700 genes (ENCODE, Hsa21, 10Mb region of Hsa20) in a sample of lymphoblastoid cell lines derived from 60 unrelated CEPH individuals, using Illumina Expression arrays. We performed association analyses using mRNA levels and SNP genotypes, focusing on the top 50% of genes exhibiting the most variability. We used SNPs from the publicly-available 5kb whole genome HapMap, the denser HapMap SNPs in 10 ENCODE regions, and a similarly dense SNP map of 20q12-13.2 from the Sanger Institute. We identified loci exhibiting highly significant associations between mRNA level and SNPs located *cis*- to the coding locus, including loci with associated SNPs spanning the coding locus, SNPs located 5- or 3- to the locus, and a locus with associated SNPs in the first intron. We observed genes where a *cis*- signal was detected, but its effect was spread over many SNPs and thus did not meet our significance threshold. By working with the genomic set of HapMap SNP genotypes, we were also able to identify significant *trans*-acting SNPs. This has allowed us to compare the relative frequency of *cis*- vs. *trans*-acting functional variants for these genes. For SNPs and regions showing association with expression variation, we are currently correlating known functional elements within the ENCODE regions. As the Phase II HapMap is becoming available shortly (4.5 million SNPs), by the time of the meeting we will have expanded the association analyses using this much higher resolution map. In addition, we are extending this work to include the three additional genotyped HapMap populations.

Severely incapacitating mutations in patients with extreme short stature identify RNA processing endoribonuclease RMRP as an essential cell growth regulator. *C.T. Thiel[1], D. Horn[2], B. Zabel[3], A.B. Ekici[1], K. Salinas[4], E. Gebhart[1], F. Rüschendorf[5], H. Sticht[6], J. Spranger[3,7], D. Müller[8], C. Zweier[1], M.E. Schmitt[4], A. Reis[1], A. Rauch[1].* 1) Institute of Human Genetics, University of Erlangen, Germany; 2) Institute of Medical Genetics, Virchow-Klinikum, Humboldt University, Berlin, Germany; 3) Childrens Hospital, University of Mainz, Germany; 4) Department of Biochemistry & Molecular Biology, SUNY Upstate Medical University, Syracuse, NY; 5) Gene Mapping Centre, Max-Delbrück-Centre, Berlin, Germany; 6) Institute of Biochemistry, Department of Bioinformatics, University of Erlangen-Nürnberg, Germany; 7) Greenwood Genetic Center, Greenwood, SC; 8) Institute of Medical Genetics, Klinikum Chemnitz, Germany.

The growth of an individual is deeply influenced by regulation of cell growth and cell division, which also contribute to a wide variety of pathological conditions, including cancer, diabetes, and inflammation. In order to identify a major regulator of human growth we performed positional cloning in an autosomal recessive type of profound short stature, Anauxetic (to let not grow) dysplasia. Homozygosity mapping led to the identification of novel mutations in the RMRP gene, which was previously known to cause two milder types of short stature with susceptibility to cancer, cartilage hair hypoplasia and metaphyseal dysplasia without hypotrichosis. We show that different RMRP gene mutations lead to decreased cell growth by impairing ribosomal assembly and altering cyclin dependent cell cycle regulation. Clinical heterogeneity is explained by a correlation between the level and type of functional impairment in vitro and severity of short stature or presence of cancer predisposition. While the CHH founder mutation affects both pathways intermediately, Anauxetic dysplasia mutations do not affect B-cyclin mRNA levels but severely incapacitate ribosomal assembly via defective endonucleolytic cleavage. Anauxetic dysplasia mutations thus lead to poor processing of rRNAs while allowing normal mRNA processing and therefore genetically separate the different functions of RNase MRP.

Identification of miRNA on chromosome 21 and their potential targets. *C. Borel[1], C. Tapparel[1], E.T. Dermitzakis[2], A. Kouranov[3], A.G. Hatzigeorgiou[3], S.E. Antonarakis[1].* 1) University of Geneva Medical School, CH; 2) The Wellcome Trust Sanger Institute, Hinxton, UK; 3) School of Medicine, University of Pennsylvania, Philadelphia, USA.

The 21 to 22 nucleotides long microRNA (miRNA) are an abundant class of non-coding RNA, that interact with mRNAs to trigger depending on the degree of complementarity with their targets either translation repression or RNA cleavage. Hundreds of miRNA genes have been reported in diverse animals, and many of these were shown to be phylogenetically conserved. To identify novel miRNA, we aligned the HSA21 genomic sequence with the syntenic mouse sequences and selected sequences between 36 and 99 bp long conserved with more than 70% identity and no gap. Note that more stringent criteria, i.e. sequences longer than 100bp, more than 70% identity and no gap were previously shown to be unsuitable to identify miRNAs, but perfect for Conserved Non-Genic sequences and coding-exons. We isolated a total of 2796 of these sequences and kept the seven candidates with the following features that characterize miRNAs: (i) folding energies below -32.5 kcal/mol; (ii) 1 to 4 nt bulges and mismatches; (iii) GC content between 32.8% and 62.5%; and (iv) evolutionary conserved secondary structures. To experimentally verify that these sequences were encoding bona fide miRNAs we tested their expression by RNase Protection Assay in total RNA extracted from 3 different cell lines. This procedure allowed to readily show that at least three of the candidates sequences hybridized to ~21-24 nt RNA. Further we analyzed the function of miRNAs on chromosome 21 with the DIANA-microT program (http://www.diana.pcbi.upenn.edu). We searched 18,000 UTRs of human genes and found more than 8 predicted target genes per miRNA. We developed a new method to screen in vitro these predictions. By trapping target genes with biotin-miRNA oligonucleotides, we identified at least 7 novel targets for the mir-let7c and mir-155. Our study provides novel insights into the identification of human miRNAs and we are currently investigating their post-translational down-regulation in order to validate their functionality in a biological context.

CTCF binding regulates ataxin-7 gene expression: a novel system for transcription control. *R.T. Libby[1], B.L. Sopher[1], D. Cho[2], S. Baccam[1], S.J. Tapscott[2], G.N. Filippova[2], A.R. La Spada[1].* 1) Lab Medicine, Univ Washington, Seattle, WA; 2) Fred Hutch Cancer Res Ctr, Seattle, WA.

Spinocerebellar ataxia type 7 (SCA7) is a polyglutamine disease characterized by retinal and cerebellar degeneration. The ataxin-7 gene consists of 13 exons with the start site of translation and CAG repeat expansion located in exon 3. The ataxin-7 CAG repeat is flanked by two binding sites for CTCF, a transcription factor with a variety of regulatory functions including the creation of insulator and silencing domains. After we subcloned a 13.5 kb genomic fragment containing the 3 region of intron 2, exon 3, intron 3, exon 4, and the 5 region of intron 4, we inserted a 92 CAG repeat expansion to create an ataxin-7 mini-gene construct (RL-SCA7 92R-wt). To test the hypothesis that CTCF binding is a determinant of ataxin-7 expression or function, we mutated the CTCF binding site 3' to the SCA7 CAG repeat in this 13.5 kb ataxin-7 mini-gene to derive a RL-SCA7-92R-CTCF(mut) construct. After demonstrating that the RL-SCA7-92R-CTCF(mut) version had lost its ability to bind CTCF, we generated RL-SCA7-92R-wt and RL-SCA7-92R-CTCF(mut) transgenic mice. While multiple lines of RL-SCA7-92R-wt mice are normal and express negligible amounts of ataxin-7 mini-gene mRNA and protein, independent lines of RL-SCA7-92R-CTCF(mut) mice develop a phenotype of progressive ataxia and retinal degeneration. The RL-SCA7-92R-CTCF(mut) mice express ataxin-7 mini-gene mRNA and protein, with pronounced aggregate formation in cerebellum and retina. Bioinformatics analysis of intron 2 revealed the presence of an alternative promoter and the existence of a putative exon that we have designated as exon 2A. As mutation of the CTCF binding site permitted this alternative promoter to function, our results indicate that CTCF levels can modulate expression of ataxin-7. Furthermore, recent studies have established that ataxin-7 is a transcription co-factor in the STAGA co-activator complex and that impairment of ataxin-7 normal function contributes to retinal degeneration in SCA7. Our findings therefore suggest that CTCF may regulate STAGA co-activator function through its modulation of ataxin-7 expression.

Extensive Short-Range Copy-Number Polymorphism In The Human Genome And Its Likely Affect Upon Common Disease Phenotypes. *A.J. Brookes.* Department of Genetics, University of Leicester, UK.

Our unpublished data suggests that previously unrecognized short-range Copy-Number Polymorphism (CNP) may span a substantial fraction of the human genome, and these variants may play a direct role in common disease etiology.

DNA regions of >1kb are sometimes represented multiple times in the human genome, and these are termed segmental duplications. These duplicons make up ~5% of the human genome and, as our group first reported in 2004, they almost always show copy-number variability within populations. Others have shown that a large number of long regions (>0.1Mb), enriched for known duplicon domains, also show copy-number variability between individuals. Thus, from mid-2004, it became clear that long-range CNP affects 5-10% the human genome.

We have now uncovered evidence that copy number variations; i) are often present as short (few-kb or sub-kb) domains in regions believed to be single copy, affecting 10-20% of the genome (alleles >1% frequency), ii) contain many sites erroneously listed as SNPs in public databases (and which may behave as such when genotyped on standard platforms) but which are in fact single base differences in paralogous CNP versions (we call these Multi-Site variations: MSVs), iii) include markers represented in the HapMap as normal SNPs along with allele frequency data in various populations, and iv) associate with disease state in case-control analyses, and so may have a direct effect upon gene function and disease causation.

These findings, in conjunction with emerging data on deletion and inversion polymorphism, are of critical importance for genome sequencing, population genetics, and genetic disease studies - all of which previously assumed that the human genome is far less jumbled than it actually is. This calls for new methods for genome characterization, and we are working on this by using the above observations (particularly the disease scenarios) as a test-bed for our innovations.

The implication of the repetitive element Alu in the genetic etiology of HNPCC. *L. Li[1], S. McVety[1,3], R. Younan[2, 4], D. DuSart[5], P.H. Gordon[2], P. Hutter[6], F.B. Hogervorst[7], P. Liang[8], G. Chong[1, 3, 4], W.D. Foulkes[1, 3, 4].* 1) Human Genetics, Lady Davis Inst., Montreal, QC, Canada; 2) Dept Surgery, McGill University, Montreal, QC, Canada; 3) Dept Human Genetics, McGill University, Montreal, QC, Canada; 4) Dept Diagnostic Medicine, SMBD-Jewish General Hospital, Montreal, QC, Canada; 5) Murdoch Childrens Research Institute, Royal Childrens Hospital, Victoria, Australia; 6) Institut Central des Hopitaux Valaisans, Sion, Switzerland; 7) Family Cancer Clinic, Netherlands Cancer Institute, Amsterdam, Netherlands; 8) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, New York.

A high frequency of germ-line genomic rearrangements in *MSH2* and *MLH1*, among HNPCC patients from different ethnic populations, has been observed in the past few years. A detailed analysis of the known DNA breakpoints in the two genes was performed to explore the underlying mechanism causing this type of mutagenesis. Distinct deletion patterns were observed at the two loci, Alu mediated homologous recombinations account for 85% of the deletions in *MSH2*, but only 25% for *MLH1* ($p<0.0001$). It is notable that the average Alu density for the intronic regions of *MSH2* is 34.2% or 1.325 elements per kilobase (kb), is significantly higher than that of *MLH1*, 21%, or 0.748 elements/kb ($p<0.0001$). Both are higher than the average density of the genome, which is 13%, or 0.33 elements/kb. Plotting the distribution of the known DNA breakpoints among the introns of the two genes showed that the highest breakpoint density is co-localized with the highest Alu density. Our study suggests that, instead of being involved passively, Alu is a promoting factor for the genomic deletions in both *MLH1* and *MSH2*. This may be achieved by modulating the local organization of the chromatin, consequently contributing to its susceptibility to genomic rearrangement. At a locus predisposed to recombination, the local Alu density predicts the deletion pattern by serving as a favorable substrate for the recombination event.

Quantitative phenotypic variation in long- and middle-wave cone photoreceptors due to polymorphism in an upstream insulator element. *J. Stamatoyannopoulos[1], R. Thurman[2], W. Noble[3], T. Kutyavin[1], A. Shafer[1], M. Dorschner[1], S. Deeb[2].* 1) Dept. of Molecular Biology, Regulome, Seattle, WA; 2) Div. of Medical Genetics, University of Washington, Seattle, WA; 3) Dept. of Genome Sciences, University of Washington, Seattle, WA.

Little is currently known about the genetic mechanisms that mediate quantitatively varying phenotypic traits. The ratio of long- (L) and middle-wave (M) cone photoreceptors in the human retina is a well-described model trait that exhibits high variability (~13-fold) between individuals. Previously, we used quantitative chromatin profiling (Nature Meth. 1:219-25, 2004) to map cis-regulatory elements in the long-wave photoreceptor (OPN1LW) locus, and resequenced these elements in males with known L:M ratios. This study revealed that inter-individual variability in the L:M ratio is regulated in cis, but not by variation in the locus control region (LCR) or OPN1LW promoter. Rather, common variation in a DNaseI hypersensitive site 7.4kb upstream of the OPN1LW gene accounts for the majority of interindividual variability in L:M ratio ($P<0.0074$). We found this novel element to be constitutively active, as revealed by chromatin profiles in retinal, neural, intestinal, lymphoid, hepatic, and erythroid cells. Here we show that variants associated with high L:M ratios disrupt a strongly evolutionarily constrained nucleotide within the core binding site for the insulator protein CTCF. This element appears to demarcate the functional boundary of the X-linked photoreceptor domain from the upstream MECP2 gene, and is conserved in all species which display conserved synteny between OPN1LW and MECP2. The results provide a novel genetic mechanism underlying common quantitative phenotypic variation.

RSK2 mediated chromosomal remodeling of Utrophin-A promoter. *U. Basu[1], M. Gyrd-Hansen[2], T.O.B. Krag[1, 2], C.J. Jensen[2], M. Frödin[2], T.S. Khurana[1].* 1) Department of Physiology & Pennsylvania Muscle Institute, University of Pennsylvania Medical School, Philadelphia, USA; 2) Department of Clinical Biochemistry and Experimental Medicine, Glostrup Hospital, Denmark.

Duchenne muscular dystrophy (DMD) is a fatal genetic disorder caused by absence of dystrophin. Utrophin, the autosomal homolog of dystrophin can compensate dystrophins absence when overexpressed. In skeletal muscle, utrophin is synaptically enriched, in part due to the selective transcription of utrophin at sub-synaptic nuclei. Currently, utrophin transcription is known to be driven by two promoters (A and B). Although some of the molecular regulatory mechanisms have been identified, transcriptional regulation of the utrophin-A promoter is not yet fully understood. The neurite-associated growth factor heregulin activates the promoter via ERK pathway-dependant phosphorylation of the ets-related transcription factor complex GABP, which recognizes and binds the N-box motif in the utrophin promoter. However, little is known about changes at the level of chromatin that ultimately allow increased transcription of utrophin in muscle. Here, we demonstrate that heregulin phosphorylates and activates ribosomal S6-kinase 2 (RSK2) in an ERK-dependent manner. RSK2 overexpression was sufficient to increase de novo transcription from the utrophin promoter. Heregulin stimulation phosphorylates histone H3 (Ser10) in an ERK-dependent manner and increases phosphohistone H3 content of the stimulated utrophin-A promoter. Since Histone 3 phosphorylation at Ser10 is an important nucleosome structure-altering modification, RSK2 mediated remodeling of the utrophin promoter may play a critical role in transcriptional regulation of utrophin expression. These findings help further define transcriptional control mechanisms, as well as identify chromosomal remodeling of the utrophin promoter as a potential target for DMD therapy.

Identification of a candidate FMRP phosphatase and investigation of phosphorylation as a rgulator of FMRP suppression of translation. *U. Narayanan[1], S. Ceman[2], S.T. Warren[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Cell and Structural Biology, University of Illinois, Urbana, IL.

Fragile X syndrome is a common form of inherited mental retardation and is caused by the functional loss of the fragile X mental retardation protein (FMRP). FMRP is a RNA-binding protein that negatively regulates translation of specific mRNA ligands. FMRP has been identified as a phosphoprotein that specifically associates with stalled ribosomes when phosphorylated at serine 499. This suggests that FMRP phosphorylation may suppress translation of ligand mRNAs while dephosphorylation may be the signal to release translational suppression. Using pharmacological phosphatase inhibitors we sought to identify the FMRP phosphatase(s). Persistence of FMRP phosphorylation in cultured mouse cells in the presence of 0.5 nM okadaic acid revealed protein phosphatase 2A (PP2A) as an FMRP phosphatase. Co-immunoprecipitation analyses confirmed an association between the catalytic subunit of PP2A and FMRP in vivo. Subsequently, metabolic labeling demonstrated that FMRP remained phosphorylated in the presence of a dominant negative mutant of PP2Ac (L199P) relative to wildtype PP2Ac. These data suggest that phosphorylated FMRP may hold certain mRNAs translationally repressed on stalled ribosomes until a signal mediated by PP2A dephosphorylates FMRP resulting in the synthesis of the required protein(s) encoded by the bound mRNAs. However, it remains unclear how phosphorylated FMRP represses translation. Recently, FMRP has been known to interact both biochemically and genetically with the microRNA pathway. MicroRNAs have been shown to negatively regulate translation of partially complementary mRNAs, indeed by ribosome stalling. We show phosphorylated FMRP is preferentially associated with micoRNAs relative to unphosphorylated FMRP. Thus, the phosphorylation status of FMRP may influence microRNA association thereby regulating the translation of key messages in the brain.

DNA methyltransferase (DNMT) variants associated with aberrant MLH1 methylation in endometrial cancer. *H. Chen[1], A. Liu[1], N. Taylor[2], D.G. Mutch[1], S. Feng[3], P.J. Goodfellow[1, 2].* 1) Department of Surgery; 2) Obstetrics & Gynecology; 3) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO 63110.

Loss of DNA mismatch repair leading to microsatellite instability (MSI) is seen in ~28% of endometrial cancers. Epigenetic silencing of MLH1 is the most common cause of defective DNA mismatch repair. In our large series of endometrial carcinomas, >20% have MLH1 promoter methylation. We previously showed MLH1 methylation is associated with increased age at diagnosis. To date, no genetic factors associated with MLH1 methylation have been identified. We hypothesized that variation in DNMT genes might contribute to risk for MLH1 methylation. We undertook a case-control study to test for association between DNMT variants and abnormal MLH1 methylation. Five SNPs in each of DNMT1, -3A, -3B and -3L were typed in the normal DNA from women with endometrial carcinoma. Tumors were assessed for MSI and MLH1 methylation and clinical data were extracted from patient charts. For these studies, cases are women with cancers with MLH1 methylation (N=97) and controls are women with cancers without MLH1 methylation (N=220). Cases and controls were matched for race and tumor histology. Patient age and body mass index (BMI) were significantly associated with MLH1 methylation. Two DNMT3L SNPs, rs2070565 and rs968447, were also associated with the methylation phenotype (P=0.019 and P=0.003, respectively, logistic regression analysis including patient age and BMI). A risk haplotype for the rs968447 and rs2070562 DNMT3L SNPs was over-represented in cases (P=0.003). Analysis of 335 cancer-free controls from the St. Louis region (women >65 years of age with no history of cancer) confirmed DNMT3L SNP frequencies were different in women with endometrial cancers with MLH1 promoter methylation. This is the first report of association between variants in a DNMT gene and somatic epigenetic inactivation of MLH1. Identification of risk alleles for MLH1 methylation could shed light on mechanisms of epigenetic silencing and may lead to new approaches to the prevention of malignancies associated with MLH1 inactivation.

Identification of the dyslexia susceptibility gene for DYX5 on chromosome 3. *J. Kere[1], K. Hannula-Jouppi[2], N. Kaminen-Ahola[2], M. Taipale[3], R. Eklund[2], J. Nopola-Hemmi[4], H. Kääriäinen[5].* 1) Department of Biosciences at Novum, Karolinska Institutet, Huddinge, Sweden; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) EMBL, Gene Expression Programme, Heidelberg, Germany; 4) Department of Pediatrics, Jorvi Hospital, Espoo, Finland; 5) Department of Medical Genetics, University of Turku, Turku, Finland.

Dyslexia, or specific reading disability, is the most common learning disorder with a complex, partially genetic basis, but its biochemical mechanisms remain poorly understood. A locus on chromosome 3, DYX5, has been linked to dyslexia in one large family and speech-sound disorder in a subset of small families. We found that the axon guidance receptor gene ROBO1, orthologous to the Drosophila roundabout gene, is disrupted by a chromosome translocation in a dyslexic individual. In a large pedigree with 21 dyslexic individuals genetically linked to a specific haplotype of ROBO1 (not found in any other chromosomes in our samples), the expression of ROBO1 from this haplotype was attenuated in affected subjects. Sequencing of ROBO1 in apes revealed multiple coding differences, and we observed significantly different evolutionary rates between orangutan on one hand and human, chimpanzee and gorilla on the other hand. We also identified novel exons and splice variants of ROBO1. We conclude that dyslexia may be caused by haploinsufficiency for ROBO1 in rare families. Thus, our data show that neuronal axon crossing across the midline between brain hemispheres, dendritic guidance, or another function of ROBO1 is a developmental process contributing to reading ability.

Evolution and distribution of haplotypes in the complement factor H (HF1/CFH) gene that predispose to age-related macular degeneration. *M. Dean[1], B. Gold[1], J. Bergeron[2], D.H. Anderson[3], L.V Johnson[3], R. Allikmets[4], G. Hageman[5].* 1) Lab Genomic Diversity, NCI-FCRDC, Frederick, MD; 2) SAIC-Frederick, Frederick, MD; 3) University of California, Santa Barbara, CA; 4) Columbia University, New York, NY; 5) University of Iowa, Iowa City, IA.

Age-related macular degeneration (AMD) is the most frequent cause of irreversible blindness in the elderly in developed countries, affecting more than 50 million individuals worldwide. Our previous studies implicated activation of the alternative complement pathway in the formation of ocular drusen, the hallmark lesion of AMD, and demonstrated that the Factor H protein, the major inhibitor of the alternative complement pathway, accumulates within drusen. We also demonstrated that specific haplotypes in the Factor H gene (HF1/CFH) are highly associated with AMD, and may contribute as much as 50%; to the risk of this disease. Haplotype analysis revealed that multiple CFH variants confer either an elevated or a reduced risk of AMD.

Here we show using haplotype network analysis that the protective haplotypes are closely related to the ancestral haplotype and that the major risk haplotype is the most distantly related. The major haplotype determining variant in this gene (Y402H) displays extensive variation across samples from the Human Genome Diversity Panel, with high frequency in African, European, and Middle Eastern population, low frequency in most Eastern Asian groups and very low to absent in Native North and South American populations. The risk haplotype is also of low frequency (20%) in the Rapa Nui population of Easter Island, a group with an extremely low frequency of AMD. Several populations including those of Orkney Island (Scotland) Biaka Pygmy (Central African Republic) and Burusho (Pakistan) have very high frequencies of the Y402H allele (42-69%). These data indicate that variation in the distribution of CFH haplotypes are an important factor determining the incidence of AMD in world populations.

The effect of common variants of the glucokinase gene on fasting blood glucose differs in pregnant and non-pregnant subjects. *M.N. Weedon[1], A.T. Hattersley[1], B. Shields[1], B. Knight[1], T. Wilkin[1], L. Voss[1], B. Metcalf[1], G. Davey-Smith[2], Y. Ben-Shlomo[2], T.M. Frayling[1].* 1) Peninsula Medical School, Exeter, UK; 2) Department of Social Medicine, Bristol, UK.

Glucokinase is a key regulator of fasting glucose. Monogenic mutations in *GCK* result in raised fasting blood glucose (FBG) and increased offspring birth weight (BW). It is not known how common *GCK* variants affect FBG and BW.

We determined the LD pattern across *GCK* and flanking regions (116kb) by re-sequencing 84 dbSNPs in 43 unrelated individuals. 23 tagging SNPs (tSNPs) captured 71% of SNPs at r^2 0.8 and 92% of SNPs at r^2 0.5. We genotyped these SNPs in 781 normal glucose tolerant fathers from the Exeter Family Study (EFS). SNPs with a P 0.10 for FBG association were genotyped in two further NGT cohorts (Plymouth N=301; Barry-Caerphilly Growth N=606).

Two tSNPs in the 5 *GCK* region were reproducibly associated with FBG: GCK(-30), MAF 18%, FBG increase of 0.06 mmol/l for GA/AA versus GG subjects (combined P=0.0001); and rs3757840, MAF 47%, FBG increase of 0.09 mmol/l (combined P=0.00002). GCK(-30) and rs3757840 are in LD (r^2=0.2,D=1). Regression analysis demonstrates that the GCK(-30) effect is explained by rs3757840 in NGT subjects.

We then went on too determine the impact of these 2 SNPs in pregnancy. GCK(-30) was strongly associated with FBG in 755 28-week pregnant females from the EFS (0.075mM, P=0.003), but, in contrast, rs3757840 was not (0.025mM, P=0.44). In pregnant females, therefore, GCK(-30) is associated with FBG independently of rs3757840. Birth weight data support this finding: using 2689 mother/child pairs we have shown that maternal, but not fetal, GCK(-30) genotype is associated with offspring BW (64g, P=0.001); conversely, maternal rs3757840 genotype is not associated with offspring BW.

In conclusion, we have demonstrated that variants upstream of the glucokinase gene are associated with fasting blood glucose and birth weight. The effect of these SNPs is dependent on pregnancy status, and is an example of gene-environment interaction.

Variant of a gene located on chromosome 10q confers risk of type 2 diabetes mellitus. *S.F.A. Grant[1], G. Thorleifsson[1], I. Reynisdottir[1], R. Benediktsson[2,3], A. Manolescu[1], J. Sainz[1], H. Stefansson[1], V. Emilsson[1], A. Helgadottir[1], U. Styrkarsdottir[1], M.P. Reilly[4], D.J. Rader[4], Y. Bagger[5], C. Christiansen[5], V. Gudnason[2], G. Sigurdsson[2,3], U. Thorsteinsdottir[1], J.R. Gulcher[1], A. Kong[1], K. Stefansson[1].* 1) deCODE Genetics, Reykjavik, Iceland; 2) Icelandic Heart Association, Reykjavik, Iceland; 3) Landspitali-University Hospital, Reykjavik, Iceland; 4) University of Pennsylvania Health System, Philadelphia, USA; 5) Center for Clinical and Basic Research A/S, Ballerup, Denmark.

We previously reported suggestive linkage of type 2 diabetes mellitus (T2D) to chromosome 10q. The 10q linkage region has also been observed in Mexican Americans. Two hundred and twenty eight microsatellite markers were genotyped in Icelandic T2D patients and controls throughout a 10.5Mb interval. One of these microsatellites was associated with T2D ($P=2.1\times10^{-9}$). This was replicated in a Danish cohort ($P=2.4\times10^{-3}$) and a US cohort ($P=1.7\times10^{-9}$). Heterozygous and homozygous carriers of the at-risk alleles, 38% and 7% of the population respectively, have relative risks of 1.45 and 2.39 compared to non-carriers. This corresponds to a population attributable risk of 21%. The marker is located in the intron of a gene and is within a well defined LD block (based on CEPH Caucasian HapMap v16) that contains no additional genes. The gene encodes for a protein that resides within a pathway that has a potential role in T2D. In conclusion, these data in three populations constitute strong evidence and support of the notion that variants of this gene contribute to the risk of T2D. The identity of the gene and the corresponding data will be presented.

Polymorphisms at the Chromogranin A and B Loci are Risk Factors for Hypertensive End-stage Renal Disease in African Americans. *R.M. Salem, P.E. Cadman, G. Wen, B.K. Rana, D.W. Smith, E. Eskin, M. Stridsberg, H.J. Ward, L. Taupenot, N.J. Schork, D.T. O'Connor.* Dept of Medicine, UCSD, La Jolla, CA.

Background: Chomogranins A (*CHGA*) and B (*CHGB*), stored with catecholamines, are differentially expressed in genetic hypertension. Since hypertensive end-stage renal disease (HT-ESRD) is highly prevalent in African Americans, we tested whether common polymorphisms at *CHGA/B* predict HT-ESRD. Methods: We genotyped 24 *CHGA/B* SNPs in n=58 blacks with HT-ESRD, and n=150 controls. Genotype/haplotype frequencies were compared between HT-ESRD and controls. Plasma levels of product peptides were measured. To probe the role of CHGA in catecholamine storage vesicles, expression was silenced in chromaffin cells by siRNA targeting of *Chga*. Results: Three genomic regions were associated with HT-ESRD: 2 at *CHGA* and 1 at *CHGB*. In *CHGA* promoter region G-462AT-415CC-89A, ATC was more frequent in the HT-ESRD group (OR=2.42; 95% CI: 1.04-5.67). *CHGA* haplotype spanning a portion of the coding region: G8540C[Glu246Asp]C9610T[Arg381Trp]G12602C, contained 2 haplotypes acting in opposing fashion: CCG conferred risk of HT-ESRD (OR=3.65; 95% CI: 1. 49-8.92), while GCC was protective (OR=0.22; 95% CI: 0.07-0.72). In *CHGB* region C10501TA11727G[Glu348Glu], the CA was protective (OR= 0.49; 95% CI: 0.24-0.98). Coding haplotypes of *CHGA* associated with a proximate biochemical phenotype (p=0.024): a progressive rise in $CHGA_{116\text{-}439}$ from the protection haplotype (GCC) to the risk haplotype (CCG) group. Thus, risk haplotype CCG activated gene expression *in vivo*. A similar trend was seen with *CHGB*. Application of *Chga* siRNA caused disappearance of chromaffin granules; dense-core granules per cell XY cell plane declined by ~2/3 (p0.0001). Conclusion: Common variants at both *CHGA/B* associate with risk of HT-ESRD. These haplotypes also associated with altered plasma levels of *CHGA/B*, consistent with augmented chromaffin granule biogenesis and sympathetic hyperactivity by risk variants. The results indicate that common genetic variants in the catecholamine storage and release pathway confer risk of HT-ESRD, and suggest novel approaches for prediction, diagnosis, and treatment of this disorder.

A whole-genome admixture scan finds a candidate locus for multiple sclerosis susceptibility (LOD=5.2). *D. Reich[1], N. Patterson[2], P.L. De Jager[2,3], G.J. McDonald[1,2], A. Waliszewska[1,2,3], A. Tandon[1,2,3], R.R. Lincoln[4], C. DeLoa[4], S.A. Fruhan[1,2,3], P. Cabre[5], O. Bera[5], G. Semana[6], M.A. Kelley[7], D.A. Francis[7], K. Ardlie[8], O. Khan[9], B.A.C. Cree[4], S.L. Hauser[4], J.R. Oksenberg[4], D.A. Hafler[2,3].* 1) Dept Genetics, Harvard Univ, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Laboratory of Molecular Immunology, Center for Neurologic Disease, Brigham and Womens Hospital, Boston, MA; 4) Department of Neurology, University of California, San Francisco, CA; 5) Clinique Neurologique, LHôpital Quitman, Fort-de-France, France; 6) Laboratoire Universitaire dImmunologie, University de Rennes 1 and Etablissement Français du Sang Bretagne, Rennes, France; 7) Department of Medicine, Division of Medical Sciences, University of Birmingham, UK; 8) Genomics Collaborative, Division of SeraCare Life Sciences Inc, Cambridge, MA; 9) Multiple Sclerosis Center, Depart.

Multiple sclerosis (MS) is a common disease with proven heritability in families that has resisted large-scale attempts to identify risk genes. Traditional linkage scans have so far identified only one risk haplotype for MS, but this explains only a fraction of the increased risk to siblings. Association scans such as admixture mapping have much more power in principle to find the weak factors that must explain most of the risk. We describe the first high-powered admixture scan, focusing on 605 African Americans with MS and 1,043 African American controls, and find a locus that is significantly associated to MS on chromosome 1 (LOD = 5.2). The signal is present in cases, but not controls, and grows stronger after follow-up genotyping. The apparent success with MS suggests that admixture mapping may be a practical way of finding disease genes more generally, and lends momentum to its application, in high-powered studies with more than two thousand cases each, to other diseases where it has the best prospects of working, to assess how useful it will be as a disease-gene finding method.

Clustering of autoimmune diseases in multiple sclerosis (MS) families: evidence for genetic influences. *L.F. Barcellos[1,2], B. Kamdar[2], P.P. Ramsay[1], R.R. Lincoln[2], S. Schmidt[3], G. Artim[1], S. Caillier[2], C. DeLoa[2], M.A. Pericak-Vance[3], J.L. Haines[4], J.R. Oksenberg[2], S.L. Hauser[2].* 1) Univ California, Berkeley; 2) Univ California, San Francisco; 3) Duke Univ Medical Center; 4) Vanderbilt Univ Medical Center.

A large body of research supports the hypothesis that autoimmune mechanisms play a major role in MS pathogenesis. Familial clustering of multiple autoimmune diseases has been reported, and a careful examination of associations between diseases may provide important clues to defining common etiologic pathways. We determined the prevalence of co-existing autoimmune phenotypes in MS cases and first degree relatives. Comprehensive data was collected from 176 MS families (1317 first degree relatives, 386 MS cases). A total of 26% of MS index cases (1 per family) reported at least 1 coexisting autoimmune disorder. The most common conditions present were Hashimoto thyroiditis (HT) (9.7%) and psoriasis (5.6%). A total of 105 (60%) MS families reported at least 1 first degree relative with an autoimmune condition, whereas 71 families (40%) had no history of autoimmunity other than MS. As observed in cases, HT and psoriasis were the most prevalent conditions in family members. In fact, index cases diagnosed with HT and/or psoriasis were more likely to have first degree relatives with these same conditions (OR=3.4, p=0.003). Genome screening (390 markers) and nonparametric mpt analyses was performed in families with these 2 additional diseases (n=64). Chr 16 had the highest score (D16S764; MLOD=2.80); MS families in which no HT or psoriasis was present (n=112)showed no evidence for linkage to this region (MLOD=0.05).In addition, a common variant within CTLA4, a proposed autoimmunity gene, was strongly associated in MS families with other autoimmune diseases (p=0.008).Our results confirm that other autoimmune conditions are present in MS cases and family members, and suggest that certain diseases are associated with MS. In addition, we propose that different MS phenotypes may exist which are defined by the presence/absence of other autoimmune diseases, and for which susceptibility may be conferred by different genetic factors.

Polymorphisms in genes from the interferon signaling pathway are associated with systemic lupus erythematosus. *S. Sigurdsson[1], G. Nordmark[1], H. Göring[2], M-L. Eloranta[3], G. Alm[3], L. Rönnblom[1], A-C. Syvänen[1].* 1) Department of medical sciences, Molecular Medicine, Uppsala, Uppsala, Sweden; 2) Dept of Genetics, Southwest Foundation for Biomedicial Research, San Antonio, Texas, USA; 3) Dept of Molecular Biosciences, Swedish University of Agricultural Sciences, Uppsala, Sweden.

Systemic lupus erythematosus (SLE) is a complex systemic autoimmune disease caused by both genetic and environmental factors. We have previously, using SNP genotyping and joint linkage and association analysis dissected the function of the type I IFN system in SLE. In two genes, the tyrosine kinase 2 (TYK2) and interferon regulatory factor 5 (IRF5) genes, we identified SNPs that displayed strong signals of joint linkage and association ($p < 10E-7$) with SLE in the Swedish, Finnish and Icelandic populations. (Sigurdsson S. et al. 2005, Am J Hum Genet 76:528). Haplotype association analyses of multiple SNPs in both genes revealed no association with SLE with higher statistical significance than analysis of the individual SNPs. We are now performing functional studies on the consequences of the identified SNPs. The TYK2 SNP alters an amino acid in a domain of TYK2 that interacts with the type I IFN receptor, and is required for maintaining expression of the receptor on cell membranes. Transfection analyses in TYK2 deficient cells indicate that the TYK2 SNP alleles play a functional role in the type I IFN signaling system. The IRF5 SNP is the first nucleotide of intron 1 of the gene, and could be functional by causing alternative splicing. Accordingly, we observe complex splicing patterns in RNA samples from 44 SLE patients collected so far. Both our genetic and functional data support a disease mechanism in SLE that involves key components of the type I IFN system. Consequently, we are also performing a large scale genetic linkage and association study of 1500 SNPs in over 100 genes from the type I IFN system using the Illumina genotyping platform available in our laboratory.

Association of the Regulatory Regions of *OX40L* with Systemic Lupus Erythematosus (SLE). *D.S. Cunninghame Graham[1], A.M. Richardson[2], T.W. Behrens[3], J.D. Rioux[2], T.J. Vyse[1].* 1) Imperial College, LONDON, UK; 2) Broad Institute, MIT, Boston, USA; 3) University of Minnesota, Minneapolis, USA.

Purpose: SLE is a complex autoimmune disease trait of uncertain aetiology. Evidence supports a genetic contribution to disease susceptibility. *OX40L (TNFSF4)* was chosen as candidate susceptibility gene for SLE in this family-based association study, because of its important role in T-B cell interaction. *OX40L* (1q25), is in a region identified in two genome-wide linkage scans. Additionally, 1q24 is homologous to a region on mouse distal chromosome 1 important in murine models of SLE. *OX40L* provides a co-stimulatory signal to T cells and may play a role in the migration of lymphocytes to sites of inflammation through its expression on the surface of endothelial cells. **Methods:** The study cohort consists of 474 SLE European Caucasian families, from a total collection of 630 SLE families. 33 variants in *OX40L* were identified from SNP databases or by re-sequencing typed by MALDI-TOF mass spectrometry or PCR-RFLP. Initial haplotype maps in SLE trios were constructed in Haploview. TDT analysis, on both single SNPs and on haplotypes, was performed using GENEHUNTER on trios and TRANSMIT to include single parent families. **Summary:** There are two clear haplotype blocks across *OX40L*. TDT analysis for SNPs in the 5 block, showed a significant over-transmission for the rare G allele of SNP6 in the promoter (p=2.7E-05). This was corroborated in an independent collection of ~ 450 US SLE families (p=0.02). The 3 haplotype block shows an independent genetic effect, but is more heterogenous. There were different associated alleles in the two populations, but the UK over-transmitted haplotype carried the over-transmitted alleles in the US population. **Conclusion:** In the 5 haplotype block for *OX40L* we have corroborated an association with SNP6, a variant predicted to disrupt the binding site for Upstream Stimulatory Factor. In the 3UTR, the associated SNP may play a role in mRNA stability. We are currently investigating the functional significance of both of these variants. Increased transcription and/or mRNA stability may increase the co-stimulatory signal and hence immune response.

Genetic association of celiac disease to myosin IXb points to an intestinal barrier defect as an early pathogenic event. *C. Wijmenga[1], P.I. de Bakker[2], B.Z. Alizadeh[1], M. Daly[2], M.R. Bevova[1], M.C. Wapenaar[1], B.P. Koeleman[1], A.J. Monsuur[1].* 1) Complex Genetics Section, Univ Medical Center, Utrecht, the Netherlands; 2) Broad Institute of M.I.T. and Harvard, Cambridge, MA 02142, USA.

Celiac disease is a chronic systemic autoimmune disease resulting from intolerance to gluten, a storage protein present in wheat, rye and barley. Ingestion of gluten leads to inflammation and damage of the small intestine, resulting in malnutrition and associated complications. With a prevalence of close to 1%, celiac disease is the most common food intolerance in general Western populations. It is strongly associated to HLA class II molecules that explain some 40% of the familial clustering. A previous study identified a novel susceptibility locus on 19p13.1 (CELIAC4 locus), and showed association to one of the microsatelite markers (D19S899) tested in the linkage screen. Recently, we tested 15 single nucleotide polymorphisms (SNPs) around D19S899 in two independent case-control cohorts and found significant association to variants in the myosin-IXb gene (MYO9B). The strongest signal was observed for an intronic SNP, (P = 2.1.10-6). The genotype frequency data for this SNP revealed an increased risk of celiac disease in both homozygote carriers (OR 2.27; CI 1.56 to 3.30) and heterozygote carriers (1.66; CI 1.23 to 2.13), suggesting a co-dominant effect of this MYO9B variant. In addition, a comprehensive screen with 269 SNPs covering the entire linkage region was performed to rule out that an association signal somewhere else in the CELIAC4 region had been overlooked. This comprehensive screen revealed a single peak of association, in the MYO9B gene with one SNP showing strong significance (P = 7.8.10-5) after stringent Bonferroni correction. This SNP is in strong LD with the SNPs identified in the previous analysis. With regard to its function, MYO9B may point to an underlying intestinal barrier abnormality as a primary etiological event. Hence, this gene may be one of the long-sought factors involved in the early mucosal events preceding the well-understood inflammatory response. Importantly, this gene may be relevant for other autoimmune disorders with enhanced intestinal permeability.

Loss of imprinting of IGF2, H19, PEG1/MEST and PEG3 in Head and Neck Cancers. *H. Kataoka[1], S. Nakano[2], M. Oshimura[2], H. Kitano[1].* 1) Otolaryngology, Head and Neck Surgery, Tottori University, Tottori, Japan; 2) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, Tottori, Japan.

INTRODUCTION: Genomic imprinting is an epigenetic feature that may play a significant role of tumorigenesis. Previous studies showed that abnormal imprinting was observed in the human chromosomes 11p15.5 region containing H19, IGF2 and p57KIP2 imprinted genes in head and neck cancer. However, few study regarding other imprinted genes in head and neck cancers was reported. Therefore, to further identify and to characterize genetic events associated with these carcinomas, we examined the imprinting status of several imprinted genes in 22 cases of head and neck carcinomas. MATERIALS AND METHODS: Head and Neck cancers, diagnosed by histopathologic examination, and matched normal tissues of 22 patients were analyzed. These consisted of 5 tongue carcinomas, 4 hypopharyngeal carcinomas, 2 oropharyngeal carcinomas, 9 laryngeal carcinomas, 2 thyroid carcinoma. Genomic DNA and RNA were isolated and allelic expression of the genes has been determined by PCR-RFLP utilizing restriction enzymes. Restriction enzymes were as follows: ApaI for IGF2, RsaI for H19, AflIII for MEST and MnlI for PEG3. RESULTS: We analyzed 22 primary head and neck carcinomas for the loss of imprinting in the IGF2, H19, PEG1/MEST and PEG3. After PCR amplification and endonuclease cleavage, informative case of H19, IGF2, PEG1/MEST and PEG3 showed 4, 2, 4 and 2 cases, respectively. LOI of H19, IGF2, PEG1/MEST and PEG3 were observed in 2, 1, 4 and 1 cases, respectively. LOI of H19 and PEG3 were only observed in tumor specimens, while LOI of IGF2 and PEG1/MEST were observed in both tumor and proximal normal specimens. Conclusions: We detected the LOI of IGF2 and H19 as previously reported. In addition, we newly identified the epigenetic changes at PEG1/MEST and PEG3. These findings suggest that a number of imprinting genes play possible roles of oncogenesis of head and neck cancer. Further studies are necessary for their biological significance and prognostic parameter and cancer predisposition of LOI in normal tissues.

Refinement of critical regions of 7q deletions in uterine leiomyomas using high-resolution microarray CGH. *N.C. Wortham[1], S. Vanharanta[2], C. Langford[3], W.F. Bodmer[4], L.A. Aaltonen[2], I.P.M Tomlinson[1].* 1) Molecular & Population Genetics Laboratory, Cancer Research UK, London, United Kingdom; 2) Dept of Medical Genetics, Biomedicum Helsinki, PO Box 63 (Haartmaninkatu 8), FIN-00014 University of Helsinki, Finland; 3) Microarray Facility, Wellcome Trust Sanger Centre, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SA, United Kingdom; 4) Cancer and Immunogenetics Laboratory, Weatherall Institute of Molecular Medicine, University of Oxford, John Radcliffe Hospital, Oxford, United Kingdom.

Deletions involving 7q are common cytogenetic events in uterine leiomyomas, occurring in approximately 25% of cases. Current techniques involving micorsatellite-based loss-of-heterozygosity analysis have demonstrated several different minimal regions in 7q22.2-7q22.3. We have constructed a high-resolution microarray of 1083 overlapping BAC clones from 7q to further refine this region, and to define deletion breakpoints. We have refined the region to approximately 2.5Mb in 7q22.3-q31.1. Furthermore, we have identified a novel region of deletion in 7q34, and have refined this to approximately 2.5Mb.

Differential Expression of Adhesion Molecules in H460 Human Non-small Cell Lung Cancer Cells and the Paclitaxel Resistant Mutant H460/TAX. *L. Tan Chen[1], Y.C. Lin[2], J.J. Chu[3].* 1) Department of Medical Technology, Chung Tai Institute of Department of Medical Technology, Chung Tai Institute of Health Sciences and Technology ,Taiwain; 2) College of Veterinary Medicine, Nation Chung Hsing University,Taiwain; 3) Division of Chest Medicine, Taichung Veterans General Hospital, Taichung, Taiwan, ROC.

The purpose of this study was to fine the integrins in differential _expression of adhesion molecules in H460Human Non-small Cell Lung Cancer Cells (NSCLC) and the Paclitaxel Resistant Mutant H460/TAX. Paclitaxel is among the most promising new agents in the treatment of advanced NSCLC. Most patients with advanced NSCLC initially respond to paclitaxel (30% response rate); however, overall survival has not improved in part because of the development of acquired paclitaxl resistance. The best understood mechanism paclitaxel resistance is the expression of the P-glycoprotein (Pgp), encoded by mdr1 gene, which is responsible for the multidrug resistance (MDR phenotype). Pgp-mediated resistance to paclitaxel is characterized by cross-resistance to many structurally and functionally distinct anticancer agents, including anthracycline (doxorubicin and epirubicin), Vinca alkaloids (vincristine and vinblastine), epipodophyllotoxins, and camptothecins. How to Use the Online NCI/NCBI Entrez Cancer Chromosomes Search Database. *T. Knutsen[1], V. Gobu[2], T. Ried[1], K. Sirotkin[2].* 1) Genetics Branch, NCI/NIH, Bethesda, MD; 2) National Center for Biotechnology Information, NIH, Bethesda, MD.

The NCI/NCBI Entrez Cancer Chromosomes database (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=cancerchromosomes) was developed as a part of the NCI Cancer Chromosome Aberration Project (CCAP) initiative to integrate the cytogenetic and physical maps of the human genome and to identify new cancer-associated genes. It integrates the SKY/M-FISH & CGH Database, the Mitelman Database of Chromosome Aberrations in Cancer, and the Recurrent Chromosome Aberrations in Cancer databases. All three databases are searched simultaneously, and seamlessly, and a variety of queries can be performed to track specific abnormalities and relate them directly to map and sequence data through the Map Viewer database. CGH abnormalities can be directly compared to karyotypic aberrations. All cases are directly linked to their PubMed abstracts. Searching can be done a variety of ways, including the Entrez standard free text search, and customized fielded searches. Search results can be viewed as: (1) a "summary" report that shows the number of cases in each database matching the query, with an abstract for each case giving a partial karyotype, diagnosis, and links to the full karyotype, CGH profile, clinical information, and PubMed abstract; (2) a "detailed" report that lists all the cytogenetic aspects of each case and reference information; and (3) a "similarity" report that lists all affected diseases, sites, chromosomal breakpoints, junctions, numerical abnormalities, and bands gained/lost. The similarity report presents both the textual and cytogenetic elements with a count (number) that links to those cases containing that element. For example, if a similarity report is performed on a set of cases where 59 of 80 have a breakpoint at 11p12, then "59" will be displayed by that breakpoint, and by clicking on "59," the user will go to a page displaying summary reports for those 59 cases. Cases related textually or genetically are linked from all the input databases. This presentation will demonstrate how to make use of the advanced and innovative features of the database and its interface, including the ability to discover similar genetic features from a set of cases.

Computational aspects of large cytogenetic data collections. *M. Baudis*[1,2]. 1) Dept. of Pediatrics, U of Florida, Gainesville, FL; 2) UF Shands Cancer Center, Gainesville, FL.

Over the last decades, thousands of (molecular-) cytogenetic studies have led to the description of karyotype abnormalities in tumor cells. In agreement with the multistep model of oncogenesis, repetitive chromosomal aberration patterns may reflect the cooperation of different genes in most malignant diseases. A systematic analysis of these patterns for oncogenomic pathway description requires the large scale compilation of (molecular-) cyogenetic tumor data, and the development of specific tools for cytogenetic data mining purposes. Major questions addressed by computational analysis of large scale cytogenetic data collections are:

Do complex cytogenetic aberration patterns reflect disease specific mechanisms, or are they signs for general co-operative mechanisms during tumor development?

Do non-random genomic aberration patterns relate to specific genes relevant for the development of the corresponding tumor type?

As part of the Progenetix project, a collection of cytogenetic data from human neoplasias has been made publicly available. Currently, results from more than 12,000 predominantly CGH experiments are accessible in a format suitable for standard data mining techniques. In limited datasets, cytogenetic aberrations have been successfully utilized by us and others for deliniating clinically relevant disease subentities. Also, the construction of sequential and forked models for the accumulation of specific cytogenetic changes has been attempted. However, the global view on tens of thousands of tumor cases available through the Mitelman database and Progenetix requires new models which take into account the high diversity of possible genomic hot spot regions. In our current view, emphasis is being put on the correct identification of relevant genomic intervals with a high probability of non-random change. Here, an overview of the data sources as well as a presentation of our current large scale data mining attempts will be presented.

The Expression of CD56 is Highly Increased in a Paclitaxel-resistant Human Non-small Cell Lung Cancer Cell Line. *T.C. Lai[1], J.J. Chu[2], J.Y Hsu[2].* 1) Department of Medical Technolo, Chung Tai Institute of Health Sciences and Technol, Taichung,, Taiwan; 2) Division of Chest Medicine, Taichung Veterans General Hospital, Taichung, Taiwan, ROC2.

Drug resistance to paclitaxel is a major problem during cancer chemotherapy. For study the cellular and molecular mechanism, we have established a paclitaxel resistant mutant cell line called H460/TAX derived from human non-small cell lung cancer (NSCLC) H460 cells (Chu et al., Anticancer Res. 20: 2449-56., 2000). Recently, we found the cell adhesion activity of H460/TAX is different from that of the parental H460. We were thus interested in identifying any alterations in the expression of adhesion molecules. Using immunofluorescence staining and flow cytometer, a variety of adhesion molecules were monitored, such as integrins, ICAMs, VCAMs, NCAMs. Among them, we found that the expression of CD56 was dramatically elevated in H460/TAX as compared with that of H460. CD56 is a member of the family of neural cell adhesion molecules expressed on the surface of tumor cells of neuroendocrine origin, including small cell lung cancer (SCLC), carcinoid tumors, neuroblastomas, and neuroectodermal tumors such as astrocytomas. It is also cross-reactive with cardiac, neurologic, and neuroectodermal tissue as well as natural killer T cells. To our information, there are no previous studies reported the relation between CD56 and drug resistance on NSCLC. The study of genetic regulation of CD56 in both H460 and H460/TAX is also carry out in our laboratory.

Complex translocation (8;21;2): a new variant of translocation (8;21) in acute myeloid leukemia. *J. Xu[1], S. Nan[1], D. Munavish[1], I. Chin-Yee[2], R.M. Barr[2], L. Minuk[2], A. Xenocostas[2].* 1) Cytogenetics; 2) Hematology, London Health Sciences Centre, University of Western Ontario, Canada.

In acute myeloid leukemia (AML), the standard t(8;21)(q22;q22) which generates the ETO/AML1 fusion protein is generally associated with favorable outcomes. Variants of t(8;21) involving other chromosomes account for approximately 3% of t(8;21) in AML cases. Because of rare occurrences, the clinical significance of these variants is yet to be established. We report the first case of t(8;21;2) associated with AML. The patient is a 31-year-old male who presented with one month history of progressive fatigue and dyspnea. His past medical history includes obstructive sleep apnea and a seizure disorder. His physical examination was normal with no evidence of lymphadenopathy or organomegaly. The blood count showed a WBC of 2.3X109/L with 31% blasts, neutropenia, anemia, and thrombocytopenia. The bone marrow was hypercellular with a marked increase in poorly differentiated blast cells (80%), histologically consistent with the AML-M1 subtype. Flow cytometry demonstrated that blasts expressed CD34, CD33, CD13, CD117, HLA-DR, myeloperoxidase, and dim cytoplasmic CD79a, confirming the myeloid origin. Of 25 G-banded metaphase cells examined, 24 cells had 45,X,-Y,t(8;21;2)(q22;q22;p21) and one cell had 46,XY. FISH showed 89% (177/200) of the cells with ETO/AML1 fusion signals on derivative chromosome 8, der(8)t(8;21). The patient is currently undergoing induction chemotherapy. More case reports are needed for understanding of diagnostic and prognostic implications of such variants.

A Rarity of del(16)(q22) in an Acute Promyelocytic Leukemia (FAB AML M3v) with Classic Cytogenetic Alteration (15;17)(q22;q21). *J.H. Lin[1,2], E. Suguerra, Jr.[1], M. Zhuang[1], A. Karnik[1], H.O. Shah[1,2].* 1) Pathology & Labs, Nassau Univ Medical Ctr, East Meadow, NY; 2) State Univ. New York at Stony Brook, Stony Brook, NY.

A 39 year-old woman underwent a maxillary sinus antrostomy for sinusitis, epistaxis and nasal polyps. Blood tests revealed WBC of 0.9x103/mm3 with 74% immature cells, 11% segmented neutrophils, 12% monocytes and 4% lymphocytes. The RBC was 2.19x106/mm3, Hb 6.6 gm/dL, Hct 20%, MCV 91.5 fl and platelets of 36x103/mm3. The marrow specimens showed rather similar findings with cellularity approaching 100%. The immature cells display reniform nuclei with occasional nucleoli and fine granules and rare delicate Auer rods in cytoplasm. The acute granulocytic leukemia FAB AML M3v (APL) was confirmed and the chromosome studies showed 46,XX,t(15;17)(q22;q21)[7]/46,XX.t(15;17)(q22;q21) del(16)(q22)[13]. The patient was treated with trans retinoic acid (ATRA) and corticosteroids followed by scheduled chemotherapy and is doing fine one year later. The conventional APL are known to exhibit PML and RARA genes fusion giving rise to the concept of treating APL with retinoic acid compounds with good initial response. Chromosome 16 alterations i.e. inv16, 16q- and del(16)(q22) and del(16)(q11) etc. have frequently been reported in FAB AML M4e, M5a and M1. A combined (15;17)(q22;q11) and del(16)(q22) alteration is extremely rare. Two cases have been reported and one of which has been reported as M6 with a complex karyotype involving chromosomes 1, 2, 11 and 17, which on a subsequent relapse, transformed to M3. Fusion of the gene CBFB in 16q22 with MYHII in 16p13.1 can apparently render a favorable prognosis. Clonal evolution or disease modification may be associated with del(16)(q22), yet the exact mechanism by which these chromosomal changes exert in the pathogenesis related to M3 deserves further studies. Furthermore, if there is any residual del(16)(q22) re-exerting its influence on the clonal transformation to induce secondary leukemia other than M3 remains speculative.

A CASE REPORT: PATIENT WITH IMMUNOSUPRESION PATTERNS, CLINICAL CARDIOPULMONARY MALFORMATION AND CELL PROLIFERATION, IN RELATION TO 11;14 TRANSLOCATION (47,XY, t(11;14) (q25;q24.1), +der(14) t(11;14) (q25;q24.1). *J.M. Aparicio[1,8], N.C. Gil-Orduña[2,8], M. Barrientos-Pérez[3], L. Pérez-Ricardez[4], R. Maldonado-Alonso[5], W.B. San Martín[2], F. Mezquita-Lopez[2], T.K. Carral-Valdez[2], M.L. Hurtado Hernandez[6], M. Gil-Barbosa[7], E. Huitzil[8], C.F. Salinas[9].* 1) Medical Genetics; 2) Estomatology; 3) Endocrinology; 4) Infectology; 5) Cardiology; 6) Citogenetics; 7) Direction, Hospital para el Nino Poblano, Puebla, Mexico; 8) Estomatology, Benemerita Universidad de Puebla, Mexico; 9) Craneofacial Genetics, University of South Carolina, U.S.A.

INTRODUCTION. Translocation t(11;14) has been observed in cell proliferation as mantle cell lymphoma, plasma cell leukaemia, in chronic lymphocytic leukaemia, in multiple myeloma, immunosupresion, cardiovascular malformation and a caracteristic phenotipe. CLINICAL CASE. A Mexican newborn male with partial trisomy for the derivation of the distal part of the long arm of chromosome 14 (14q24 leads to qter) diagnosed at Pediatric Hospital in Puebla, Mexico. The anomaly was a balanced translocation t(11;14) (q25;q24.1). The clinical manfestations of the patient were, lobar neumony, hidrocele, septicemia, interauricular septal defect, cleft palate and a dismorfic phenotipe. CYTOGENETICS. Some chromosomal translocations has been reported as primary etiological factor for different kind of neoplasias. t(11;14) in relation to mantle cell lymphoma. And has reported the frequency of t(11;14): 50-70% in mantle cell lymphoma, 10-20% originating from pre-immune B-cells in the mantle zone of the primary follicles in secondary lymphoid organs, in plasma cell leukaemia, and in splenic lymphoma with villous lymphocytes, and 2-5% in chronic lymphocytic leukaemia, in multiple myeloma and also in immunosupresion. CONCLUSIONS. Two previous cases involving the same segment q25;q24 of both 11 and 14 translocated chromosome has been reported. The karyotype in this study was confirmed as 47,XY, t(11;14) (q25;q24.1), +der(14) t(11;14)(q25;q24.1). clinical signs and simptoms, cytogenetics aberration and the possible treatment for a better life quality were analized.

A case of CD5+ diffuse large B-cell lymphoma in bone marrow with unusual chromosome abnormalities involving amplification of the BCL-2 gene. *S.R.S. Gottesman[1], M.J. Macera[2,3], J. Cheng[1], A. Falarieh[1], J. Breshin[2,3], R. Zeng[2,3], P. Chandra[3], A. Babu[2,3].* 1) Dept of Pathology, SUNY Downstate Medical Ctr, Brooklyn, NY; 2) Div of Molecular Medicine and Genetics; 3) Dept of Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY.

A 66 year old male presented with splenomegaly and fever of unknown origin. The laboratory findings were Hb 10.0 g/dl; Hct 29.5%; WBC 3.15 x109/L; Plts 89,000 x 109/L; LDH 2,090 U/L. A bone marrow biopsy showed a diffuse infiltrate ~ (20 %) of large regular cells that were CD5+, CD20+. Cytogenetic analysis of bone marrow metaphases, revealed two related abnormal clones, a stemline and a sideline with an additional abnormality, in addition to normal cells. The karyotypes were: 47,XY,del(6)(q15),+i(18)(q10).ish i(18)(wcp7-,wcp18+,BCL-2++)[11]/ 47,idem,der(14) t(14;18)(p11.2;q21).ish der(14)(wcp18+,BCL-2+)[3]/46,XY[6]. The IGH/BCL-2 gene rearrangement that is common in diffuse large B-cell lymphoma, was absent in this case. The dual fusion IGH/BCL-2 probe (Vysis) and wcp18 were applied to metaphase chromosomes. No IGH/BCL-2 rearrangement was found, however, the additional i(18)(q10) was shown to have two extra copies of BCL-2, resulting in 4 copies of BCL-2 in the stemline. The uncommon rearrangement, der(14)t(14;18)(p11.2;q21), also contained one more copy of the BCL-2 gene, contributing to a total of 5 copies of BCL-2 in the sideline. The argyrophilic nucleolar organizer regions (AgNORs) are located in the stalks of the five acrocentric chromosomes and are loops of ribosomal DNA associated with the proliferative potential of the cells. AgNOR staining of metaphases failed to show any silver located on the der(14) chromosome. Negative silver staining indicates lack of production of the argyrophilic NOR-related proteins; nucleolin, C23 protein, RNA polymerase I or B23 protein. The possibility remains that the regulatory sequences of the ribosomal cistrons are influencing BCL-2 production on the der(14). This is a case of BCL-2 gene amplification, rather than translocation, the classical cause of over expression in B-cell lymphoma.

A new complex chromosomal translocation (12;21;2)(p13;q22;q33) in acute lymphoblastic leukemia. *E.A. Vásquez[1,2], J.P. Meza[4], M.L. Ayala[1], B. López[3], J.A. Morales[1,2], J.R. González[2].* 1) Doctorado en Genética Humana, Universidad de Guadalajara; 2) División de Genética, CIBO-IMSS; 3) Departamento de hematología, Hospital de Pediatría CMNO-IMSS; 4) fUnidad Academica de Ciencias de la Salud y Tecnologia. Facultad de Medicina de la Universidad Autonoma de Tamaulipas.

Introduction: Chromosomal translocation t(12;21)(p13;q22) fuses ETV6 (TEL) and AML1 (CBFA) genes located on 12p13 and 21q22, respectively. This translocation is present in about 25% of children with precursor-B acute lymphoblastic leukemia (ALL) and can not be detected by conventional cytogenetic methods. Objective: To describe a new complex chromosomal translocation in an ALL patient. Material and method: A 4-year-old girl was diagnosed with B-precursor ALL. Physical examination reveled bone pain, ganglions of big size, hepatomegaly and splenomegaly. Hematological data were as follows: hemoglobin 7.8 g/dL, leukocytes 4.1 X103 /mm3 with 82.4% lymphocytes and platelets 24,000/ mm3. Immunophenotype, karyotype and FISH were done in a bone marrow sample. Results: Immunophenotype of the blast cells was CD19+(all cells B and their precursors), CD20+(cells B but, not plasmatic cells) and CD22+(mature B cells but, not plasmatic cells). The karyotype was: 46,XX,t(2;12)(q33;p13)[2]/47,XX,t(2;12)(q33;p13),+21[2]/46,XX[12]. FISH detected the fusion of ETV6/AML1 genes. Sub-clones with +21 displayed the fusion ETV6/AML1 and two independent AML1 signals. Moreover, a small red signal corresponding to AML1 gene sequences was observed on the derivative 2. Discussion: Complex translocations associated with t(9;22) in chronic myelocytic leukemia are frequently observed. In contrast, they have rarely been observed linked to t(12;21). To our knowledge, there are only seven complex translocation related to the t(12;21) and ETV6/AML1 fusion. These complex rearrangements may result from two consecutive translocations. The prognosis for these variant translocations remains to be determined.

A constitutional ins(6;7)(q23;q36q31)c in a patient with smoldering multiple myeloma. *R.A. Conte[1], L. Rajdev[2], D.T. Walsh[1], D. Wei[1], M. Zohouri[1], A.R. Deshikar[1], T. Zhou[1], C. Johnson[1], H. Ratech[1], V.R. Pulijaal[1], K.H. Ramesh[1], L.A. Cannizzaro[1].* 1) Dept. Pathology, Montefiore Medical Ctr/AECOM, Bronx, NY 10461; 2) Dept. Oncology, Montefiore Medical Ctr/AECOM Bronx, NY10461.

A 50 year-old male with a 4-year history of smoldering multiple myeloma (SMM) presented with fatigue, anemia and loss of appetite. SMM is a plasma cell dyscrasia where the disease is asymptomatic and is diagnosed by the finding of an elevated serum monoclonal-protein concentration (>3g/dL) during a screening examination, as was the case for this patient. The bone marrow was normocellular (50%) with a myeloid to erythroid ratio of 3:1. There were interstitial aggregates of plasma cells, some of them with Dutcher bodies, in the interstitium and constituted 50% of the overall cellularity. There were no granulomas. Stainable iron was reduced. The bony trabeculae were unremarkable. Immunohistochemical stain demonstrated that there were 50% CD138+ plasma cells, which were kappa-restricts, (plasma cells with Kappa light chain excess) consistent with plasma cell neoplasm. GTG banding and FISH analyses of unstimulated bone marrow followed by peripheral blood chromosome analysis revealed a: 46,XY,ins(6;7)(q23;q36q31)c.ish ins(6;7)(6ptel+,wcp6+,wcp7+,wcp6+,6qtel+; 7ptel+,wcp7+,D7S522+,wcp7+,7qtel+). FISH analysis using the following probes: 6ptel, 6 whole chromosome paint (WCP), 7 WCP, 6qtel, 7ptel and D7S522 confirmed the ins(6;7) and also that the 7q31 locus was still intact and present on the abnormal chromosome 7. This chromosomal rearrangement was determined to be constitutional in the patient when cytogenetic analysis of PHA stimulated peripheral blood was performed. It is interesting to note that the breakpoints involved in this genomic alteration are the putative locations of genes that are likely to play a role in leukemogenesis. The breakpoint on 6q and the proximal breakpoint on 7q apparently lie within the respective common regions of chromosome loss observed in hematological neoplasms, including multiple myeloma. Further molecular and clinical studies will help to shed light on a correlation between SMM and the genomic regions that play a predisposing developmental role.

Comparison of interphase panel FISH and routine chromosome analysis results in patients with hematological malignancies. *M. Zohouri, D.T. Walsh, L.A. Cannizzaro, V.R. Pulijaal, R.A. Conte, D. Wei, A.R. Deshikar, T. Zhou, C. Johnson, K.H. Ramesh.* Dept Pathology, Montefiore Medical Ctr, Bronx, NY.

Conventional cytogenetic evaluation of G-banded chromosomes can be an important tool in establishing a diagnosis and prognosis in a number of hematological disorders. However, the utilization of an appropriate combination of fluorescence in situ hybridization (FISH) probes can give us valuable information when routine cytogenetic results are normal or when not possible. We employed 6 panels of FISH probes, based on clinical findings, to compare cytogenetic results of bone marrow (BM) or unstimulated peripheral blood (PBU) with interphase FISH results in 50 patients with suspected clinical diagnoses of myelodysplastic syndrome (MDS), acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia (CLL), multiple myeloma (MM) or non-Hodgkins lymphoma (NHL) at Montefiore Medical Center, Bronx, NY. In 5 cases (10%), both routine chromosome analyses and FISH results were abnormal; in 19 cases (38%), both chromosome and FISH results were normal; 3 cases (6%) were abnormal by karyotype alone, and 10 cases (20%) were abnormal by FISH findings only. Additionally, of 13 cases where chromosome analyses had failed, FISH studies revealed normal results in 5 cases (10%) and abnormal results in 8 cases (16%). This study of 50 cases showed that in 36% of the cohort with normal cytogenetic results or where chromosome analyses were not possible, chromosome abnormalities were detected by panel FISH alone. These findings confirm that panel FISH analysis is a useful and powerful tool to detect disease specific chromosome abnormalities, and, when used in conjunction with conventional cytogenetic studies, can improve the detection rate of chromosome abnormalities in patients suspected of or having hematological malignancies. Performing panel FISH analysis not only provides a rapid diagnosis, but also has a significant impact on prognosis.

Changing Signal Patterns - Fluorescent in- situ hybridization in monitoring CML. *Y. Ding, P. Koduru, S. Gupta.*
Laboratory Medicine, North Shore University Hospital, Manhasset, NY.

New molecular cytogenetic techniques are being increasingly applied as routine investigative tool in hematological malignancies. The BCR-ABL gene rearrangement generated by Philadelphia translocation(Ph), t(9;22)(q34;q11.2), is the hallmark of chronic myeloid leukemia. The technique of fluorescent in -situ hybridization (FISH) is extensively applied at the initial diagnosis of CML,to investigate cases with failed cytogenetics,to detect cryptic BCR-ABL gene fusion and to monitor disease response. A deletion of prognostic significance encompassing ABL-BCR product from the derivative chromosome 9 occurs in 15% of CML cases, and is more common in patients with variant translocation. It may take place at the time of Ph chromosome formation, with progression of the disease or may appear at the time of relapse. Reports of physical separation of ABL-BCR in non-deleted patients as well as evolution from classical to variant translocation introduce further heterogeneity.The correct diagnosis using FISH technique in such setting is influenced by the experience and interpretational skills of the investigator and DNA probes used in the study. We present interpretation of change in FISH signal pattern observed using BCR and ABL dual color dual fusion translocation probe in a 45 years old patient with leukemia. Chromosome analysis of G-banded metaphase preparation showed classical Philadelphia translocation,t(9;22)(q34;q11.2), which was confirmed by FISH studies (I Green, 1 Red, 2 Fusion signals). Patient underwent chemotherapy for CML. During follow-up studies, chromosome preparations failed and FISH studies showed normal signal pattern (2R,2G) in 98-99% of interphase cells. Eight months after the diagnosis, an atypical signal pattern (1R,1G, 1F) was detected in 40% of interphase cells. Use of ASS gene probe confirmed deletion on derivative 9. RT-PCR was positive for BCR-ABL product. We suggest that atypical interphase FISH patterns should not be interpreted in isolation. Information gathered through more than one source, i.e. conventional cytogenetics, molecular cytogenetics and molecular genetics should be used collectively to interpret patient results.

Sequential Genomic Changes in Chronic Lymphocytic Leukemia. *C. Wang, L. Zou, L. Li, J. Lian, R. O'Dell, M. Shaver, J. O'Malley, J. Defeo, N. Wang.* University of Rochester School of Medicine, Rochester, NY.

To define the sequential genomic aberrations associated with the genesis and progression of CLL, 80 cases were analyzed using G-banding and FISH with a panel of probes specific for 11q22.3(ATM), 12 centromere, 13q14.3, 13q34, and 17p13.1(p53). Genomic aberrations were detected by G-banding in 45% of the cases and by FISH in 65% of the cases. Single genomic aberrations were detected in 29 cases; 54% with deletion of 13q14.3, 25% with +12, 11% with deletion of ATM gene, 7% with del of p53, and 4% with deletion of 13q34. Among the 22 cases with multiple genomic aberrations, 84% with del(13)(q14.3), 47% with del(11)(q22.3), 37% with +12, 32% with del(13)(q34), and 21% with del(17)(p13.1). Correlations of the coexistence between individual genomic abberations were then inspected statistically. Trisomy-12 and deletion of 17p13.1 were found positively correlated with a p value of 0.003. Furthermore, a positive correlation at a lesser degree was found between deletion of 13q14.3 and deletion of 13q34 as well as between deletion of 13q14.3 and deletion of 11q22.3. Conversely, a negative correlation was found between the deletion of 13q14.3 and +12; deletion of 13q14.3 and deletion of 17p13.1; deletion of 11q22.3 and +12; and between 11q22.3 and deletion of 17p13.1. In summary, our data suggest that both del(13)(q13.4) and +12 are major primary genomic aberrations which occur independently in CLL onset. Then, +12 is followed frequently by deletion of 17p13.1 while deletion of 13q14.3 is followed frequently by deletion of 11q22.3 and deletion of 13q34. FISH is more efficient and sensitive in the detection of genomic aberrations than G-banding. However, G-banding can identify a broader scope of genomic aberrations, which are not included in the FISH panel and a combination of both approaches are crucial for CLL diagnosis.

Detection of Alterations of Chromosome 17 And TP53 Gene In Solid Tumors By Dual- Color FISH. *J.C. Herrera-Patiño[1], L.F. Isaza-Jimenez[2], G. Vásquez[1], J.L. Ramírez-Castro[1], F. Quintero-Rivera[3], C.M. Muñetón-Peña[1].* 1) Medical Genetics Unit, Faculty of Medicine, Antioquia University, Medellín, Antioquía, Colombia; 2) Department of Surgery, Faculty of Medicine, Antioquia University, HUSVP, Medellin, Colombia; 3) Center for Human Genetic Research, MGH, Boston, MA.

TP53 is a tumor suppressor gene located on 17p13.1, this is essential for the control of cell cycle and has been found alterated in more than 50% of all tumors. In solid tumors, changes in the copy number of specific genes or chromosome and LOH are evaluated in interphase cell nuclei. Our aim was to examine alterations in primary solid tumors of chromosome 17 and TP53 gene. All samples were mechanically and enzimatically disaggregated with 0.2% collagenase. Dual-color FISH was performed using direct fluorescent labeling probes for the chromosome 17 centromere and TP53 gene in interphase nuclei from primary solid tumors of different origin. Hybridized signals were counted in 200 cells. 30 primary solid tumors of different origin were analyzed. Aneuploidy of chromosome 17 was found in 14 out of 30 tumors (47%). Monosomy was the most frequent aneuplody (57%); trisomy was detected in 2 cases (14%) and 4 tumors (29%) showed heterogeneous clones (monosomic, disomic, trisomic and tetrasomic). FISH analysis showed only 5 (16%) of 30 cases have 2 signals for the TP53 gene in more than 80% of the cells. One signal in more than 20% of the cells was observed in 22 cases (73%), whereas 1 case without signals and 2 cases with 3 signals were observed. In general we found in the most cases an imbalance of signals for chromosome 17 and TP53 per nucleus. LOH was observed in 7 out of 30 tumors (23%). All these cases showed an advanced stage in the development of cancer. In different solid tumors numerical alterations of chromosome 17 and TP53 gene deletions are common. Dual-color FISH detect these abnormalities per nucleus in individual cells of primary tumors, at this level we may have demonstrate that imbalance signals for chromosome 17 and TP53 gene and chromosome 17 aneuploidy had occurred during the development of cancer. The genetic instability of cancer cells is a common event which is caused by aneuploidy and gene mutation.

A t(2;5)(p23;q35),+7 karyotype in a case of ALK+ anaplastic large cell lymphoma. *D. Wei[1], L.A. Cannizzaro[1], V.R. Pulijaal[1], M. Zohouri[1], D.T. Walsh[1], R.A. Conte[1], A.R. Deshikar[1], T. Zhou[1], C. Johnson[1], H. Ratech[1], E.A. Kolb[2], K.H. Ramesh[1].* 1) Dept Pathology, Montefiore Medical Ctr, Bronx, NY.10467; 2) Dept Pediatrics/Hematology/Oncology, Montefiore Medical Ctr, Bronx,NY, 10467.

Anaplastic large cell lymphoma (ALCL) has been recognized as a distinct clinicopathologic entity of T-cell or null cell lineage in the Revised European-American lymphoma classification. The t(2;5)(p23q35) in ALCL causes the fusion of NPM (nucleophosmin) gene located at 5q35 with the ALK (anaplastic lymphoma kinase) gene at 2p23. This gene fusion results in the generation of a novel chimeric protein: NPM-ALK, which has been shown to have oncogenic properties in a variety of experimental systems. The variant rearrangements in ALCL involving the ALK locus at 2p23 include: t(X;2)(q11;p23), t(1;2)(q25;p23), inv(2)(p23q35), t(2;3) (p23;q21), t(2;17)(p23;q23), t(2;19)(p23;p13.1) and t(2;22)(p23;q11.2). Expression of ALK gene in ALCL, either with t (2;5)(p23;q35), or other translocation variants, is known to be associated with a favorable prognosis. We report a 4-year-old female diagnosed with ALCL. The immunohistochemical stains revealed large atypical lymphoid cells that expressed CD3, CD30, CD45, ALK, AIA-1(T-cell intracellular antigen-1), granzyme B and a background population of scattered CD68 histiocytes. Flow cytometry showed a mixed T and B-cell population, without clonal B-cell expansion. Cytogenetic and FISH analysis of the lymph node revealed the karyotype: 47,XX,t(2;5)(p23;q35),+7[18]/46,XX[2] .ish t(2;5)(p23;q35)(wcp2+,wcp5+). nuc ish 2p23(pcp 2p sp). These results were consistent with the clinical diagnosis of anaplastic large cell lymphoma. Additional chromosomal abnormalities have been reported in about 20% of ALCL cases with t(2;5)(p23;q35). However, the significance of the secondary abnormalities is not clear. Studies with long-time follow up are essential in determining the significance of secondary chromosomal abnormalities associated with t(2;5)(p23;q35) in ALCL.

A novel translocation (12;14)(q24.3;q11.2) in a patient with a therapy related AML. *Y. Maroz, S.Y. Dong, T.C. Brown.* Genzyme, Phoenix, AZ.

Cytogenetic abnormalities implicating the locus 12q24 are not rare in acute myeloid leukemia (AML). Several chromosomal partners involved in 12q24 translocations have been described in patients with AML such as 2q21, 3q21, 7q32, 14q32 and some others. We report a balanced translocation between 12q24.3 and 14q11.2 in a patient with a therapy-related AML. A 75-year-old male with a previous history of basal cell carcinoma was initially diagnosed with a myelodysplastic syndrome. At the time of the diagnosis he had leukopenia, thrombocytopenia and slight anemia. No abnormal cells were present by flow cytometry. The cytogenetic analysis on bone marrow revealed a karyotype of 46,XY,t(12;14)(q24.3;q11.2)in 16 of the 20 metaphases analyzed. Within two years the patient developed a relapse of AML. Flow cytometry analysis revealed 88% blasts, which coexpressed CD4, CD11, CD13, CD33 and CD38. This time the leukemic cells showed a karyotype of 46,XY,del(3)(q21q29),t(12;14)(q24.3;q11.2) in all 20 metaphases analyzed, which reflected an evolution of the original clone. The 14q11.2 breakpoint involved in this translocation is not typical for myeloid abnormalities. Two genes, T-cell Receptor Alpha (TRA) and T- cell Receptor Delta (TRD) have been well-described at locus 14q11.2. These genes are typically involved in translocations observed in T-cell acute lymphoblastic leukemia and lymphoproliferative disorders. According to data provided in the Atlas of Genetics and Cytogenetics in Oncology and Haematology there are approximately 17 other identified genes in the 14q11.2 region that may be involved in causing cancer. These include genes that play a role in DNA repair, cell death, and members of the RAS oncogene family. The gene(s) at 12q24 responsible for oncogenesis are not known at this time, however, there are several possibilities including genes involved in cell cycle regulation, transcription factors, and again members of the RAS oncogene family. Deletions of the long arm of chromosome 3 are a common finding in treatment-related myelodysplasia and AML. To our knowledge, this (12;14) translocation has not been reported previously in the literature and may aid in determining what genes in these two regions are involved in myeloid malignancies.

A t(8;22)(q24;q11) In A Patient Diagnosed With a Rapidly Growing Plasmacytoma of the Scalp. *T. Mercado[1], A.L. Zaslav[1], K. Zamkoff[2], D. Gladstone[2].* 1) Cytogenetics, Suny Stony Brook, Stony Brook, NY; 2) Blood and Marrow Stem Cell Transplantation Program, University Medical Center, State University of New York at Stony Brook, N.Y.

A 49-year-old male presented with a rapidly enlarging scalp mass. Biopsy of the mass demonstrated by both morphology and flow cytometry a diagnosis of plasmacytoma. Radiographic bone survey, bone marrow and flow cytometry of the bone marrow aspirate showed no evidence of either multiple myeloma or lymphoma. Standard and molecular cytogenetic evaluation was performed on the bone marrow aspirate material. Cytogenetic results revealed a karyotype of 46,XY,t(8;22)(q24;q11),der(13)t(1;13)(q12;q22)[8]/46,XY[12]. FISH results on the original scalp mass using the 8q24 LSI MYC probe (Vysis, Downers Grove, IL) demonstrated a signal pattern consistent with an 8q24 translocation in 4 of 100 nuclei [i.e., nuc ish 8q24(MYCx1)[4]]. Based on the presence of the t(8;22)(q24;q11) in the bone marrow, the patient was diagnosed with multiple myeloma having an unusual karyotype i.e., t(8;22). Prior to knowledge of the bone marrow karyotype, the patient was treated with radiation therapy to the scalp mass. Three weeks later the patient returned with pain in the left hip. MRI showed evidence of new bone lesions, not present prior to this examination. Based on the rapid progression of the disease and the finding of the t(8;22) in the patients marrow and original scalp lesion, the patient was then started on an aggressive multiagent chemotherapy program used in high grade Burkitt like lymphomas. The only evidence of the systemic and aggressive nature of the patients disease originally was the presence of the t(8;22) found at the time of the original diagnosis. The patient is now in clinical remission and is awaiting an autologous stem cell transplant. This finding was significant in diagnosis, prognosis and treatment for this patient and will be useful in diagnosis of other patients with this disease.

Dicentric (17;20)(p11.2;q11.2): An uncommon abnormality associated with poor prognosis in myeloid disorders.

C.A. Tirado[1], A. M. Meloni-Ehrig[1], J. Kelly[1], E. Wallenhorst[1], J. Scheerle[1], K. Burks[1], A. Spira[2], L. Glasser[3], CD. Croft[1], D. Heritage[1], P. Mowrey[1]. 1) Cytogenetics, Quest Diagnostics Nichols Inst, Centreville, VA; 2) Arlington-Fairfax Hematology-Oncology, Arlington, VA; 3) Rhode Island Hospital, Providence, RI.

We report 2 patients with a dic(17;20)(p11.2;q11.2). The cytogenetic result of this dicentric chromosome is the partial loss of 17p and 20q. The dic(17;20) was confirmed by FISH. The first patient was a 74-year-old female with history of lymphoma since 1980, for which she received chemotherapy and radiation. Her recent blood findings included a WBC of approximately 3.5x103/L, a normal platelet count, a hematocrit of 30%, and a MCV of 103, suggestive of a myelodysplastic syndrome (MDS), likely therapy related. Chromosome analysis of her bone marrow showed an abnormal karyotype, which included a dic(17;20). The second patient was a 47-year-old male that presented with pancytopenia. His WBC was 6x103/L, hemoglobin was 6.0g/dL, and his platelet count was 20x103/L, without circulating blasts. His bone marrow was hypercellular (75% cellularity) with 58% blasts. Immunophenotyping showed that the blasts were of myeloid origin, expressing myeloperoxidase and the markers CD13, CD33, CD64, CD34, and CD117. The diagnosis of an acute myeloid leukemia (AML) was made at that time. Chromosome analysis of his bone marrow showed a complex karyotype, which included a dic(17;20). This patient subsequently received induction chemotherapy. At day 14, the marrow still showed persistence of the leukemia, for which the patient received additional rounds of chemotherapy. Deletions of 17p and 20q are recurrent abnormalities in various hematologic disorders including MDS and AML; however a dic(17;20) is an uncommon finding. According to the few reports in the literature, dic(17;20) is associated with an unfavorable prognosis. The prognostic outcome is similar to the one seen in the so-called 17p- syndrome. The common factor between the dic(17;20) and the 17p- syndrome is the loss of *TP53*, highlighting the critical role of this tumor suppressor gene in the development and/or progression of some hematologic disorders.

ACUTE BASOPHILIC LEUKEMIA WITH TRISOMY 19 AND COMPLEX BCR-ABL. *A. Rojas-Atencio[1], M. Soto-Quintana[1], K. Urdaneta[1], F. Alvarez Nava[1], E. Avila[2], L. D`Salvo[3], J. Cañizalez[1].* 1) Unidad de Genetica Medica, Univ del Zulia, Zulia, Zulia, Venezuela; 2) Servicio de hematologia, Hospital Universitario, Maracaibo, Venezuela; 3) Instituto Hematologico de occidente Maracaibo, Venezuela.

Acute basophilic leukemia (ABL) has been recently included into the acute myeloid leukemias, proposed by the WHO panel. Due to the rarity of this disease diagnostic criteria are lacking. The objective of this report is to describe a case of ABL based upon of the clinical, morphological, cytogenetic and molecular evaluations. Patient was evaluated when she was 44 years old by widespread weakness, fever, and difficult to breath. Hepatospleen grade II was appreciated on phisycal examination. The haemoglobin was 5 g/dL, the white blood cell count was 23,1 x 109/L with 23 % of polymorphonuclear neutrophils, 20% of lymphocytes, 9% of monocytes, 2% of eosinophils, 2% of mielomonocytes, 4% of metamielocytes and 40% basophils. The thrombocyte count was 200,000/mL. The bone marrow was replaced by 80% of cells with basophil granules in their cytoplasm and 20% of immature nuclei. These cells were positive by black Sudan. Immunohistochemistry showed Dr=negative, CD34=12%, CD33=neg, CD14=neg, CD7=25%. Conventional cytogenetic analysis demonstrated a trisomy of the chromosome 19 and a translocation 9; 22 (Ph chromosome +). FISH analysis showed the presence of the complex BCR-ABL in 95% of the screened nuclei. In the patient ABL was diagnosed on these findings. The patient was treated with hidroxiurea which resulted in partial remission. The patient died 2 months of the initial diagnosis. The clinical and morphological features and the dramatic evolution in this patient make us suspect in ABL with Philadelphia chromosome positive. A better definition of the diagnostic criteria is necessary for this illness.

Constitutional Partial 1q Trisomy Mosaicism and Wilms Tumor. *H.F.L. Mark[1,2], H. Wyandt[1,2], A. Pan[1], J.M. Milunsky[1,3,4].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pathology,Boston University School of Medicine, Boston, MA; 3) Department of Pediatrics,Boston University School of Medicine, Boston, MA; 4) Department of Genetics and Genomics,Boston University School of Medicine, Boston, MA.

We report a female patient with severe-profound mental retardation, multiple congenital anomalies, and a history of mosaicism for partial 1q trisomy in amniotic fluid and a previous Wilms tumor specimen. Peripheral blood and fibroblasts were studied and did not demonstrate the mosaicism initially detected for chromosome 1q. Array comparative genomic hybridization (CGH), yielded negative results. Additional cytogenetic studies were performed that help clarify the previous findings, and reveal evidence of partial 1q trisomy mosaicism in normal kidney tissue and in a kidney lesion. GTG-banded results showing low-percentage mosaicism for the structural rearrangement der(1)t(1;1)(p36.1;q23) in both tissues are corroborated by fluorescent in situ hybridization (FISH) studies. We hypothesize that the partial 1q trisomy predisposed the target tissue (in this case kidney) to neoplasia. This study provides further support for the hypothesis that certain constitutional chromosomal abnormalities can predispose to cancer. As detection of a low percentage mosaicism may be hampered by the limits imposed by currently available technology and the constraint of a finite sample size, extra vigilance in monitoring other somatic tissues will be needed throughout the patients lifetime. Anticipatory clinical guidance and prognostication are meaningful only if given accurate cytogenetic diagnoses. To the best of our knowledge, this is the first reported case of Wilms tumor associated with constitutional partial 1q trisomy, either in pure or mosaic form, or with the particular 1q23 breakpoint in conjunction with a break on 1p36.1.

Malignant transformation of 45,X and 46,XY cell lines in gonadoblastoma arising in dysgenetic gonads. *A. Al Saadi.* Dept Anatomic Pathology, William Beaumont Hosp, Royal Oak, MI.

TITLE: Malignant transformation of 45,X and 46,XY cell lines in gonadoblastoma arising in dysgenetic gonads Gonadoblastoma (GB) develops in 15-20% of 45,X/46,XY individuals. GBY gene on the Yq is believed to predispose to GB. It is not known however if both 45,X and 46,XY cell are equally involved in the developing GB. In this report we present cytogenetic and FISH of bilateral GB in a 15 1/2-year-old, phenotypic female with hypogonadism. The history includes breast development at age 11, normal growth, normal pubic hair and 3 menses at age 13 followed by amenorrhea. Lab results revealed elevated FSH and LH but normal TSH, T4, prolactin and estradiol. Blood chromosomal analysis revealed a 46,XY karyotype. Pelvic ultrasound showed normal uterus and a left gonad. MRI revealed a small atrophic right gonad. Echocardiogram was normal with no coarctation of the aorta. Bilateral GB was diagnosed following gonadectomy. Tissue from both sides was submitted for cytogenetic analysis. Fifty spreads from each side were analyzed. The left had 54% with 45,X and 46% with 46,XY complements. The right had 76% 45,X and 24% of 46,XY complements. Tissue sections, from various parts of both sides, which had different histopathology, were hybridized with CEPX and CEPY probes. Two hundred nuclei from each of DA, sex chord element (SC) and stromal tissue (ST) were scored. All three tissues had 45,X/46,XY constitution. In the DA and SC 69% of the cells had X and Y signals and 31% had X signals only. In the ST, 41% had X and Y signals and 59% had X signals only. These results suggest that both 45,X and 46,XY cells undergo transformation to form GB. Further studies are needed to determine if either the 45,X or 46,XY cells are more susceptible to form GB.

A novel t(14;20)(q32;p13) in acute myelogenous leukemia. *M.P. Ornelas, C.S. Berger, S. Karamanov, T.C. Brown.*
Genzyme Genetics, Phoenix, AZ.

A bone marrow sample from a sixty-two year old male was evaluated for a clinical diagnosis of leukemia. Flow cytometry results were suggestive of acute myelomonocytic leukemia and cytogenetic results were normal 46,XY. A month later, flow cytometry results were consistent with a remission bone marrow. Follow-up cytogenetic testing three months after the initial cytogenetic study showed 7 of the 20 cells analyzed with the following abnormal karyotype: 46,XY,add(14)(q32),del(20)(q11.2q13.3). Cytogenetic studies performed five months later showed 13 of the 20 cells analyzed to have the same abnormal karyotype. Six months later all 20 cells were abnormal. With much better resolution on this final sample, it was questionable whether the deletion of chromosome was actually 20q or possibly 20p. FISH probes for the 20q12 region revealed two signals thereby showing the deletion was on 20p not 20q as was reported. Hybridization with the IGH probe at 14q32.3 showed that this gene was not directly involved but was translocated to the der(20). Whole chromosome paints of chromosomes 14 and 20 provided final evidence that the actual karyotype was a balanced translocation between 14 and 20, 46,XY,t(14;20)(q32;p13). This is quite unusual since 20q is typically involved in myeloid disorders. This is a new, previously unreported translocation associated with acute myelogenous leukemia.

Amplification of the MLL gene localized by FISH on dmins and hsrs in a patient with RAEB-2. *C. Sreekantaiah, P.K. Berry.* Dianon Systems/Labcorp, Stratford, CT.

Amplification of the MLL gene is a rare but recurrent aberration in acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS). It is associated with karyotypic complexity and adverse prognosis. We report the cytogenetic and fluorescence in-situ hybridization findings in an 81-year-old woman with refractory anemia with excess blasts (RAEB-2). The patient received palliative care and died shortly after diagnosis.

Cytogenetic analysis of the bone marrow revealed two related clones with multiple and complex chromosomal abnormalities, including a ring chromosome, double minute chromosomes (dmins) and homogeneously staining region (hsr), the latter two representing cytogenetic manifestations of gene amplification. The karyotype was as follows: 44~46,XX,der(9)ins(9;11)(q11;q11q23),-11,-17,der(20) t(17;20)(q11.2;q11.2),+0-1r,0~11dmin [cp6]/44~46,XX,der(9)ins(9;11)(q11;q11q23)inv(11)(q13q21)hsr(11)(q23), -11,-17,der(20)t(17;20)(q11.2;q11.2),+0-1r[cp14].

FISH analysis with the MLL probe (Vysis, Inc.) showed multiple hybridization signals on the ring chromosome, the dmins and within the hsr at 11q23 reflecting amplification of the MLL gene.

Our findings are unique in that both intrachromosomal and extrachromosomal amplification of the MLL gene were noted in the same patient. It also confirms the poor prognostic outcome associated with MLL amplification and karyotype complexity.

A rare but recurrent chromosome abnormality, ider(9)(q10)t(9;22)(q34;q11.2) identified in a patient with ALL.

S. Wei[1], A. Mohindra[2], P. Kuriakose[2], A. Adeyinka[1]. 1) Dept Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Dept Oncology/Hematology, Henry Ford Health System, Detroit, MI.

A t(9;22)(q34;q11.2) resulting in a chimeric BCR-ABL gene is found in 95% of patients with chronic myeloid leukemia (CML), 5% of children with Acute lymphoblastic leukemia (ALL) and 20% of adults with ALL. The chimeric BCR-ABL gene on the derivative 22 chromosome encodes a fusion protein with constitutive protein kinase activity contributing to malignant transformation and growth. Rearrangements of the der(22) and der(9) chromosomes generated by the t(9;22) as well as acquisition of other chromosome anomalies have been documented as part of disease progression in hematologic disorders with a t(9;22)(q34;q11.2). Rearrangements of the der(22) are observed more often, whereas changes to the der(9) are rarer. Here we present a case, a 23-year-old female with ALL associated with ider(9)(q10)t(9;22)(q34;q11.2). Fluorescence in situ hybridization (FISH) studies on bone marrow using the dual-fusion dual-color FISH probe for BCR and ABL showed three fusion signals suggestive of an extra copy of der(22) or der(9), and the karyotype obtained from G-banded chromosome analysis was 46,X,der(X)t(X;1)(q28;q11),ider(9)(q10)t(9;22)(q34;q11.2),der(22)t(9;22)(q34;q11.2)[3]/46,XX[17] leading to a net gain of 1q, 9q and proximal 22q as well as loss of 9p. Reverse transcriptase polymerase chain reaction (RT-PCR) on peripheral blood detected a BCR-ABL gene fusion transcript coding for a 190 kd protein. Flow cytometry results and bone marrow morphology were consistent with precursor B lymphoblastic leukemia/lymphoblastic lymphoma. So far six cases of ider(9)(q10)t(9;22)(q34;q11.2) have been reported, including three individuals with lymphatic blastic phase of CML and 3 patients with ALL. Survival data have been documented in only 4 of them. The present case coupled with published cases show that development of an ider(9)(q10)t(9;22)(q34;q11.2), though seemingly rare, is a pathway of progression in hematologic disorders with a t(9;22)(q34;q11.2).

MYC Amplification in Acute Myeloid Leukemia. *S. Sait[1], L.A. Ford[3], M. Barcos[2], M.R. Baer[3].* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Ctr, Buffalo, NY; 2) Department of Pathology, Roswell Park Cancer Ctr, Buffalo, NY; 3) Department of Medicine, Roswell Park Cancer Ctr, Buffalo, NY.

Although occurring frequently in solid tumors, gene amplification is reported in only ~ 1% of karyotypically abnormal leukemias, with double minute chromosomes (dmin) and homogenously staining regions (hsr) as its cytogenetic hallmarks. Regions commonly amplified in leukemias include 8q24 (MYC) and 11q23 (MLL). We report 7 patients with acute myeloid leukemia (AML) seen at Roswell Park Cancer Institute since 1985 with dmin in whom amplification of the MYC gene was demonstrated by fluorescence in situ hybridization. Six patients were elderly (>75 years) and six were females. FAB types were diverse. Two patients had therapy-related AML, and one had a prior myelodysplastic syndrome. Five had other chromosome abnormalities in addition to dmin. Six patients had primary refractory disease, and one had only a brief remission. Thus MYC amplification is rare in AML, and is associated with a poor response to treatment. The mechanism of generation of double minutes is incompletely understood, although it has been suggested to occur through extra replication (or loop- formation)-excision-amplification. Studies have also shown that the amplicon generated contains other genes that might be functionally important, and thus MYC may not be the only target gene.

Chromosomal Instability, Centrosome Aberrations and Expression Changes in BRCA1-pathway dependent Genes in Sporadic Ovarian Carcinoma. *J. Bayani[1, 2], M. Yoshimoto[1], B. Vukovic[1, 3], J. Weberpals[1, 2], M. Zajac[1], P. Marrano[1], J. Karaskova[1], B. Rosen[2], M. Zielenska[4], J.A. Squire[1, 2, 3].* 1) Dept.Cell&Mol Bio, Ontario Cancer Institute; 2) Dept.Lab. Med.& Pathobio; 3) Dept.Med. Biophys. University of Toronto; 4) Dept.Lab Med& Pathobio. Hosp.for Sick Children, Toronto.ON.

Ovarian cancer is the leading cause of death from a gynecological malignancy among North American women. Cytogenetic analysis shows them to be highly aneuploid with complex chromosomal aberrations suggesting errors in DNA repair and cytokinesis. Since somatic mutations of BRCA1 are rare in sporadic disease, it has been postulated that they play a limited role in its pathogenesis. However, the inactivation of BRCA1 at the RNA is relatively frequent in sporadic cases, suggesting a shared feature of between BRCA-mutated and non-BRCA-mutated ovarian tumors is the dysfunction of BRCA-dependant pathways, influencing the observed karyotypic and genomic complexity. Chromosome instability (CIN) studies were performed for 11 sporadic ovarian cancer specimens, from 8 patients previously described by our group (Bayani et al 2001) using SKY, CGH and interphase FISH. Centrosome amplification was also determined by immunostaining. In 5 patients, microarray analysis using the GEArray-Q DNA Damage Array was performed. Increasing CIN was associated with increasing centrosome aberrations. Diploid/near-diploid tumors were characterized by low-level CIN and centrosomal aberrations, but high frequencies of chromosomal breakage. Tetraploid tumors showed increasing CIN and centrosomal aberrations, with triploid tumors having the greatest CIN and centrosomal aberrations. In all tumors studied, microarray findings revealed reduced expression of BRCA1 to be statistically significant (p-value 0.01). Reduced expression of APAF1, ATM, PPMID, PRKDC and RAD50 was also detected in all tumors. Overexpression of HIST1H2AC and KIF23 was identified in all tumors tested. These findings suggest that impaired DNA repair and cell cycle checkpoints along BRCA1 pathways occur in sporadic ovarian cancers and play a contributing role in the pathogenesis of the disease.

Loss of 17p is a major consequence of whole-arm chromosome translocations in hematologic malignancies. *A. Adeyinka[1], D. Kramer[1], D. Van Dyke[1,2].* 1) Dept Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Dept Lab Medicine and Pathology, Mayo Clinic, Rochester, MN.

Whole-arm translocations reportedly are rare in hematologic malignancies. Indeed, very few whole-arm translocations have been documented as sole anomalies in hematologic malignancies. In order to ascertain the distribution of whole-arm translocations and their consequential imbalances, we surveyed the cytogenetic database at the department of Medical Genetics, Henry Ford Health System. Imbalances related to chromosomes involved in clonal acquired whole-arm translocations were ascertained from tumors with near-diploid karyotypes. One hundred and one (101) tumors met the search criteria and seven of these had balanced whole-arm translocations. The remaining 94 samples had whole-arm translocations that rarely or never involved chromosome 2, 3, 4, 6, 19, 20 or the sex chromosomes. Chromosome arms were lost more often than they were gained and p-arms were lost more than q-arms except for chromosome 7 (17% q-arm loss and 2% p-arm loss) and chromosome 11 (both arms were equally lost). Chromosome 1 q-arm was the only chromosome arm substantially gained (30% of tumors). 7p and acrocentric long arms were involved in 50% and 25%, respectively, of whole-arm translocations resulting in gain of 1q. Acrocentric chromosome were involved in acquired whole-arm translocations at a frequency of 4% (G-group) and 12-14% (D group), and were more likely to be involved in non-Robertsonian than Robertsonian translocations (P= 0.0027, Normal test). Loss of 17p was the most common p-arm loss, was present in 16% of tumors (myeloid and lymphoid), and often occurred as part of complex karyotypes suggestive of disease progression. Deletion of the TP53 gene is often regarded as an important molecular genetic outcome of loss of 17p. The present findings show that acquired whole-arm chromosome translocations in hematologic malignancies are nonrandom and that loss of 17p, often associated with a poor prognosis in a wide spectrum of hematologic malignancies as well as with the 17p- syndrome, is an important consequence of whole-arm translocations in these disorders.

Genome-wide SNP scan detects submicroscopic chromosomal aberrations in acute lymphoblastic leukemia. *L-H. Li[1], A. Yu[2], Y-C. Lin[2], M. Dicciannni[2], S-F. Ho[1], C-H. Chen[1], K-C. Jiang[1], J-Y. Wu[1], Y-T. Chen[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Genomics Research Center, Academia Sinica, Taipei, Taiwan.

Cytogenetic analysis of acute lymphoblastic leukemia (ALL) is difficult due to the low mitotic rate and poor quality of the metaphases; the reported chromosomal abnormalities are less frequently observed in T-ALL than in B-ALL. Here we report the ultilization of Affymetrix GeneChip Human Mapping 100K set to detect both submicroscopic chromosomal abnormalities and allelic alterations in ALL patients (5 T-ALL and 1 B-ALL). Using this technology, we identified chromosomal aberrations in all but one T-ALL samples. One patient had double trisomy for chromosomes 18 and 21. Deletion of 6q, a frequent structural abnormality in ALL, was detected in another patient. Most significantly, we detected six loci with deletion less than 4.0 Mb in five samples. A deletion interval of 1 Mb within 14q11.2, where the TRAC gene is located, was identified in two samples. This suggests that deletion involving 14q11 is not infrequent in ALL patients. The lower rate of previously reported cases is mot likely due to the limited resolution of detection methods. We also identified deletion involving 13q14 in two samples. Interestingly, the deletion interval was 1.3 Mb within 13q14.2 including the RB1 gene in one sample, and 3.6 Mb within 13q13.3 to 13q14.11 in the other sample. In addition to samll deletions, one sample showed LOH of 9p without any sign of chromosomal copy number change, suggesting the existence of uniparental disomy. Taken together, these results demonstrate the power of the genome-wide SNP analysis in detecting small deletions and allelic alterations, and in defining the boundaries of cytogenetic abnormalities, which is useful in the seletion of candidate genes for further study to increase our understanding of leukaemogenesis.

Development of a robust algorithm for genetic alterations in cancer genomes using Affymetrix SNP-genotyping microarrays with its applications to large-scale copy number/LOH/allelic imbalance mapping of cancer genomes.

Y. Nannya[1], M. Sanada[1], K. Nakazaki[1], F. Kanai[2], N. Hosoya[1], L. Wang[1], A. Hangaishi[1], M. Kurokawa[1], S. Chiba[1], M. Omata[2], D.K. Bailey[3], G.C. Kennedy[3], S. Ogawa[1]. 1) Hematol/Oncol, Tokyo University, Tokyo, Japan; 2) Gastoenterology, Tokyo University, Tokyo, Japan; 3) Affymetrix, Inc., Santa Clara, CA.

Genetic alterations are cardinal features of cancer genomes and inseparably related to the pathogenesis of cancers. Since cancer cells may heavily accumulate large number of genetic changes, genome-wide detection of these changes using high-throughput techniques is essential clue to the comprehensive understanding of how cancer develops. Here we report a robust algorithm for detecting genetic alterations of cancer genomes using Affymetrix GeneChip mapping arrays, which were originally developed for large-scale SNP genotyping in genetic epidemiologic studies. Advantages of this algorithm include the increased signal-to-noise (S/N) ratios and the use of optimized references. The raw S/N ratios were improved by accounting for the length and GC content of the PCR product using quadratic regressions. The use of a self-reference, when available, gives the lowest standard deviation (SD) values and also allows allele-specific copy number detection in cancer genomes, which can unmask otherwise concealed allelic imbalances. In the absence of a self-reference, optimized selection of multiple best-fit references dramatically improves SD values. These improvements allow for highly reliable comparison of data across different experimental conditions, detection of allele-based copy number changes, and more accurate estimations of the size of copy number aberrations. Using this algorithm we analyzed more than 300 tumor samples and thereby generated large-scale copy number/LOH/allelic imbalance maps, which unveiled a number of common regions harboring genetic abnormalities in cancer genomes and also underpinned that the Affymetrix 100K or 500K mapping arrays, in combination with the newly developed algorithm (CNAG; Copy Number Analyzer for Affymetrix GeneChip), provide an ideal platform for finely analyzing cancer genomes having complex abnormalities.

Variant chronic myelogenous leukemia (CML) patients: a clinical and molecular cytogenetic study. *A. Block[1], S.N.J. Sait[1], S. Kakati[1], P. Starostik[2], M. Wetzler[3].* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Molecular Diagnostics Lab, Roswell Park Cancer Inst, Buffalo, NY; 3) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

Chronic myelogenous leukemia (CML) is a clonal hematologic malignancy that originates in an abnormal pluripotent bone marrow stem cell. The majority of patients (pts) have the characteristic t(9;22)(q34;q11.2) which fuses sequences of the BCR gene with the ABL gene. The clinical course of CML is heterogeneous, with inter-individual variability in clinical and laboratory findings at diagnosis, in the rate of progression to blast crisis (BC), and in survival. The nature of this heterogeneity and the molecular basis of the progression to BC are poorly understood. To determine the effect of baseline cytogenetic characteristics on the efficacy of current drug (imatinib) therapies, we identified a subgroup of 12 CML pts treated at our institution within the past three years with normal karyotypes (NK), complex variant translocations (CVT), and/or atypical BCR/ABL fluorescence in situ hybridization (FISH) patterns often resulting in microdeletion events. Molecular responses to therapy were seen at 3 months in 1/2 pts with NK, 1/2 evaluable pts with CVT and 5/5 evaluable pts with derivative chromosome 9 deletions (der9del). Complete responses (CR) to therapy were observed in 1/2 pts with NK and 3/7 pts with der9del. Hematologic and/or cytogenetic responses were achieved in 2/7 pts with der9del and 1/1 evaluable pts with CVT. Disease progression occurred in 1/3 der9del pts with CR. Longer follow-up and study of more pts will be required to determine the effects of microdeletions on disease progression and overall survival. Time-line of patient response and details of molecular cytogenetic abnormalities will be presented.

Molecular Cytogenetic Basis of 2+ HER-2/neu IHC Expression in Breast Cancers: A FISH Study of 110 Cases.
M.R. Quddus, M.M. Steinhoff, C.J. Sung, J.M. Kasznica, T. Pasquariello, U. Tantravahi. Dept of Pathology & Molecular Cytogenetics, Women & Infants Hospital, Brown Medical School, Providence, Rhode Island.

Purpose: Proto-oncogene HER-2/neu is an important biomarker in breast cancer and its amplification is correlated with poor prognosis. Specific treatment protocols are available to breast cancer patients with amplified HER-2/neu gene. HER-2/neu status is currently assessed by immuno-histochemistry (IHC) as a primary diagnostic test and 2+ IHC cases are reflexed to HER-2/neu testing by FISH to determine the amplification status of the gene. A significant number of cases that are 2+ positive for HER-2/neu by IHC are found to be discordant with the FISH results. We investigated the underlying molecular cytogenetic abnormalities of breast cancer cases with 2+ HER-2/neu IHC expression by FISH. Methods: 110 cases of breast carcinoma with 2+ IHC HER-2/neu expressions with both IHC and FISH HER-2/neu status available were selected after IRB approval. IHC and FISH were performed at Women & Infants Hospital using FDA approved Dako Cytomation reagent for IHC (HercepTest) and VYSIS (PathVysion) detection system for FISH. IHC was scored according to the manufacturers guidelines as 0-1+ (negative), 2+ positive and 3+ positive. FISH results are interpreted as HER-2/neu signal over chromosome 17 signal ratio of <1.8 as non-amplified, >2.2 as amplified and 1.8-2.2 as borderline amplified. Results: 31 of 110 (27%) cases had underlying molecular cytogenetic abnormalities detected by FISH under one of four categories: 8 cases were HER-2/neu amplified; 3 borderline amplified; 11 with focal amplification (few cells were amplified but not significant to alter the ratio); and 9 cases with polysomy of chromosome 17. Conclusion: A significant number (27%) of breast cancer with 2+ HER-2/neu IHC expression showed underlying molecular cytogenetic abnormalities detected by FISH. Two categories, borderline and focal HER-2/neu amplification, may be of clinical significance and possibly represent the earliest phase of HER-2/neu amplification. It may be prudent to treat these subsets of breast cancers similar to bona fide HER-2/neu amplified cases.

Complex t(der(8)t(8;14);18)in an aggressive follicular lymphoma. *A. Meloni-Ehrig[1], C.A. Tirado[1], J.C. Kelly[1], C. Caldwell[1], J. Jahn[1], J. Scheerle[1], P. Beveridge[2], W.M. Ueno[2], P.. Francis[2], C.D. Croft[1], D. Heritage[1], P.N. Mowrey[1].*
1) Dept Cytogenetics, Quest Diagnostics Nichols Inst, Chantilly, VA; 2) Fairfax Oncology Hematology, Fairfax, VA.

We report a rare complex t(8;14;18)(q24;q32;q21) involving simultaneously the *C-MYC(8q24)*, *BCL2 (18q21)*, and *IGH (14q32)* regions, which was confirmed by FISH. The patient is a 63-year-old male diagnosed with low-grade non-Hodgkin lymphoma (NHL) in 2002 for which he received chemotherapy but failed to achieve complete remission. Flow cytometry performed in February 2005, detected a monoclonal CD10+ population. CD10 can be seen in follicular lymphoma (FL), Burkitt lymphoma (BL), immunoblastic lymphoma, and diffuse large B-cell lymphoma (DLBCL). Chromosome analysis of a recent bone marrow aspirate showed a complex karyotype with numerical and structural abnormalities including a three-way t(8;14;18) in 12/20 metaphases analyzed. A similar variant t(8;14;18)(q24;q32;q21) has been reported in few cases of NHL and acute lymphoblastic leukemia (ALL). Commonly, t(8;14)(q24;q32) is recurrent in ALL and NHL, especially BL, whereas t(14;18)(q32;q21) is typically seen in 85% of FL and 20-30% of DLBCL. The concurrent FISH study was performed using the dual-color dual-fusion translocation probes *IGH/MYC/CEP8* and *IGH/BCL2* (Vysis, Downers Grove, IL). The probe IGH/MYC/CEP8 detected a variant pattern: two *IGH* signals were located on the two derivative chromosomes 18 and two *IGH/MYC* fusion signals were located on the derivative chromosomes 8 and 14. The *IGH/BCL2* probe showed a variant pattern, which consisted of three *IGH/BCL2* fusion signals: two on the derivative chromosomes 18 (*BCL2* region) and one on the derivative chromosome 8 (*C-MYC* region). As a result, the derivative chromosome 8 contained both the *IGH/MYC* and the *IGH/BCL2* fusion signals, suggesting a possible 2-step mechanism in the generation of the t(8;14;18). These findings, i.e., the simultaneous activation of *C-MYC* and *BCL2* by translocation with the IGH locus, are suggestive of an aggressive type of FL.

Tumor Genome Anatomy Project (TGAP); Gene discovery in tumors in the genome era. *S.D.P. Moore[2, 4], O. Offor[1], J. Feryi[3], P. Amrein[3], P. Dal Cin[1, 4], C.C. Morton[1,2,4].* 1) Dept Pathology, Brigham & Women's Hosp., Boston, MA; 2) Dept of Obstetrics, Gynecology and Reproductive Biology, Brigam & Women's Hosp., Boston, MA; 3) Hematology-Oncology Unit, Massachusetts General Hosp., Boston, MA; 4) Harvard Medical School, Boston, MA.

TGAP is a new initiative to identify genes involved in neoplasia in a high throughput manner taking advantage of naturally occurring human genomic and genetic changes resulting from chromosome rearrangements in individuals with a wide spectrum of neoplasms. The completion of the Human Genome Project is redefining the rapidity of genetic discoveries with potential clinical applications. TGAP will exploit these growing biological resources, and will coordinate an integrated group of researchers with expertise in cytogenetics, molecular biology and oncology. This gene discovery initiative is a natural extension in the application and translation of the complete human DNA sequence.

The current strategy of TGAP is first to identify a tumor with novel rearrangements primarily from tumor samples submitted for analysis to the Cytogenetics Laboratory at the Brigham & Women's Hospital. Chromosomal breakpoints are mapped by FISH to discover candidate genes or regions of conserved non-genic sequence. Molecular analysis ensues to pinpoint potential disruption or position effects on gene function.

We have uncovered two novel fusion transcripts associated with Acute Myeloid Leukemia. Preliminary work on a t(8;9)(p22;p21.3) rearrangement indicates a fusion transcript between *ASAH1* and *MLLT3*. ASAH1 has a role in Sphingolipid metabolism and associated with Farber disease but has not previously been shown to be involved with cancer. The second rearrangement involves a t(X;21)(q26;q22). In this case, a fusion transcript between *ELF4* and *ERG* is created. This novel fusion is between two known *ETS* family members and is the first evidence that directly supports a role for *ELF4* in cancer.

Multicolor fluorescence in situ hybridization (SKY) in mycosis fungoides and Sezary syndrome: search for recurrent chromosome abnormalities. *D.A.S. Batista[1], A. Hawkins[1], L. Morsberger[1], P. Long[1], E. Vonderheid[2], C.A. Griffin[1].* 1) Dept. of Pathology; 2) Dept. of Dermatology, Johns Hopkins University, Baltimore, MD.

Cutaneous T-cell lymphomas are clonally derived lymphoproliferative disorders that preferentially involve the skin. The two major clinical expressions, mycosis fungoides (MF) and Sezary syndrome (SS) may develop overt lymph node and/or blood involvement during the course of the disease. Pathogenesis is poorly understood for either entity. Chromosome abnormalities, mostly complex karyotypes are seen in about 50% of patients with MF/SS and there are only few instances of recurrent rearrangements. We analyzed 19 blood samples from patients with MF/SS with conventional cytogenetics and SKY to better describe the complex karyotypes and search for recurrent abnormalities or breakpoints. Comparison of phytohemagglutinin (PHA) versus a combination of interleukin 2 plus interleukin 7 showed similar efficiency to detect abnormal clones for both mitogens, however the PHA cultures yielded more analyzable metaphases. 9/19 patients (47%) had an abnormal karyotype. Most frequent abnormalities involved chromosome 10 in 7/9 cases, followed by chromosome 6 in 6/9, chromosomes 3, 7, 9, 17 and 19 in 5/9, chromosomes 1 and 12 in 4/9 and chromosomes 8, 11, and 13 in 3/9. Most abnormalities were structural. Recurrent rearrangements included deleted chromosomes 6 and 13 in three cases each and recurrent breakpoints were 1p32-36, 6q22-25, 17p11.2-13, 10q23-26 and 19p13.3 occurring in three or more cases each. One patient had a pseudo dicentric translocation between the short arms of chromosomes 8 and 17, confirmed by dual color FISH and interpreted as psu dic(17;8)(p11.2;p11.2). Two patients with SS reported by Thangavelu et al.(Blood 1997, 89: 3371) had a similar translocation described as der(8)t(8;17)(p11;q11). Molecular cytogenetics was not performed in these two cases. It seems plausible based on the pictures published that these three cases represent the same rearrangement. If indeed this is true, a psu dic(17;8) is the first recurring translocation detected in a set of three patients with MF/SS.

Atypical D-FISH pattern in a patient with Juvenile Myelomonocytic Leukaemia: A case of positive Philadelphia chromosome? *G.C. Ramírez-Gaviria[1], C.M. Muñetón-Peña[1], F. Cuellar-Ambrossi[2], M. Sarmiento[2], F. Quintero-Rivera[3], J.L. Ramírez-Castro[1], G. Vásquez-Palacio[1].* 1) Medical Genetics Unit, Antioquia University, Medellín, Antioquía, Colombia; 2) Department of Hematology, Faculty of Medicine, Antioquia University, HUSVP, Medellin, Colombia; 3) Center for Human Genetic Research, MGH, Boston, MA.

A 16 months old male with fever and bronchitis was seen in June 2004. The spleen and liver were palpable 5 cm below the rib margins. Differential counts showed WBC 73.000 mm3 , myeloid hyperplasia with monocytes 11.6%, CD34 1.9% and high levels of IgM for cytomegalovirus. A hepatic biopsy suggests a Juvenile Myelomonocytic Leukaemia (JMML). Cytogenetic analysis with RGH banding on a peripheral blood specimen revealed a male normal karyotype 46,XY in 40 metaphases. D-FISH analysis for BCR/ABL was performed using a dual colour dual fusion spectrum orange/green probe set (Vysis). Hybridization with this probe in typical BCR/ABL rearrangement produce two fusion signals (yellow F) corresponding to BCR/ABL fusion on a der(22) chromosome and ABL/BCR fusion on a der(9) chromosome, in addition to one green signal and one orange signal on both normal 9 and 22 chromosomes respectively. In this patient, the hybridization pattern was normal in 90% of the interphase nuclei (90) (2O2G) corresponding to negative Philadelphia chromosome, however 10% of the cells (10 nuclei) showed atypical fusion patterns with loss of one fusion signal: 1O1G1F, 1O2G, 2O1G1F. The single fusion pattern was detected by interphase D-FISH but not in metaphase cytogenetics analysis and may represent either BCR/ABL or ABL/BCR gene fusion. It has recently been shown that the atypical D-FISH patterns may be caused by microdeletions in association with the breakpoints or DNA loss around the breakpoint in 9q34. These atypical fusion patterns are present in near 20% of patients with Chronic Myeloid Leukaemia and they must be observable in above of 1.8% of analysed cells. Those rearrangements have not been reported in JMML. Additional studies are in progress to further syndrome delineation and the molecular characterization of prognosis factors in this patient.

Identifying and mapping the human penumbra gene to a region on chromosome 7 frequently deleted in myeloid malignancies. *Z. Chen[1], M. Pasquini[2], B. Hong[1], S. DeHart[2], M. Heikens[2], S. Tsai[2].* 1) Dept Pediatrics/Cytogenetics, Univ Utah Sch Medicine, Salt Lake City, UT; 2) Division of Hematology, Department of Medicine, University of Utah School of Medicine, Salt Lake City, Utah.

In a search for new genes that might be involved in the regulation of hematopoiesis, we performed cDNA representational difference analysis on the multipotent murine hematopoietic cell line, EML C1 , using a syngeneic promyelocytic cell line, MPRO, as the subtractor. One of the new genes that we have identified is the murine Penumbra (for proerythroblast nu[new] membrane), which exhibits differential expression in proerythroblasts/erythroblasts in Northern analysis. Penumbra encodes a new member of the evolutionarily conserved tetraspanin membrane protein family that includes CD9, CD53, CD63, CD81, CD82, CD151 and peripherin. Using murine Penumbra as a probe, we identified human Penumbra from a normal human bone marrow cDNA library. The human Penumbra encodes a protein of 283 amino acids and is 97% identical to the murine Penumbra protein. This high degree of sequence homology suggests that Penumbra serves an important function. Interestingly, an expressed sequence tag (est AI480218) corresponding to the end of the 3 untranslated region of human Penumbra cDNA is predicted to be at chromosome7q32.1 in the National Center for Biotechnology Information (NCBI) human genome database. This region of chromosome 7 is a hotspot for cytogenetic abnormalities in myeloid malignancies associated with poor prognoses. Based on these data, we further designed a human Penumbra probe contig and used fluorescent in situ hybridization (FISH) to analyze seven cases of myeloid malignancies with 7q deletions. Five patients with cytogenetic deletions involving 7q31.2q32 also showed deletions of Penumbra by FISH; these were not present in two patients with cytogenetic deletions not involving 7q31.2q32. Our findings provide the first FISH evidence supporting the mapping of human Penumbra to 7q31.2q32 and demonstrate the potential use of the Penumbra probe in the detection of 7q31q32-related deletions in myeloid malignancies.

High resolution analysis of linearized cancer genomic DNA using parallel nanochannel arrays. *H. Cao, P. Deshpande, M. Austin, C. Tan, M. Boyce-Jacino.* BioNanomatrix, Inc. 3701 Market St, Suite 340 Philadelphia, PA 19104.

We are developing a nanochip device for manipulating long genomic DNA for high-resolution (< kilobase), whole-genome analysis of cancer biomarkers such as gene amplifications, deletions, and translocations. These chromosome structural aberrations are strongly implicated in the process of malignant transformation,and are important diagnostic, prognostic, and therapeutic indicators for many types of cancer. Techniques that rely on probing chromosomes, such as metaphase FISH, while providing a pan-genomic view, cannot resolve structures below the Mb range. By probing uncompressed interphase DNA, resolution can be improved, but spatial organization of the genome is lost, so multiplexed and quantitative information is difficult to obtain. By stretching out (linearizing) interphase DNA, using techniques such as molecular combing or optical mapping, it is possible to probe specific loci in a spatially-significant way, and with resolutions in the kb range. However, techniques for mechanically linearizing DNA are inherently variable, leading to inconsistent stretching of molecules, which often cross over and retract upon themselves. We are developing an innovative alternative to mechanical stretching of DNA. We have found that megabase individual DNA molecules because of the self-avoiding nature of the DNA polymer, will elongate and straighten in a consistent manner when streamed into confining nanometer-scale channels (nanochannels)in massive parallel fashion (50,000 channels on 1 cm nanochip). We have used a novel nanofabrication technique to manufacture nanochannel structures in silicon chips, and have demonstrated that linear DNA in these nanochannels can be measured with precision of < 400 bp within 1 minute. We are quantitatively interrogating these linearized DNA with locus-specific probes for the detection of genomic instability events associated with cancer. Our product, the nanochannel array chip, will comprise part of an integrated platform for the routine and standardized quantitative analysis of cancer DNA structure that will enable archiving and cross-laboratory comparison of data.

Complex rearrangement of *cMYC, BCL2, BCL6,* and *IGH* in an aggressive B-cell lymphoblastic lymphoma/leukemia. *C.W. Rehder[1], P.J. Buckley[1], J.Z. Gong[1], A.S. Lagoo[1], J.O. Moore[2], B.K. Goodman[1].* 1) Dept. of Pathology; 2) Dept. of Medical Oncology & Transplantation, Duke University, Durham, NC.

Concurrent translocations involving *cMYC/IGH* as well as *BCL2* or *BCL6/IGH* have been reported previously in cases of aggressive lymphoma. We report a case of precursor B-cell lymphoblastic lymphoma/leukemia showing the classic t(8;14) plus a complex variant translocation involving *BCL6*, *BCL2*, and *IGH*, t(3;14;18). The patient, a 36 y.o. female, presented with fatigue and a left neck mass. Excisional biopsy of the mass showed Burkitt-like morphology. A hypercellular bone marrow showed 94% blasts which expressed pan-B cell antigens, as well as CD10, *Bcl-2* and TdT, but not surface immunoglobulin. Interphase FISH using dual fusion probes specific for the t(8;14) and t(14;18) showed complex abnormal patterns in 82.5% and 92% of nuclei, respectively. Cytogenetic analysis of unstimulated bone marrow cultures confirmed the presence of both the 8;14 and the 14;18 translocations. Additional FISH studies showed that the 14;18 translocation was actually a three-way translocation that also involved the distal long arm of chromosome 3. An *IGH/BCL2* fusion signal was present on the derivative (der) chromosome 18, while the residual *BCL2* signal was observed on 3q, and the residual *IGH* signal on the der(14). Because these cells lacked a fusion signal on the der(14), which is usually the critical fusion event, and because FISH results implicated 3q27 as a possible partner in the 3-way translocation, a FISH assay using a break-apart probe specific for the *BCL6* locus was performed on the same metaphase cells. This assay confirmed involvement of *BCL6*, with translocation of 5 *BCL6* sequences to the der(14). Residual lymphoma was detected after 1 month of treatment and a second course of therapy was initiated, leading to complete cytogenetic remission after 6 weeks of therapy. However, one month later, her abnormal cytogenetic clone returned with additional evolution (a large marker chromosome). These results implicate *BCL6* as an important translocation partner with *IGH* in aggressive B-cell lymphoblastic lymphoma/leukemia.

Loss of imprinting of LIT1 in colorectal cancers. *S. Nakano[1], M. Meguro[1], K. Murakami[1], H. Kugoh[1], H. Soejima[2], K. Higashimoto[2], T. Urano[3], T. Mukai[2], M. Oshimura[1].* 1) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, Tottori, Japan; 2) Division of Molecular Biology and Genetics, Department of Biomolecular Sciences, Saga Medical School, Saga, Japan; 3) Department of Biochemistry II, Graduate School of Medicine, Nagoya University, Nagoya, Japan.

Human chromosome region 11p15.5 contains several maternally and paternally imprinted genes, and the LIT1 locus acts as an imprinting center in the proximal domain of 11p15.5. Misregulation of LIT1 is associated with both Beckwith-Wiedemann syndrome and various cancers including colorectal cancer. To determine if LOI is a common in colorectal cancer, and to examine whether loss of imprinting (LOI) of the LIT1 is related to loss of methylation at a 11p15.5 region, we studied LOI of LIT1, IGF2 and H19, and DNA methylation of the KvDMR1, which is imprinting center at the 11p15.5, in 69 colorectal cancer tissues. LOI of LIT1, IGF2 and H19 were observed in 9/17 (53%), 11/20 (55% and 2/21 (9.5%) informative cases, respectively. LOI of LIT1 was only observed in tumor samples, while LOI of IGF2 was observed in both tumor and adjacent normal tissues in the majority of cases, suggesting that the both imprinting genes are not coordinately regulated. We carried out the LIT1 LOI analysis by RNA-FISH method, which does not require the sequence polymorphisms for the allelic expression profile. The analysis revealed that allelic expression patterns, i.e., LOI, imprinted and loss of expression of LIT1 were observed in 4, 1, and 1 cell lines, respectively. Methylation analysis performed at the KvDMR1. Two of the 4 cell lines with LIT1 LOI showed hypomethylation, while differential methylation was observed in the others. The cell line with the monoallelic imprinted pattern showed differential methylation, and the cell line with the loss of expression showed hypermethylation. Thus, there were two LIT1 LOI cell lines which maintained methylation status at the KvDMR1, suggesting that the KvDMR1 methylation status is not necessarily required for LIT1 LOI. We are currently studying other epigenetic profiles, such as histone modifications.

Partial 3 or 5 IGH Deletions in Lymphoma. *J.H. Tepperberg, I. Gadi, V. Jaswaney, J. Kesler, L. Burgin, R. Royster, H. Waters, P. Papenhausen.* Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC.

Molecular cytogenetics, using an IGH break apart DNA probe, is an efficient, sensitive method for identifying most cases of B-cell Non-Hodgkins lymphoma. Lymphomas generally involve a reciprocal translocation of the heavy chain IGH gene, located at 14q32, resulting in the juxtaposition with an proto-oncogene, such as CMYC in Burkitt lymphoma, Cyclin D1 (BCL1) in Mantle Cell lymphoma or BCL2 in Follicular lymphomas. The result is transcriptional deregulation of the proto-oncogene and onset of disease. We report 4 cases (A-D) referred for FISH to rule out B-cell NHL in which either the 3 centromeric region or 5 telomeric portion of the IGH gene was deleted. The IGH break apart DNA probe (Vysis, Inc.) was designed with the 3 region flanking the constant region and the 5 variable segment distal to the J and D segment regions. In cases A-C, the 5 variable region was deleted suggesting that juxtaposition of the proto-oncogene with the 3 J region of IGH was sufficient to deregulate the proto-oncogene. Case A showed a reciprocal IGH-BCL2 gene rearrangement suggesting that the loss of the 5 gene segment was a secondary event. Case B showed a significant number of cells with a diminished 5 segment and an apparent deletion of the 5 region. The fourth case (D) showed a loss of the 3 region proximal to the IGH constant region. This suggests an oncogenic rearrangement with the 5 telomeric IGH region. Since the FISH probe does not cover the constant and VDJ regions, gene fusion could occur anywhere along this gene segment. A review of the literature revealed only one article describing a 5 IGH gene deletion in a patient with chronic lymphocytic leukemia associated with a poor prognosis. However, personal communications suggest that partial IGH deletions may be more common than previously reported, especially with the use of the break apart DNA probe. Histology, pathology, cytogenetic and FISH analyses of these lymphoma cases will be discussed with respect to prognosis.

Quantum Dots Detection for HER2 Standard Reference Material. *Y. Xiao, P. Barker.* Biotechnology Division, National Institute of Standards and Technology, 100 Bureau Drive, Gaithersburg, MD 20899-8311.

Approximately 30% of breast cancers have a cancer-specific genetic amplification of the HER2 gene. The result is that breast cancer cells in some patients have higher levels of HER2 receptor. Because of this, a newly developed drug (trastuzumab, or trade name Herceptin) can be used to treat HER2 positive patients. This drug targets tumor cells that have high HER2 receptor numbers. Two issues render HER2 diagnostic accuracy critical: 1) trastuzumab costs $40,000/year for treatment and 2) a similar receptor in normal heart tissue may also bind drug causing cardiotoxicity, and in some cases, death. Therefore, it is vital that the correct patients are identified for treatment. To avoid unnecessary risk and expense, it is also important to definitively ascertain those breast cancer patients for whom trastuzumab will not be effective. Unfortunately, the two diagnostic tests (FISH and IHC) for HER2 in breast cancer do not always identify the same patient subsets as candidates for drug therapy. So it is important to have HER2 standard reference material (SRM). We created the HER2 BAC clone as FISH probe(1), and designed anti-HER2 chicken antibody for IHC study. We used fluorescein and quantum dots labeled HER2 gene or receptor to directly and quantitatively measure HER2 gene or receptor in whole cells. Unlike organic fluorophores that photobleach during exposure, quantum dots are photostable, allowing quantitative bioimaging. By using 3D deconvolution imaging to capture all informative signals and minimize z-plane focal artifacts, we performed 3D quantitative analysis for HER2 gene copy numbers and HER2 receptor numbers in normal and breast cancer cells with tags detected with fluorescein- and quantum dot-streptavidin conjugates. We found that in breast cancer cells HER2 gene copy numbers was 18 times higher, and HER2 receptor numbers was 17 times higher than normal cells. (Supported in part by NIST HER2 SRM and the Office of Womens Health, NIH). References 1. Yan Xiao and Peter E. Barker, (2004) Nucleic Acids Research, 32 (3), e28.

Skewed X chromosome inactivation is limited to BRCA1 mutation negative breast and ovarian cancer patients.

S.H. Harbord[1], C.J. Brown[1], D. Horsman[2], W.P. Robinson[1]. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pathology, University of British Columbia, Vancouver, BC, Canada.

A higher occurrence of skewed X chromosome inactivation (XCI) has been observed in breast and ovarian cancer with an early age of onset. As BRCA1 is implicated in both early onset breast/ovarian cancer and with the colocalization of XIST to the inactive X-chromosome, we hypothesized that skewed XCI would be limited to BRCA1 mutation carriers and associated with onset of disease. To test this, skewed XCI was evaluated using the methylation based PCR assay at the AR locus in peripheral blood samples from women with hereditary breast/ovarian cancer including: 42 affected BRCA1 mutation carriers, 16 unaffected BRCA1 mutation carriers, 30 BRCA1 mutation negative (22 BRCA2 carriers and 8 negative for BRCA1 and BRCA2 mutation testing) and 42 unaffected relatives. There was no increase in skewing above 90% in the BRCA1 mutation carriers (1 of 42 patients, 2.4%) when compared to unaffected BRCA-1 carriers (1/16; 6.2%) or control women (1 of 25 patients, 4.0%). However, there was an increase in extreme skewing in the BRCA mutation negative group (5 of 30, 17%) as compared to the BRCA1 carrier group (2/58,3.5%) (p=.04; Fishers test). Similar results were obtained using 75% as a cutoff for skewing. These results indicate a potential role for X-chromosome involvement in breast and ovarian cancer pathogenesis that does not involve BRCA1 mutations but may mirror BRCA1 cancer etiology.

Molecular cytogenetic characterization of the 11q13 amplicon in head and neck squamous cell carcinoma. *C. Jin[1], Y. Jin[1], D. Gisselsson[1], S.W. Tsao[2], B. Strömbäck[1], M. Höglund[1], N. Mandahl[1], Y.L. Kwong[3], F. Mertens[1].* 1) Dept Clinical Genetics, University Hospital, Lund, Sweden; 2) Dept of Pathology, Faculty of Medicine, University of Hong Kong Hong Kong; 3) Dept of Medicine, Queen Mary Hospital, Pokfulam Road, Hong Kong.

Amplification of 11q13 DNA sequences or overexpression of *CCND1* is a common finding in head and neck squamous cell carcinoma (HNSCC), identified in about 30% of the cases. However, little is know about how the amplification is initiated or how the amplicon is organized. In order to study the structure of the amplicon in more detail and to learn more about the mechanisms involved in its initiation, prometaphase, metaphase, and anaphase fluorescence in situ hybridization (FISH) with 36 BAC clones spanning a 14 Mb region in chromosome bands 11q12.2 to 11q13.5 was undertaken in nine HNSCC cell lines with homogeneously staining region (hsr). The BAC clones covered oncogenes *CCND1*, *FGF4*, and *EMS1*. FISH analysis showed that the size of the amplicon varied among the 9 cell lines, the smallest being 2.32 Mb and the largest 8.34 Mb. The smallest overlapping region of amplification was approximately 1.64Mb, covering the region from BAC RP11-729E14 to BAC RP11-102B19. Eight cell lines could be further used to study the internal structure of the amplicon. A random pattern of amplified DNA sequences within the amplicon was found in all 8 cell lines. Even within the same cell line, different amplicon structures could be found in different cell populations, indicating that the mechanisms involved in the development of the amplicons in HNSCC were more complex than previously hypothesized. The frequent finding of inverted repeats within the amplicons suggests that breakage-fusion-bridge cycles are important in the initiation, however, the fact that such repeats constituted only smaller parts of the amplicons indicate that they are further rearranged during tumor progression.

The simultaneous occurrence of Trisomy 1, 8 and 10 in Acute Myeloid Leukemia - a Case Report. *L. Karp, S. Gupta.* Laboratory Medicine, North Shore University Hospital, Manhasset, NY.

The presence of cytogenetic abnormalities with favourable and unfavourable prognostic significance is the strongest predictor of outcome in acute myelocytic leukemia and acute lymphocytic leukemia. Although well described in ALL, hyperdiploidy and teraploidy are rare cytogenetic abnormalities in MDS and AML. We present a 84 year old male with history of lethargy and fatigue:hemoglobin 9.5g/DL, platelets $56x10^9$/L, leucocytes $26x10^9$/L with 11% neutrophils, 75% lymphocytes, 4% monocytes and 3% eosinophils. Bone marrow examination showed hypercellular bone marrow with immature infilterate, erythroid hyperplasia, dyserythropoises, dysplastic megakaryocytes, focal lymphoid aggregates and increased iron stores. A minimal myeloperoxidase positivity was observed, chloroacetate esterase was positive in maturing myeloid component, naphthyl butyrate esterase negative. Flow cytometery results showed 26% myeloblasts, positive for CD34, CD117, HLA-Dr, CD33, CD13, CD15 and CD4. A diagnosis of acute myeloid leukemia was made. Chromosome studies of bone marrow cells revealed a kayotype with 48,XY,+1,del(5)(q22q33),+8,+10,-17[18]/ 46,XY[2]. Within various subtypes of AML, trisomies affecting chromosomes other than 8 are relatively uncommon. In AML trisomy 10 as sole karyotypic abnormality is a rare finding and karyotype with trisomy 1 as only chromosome abnormality is not known. Hyperdiploidy is present in 18% to 36% of all cases of ALL, and has favourable prognostic significance. Only a few cases of hyperdiploidy are known in AML, with most frequent gain of chromosomes 8, 21 and 19. This is the first report of the simultaneous occurrence of trisomy 1, 8 and 10 in acute myeloid leukemia.

Detection of cryptic abnormalities in pediatric precursor B-cell acute lymphoblastic leukemia using an interphase FISH panel. *K.D. Tsuchiya, C. Gray, D. Williams, K.E. Opheim.* Dept of Laboratories, Children's Hosp & Regional Med Ctr, Seattle, WA.

Cytogenetic results in precursor B-cell acute lymphoblastic leukemia (pre-B ALL) are critical for determining prognosis and treatment stratification. Despite the importance of detecting cytogenetic aberrations in pre-B ALL, these cases remain challenging due to difficulties in obtaining sufficient numbers of high quality metaphase cells for analysis. We have instituted an interphase FISH panel for the detection of chromosome abnormalities that have known or suggested clinical significance in pre-B ALL. This panel includes probes for identifying MLL, BCR-ABL, and ETV6-RUNX1 (TEL-AML1) rearrangements, and deletions of 9p21. Over a one year period, we have applied this panel to 50 consecutive cases of pre-B ALL (45 initial diagnoses and 5 relapses). The frequency of abnormalities for initial diagnoses by G-banded analysis alone was 76% (34 out of 45 cases). This frequency increased to 91% (41 out of 45 cases) when FISH was combined with karyotyping. Cases that were apparently normal by G-banding, but abnormal by FISH included four cases with an ETV6-RUNX1 fusion, two cases with loss of one ETV6 signal, and one case with an extra copy of BCR due to trisomy 22. Another FISH finding of potential significance consisted of 24% of cases (11 out of 45 cases) showing deletion of 9p21 (four cases with homozygous deletions), five of which would not have been detected without the use of FISH. In two of these patients, cryptic 9p21 deletions occurred in the setting of high hyperdiploidy with trisomies for chromosomes 4, 10, and 17. The latter finding usually indicates a good prognosis, while cytogenetically visible 9p abnormalities have been reported to confer an increased risk of treatment failure (Heerema et al., Blood 94:1537,1999). The impact of cryptic 9p21 deletions identified by FISH in the setting of otherwise favorable cytogenetic findings remains to be determined. In conclusion, while there is no substitute for thorough G-banded analysis, interphase FISH can increase the detection of potentially clinically significant cryptic cytogenetic abnormalities in pre-B ALL.

FISH analysis of B-cell non-Hodgkin lymphomas with t(8;14;18): Concurrent translocation of BCL2 and MYC to the same IGH locus. *J. Sanchez, D. Kramer, A. Adeyinka.* Medical Genetics, Henry Ford Health System, Detroit, MI.

A t(14;18)(q32;q21) involving the IGH locus on 14q32 and BCL2 locus on 18q21 is associated with follicular lymphoma, whereas a t(8;14)(q24;q32) involving the MYC locus on 8q24 is strongly associated with Burkitt lymphoma and to a lesser degree with large cell lymphoma or multiple myeloma. A few cases of highly malignant leukemia/lymphoma carrying both a t(8;14) and a t(14;18) have been reported. In these cases, each translocation usually involves a different chromosome 14 homolog. We present molecular cytogenetic findings in three cases of B-cell NHL with t(8;14;18)(q24;q32;q21). Two cases had near-diploid karyotypes and one had a near-tetraploid karyotype. Bone marrow sample cells were analyzed using commercially available dual-color dual-fusion probes for MYC/IGH and IGH/BCL2. Interphase FISH analysis showed the presence of IGH-MYC and IGH-BCL2 fusions in all three cases. The derivative chromosomes were better characterized by metaphase FISH analysis of cells from the two samples with diploid karyotypes. They include a der(8)(8pter8q24::14q32::18q2118qter) with MYC-IGH and IGH-BCL2 fusion signals, a der(14)(14pter14q32::8q248qter) with MYC-IGH fusion signal and a der(18)(18pter18q21::14q3214qter) with IGH-BCL2 fusion signal. There was a normal chromosome 14 in each of these two cases. These FISH findings suggest that the t(8;14;18) was derived from a translocation between chromosome 8 and a pre-existing der(14)t(14;18)(q32;q21). Reports exist of a few lymphoma cell lines with cytogenetically detected t(14;18) or t(8;14;18) and simultaneous activation of both BCL2 and MYC, the t(8;14) being cryptic in the cell line with t(14;18). Presumably, the molecular consequence of the t(8;14;18) in the present set of lymphomas is the concurrent activation of both BCL2 and MYC, similar to tumors with coexisting t(8;14) and t(14;18) that involve separate IGH loci, as a pathway of tumorigenesis and/or tumor progression.

Identification of a complete genomic BRCA1 deletion in six belgian families. *K. Segers, P. Germeau, V. Bours.* Dept Genetics, Ctr Hosp Univ, Liege, Belgium.

Inherited mutations in the BRCA1 and BRCA2 genes are known to confer a predisposition to breast and ovarian cancer. The vast majority of mutations found in the BRCA1 gene are point mutations or small insertions and deletions scattered over the whole coding sequence and the splice junctions. Large deletions and duplications including one or several exons of the BRCA1 gene have also been described. Here we describe the complete loss of one copy of the BRCA1 gene at the genomic level. BRCA1 and BRCA2 are studied in our laboratory. A search for gross genomic rearrangement is first performed by MLPA. If normal, the screening for point mutation is done by DHPLC and sequencing. Nine patients representing six families and presenting a particular pattern for the BRCA1 gene were identified during the MLPA screening. All the amplification peaks were decreased suggesting a complete deletion of the gene. To date, no other patient presenting a complete BRCA1 deletion has been identified in Belgium. As our laboratory doesnt perform FISH analysis, several methods were used to confirm the absence of one BRCA1 copy. Seven common polymorphisms S1613G, S1436S, P871L, L771L, D693N, S694S and K1183R were studied. All the deleted patients were hemizygous for one allele. The highly polymorphic D17S855 microsatellite was also genotyped. All the deleted patients were hemizygous for one allele while the other members of the family that could be tested were all heterozygous. To exclude any error inherent to our laboratory, some samples were tested by MLPA in an independant laboratory. The results confirm those obtain in our lab. And finally, the samples were tested by a second MLPA kit that has been developed to confirm any abnormality observed with the first kit. The previous results were all confirmed by this second analysis. The absence of one BRCA1 copy is now confirmed. However, the extend of this deletion is not defined yet. We were not able to connect all our patients but the informations we have at the present time are poor. We can however speculate that all these families could be related to a common ancestor but we do not have any evidence for such a relationship.

Interactions of sequence variants in IL-1 receptor-associated kinase 4 (IRAK4) and Toll-like receptor 1 (TLR1) genes increase prostate cancer risk. *J. Sun[1], K. K. Augustsson-Balter[2], F. Hsu[6], M. Hedelin[2], S.L. Zheng[1], H.O. Adami[2], B. Chang[1], J.E. Johnasson[4], T. Li[1], A.R. Turner[1], G. Li[1], W.B. Isaacs[5], J. Xu[1,6], H. Gronberg[3].* 1) Ctr Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Dept. of Medical Epi and Biosta, Karolinska Inst,Stockholm, Sweden;; 3) Dept.of Radiation Sciences, Oncology, Univ of Ume, Ume, Sweden;; 4) Dept. of Urology and Clinical Medicine, rebro Univ Hospital, Sweden and Regional Oncological Center, Univ Hopsital Uppsala, Sweden;; 5) Dept. of Urology, Johns Hopkins Medical Inst, Baltimore, MD; 6) Dept. of Public Health Sciences, Wake Forest Univ Sch of Med,.

Our previous research supports the hypothesis that the three inflammatory genes in the Toll like receptor (TLR1-6-10) gene cluster are involved in the prostate cancer risk. Interleukin-1 receptor-associated kinase 1 and 4 (IRAK1 and IRAK4) are critical components in the Toll/IL-1 receptor (TIR) signaling pathway, and they mediate downstream signaling following the binding of liands to TLRs. Considering the important role of IRAKs in the TIR signaling pathway, we proposed two hypotheses: First, sequence variants in IRAK1 and IRAK4 are associated with susceptibility to prostate cancer. Second, interactions between sequence variants in IRAK1/4 and TLR1-6-10 confer stronger risk to prostate cancer. To test these hypotheses, we performed a systematic genetic analysis of IRAK1 and IRAK4 genes by evaluating 11 single nucleotide polymorphisms (SNPs) (four in IRAK1 and seven in IRAK4) among 1,383 newly diagnosed prostate cancer patients and 780 age and residence matched controls in Sweden. While the SNPs in IRAK1 and IRAK4 alone are not significantly associated with prostate cancer risk, two SNPs in IRAK4, when combined with the risk genotype at TLR6-1-10, conferred a strong risk to prostate cancer. In particular, men with the combined genotypes of TLR1-6399 (CT/CC) and IRAK4-7987C/G (CG/CC) have a significantly increased risk to prostate cancer, with an OR of 9.68 (P = 0.03), when compared with men who have wild-type genotypes at these two SNPs. Our study supports a role of the TIR signaling pathway in prostate cancer risk.

microRNA signature in breast cancer detected by a novel microsphere-based array, mirMASA. *Y. Feng[1], J. Han[2], Q. Yang[2], C. Lu[2].* 1) Dept Pharmacology, Emory Univ, Atlanta, GA; 2) Genaco Inc.

MicroRNAs (miRNAs) are an evolutionarily conserved novel class of small non-coding RNAs, which functions in gene silencing by posttranscriptional mechanisms. More than 300 miRNAs are encoded by the human genome. The expression level of many miRNAs is vigorously regulated during normal development. Moreover, emerging evidence indicates misregulation of miRNAs in human cancer, suggesting that miRNAs may play important roles in governing cell growth and development. We have developed a novel microsphere-based miRNA detection array, called mirMASA, which employs locked nucleic acids (LNA) to stabilize hybridization and allows direct capture of miRNAs in a multiplex reaction with digital output in real time. This technology offers greatly improved sensitivity and specificity as compared to conventional microarrays and northern hybridization. Further analysis reveals that mirMASA preferentially detects mature miRNAs over their precursors, and can distinguish closely related miRNA isotypes. Using mirMASA, we compared miRNA profiles in breast cancer specimens with that in normal breast tissue derived from the corresponding patients. Our results revealed a small group of miRNA that are abnormally expressed in all the cancer samples. More interestingly, these misregulated miRNAs gives two distinct ¡signature patterns¡ in different cancer samples, based on which a mathematical model is derived for diagnostic prediction of breast cancer. Hence, our studies established a highly sensitive and specific system for miRNA detection, which provided compelling evidence that misregulation of miRNA may serve as a signature for cancer genesis.

An investigation of cholesterol biosynthesis by cortisol-producing, benign tumors of the adrenal gland. *C. Wassif[1], A. Horvath[2], A. Sterner[2], F. Porter[2], C. Stratakis[1, 2].* 1) NICHD/HDB/NIH, Bethesda, MD; 2) NICHD/DEB/NIH, Bethesda, MD.

Primary pigmented nodular adrenocortical disease (PPNAD) and other adrenal tumors (AT) may be caused by inactivating *PRKAR1A* mutations. cAMP/PKA pathway abnormalities have been found in sporadic cortisol-producing adenomas (CPAs) and the massive macronodular form of bilateral adrenocortical disease (MMAD). The cAMP pathway regulates many of the steps involved in cholesterol and steroid biosynthesis. Up-regulation of the enzymes involved in steroidogenesis has been shown in ATs; in this study, we investigated cholesterol biosynthesis by PPNAD (both assotiated with *PRKAR1A* mutations and caused by yet unknown genetic defects), CPAs, and MMAD. We analyzed 24 ATs for cholesterol and lathosterol content by gas chromatography/mass spectrometry, corrected for protein and tissue mass. We then looked at the expression of hydroxy-methyl-glutaryl-CoA reductase (*HMGCR*), LDL-receptor (*LDLR*), sterol delta-24 reductase (*DHCR24*), the reverse cholesterol transport-involved ATP-binding cassette, subfamily A, member 1 (*ABCA1*) and steroidogenic acute regulatory protein (*STAR*) in the tumor samples against mRNA from normal human adrenals. The lathosterol/cholesterol ratio of CPAs was 0.67 + 0.53 which was higher than that of PPNAD (0.12 + 0.06, $p<0.01$) and of MMAD (0.24 + 0.20, $p<0.05$). There were no differences between PPNAD and MMAD, and between ATs with and without *PRKAR1A* mutations ($P>0.5$). Consistent with the above, CPAs also had a tendency for higher expression of the *HMGCR*, and *LDLR* genes ($P=0.1$) and decreased expression of *ABCA1* ($P=0.06$); there were no differences between PPNAD and MMAD and tumors with and without *PRKAR1A* mutation. There were no differences in *DHCR24* and *STAR* expression between the various AT types. We conclude that sporadic cortisol producing tumors behave as cholesterol-starving tissues when compared to PPNAD, MMAD, and other ATs: increased cholesterol biosynthesis in the former is supported by a higher lathosterol/cholesterol ratio and *HMGCR* and *LDLR* expression, and a down-regulation of the cholesterol efflux-controlling *ABCA1* gene. *PRKAR1A* mutations do not appear to have distinct effect on these measures of cholesterol biosynthesis by ATs.

Immunohistochemical Analysis of BRCA1-, BRCA2- and BRCAx-related Familial Breast Tumors. *R.S. Seitz[1], B.Z Ring[1], M.T. Schreeder[2], R. Beck[1], D.T. Ross[1], G. Chenevix-Trench[3], Kathleen Cuningham Foundation Consortium for Research into Familial Breast Cancer.* 1) Applied Genomics, Inc., Huntsville, AL. and Sunnyvale, CA; 2) Comprehensive Cancer Institute Huntsville, AL; 3) Cancer & Cell Biology Division, Queensland Inst Med Research, Brisbane, QLD, Australia.

cDNA microarray studies have revealed reproducible breast tumor subtypes distinguished by characteristic gene expression signatures (Perou 2000; Sorlie 2001). Patients with BRCA1 mutations are highly enriched for expression of the 'basal-like' gene expression profile relative to sporadic cases (Sorlie 2003). Similarly, immunohistochemistry studies have demonstrated that BRCA1 associated tumors are associated with basal cytokeratin (CK5/6) expression (Foulkes 2003). We have generated over 700 novel antisera targeted by gene expression data in order to characterize the biologic and clinical diversity of breast cancer in paraffin blocks from tumor cohorts. We have identified a subset of forty-five reagents that distinguish reproducible heterogeneity in independent cohorts and have identified novel prognosticators for estrogen-receptor expressing breast carcinoma (Ross, SABCS, 2004). In order to explore the association between genetic predisposition to breast cancer and immunohistochemical subtypes of breast cancer, the Kathleen Cuningham Foundation Consortium has developed a pilot tissue microarray (TMA), containing 34 familial breast cancer cases (12 BRCA1-, 17 BRCA2- and 15 BRCAx-related) and 12 patients with sporadic tumors. A refined immunohistochemical profile of basal-like tumors will be compared to the protein expression profiles in BRCA1-associated patients. Immunohistochemical staining data with the panel of antisera will be presented to further explore whether a protein expression phenotype can distinguish familial from sporadic breast tumors, and whether there is an association between other mutation subtypes and immunohistochemistry phenotype.

Estrogen-metabolizing enzyme polymorphisms and risks of breast cancer versus fibroadenoma. *E. Corder[1], L.A. Hefler[2].* 1) Demographic Studies, Duke Univ, Durham, NC; 2) Department of Obstetrics and Gynecology, Medical University Vienna, Vienna Austria.

Estrogen-metabolizing enzyme gene variants have been individually associated with risks of breast cancer (BRCA) and fibroadenoma (F) (Hefler et al., 2004). Distinct risk sets of polymorphisms, i.e. multilocus genotypes, have not been identified. To this end, we jointly investigated 10 candidate genotypes for BRCA (n=393) and F (n=154) patients and for control subjects (n=1936), cross-classified according to age (< age 50, 50-64 years, age 65+). The data analytic approach was a form of latent classification called grade-of-membership analysis (GoM) (Woodbury et al., 1978). The following 10 SNPs were analyzed using sequencing-on-chip technology via a solid-phase polymerase chain reaction assay performed on oligonucleotide microarrays: catechol-O-methyltransferase Val158Met G-->A, 17-beta-hydroxysteroid dehydrogenase type 1 vIV A-->C, cytochrome P-450 (CYP) family 17 A2 allele T-->C, CYP1A1-1 MspI restriction fragment length polymorphism (RFLP) T-->C, CYP1A1-2 Ile462Val A-->G, CYP19-1 Trp39Arg T-->C, CYP19-2 Arg264Cys C-->T, CYP19-3 Cys1558Thr C-->T, steroid-5-alpha reductase type 2 Val89Leu G-->C, and vitamin D receptor BsmI RFLP. Three GoM groups were requested. They were labeled as I, II & III and differed in disease frequencies (BRCA, F): I: 4%, 31%; II: 45%, 0%; III: 13%, 0%. They had distinct multilocus genotypes. Briefly, certain genotypes were limited to group II: CYP17(3), CYP1A1_1(2,3), CYP1A1_2(2,3), and CYP19_3(3), others to group I: COMT(3), SRD5A2(3), and VDR(3). Individual-level membership, i.e. resemblance, scores were used to predict disease status in logistic models [OR (95% CI)], according to age group. Group II membership predicted BRCA risk: 0.7 (0.3-1.6), 29 (15-59), 3.0 (1.0-9), respectively. Group I membership predicted F risk: 8.2 (4-17), 25 (10-68), n/a. We conclude that distinct sets of polymorphisms in genes that metabolize estrogen predict BRCA and F, most effectively (ORs > 25) for disease occuring in late middle age.

Gene-expression profiles predict survival of patients with stage I non-small cell lung cancer: Results from a meta-analysis of four microarray studies. *Y. Lu[1], R. Yao[1], Z. Sun[2], W. Lemon[1], M. Watson[1], R. Govindan[1], P. Yang[2], Y. Wang[1], M. You[1].* 1) The Alvin J Siteman Cancer Center,Washington Univ. in St. Louis, St. Louis, MO; 2) Department of Health Science Research, Mayo Clinic, Rochester, MN.

Lung cancer is the most common cancer with the lowest overall 5-year relative survival rate of any tumor type. Patients diagnosed with stage I lung cancer have an extremely variable prognosis, ranging from relapse or death within 6 months to disease-free survival beyond five years. Microarray expression profiling has been widely used to identify genes related with lung cancer subtypes and development. To extract maximum value from the available microarray data, we applied a meta-analysis to search for commonly differentially expressed genes related to survival time (less than 3 years and greater than 5 years), cancer subtypes (ADC and SQCC), cancer stage (T1N0 and T2N0) and their interactions in lung cancer. We obtained data sets from four different microarray studies on lung cancer. We selected a consensus set of 4905 genes measured in all of the four studies and performed systematic bias adjustment in these data using Distance Weighted Discrimination (DWD). Meta-analysis identified 105, 181 and 28 genes related to survival, cancer subtype and stage respectively in the combined data, which were consistently altered in all of the four studies. Of the genes identified as differentially expressed, several were validated using RT-PCR. Functional annotation of these genes revealed that genes associated with cell growth and/or maintenance potentially determine survival time in lung cancer. Additionally, we used a penalized Cox regression model to predict survival after surgery for patients with stage I lung cancer and evaluated its performance in prediction by splitting the data into training and testing sets and using the time dependent receiver operating characteristic (ROC) curves. Kaplan-Meier curves showed very significant difference ($p<0.001$) in overall survival between high-risk and low-risk groups. Our findings provide a strategy to predict which stage I lung cancer patients may benefit from a surgical approach.

Statistical and computational analysis of missense substitutions in BRCA2. *S.V. Tavtigian[1], A.M. Deffenbaugh[2], S. Monnier[1], L. Barjhoux[1], F.J. Couch[3].* 1) IARC, Lyon, France; 2) Myriad Genetic Laboratories, Inc., Salt Lake City, USA; 3) Mayo Clinic College of Medicine, Rochester, USA.

Genetic testing of high-risk cancer susceptibility genes contributes to the medical management of individuals who may have inherited risk of one or more cancers. Mutation screening of the breast and ovarian cancer susceptibility genes BRCA1 and BRCA2 is one such widely used genetic test. Clinical testing for deleterious mutations in these genes achieves very high sensitivity but also detects many unclassified variants, most of which are missense substitutions. We have developed in silico techniques that allow us to survey large numbers of missense substitutions in a specific gene, divide the substitutions into sets that are highly enriched for neutral variants or highly enriched for deleterious variants, and estimate average risks associated with the sequence variants in each defined set. Applied to BRCA1 or BRCA2, the basic requirements for the analysis are: a table of missense substitutions observed during mutation screening of high-risk individuals, including observational data such as the number of times that each substitution was observed, the number of times it was observed in an individual who was also found to carry a high risk mutation in that gene, and the number of times it was observed in an individual who was also found to carry a high-risk mutation in the other gene; and an informative protein multiple sequence alignment of the gene of interest. Although risks attributable to these two genes are similar, analysis of substitutions has focused on BRCA1. Here we present the first large-scale analysis of missense substitutions in BRCA2. Using a multiple sequence alignment of 9 full-length BRCA2 orthologs including sequences from pufferfish and sea urchin, we have analyzed all 1,143 missense substitutions that were observed during a series of 60,000 full sequence BRCA2 tests. As observed previously for BRCA1, we find that many of the missense substitutions falling at highly conserved positions in the BRCA2 alignment are likely to be deleterious and that the longer the period over which the position has been invariant, the stronger the evidence that this is so.

Genome-wide expression analysis identifies cholesterol homeostasis genes as downstream targets of progesterone in ovarian surface epithelial cells. *J.E. Willett-Brozick, J.A. DeLoia, J. Patterson, L.C. Hsu, C.B. Wilcox, B.E. Baysal.*
Ob/Gyn, Univ Pittsburgh Sch Med and Magee-Womens Research Institute Pittsburgh, PA.

Background and Methods: Ovarian cancer, with a lifetime incidence of approximately 1%, accounts for more deaths than all other gynecologic malignancies combined. Ovarian cancer most often derives from ovarian surface epithelial cells. Several lines of evidence strongly suggest that progesterone exposure protects against ovarian cancer. However, the underlying mechanisms of this protection are incompletely understood. Here, we established short term *in vitro* cultures of non-neoplastic ovarian surface epithelial cells from six subjects, exposed the cells to progesterone (10^{-6} M) for five days and performed transcriptional profiling with oligonucleotide microarrays containing over 22,000 transcripts.

Results: We found that, in three of the six cultures, transcripts encoding 14 cholesterol biosynthesis enzymes, including the rate-limiting enzyme 3-hydroxy-3-methylglutaryl coenzyme A reductase, insulin-induced gene 1, low density lipoprotein receptor, ABCG1, endothelial lipase, stearoyl- CoA and fatty acid desaturases, long-chain fatty-acyl elongase, and MAC30 were upregulated; steroidogenic acute regulatory protein and ABCC6 were downregulated by progesterone. We confirmed the microarray results for a subset of the genes by quantitative RT-PCR analysis, and in one of three additional ovarian surface epithelial cell cultures. The cultures derived from a BRCA1 mutation carrier and another subject with early-onset breast cancer showed no evidence of transcriptional response to progesterone.

Conclusions: These findings indicate that progesterone regulates a very broad network of genes involved in cholesterol homeostasis in certain ovarian surface epithelial cells and provide new insights for understanding the protective role of progesterone against ovarian cancer.

Clear cell ependymoma is characterized by trisomy 19. *E. Rousseau[1], M.M. Ruchoux[2], M. Vikkula[1], C. Godfraind[3], the two last authors contributed equally.* 1) Lab of Human Molecular Genetics, Christian de Duve Institute, Brussels, Belgium; 2) Lab of Pathology, CHU-Lille, France; 3) Lab of Pathology, University of Louvain and St Luc Hospital, Brussels, Belgium.

Ependymal tumors present a broad spectrum of clinical and histological subtypes. Few genetic clues have been reported suggesting that these different tumor subtypes follow independent genetic pathways during tumorigenesis. We describe a new genetic association to one ependymal tumor subtype reinforcing this concept as well as providing a new diagnostic tool. A series of 149 paraffin-embedded ependymal tumors were analysed by microsatellites in order to detect chromosome 9 monosomy, which has been implicated in 10-15% of ependymal tumors. Ten tumors presenting this abnormality were identified. They all presented histologically compact appearance. They bore a rich vascular network that consisted of regularly dispersed, geometrically branching capillaries. Tumor cells were regularly distributed and their cytoplasm could appear as clear (n=4). Areas of classical ependymal architecture were observed in some tumors. These tumors were classified as clear cell ependymomas. These tumors and additional ones, some of which lacked monosomy 9, but with similar histological findings, were further studied by array-CGH (Spectral Genomics). This allowed us to observe trisomy 19 in all tumors. Additional recurrent aberrations were found to involve chromosomes 1, 7, 11, 13, 17 and 20. Correlation between a genetic anomaly and ependymal tumors has never been described. Meanwhile, other cerebral tumors, including small cell glioblastomas and oligodendrogliomas, have been associated with, EGFR amplification and 1p/19q deletion, respectively. Such correlations are important tools for diagnosis. They also suggest the genetic pathways implicated in tumorigenesis. (catherine.godfraind@anpg.ucl.ac.be).

Central nervous system atypical teratoid/rhabdoid tumor in a patient with Beckwith-Wiedemann syndrome. *N. Unanue[1], J. Biegel[1], F. Zhang[1], K.L. Ciprero[1], R. Weksberg[2], A. Judkins[3], B. Lange[4], J. Belasco[4], E.H. Zackai[1].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada; 3) Pathology Core Laboratory, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Oncology, Children's Hospital of Philadelphia, Philadelphia, PA.

A patient was diagnosed at 10 month of age with Beckwith Wiedemann Syndrome (BWS) based on the findings of macrosomia (birth weight and birth length > 90th percentile), macroglossia, umbilical hernia, facial hemangioma and anterior ear creases. Molecular confirmation of BWS was obtained from methylation analysis of chromosome 11p15. These studies revealed hypomethylation of the maternal copy of LIT1, which silences the expression of a number of maternal genes, including CDKN1C. The child was followed by serial abdominal ultrasounds and AFP levels to rule out abdominal tumors, which were normal. At 20 months of age, after a head CT scan due to a sinus infection, he was noted to have a large fourth ventricle mass. The biopsy revealed an atypical teratoid/rhabdoid tumor. Molecular genetic analysis demonstrated a mutation in the INI1/hSNF5 rhabdoid tumor suppressor gene at chromosome 22q11.2. A C472T point mutation in exon 4 is predicted to result in an ArgStop codon change, and premature truncation of the protein. This was accompanied by loss of the wild type allele. This is the first case of an AT/RT seen in association with BWS, and suggests that patients with BWS may be susceptible to a variety of embryonal tumors not limited to rhabdomyosarcoma, Wilms tumor and hepatoblastoma. Previously reported loss of heterozygosity studies of renal rhabdoid tumor (Schofield et al) has implicated both loss of 22q11.2 and 11p15.

The relationship between BRCA1 mutations and uterine serous papillary carcinoma in Ashkenazi Jewish women. *R.D. Legare, E.K. Brown, J.S. Wilbur.* Program in Women's Oncology, Women & Infants' Hospital, Brown University Medical School, Providence, RI.

Introduction: Several studies report a possible correlation between BRCA1 deleterious germline mutations and uterine serous papillary carcinoma (USPC) in Ashkenazi Jewish women. These studies outline a total of eight cases of women diagnosed with USPC who were also found to have inherited a BRCA1 mutation. Four women had the 187delAG mutation, and four women had the 5382insC mutation, which are two of the three most common mutations found in Ashkenazi Jewish individuals. Also, of the women who were diagnosed with USPC, twelve had a previous history of breast carcinoma, and sixteen had at least one first-degree relative with breast or ovarian cancer.

Case Study: This case report initially presented with a 51 year old Ashkenazi Jewish woman who was diagnosed with left breast DCIS at age 43 and ovarian cancer at age 50. She pursued comprehensive cancer genetic counseling and tested positive for the BRCA1 mutation 187delAG. Her paternal and maternal lineages were both suspicious for harboring this deleterious mutation. Since her mother had died of USPC, site specific BRCA1 gene analysis was able to be performed on her paraffin tumor block which was found positive for the 187delAG mutation confirming maternal inheritance.

Conclusion: This abstract reports another case of USPC in a heterozygote BRCA1 Ashkenazi Jewish woman. Therefore, USPC may be a manifestation of hereditary breast ovarian cancer syndrome (BOCS) in Eastern European Jewish patients and should be included in routine pedigree analysis. Further, a history of uterus carcinoma in this cohort should necessitate thorough review of pathology to rule out USPC. A larger study of USPC is necessary to substantiate its relationship to BOCS and may possibly impact the consideration of hysterectomy in individuals pursuing prophylactic oophorectomy.

Review of Chronic Lymphocytic Leukemia cases with Ig/MYC translocation. A Burkitts lymphoma moniker translocation t(8;14)(q24;q32) in a Chronic Lymphocytic Leukemia patient had a cryptic deletion in the MYC region. *K. Reddy[1], R. Satyadev[1], D. Bouman[1], M. Hibbard[1], G. Lu[1], R. Paolo[2].* 1) US Labs, Irvine, CA; 2) Cancer Center of the Rockies, Fort Collins, CO.

A 53-year-old male was diagnosed with chronic lymphocytic leukemia [CLL]/small cell lymphoma [SLL] following splenectomy. The spleen and bone marrow [BM] showed 93% and ~70% of the viable cells were monoclonal lambda B-cells co-expressing CD5 with CD20, CD19, CD23, CD22, CD38, and low FMC-7. The smear showed a marked increase in small, mature lymphoid cells, with <2% prolymphocytes. The BM karyotype was 46,XY,t(8;14)(q24;q32),-18,+mar[3]/46,XY[27]. FISH: atypical interphase result with IgH(green)/MYC(red) dual fusion signal probe of one fusion, 2 green and one red signals in 70% of the cells and the expected t(8;14) pattern with MYC dual red-green split apart probe in 62% of the cells, indicated a cryptic deletion. Sequential FISH on a GTG-metaphase with t(8;14)showed a single fusion signal on derivative chromosome 8 and only a green signal on der(14) for IgH/MYC dual fusion probe and a green signal on der(14), red signal on der(8) and fusion signal on the normal chromosome 8 for MYC split apart probe. Hence, the apparently balanced t(8;14) had a cryptic deletion in between the red and the green regions flanking the MYC gene of the MYC split apart probe or 128,585,631 bp-130,226,339 bp [~1.6Mb] from 8pter. The single IgH/MYC fusion on der(8), green signal on der(14) and the consistent small MYC signal in the fusion compared to the normal MYC signal in interphases denoted a break and loss of the distal MYC probed region i.e. breakpoint to 129,141,156 bp and probably included the MYC gene. Post-chemotherapy, a decrease in the disease load, with the residual B-cells ~10% of the total population and aberrant FISH signal patterns for IgH/MYC and MYC split apart probes in 8% and 10% interphases, respectively was observed. The karyotype was 47,XY,t(8;14),-18,+2-3mar[cp2]/46,XY[18]. The rarity of t(8;14) in CLL, plus the cryptic deletion in the MYC gene region in our patient with CLL suggests an agressive clinicopathological role for MYC translocations in CLL.

Automated Detection and Analysis of Circulating Tumor Cells. *M.W. Kilpatrick[1], F. Tafas[1], A. Seppo[1], I. Ichetovkin[1], Y. Kim[1], S. McGregor[2], G. Yardy[2], W.F. Bodmer[2], P. Tsipouras[2].* 1) Ikonisys Inc, New Haven, CT; 2) Cancer Research UK, WIMM, Oxford, UK.

Identification and analysis of rare circulating carcinoma cells has great potential; for detection of disease recurrence or minimal residual disease following treatment, or screening for malignancies. The challenge to the utilization of rare tumor cells diagnostically is to be able to accurately detect, quantify and analyse cells present in small numbers in a large, complex cellular background. The *Ikonisys*^{TM} platform is a customized system developed specifically for cell identification and analysis by automated fluorescence microscopy. All steps including slide loading, exposure setting, focusing, scanning, image capture and analysis, and slide unloading are accomplished in a completely unattended manner. This allows analysis of samples for the presence of rare cells avoiding complex purification procedures which a) risk loss of the cells being sought, b) are often unsatisfactory for scanning millions of cells or c) create unresolved clusters of normal and cancer cells. Initial experiments using dilutions of cultured tumor cells in a normal lymphoblastoid cell line, identified as few as 1 cell in 10^6 background cells. Samples were stained with two antibodies, Cam5.2 (anti-cytokeratin 8,18,19) and AUA1 (anti-EpCAM). Analysis of 20ml peripheral blood samples from 3 prostate cancer patients identified Cam5.2 +ve/AUA1 -ve cells in 2 patients, but identified 7 Cam5.2 +ve/AUA1 +ve cells in a patient with bone metastasis and extensive lymph node involvement. The automated slide scanning algorithms identify potential tumor cells at 5x magnification, based on the presence of Cam5.2 signal, and image all such cells at 50x for both Cam5.2 and AUA1 signal. In addition, slides can be scanned following combined antibody and FISH staining, and both antibody and FISH signals imaged at 50x, demonstrating the potential for further analysis of identified tumor cells. To date, the time-consuming search for rare cells makes it impractical to phenotype circulating tumor cells in depth. Further development of the *Ikonisys*^{TM} platform has great potential in the screening and diagnosis of cancer.

Linkage analysis and comparative genomic hybridisation in a large familial prostate cancer pedigree. *L.M. FitzGerald[1], J.D. McKay[1,2], J. Stankovich[3], D. Challis[4], J. Brohede[5], J. Slavin[6], G. Hannan[5], R. Thomson[1], S. Quinn[1], D. Venter[1,7], J.L. Dickinson[1].* 1) Genetic Epidemiology, Menzies Research Institute, Hobart, Tasmania, Australia; 2) International Agency Against Cancer Research, Lyon, France; 3) Walter and Eliza Hall Institute of Medical Research, Parkville, Melbourne, Australia; 4) Histopathology Department, Royal Hobart Hospital, Hobart, Tasmania, Australia; 5) CSIRO Molecular Science, North Ryde, Sydney, New South Wales, Australia; 6) Department of Anatomical Pathology, St. Vincent's Hospital, Melbourne, Australia; 7) Mater Medical Research Institute, South Brisbane, Australia.

The complex genetic nature of familial prostate cancer (PC) has meant that the identification of the genes predisposing towards this disorder has proven challenging. The study of single large pedigrees provides considerable power to detect linkage, and also a degree of genetic homogeneity, both crucial to the elucidation of disease genes in complex disorders. We have combined the two technologies of SNP array analysis and Comparative Genomic Hybridisation in a large familial PC family originating from Tasmania, Australia. Analysis of the high-resolution GeneChip Human mapping 10K microarray, followed by targeted microsatellite genotyping, provided further evidence for linkage to the centromeric region of chromosome 5 (5p13-q12). Eight cases from the pedigree inherited a shared haplotype in this region and Simwalk2 analysis of microsatellite data gave a Statistic B score of 1.88 (p=0.013). High resolution BAC a-CGH in the same pedigree identified recurrent somatic genomic loss on 7p21 and 19p13.3, regions that have been identified in previous PC CGH studies. One patient who contributed to the evidence for linkage at 5p13-q12, also showed a gain of genetic material across this same region. These findings provide further evidence for a potential candidate prostate cancer gene on chromosome 5 and present insights into the somatic events of tumourgenesis.

Incidence of genomic markers detected by FISH and their correlation with CD38 in B-cell chronic lymphocytic leukemia. *G. Lu, A. Anthony, C. Yue.* Department of Pathology, US LABS, Irvine, CA.

B-cell chronic lymphocytic leukemia (B-CLL) is the most common adult leukemia. Studies on characteristic genomic markers of B-CLL have made significant progress in the diseases diagnostic and prognostic evaluation. The most frequent markers detected by FISH are deletions at 13q14, 17p13/P53, and 11q22-23/ATM, trisomy 12 as well as IgH rearrangements. High CD38 expression, originally described as a surrogate for unmutated IgVH genes, has also recently been used to evaluate aggressive B-CLL. Correlation of the chromosomal abnormalities with CD38 expression has been studied; however, there has been an evidence of discordant results between the few groups in the literature. The aim of this study was to establish the correlation of the different genomic markers with CD38 expression. This study included a total of 160 cases of B-cell CLL with FISH evaluation, conventional cytogenetics study, and flow cytometric analysis. Of the 160 cases, 107 (66.9%) were found to be FISH positive, whereas only 34 (21.3%) showed clonal abnormalities detected by conventional cytogenetics technique. Of the 107 FISH abnormal cases, as the sole or as one of the multiple changes, 11q/ATM deletion, 13q Deletion, 17p/P53 deletion, trisomy 12, or IgH rearrangement, was observed in 12, 41, 13, 21, and 17 cases, respectively. CD38 expression correlated with each genomic entry showed a low mean for 13q deletion or 17p deletion but particularly high for IgH rearrangement. Using > 30% as cut-off, we evaluated each FISH marker as the sole abnormality for positive CD38 correlation. This study showed (1) FISH studies in B-CLL were significantly sensitive over conventional cytogenetics (consistent with the literature); (2) 17p/P53 deletion is not significantly correlated with CD38 expression compared to the other markers; and (3) IgH rearrangement either as the sole abnormality or as part of the changes showed the most significant correlation with the cell membrane marker CD38 in B-CLL ($p<0.005$). We therefore suggest that IgH rearrangement could be a better marker for B-CLL prognostic evaluation, and should be included in the B-CLL FISH panel.

Expression of PITX1 Homeobox Gene Transcripts in Oral Squamous Cell Carcinoma by In Situ Hybridization.

T.N. Libório[1], M.G. Silva-Valenzuela[1], L.F. Matizonkas-Antonio[1], T. Acquafreda[1], D.S. Pinto Júnior[1], M. Tavares[2], J. Câmara[3], F.D. Nunes[1]. 1) Molecular Pathology Laboratory, School of Dentistry, University of São Paulo, Brazil; 2) Hospital das Clínicas, School of Medicine, University of São Paulo, Brazil; 3) Pathology Department, School of Dentistry, Federal University of Amazonas, Brazil.

Oral cancer accounts for at least 5% of all types of cancer worldwide and almost 95% of these cases are squamous cell carcinoma (OSCC). Due to the proximity of development and cancer, several studies are focusing on the participation of homeobox genes, a family of developmental regulators, in different types of cancers. Recently, PITX1 homeobox gene, related to development of stomodeum and of hind limbs, was found in OSCC cell lines through cDNA microarray analysis, but the expression of its transcripts in OSCC tissues has not been demonstrated yet. Therefore the purpose of the present study was to analyze the expression of PITX1 transcripts in OSCC and adjacent non-tumoral tissues using in situ hybridization. For such study, samples obtained from Hospital das Clínicas of São Paulo, Brazil, were divided in two parts for both RNA extraction with TRIzol and fixation in 4% paraformaldehyde. Transcripts were first amplified by RT-PCR and then localized by in situ hybridization (ISH) with specific digoxigenin-labelled riboprobes. Results showed that transcripts were amplified in 86,2% of the samples. ISH reactions showed that epithelial cells expressed PITX1 transcripts with a signal frequently intense in the non-tumoral adjacent epithelium. OSCC cells in general were weakly stained when comparing with non-tumoral epithelium. These results demonstrate the presence of PITX1 transcripts in OSCC and suggest that this gene may be involved in oral carcinogenesis.

Polymorphisms in Phase I and Phase II Enzymes and their Implications on Leukemia Susceptibility in Caucasian, Hispanic, and African-American Children. *R. Swinney.* Dept of Pediatrics, UT Southwestern Medical Center, Dallas, TX.

Preliminary research has suggested the role of polymorphisms in phase I and Phase II enzymes (CYP450, NAT, GST) as etiological factors in the development of childhood leukemia. No study has investigated differences in mutation effects in the Hispanic, African-American and Caucasian populations. Therefore, we developed this case control study to determine if single nucleotide polymorphisms (SNPs) in these enzymes contribute to novel leukemia susceptibility in these ethnic communities. Methods: DNA samples were obtained from 285 children diagnosed with B-cell leukemia at a local pediatric hospital, and matched controls from non-leukemic children were obtained from blood draws at the same hospital. Controls were matched to cases by sex and ethnicity with variable match ratios. The controls and cases were examined via allele discrimination testing for SNPs in the Phase I (CYP450) and Phase II (GST, NAT) metabolizing enzyme genes. Results: The analysis demonstrated that the CYP1A1*2A allele had a borderline effect (^{2} = 3.5285, p = .0603) and CYP1A1*2B had a significant effect (^{2} = 4.3325, p = .0374) on cancer susceptibility. In Hispanic patients, this effect was accentuated with significant values for CYP1A1*2A (^{2} = 9.2447, p=.0098) and CYP1A1*2B (^{2} = 8.4260, p = .0148). In secondary analysis, the homozygous wild-type and heterozygous variants were combined, and compared to the homozygous variant cases in a dichotomous fashion. This revealed an increased effect on the entire cohort by CYP1A1*2A (p = .0112, OR = 2.34) and CYP1A1*2B (p = .0035, OR = 4.15). The effect on the Hispanic cohort was also accentuated for CYP1A1*2A (p = .0027, OR = 3.72) and CYP1A1*2B (p = .0043, OR = 4.3). Discussion: Our study suggests that SNPs in CYP1A1 have a significant impact on leukemia susceptibility in children, especially those children of Hispanic background. Although many of the other polymorphisms were not individually significant, there remains the possibility of numerous synergistic/antagonistic interactions between these polymorphisms. Therefore, further research is needed to explore the interactions between these genetic factors and leukemia susceptibility.

Factors associated with an increased frequency of CDKN2A mutations in melanoma-prone families. *A.M. Goldstein, Melanoma Genetics Consortium (GenoMel).* Genetic Epidemiology Branch, DCEG,NCI,NIH,DHHS, Bethesda, MD.

CDKN2A is the major high-risk malignant melanoma (MM) susceptibility gene. Several variables have individually been reported to be associated with an increased frequency of CDKN2A mutations including many MM patients in a family [#MM/fam], multiple MM tumors in a patient [MPM], early median age at MM diagnosis in a family [MedAge], and pancreatic cancer [PC]. GenoMel, comprising most major familial melanoma research groups, conducted a study to explore the relationship between these four factors and mutations in CDKN2A. Families, tested for CDKN2A mutations, with at least three confirmed MM patients were eligible. The resulting sample included 384 families of which 151 (39%) had CDKN2A mutations. The frequency of mutations ranged from 20% (32/162) in Australia [Aus] to 45% (29/64) in North America [NA] to 57% (90/157) in Europe [Eur]. The four factors were evaluated across the 17 participating GenoMel groups (TOT) and in Aus, Eur, and NA. Mutation frequency increased significantly as #MM/fam increased in all groups. Mutation frequency was highest in Eur (41% for 3 MM/fam to 93% for 6 MM/fam) and lowest in Aus (12% for 3 MM/fam to 48% for 6 MM/fam). The frequency of mutations increased as MPM increased for all groups. For NA and Eur, 80% of families with 2 MPM patients had mutations. There was a significant relationship between PC and mutations in TOT, NA, and Eur but not in Aus (p=0.38). Only 3/9 Aus families with 1 PC had mutations versus 82% of families from NA (9/11) and Eur (32/39). All groups showed a significant increase in mutation frequency as MedAge decreased. Simultaneous evaluation of the four factors showed differences across the groups. In TOT, MedAge, MPM and PC, but not #MM/fam, were significantly associated with mutation. For Aus, MedAge, MPM and #MM/fam, but not PC, were associated with mutation. For NA, only MedAge and MPM were significantly associated with mutation; for Eur, only MPM and PC were related to risk of a mutation. Differences in #MM/fam, MedAge, MPM and PC may reflect distinct host, genetic, or environmental risk factors. GenoMel is exploring these factors to understand the variation across geographic regions.

Gamma Delta T-Cell Lymphoma versus Large Granular Lymphocytic Leukemia- A Clinical Challenge. *J. Lester, S. Haq, A. Moussa.* Internal Medicine, University of Oklahoma, Tulsa.

BACKGROUND This case challenged our interpretation between Large Granular Lymphocytic Leukemia (LGL) and Gamma Delta T-cell Lymphoma. LGL is a rare leukemia with a median age onset at 55 years having characteristic morphology, autoimmune disorders and indolent clinical course in females. Gamma Delta Positive T-cell Lymphoma, is an rare aggressive non-Hodgkin's lymphoma variant found in young males. **CASE PRESENTATION** A 53-year-old female with a 3 year history of pancytopenia, recurrent upper respiratory infections and SLE presented with worsening cytopenia. The CT scan of chest/abdomen/pelvis revealed hepatosplenomegaly with lymphadenopathy. Blood smear showed pancytopenia with a minor population of large granular lymphocytes (RBC 3.2/l, Hb11gm/dl, Platelets 86X10 9/l, WBC 1.0, Neuts 0.1, Lymphs 80). Bone marrow biopsy revealed 40-50% cellularity with involvement by T-cell lymphoproliferative disorder of TCR-Gamma/Delta immunophenotype; positive for CD2,CD3, CD5 dim,CD7dim and negative for CD4, CD8, CD16, CD25, CD56 with variable CD57 expression. Molecular studies for T-cell receptor gene rearrangement showed no evidence of T-cell clonal population. The cytogenetics was normal diploid. The case was referred to M.D Anderson Cancer Centre for a second opinion. The final diagnosed with LGL. She was treated with cyclosporine for 8 months and responded well. **DISCUSSION** This highlights the clinical spectrum of LGL in the presence of an unusual immunophenotype. The patient was CD8- and CD3+. CD 8 negativity is not consistent with LGL; yet she had systemic signs and symptoms including fatigue, sweats, recurrent infections and arthritis, which are main clinical features of T-cell LGL. In addition the CT scan findings of hepatosplenomegaly and IgM/IgG monoclonal gammopathy supported the diagnosis of LGL, which represents 20% and 8% of the patients repectively. A female patient with an indolent clinical course and 72% lymphocytes in the peripheral blood also argues against the features of TCGD lymphoma . This case highlights the clinical spectrum of LGL and TCGD lymphoma and the importance of immunophenotypic and genotypic studies in diagnosis.

Vascular Endothelial Growth Factor: A Serum Marker in Von Hippel Lindau. *B. Hirschman[1,2], J. Spaulding[2], L. Robinson[1], R. Brekken[2], G. Tomlinson[1,2,3], UTSW Clinical Working Group.* 1) Clinical Cancer Genetics, UTSouthwestern, Dallas, TX; 2) Hamon Center for Therapeutic Oncology, University of Texas Southwestern, Dallas, TX; 3) Childrens Medical Center, Dallas, TX.

Von Hippel Lindau (VHL) is a hereditary cancer predisposition syndrome caused by a mutation of the VHL gene at 3p25. The VHL protein participates in the proteolysis of hypoxia-inducible factor (HIF). Constitutive activity of HIF induces cellular responses only appropriate in hypoxia including the upregulation of angiogenic factors such as VEGF (vascular endothelial growth factor). VHL manifestations are typically hypervascular and include hemangioblastomas of the CNS, retinal angiomas, pheochromocytomas, clear cell renal carcinoma, and pancreatic and renal cysts. Although VHL is highly penetrant, manifestation type and timing are largely unpredictable. In this study, we are analyzing VEGF as a potential serum biomarker with aims to suggest a clinically applicable assay. Blood samples were collected from patients referred to Clinical Cancer Genetics at the University of Texas Southwestern Medical Center for VHL genetic testing. Statistical analysis of serum VEGF level has been performed on 78 of 98 patients accrued to date, ages 1 to 79 years from Caucasian and Hispanic families, based on availability of clinical information. Participants with familial risk who proved to be wildtype served as the control population. Serum VEGF level was measured by ELISA. A significant difference in serum VEGF level was found between VHL mutation carriers and wildtype controls ($p=0.0167$). Presence of manifestations at time of blood draw, with or without regard to location or quantity, failed to correlate to serum VEGF level. Age at blood draw was also not a significant factor in serum VEGF presence. Serum VEGF level above 247 pg/mL, the average value in an unselected adult population from Meo et al (2005), correlates to a significant odds ratio of carrying a VHL mutation ($OR = 5.14$, $p=0.0438$). In conclusion, while serum VEGF is increased in VHL patients, the increase is not correlated to manifestation site or quantity. Further studies are needed to determine the clinical value of VEGF in VHL.

Variation in RUNX1 gene expression and its role in the development of leukemia in Down syndrome. *K.J. Rebro, M. Olivier.* Human & Molecular Genetics Center, Department of Physiology, Medical College of Wisconsin, Milwaukee, WI.

Individuals with trisomy 21 have a 500-fold greater risk of developing acute megakaryblastic leukemia (AMKL), a normally rare subtype of acute myeloid leukemia (AML), than their chromosomally normal counterparts. Around 10% of newborns with trisomy 21 initially develop transient myeloproliferative disorder (TMPD), a transient form of leukemia characterized by a clonal population of megakaryoblasts. About 20% of the affected trisomy 21 children progress to AMKL within their first four years of life.

The molecular mechanisms underlying this trisomy 21-related leukemia are unclear; however, it is reasonable to postulate that the over-expression of gene(s) on chromosome 21 may play a critical role. RUNX1, a gene that is located on human chromosome 21, is a promising candidate gene since sequence variants within this gene are known to play a role in the development of other AML subtypes.

We examined sequence variants in the RUNX1 gene and the resulting linkage disequilibrium and haplotype structure of the gene region. In addition, we examined mRNA and protein expression in lymphoblast cell lines with different RUNX1 haplotypes. Our preliminary data show varying levels in RUNX1 expression in chromosomally normal individuals. We propose that these gene expression level differences of RUNX1 are enhanced in individuals with trisomy 21 due to the general over-expression of genes on chromosome 21, and that this alteration ultimately plays a crucial role in the development of TMPD and AMKL in a subset of children with Down syndrome.

This work was supported in part through the Charles J. Epstein Down Syndrome Research Award of the National Down Syndrome Society (MO).

VHL germline mutations in Mexican patients with cerebellar hemangioblastoma. *A. Rasmussen[1,2], S. Nava-Salazar[3], P. Yescas[1], E. Alonso[1], R. Revuelta[4], I. Ortiz[4], S. Canizalez-Quinteros[5], MT. Tusié-Luna[5], M. López-López[6].*

Universidad Nacional Autónoma de México. Mexico City, Mexico.

CNS hemangioblastomas (HB) are benign vascular tumors arising either sporadically or as a manifestation of von Hippel-Lindau disease (VHL), a hereditary cancer syndrome. We studied a series of patients with CNS HB and their families, in order to identify germline mutations in the VHL tumor suppressor gene, and to establish a predictive testing and scrutiny protocol. Methods: Patients admitted during 2002-2004 at the INNN for HB, were prospectively enrolled together with their at-risk family members. We performed the molecular analysis of the VHL gene by PCR and direct sequencing. All asymptomatic mutation-carriers underwent genetic counseling and tumor surveillance. Ninety-eight individuals were tested for VHL mutations: 23 symptomatic and 75 asymptomatic individuals, belonging to 16 families. Results: 7 of the families had definite clinical criteria of VHL disease, 5 had sporadic HB and 4 had CNS HB plus minor visceral signs. Molecular genetic testing allowed us to identify five germline mutations in 6 of the definite VHL families (sensitivity 85%) but none in the possible VHL and sporadic hemangioblastoma cases; four of these mutations had been previously described and one is a novel mutation present in two unrelated families. After mutation-carriers were identified, they underwent clinical screening and asymptomatic VHL-related lesions were identified in 43% of them. We conclude that genetic testing for mutations in the VHL gene is crucial in patients with CNS HB. The prompt identification of mutation carriers allows a multi-disciplinary screening protocol to decrease morbidity and mortality in these patients, while avoiding costly and invasive procedures for non-carriers.

Long-term follow-up after genetic testing for HNPCC syndrome: impact on screening procedures and perception of genetic testing. *P.O. Chappuis[1,2], C. Gillabert[1], V. Membrez[3], A.E. Murphy[1], C. DeLozier[2], M. Gersbach[2], P. Hösli[1], P. Hutter[3], S.E. Antonarakis[2], A.P. Sappino[1].* 1) Division Oncology, Geneva Univ. Hosp., Geneva, Switzerland; 2) Division Medical Genetics, Geneva Univ. Hosp., Geneva, Switzerland; 3) Genetic Unit, Institut Central Hôp. Valaisans, Sion, Switzerland.

BACKGROUND: Regular colonoscopy in hereditary non-polyposis colorectal cancer (HNPCC) gene mutation carriers has been associated with an important reduction in the incidence of colorectal cancer. Understanding the factors influencing compliance with regular screening after genetic testing is a critical issue. Using a questionnaire, we investigated the long-term impact of testing on screening procedures and on satisfaction with the clinical process. METHODS: All HNPCC gene mutation carriers and non-carriers identified between 05.1995 and 03.2003 in 2 Swiss counselling centres were identified. An anonymous questionnaire was sent with 37 items exploring compliance with screening recommendations, basic understanding of HNPCC syndrome, and satisfaction with the counselling process. RESULTS: 198 individuals received informative HNPCC genetic testing results during the study period. 179 questionnaires were mailed; response rate was 85%. The average time of follow-up was 54 months. Answers from 61 carriers (26 m/35 f; mean age: 45.2 years; 55 *MLH1*/6 *MSH2* mutations) and 91 non-carriers (41 m/50 f; mean age: 44.7 years) were analysed. Only 5 (3%) persons did not correctly recall their genetic status. >80% of carriers and non-carriers followed all the screening recommendations. In the 12 months preceding the reception of the questionnaire, all mutation carriers had a colonoscopy. Carriers had significantly more colorectal screening than non-carriers ($P = 0.001$), due to the termination of surveillance in non-carriers. General understanding of the HNPCC syndrome was considered as good. Global satisfaction with the counselling process was >95%. CONCLUSION: In this retrospective long-term follow-up survey, compliance with screening recommendations and general satisfaction after genetic testing, both in carriers and non-carriers, were very satisfactory.

Molecular analysis of mismatch repair defects in a diagnostic setting: immunohistochemical pattern predicts hereditary origin. *M. Ligtenberg[1,2], R. Willems[2], N. Arts[1], M. Schliekelmann[1], M. van Asseldonk[2], M. Goossens[2], K. Hebeda[2], H. van Krieken[2], N. Hoogerbrugge[1].* 1) Human Genetics, Radboud University Nijmegen, Nijmegen, Netherlands; 2) Patholgy,Radboud University Nijmegen, Nijmegen, Netherlands.

Germline mutations in mismatch repair (MMR) genes are a frequent cause of Hereditary Non-Polyposis Colorectal Cancer (HNPCC). More than 90% of HNPCC related tumors in patients with a germline mutation in one of the genes (*MLH1, MSH2, MSH6* or *PMS2*) show microsatellite instability (MSI). MSI also occurs in about 10% of the colorectal cancers of sporadic origin. Therefore MSI-analysis can be used as an overall marker of MMR deficiency, of either genetic or sporadic origin. The involvement of a specific MMR defect can be assessed by immunohistochemical(IHC) analysis and the analysis of *MLH1* promoter methylation. The latter is an indication of sporadic origin.

We have analyzed the IHC pattern and *MLH1* promoter status in 75 MSI positive tumors of patients that were counseled because of suspicion of HNPCC and matched the results with those of the mutation analysis. In 43 of the 75 patients (57%) a germline mutation in one of these genes was detected: 13 in *MLH1*, 22 in *MSH2* and 8 in *MSH6*. In 29 of 36 patients (81%) with tumors without staining of MSH2 and/or MSH6, a germline mutation was found. In 3 of 4 patients (75%) with tumors without PMS2, an *MLH1* mutation was detected. A germline mutation was detected in only 10 of 27 patients (37%) with tumors negative for MLH1 and PMS2. In 11 of 13 of these mutation negative tumors methylation of the *MLH1* promoter was detected.

These results show that a negative staining of the MMR proteins in absence of *MLH1* promoter methylation strongly predicts the presence of a germline mutation. Patients should be genetically counseled before IHC analysis of MMR proteins and determination of the methylation status of the *MLH1* promoter is performed, out of respect for the patients free choice to know or not to know the hereditary origin of their cancer.

Impact of genetic counseling and DNA testing on individuals with colorectal cancer with a positive family history.
P.T. Rowley, S. Loader, C. Shields. Univ. of Rochester, Rochester, NY.

What is the impact of a genetic evaluation for colorectal cancer susceptibility? We previously reported a study of individuals diagnosed with colorectal cancer at 60 years in a 5-county area of New York including Rochester. Subjects reporting at least one first- or second-degree relative with colorectal cancer were invited to receive genetic counseling and DNA testing. Of the 37 persons tested, six were found to have deleterious mutations in MSH2 or MLH1 and four had variants of uncertain clinical significance as previously reported (Loader et al., Genetic Testing 6:281, 2002). A deleterious mutation has since been found in a seventh subject in another laboratory.

To evaluate the impact of the testing experience, we obtained follow-up data on 36 of these 37 subjects. (1). *Colon cancer knowledge*. At 3 mos. after receiving their result, subjects knew more about colon cancer if they had more cancer of all types in their family (p=.02). At 12 mos., they knew more if they had received an abnormal result (whether a deleterious mutation or a variant of uncertain clinical significance) (p.001), were younger when DNA tested (p.01), or were younger when diagnosed with cancer (p.03). However, despite intensive counseling that the test was imperfectly sensitive, eight of those in whom no abnormality was detected thought an inherited susceptibility had been ruled out. (2) *Telling relatives*. All of those found to have an abnormality told relatives. Relatives of three subjects in whom a mutation had been found came to us for testing. (3) *Surveillance.* At 12 mos., surveillance for colon and endometrial cancer was more adherent if there were more total cancers in the family (p.05) or if the testee was more worried about cancer (p.05). (4) *Mental health*. Self-assessed mental health at 12 mos. was better for those who were married (p.05).

This study suggests that individuals undergoing a genetic evaluation for an inherited susceptibility to colorectal cancer remember their result, inform relatives of abnormalities found, and pursue recommended surveillance.

Genetic and immunohistopathological evaluation of BRCA1 and BRCA2 unclassified variants. *G. Chenevix-Trench[1], S. Healey[1], S.R. Lakhani[1,2], R. Brinkworth[2], kConFab[3], A. Marsh[1], M. Brown[2], D.F. Easton[4], S. Tavtigian[5], D. Goldgar[6], A.B. Spurdle[1].* 1) Queensland Inst Medical Res, Brisbane, Australia; 2) University of Queensland, Brisbane; 3) Peter MacCallum Cancer Centre, Melbourne; 4) Strangeways Research Laboratory, University of Cambridge, UK; 5) International Agency for Research on Cancer, Lyon, France; 6) University of Utah.

About half the BRCA1 and BRCA2 variants detected in breast cancer families cannot be classified as pathogenic or neutral and are termed unclassified variants (UVs), representing a challenge for genetic counseling. Goldgar et al. (2004) developed an algorithm to classify UVs that incorporates data on co-occurrence with pathogenic mutations in the same gene, co-segregation with affected status, the Grantham Matrix Score and information on the evolutionary conservation to classify variants as neutral or pathogenic. We have identified 10 UVs in BRCA1 and 15 in BRCA2 from 37 pedigrees from the Kathleen Cuningham Consortium for Research into Familial Breast Cancer (kConFab). Segregation (using 421 germline DNAs), loss of heterozygosity (in 35 tumors), immunohistopathology and in silico conservation and Grantham Matrix analyses were conducted. The data were included in an updated version of the model which takes into account the characteristic immunohistopathology associated with pathogenic mutations in BRCA1, and the fact that ~85% of tumors from BRCA1 and BRCA2 carriers show loss of the wild type allele. Based on a threshold of 100:1 odds in favor of neutrality, we were able to classify 6 BRCA1 and 7 BRCA2 UVs as neutral. Four of these neutral variants were also identified in at least one of 180 controls analyzed, as was BRCA2 E2856A for which we found odds of 12:1 in favor of neutrality. Although two UVs (BRCA1 G1738R and BRCA2 D2723H, which was classified by Goldgar et al as pathogenic) reached odds in favor of causality of more than 250:1, none of them exceeded the 1000:1 threshold proposed for classification as pathogenic. Use of the updated model allowed the classification of four BRCA2 UVs which would have remained unclassified under the original version of the model.

Identification of a Novel Frequent Large Genomic Rearrangement of *BRCA1* in High-risk Hispanic Families. *J. Weitzel[1], B. Hendrickson[2], V. Lagos[1], K. Lowstuter[1], M. Palomares[1], K. Blazer[1], K. Gonzalez[1], T. Scholl[2].* 1) City of Hope Cancer Center, Duarte, CA; 2) Myriad Genetic Laboratories, Salt Lake City, UT.

Background: Large rearrangements are estimated to account for 5-10% of all mutations in *BRCA1* and *BRCA2*. Prevalent founder rearrangement mutations have been described in European populations. We sought to identify rearrangements in the *BRCA* genes in a cohort of Hispanic patients. **Methods:** We identified 34 deleterious *BRCA* mutations via full sequence analysis among 110 unrelated high-risk Hispanic families enrolled in an IRB approved registry who underwent cancer risk assessment (CEBP 2005;14:1-6). To date, DNA from 45 of 76 patients without an identifiable mutation was subjected to multiplexed quantitative differential PCR (MQDP) for detection of large rearrangements. The assay consisted of multiplexed PCR reactions to assess gene dosage of all exons of *BRCA1* and *BRCA2* and the regions immediately 5 and 3 of the genes. Positive results were confirmed by long range PCR. **Results:** All 45 subjects had a history of breast cancer (1 with DCIS); 6 had bilateral breast cancer. Average age of first breast cancer diagnosis was 37.7 years. Reported ancestry included 29 Mexican, 6 Central American, 2 South American, 1 Spanish, and 7 of mixed country of origin. Mean pre-test *BRCA* mutation probability was 25.4%. In 3/45 (6.7%) families MQDP analysis identified an apparent deletion of *BRCA1* exons 9-12, indicated by a 50% loss of signal. Long range PCR resulted in the generation of a 2.5kb product in these samples, consistent with a deletion event of 15.1kb. All three families reported Mexican ancestry and were unrelated through at least a 4-generation pedigree. **Conclusion:** We identified a novel large deletion in three unrelated families of Mexican ancestry, suggesting founder effect. The frequency was 2.7% of the 110 high-risk families screened for *BRCA* mutations, bringing the overall prevalence of deleterious mutations to 33.6%(37/110). This *BRCA1* rearrangement may account for a substantial proportion of high-risk Hispanic families, and should be included in all subsequent studies of this ethnic group.

The 471delAAAG mutation and C353T polymorphism in the RNASEL gene in sporadic and inherited cancer in Israel. *R. Gershoni-Baruch[1], E. Dagan[2], Y. Laitman[3], E. Friedman[4].* 1) Inst Human Genetics, Rambam Medical Ctr and Bruce Rappoport School of Medicine, Technion, Haifa, Israel; 2) Inst Human Genetics, Rambam Medical Ctr and Dept of Nursing, University of Haifa, Israel; 3) Susanne-Levy Gertner Oncogenetics Unit and Dept of Gynecology, Sheba Medical Ctr,Tel-Hashomer, Israel; 4) Susanne-Levy Gertner Oncogenetics Unit, Sheba Medical Ctr,Tel-Hashomer and Sackler School of Medicine, Tel-Aviv University, Israel.

To evaluate the role of RNASEL 471delAAAG germ-line mutation in cancer predisposition a total of 1011 individuals including 294 Jewish men with prostate cancer (190 Ashkenazim), 361 Jewish Ashkenazi women with breast and/or ovarian cancer and 356 unaffected Ashkenazi women were investigated. Sequence anomalies in a single RNASEL gene amplicon using either of DGGE or DHPLC, restriction methods and sequencing were sought. The 471delAAAG mutation was detected in a single male with prostate cancer (1/294 and 1/190 of the Ashkenazi patients - 0.3% and 0.53%, respectively), in two ovarian cancer patients (2/141 -1.4%) one with and one without BRCA1 mutation, and in a single woman of 242 healthy controls (0.41%). An abnormal DHPLC profile identical to the one produced by the 471delAAAG mutation was noted in 23 additional women: 2 (0.94%), 16 (7.8%), and 5 (2.6%) from among carriers, non-carriers, and controls, respectively. Sequence analysis disclosed a silent polymorphism in Valine at codon 118: c.353 C->T. The rate of this polymorphism was significantly elevated in high-risk non-carrier women (16/205; 7.8%) either with breast and ovarian cancer (13/148; 8.8%) or asymptomatic (3/57; 5.3%) than in BRCA1/2 mutation carriers (2/209; 1.0%) ($X=11.670$; $p<0.001$). The 471delAAAG mutation occurs only rarely in unselected Israeli prostate cancer patients and in high-risk Ashkenazi breast and/or ovarian cancer patients, at rates that do not differ from that of the general population. A silent polymorphism in the RNASEL gene that mimics the abnormal DHPLC pattern seems to occur more prevalently in high-risk Ashkenazi breast and/or ovarian cancer patients, non-BRCA1/2 carriers, perhaps being in linkage disequilibrium with a pathogentic mutation.

Genomic and epigenetic profiling of p53 and non-p53 Li-Fraumeni syndrome tumors reveals multiple hits in the p53 pathway. *R. Krahe[1], M. Tuna[1], L.L. Bachinski[1], B. Zhang[1], S. Colella[1], R. Luthra[3], G. Lozano[1], L.C. Strong[2].* 1) Sect. Cancer Genetics; 2) Clinical Cancer Genetics; 3) Dept. Hematopathology, Univ. Texas M.D. Anderson Cancer Ctr., Houston, TX.

Common dogma in cancer genetics holds that multiple hits in the same pathway are redundant, thus unlikely. Using genomic and epigenetic profiling, we show that p53 Li-Fraumeni syndrome (LFS) tumors can harbor multiple hits in other p53 pathway members. Moreover, p53 and non-p53 LFS tumors share hits in p53 pathway members. LFS is clinically and genetically heterogeneous. Most cases (>70%) are due to mutations in p53 (17p13.1). CHK2 (22q12.1) is a minor predisposing locus, and we recently mapped a third locus to 1q23. In both p53 and non-p53 LFS, there is evidence for risk heterogeneity within and between kindreds, suggesting additional risk modifiers and factors, including epigenetic alterations. We profiled genomic DNA from primary tumors and matching constitutive DNA of 10 LFS patients (6 with p53 mutations and 4 from non-p53 kindreds), using BAC array CGH (Spectral Genomics) and the 100K SNPChip (Affymetrix) to identify patterns of global DNA changes or allelic imbalance, and PyroMethA to ascertain the methylation status of 11 known tumor suppressor genes. We resequenced known mutations in BRAF, KRAS and HRAS. Our global approach revealed several interesting patterns: for example, 5 of 6 p53 LFS patients showed loss of RB1 (13q14.2) and CCNA1 (13q13.3), while 2 of 4 non-p53 LFS patients showed gain for the same region. Five of 6 p53 LFS patients also showed loss of the p53-activated target 14-3-3e (17p13.3). Tumors of 3 unrelated p53 LFS patients showed concomitant loss of 4p13-p11, 9pter-p21.1, 10q11.1-q24.2 and 13q13-q14.2, and gain of 1q21.1-q24.1, suggesting the shared involvement of genes in these regions in p53-associated LFS. Six genes (TP73, RASSF1, BRCA1, HIC1, ESR1 and HIN1) showed significant tumor-associated promoter hypermethylation. RASSF1 hypermethylation was exclusively associated with soft-tissue sarcomas. In conclusion, different combinations of genetic and epigenetic alterations appear to act together to dysregulate a limited number of cellular pathways in LFS tumorigenesis.

Analysis of AKT-TOR-HIF pathway component genes in patient tumors: associating mutations with targeted therapy. *M.L. Nickerson[1], J.S.. Troy[1], R. Thiagarajan[1], K.B. Walters[1], T.K. Price[1], M.D. Geimer[1], J.A. Durocher[1], S. Lilleberg[1,2].* 1) Discovery Services, Transgenomic, Gaithersburg, MD; 2) Discovery Services, Transgenomic, Omaha, NE.

Though the molecular details are only partly understood, it appears possible that a common signaling pathway including AKT, TOR, and HIF may integrate environmental cues in order to allow a coordinated, holistic response by a cell. The presence of multiple tumor suppressors that down-regulate signaling by AKT-Tor-Hif pathway members, including PTEN, TSC 1 and 2, and VHL implicate disregulation of pathway signaling in multiple types of cancers and hamartoma syndromes. Although individual genes have been analyzed in specific cancers and syndromes, the mutation status of the pathway as a whole in cancer remains to be determined. This study examines the spectrum of mutations and polymorphisms in genes encoding pathway components in DNA from early stage prostate and breast tumors. A comprehensive analysis of each tumor was achieved by examination of 240 amplicons from PIK3CA, PTEN, AKT 1-3, TSC 1 and 2, Tor, HIF 1-3, VHL, and IRS 1 and 2. A novel mutation detection strategy was utilized which consisted of three independent methods to identify polymorphisms in PCR amplicons from tumor DNA: Surveyor Nuclease enzymatic cleavage of mismatches, DHPLC separation of heteroduplexes, and double-stranded fluorescent sequencing. Approximately 230 variants will be presented, some of which have therapeutic implications. Functional analyses will confirm the causative nature of these genetic variants and their contributions to tumorigenesis. Other groups have focused on gene families for analysis of somatic mutations in tumors, such as kinases and phosphatases. This study takes a signaling pathway approach to group gene targets for analysis. Analysis of pathway genes may prove useful since mutations in genes encoding upstream pathway components may be treatable using therapeutic agents directed against downstream targets. Patient health can hopefully be improved by correlating specific mutations with treatment options that delay cancer onset and progression while maximizing response and outcome.

Pilot to assess parental receptiveness to the creation of a youth cohort (LEGACY) within the Ontario familial breast cancer registry (OFBCR). *G. Glendon[1], D. Hanna[1], C. Mulhall[1], P. Ritvo[1], A. Thompson[1], I.L. Andrulis[1,2].* 1) Ont. Cancer Genetics Network, Cancer Care Ontario, Toronto, ON, Canada; 2) Mt. Sinai Hospital- Samuel Lunenfeld Research Institute, Toronto, ON, Canada.

Breast cancer risk is influenced by genetic and environmental factors that exert effects prior to adulthood. The OFBCR is a population-based breast cancer registry consisting of 2500 families with varying degrees of family history. Expanding this cohort to include family members under the age of 18 would allow the investigation of important early events in breast cancer. Specifically, hormonal, biological and genetic factors that are associated with the intermediate endpoints of puberty, menarche, body growth and composition, and breast tissue characteristics. We have conducted semi-structured, in-depth interviews with 20 adult-parent participants of the OFBCR to gain a detailed understanding of their interests and concerns regarding their offspring's enrollment in a proposed OFBCR youth cohort study entitled LEGACY (Lessons in Epidemiology and Genetics of Adult Cancers from Youth). Interviewees were females diagnosed with breast cancer between January 1996 and 1999 who have daughters between the ages of 5 and 17. Interview domains include the extent of familial cancer disclosure, receptiveness and attitudes to LEGACY enrollment, preferred level of interaction between daughters and LEGACY staff, minimum age for enrollment and all other issues identified in the interview. Qualitative analysis utilizing grounded theory was conducted from the transcribed interviews. All 20 (100%) interviewees identified LEGACY as a good idea and stated that they would be willing to enroll their daughters if only data were collected. Seventeen (85%) stated that they would enroll their daughters if data and blood were collected. All 20 (100%) stated they would be willing to act as intermediary for enrollment purposes, questionnaire data collection and blood collection. Average minimum age for minor enrollment was 9.6 and 10 years respectively for a data only vs. data and blood study with a range of age 5 to age 16. We will conduct 60 additional female interviews as well as 40 with randomly selected male spouses.

Examining Ontario Familial Breast Cancer Registry (OFBCR) proband participants response to providing kin contact information for study enrollment purposes. *A. Thompson[1,2], G. Glendon[1,2], D. Hanna[1,2], L. Anson Cartwright[2], K. Turnbull[2], K. Keast[2], M. Edwards[2], N.F. Boyd[2], I.L. Andrulis[1,2,3].* 1) Cancer Care Ontario - Ontario Cancer Genetics Network 620 University Ave. Toronto, ON, Canada M5G 2L7; 2) University Health Network - Ontario Familial Breast Cancer Registry 610 University Avenue, Toronto, Ontario M5G 2M9; 3) Mt. Sinai Hospital- Samuel Lunenfeld Research Institute 600 University Avenue, Toronto, ON, Canada M5G 1X5.

The OFBCR is the Ontario site of the NCI funded Breast Cancer Family Registry consortium. It is a familial cancer registry that collects cancer family history, epidemiological breast cancer risk information, and biological samples from individuals with incident breast cancer and selected kin. The purpose of the present study was to determine the reasons why some OFBCR proband participants were unwilling to provide kin contact information for study enrollment purposes. We identified these proband participants and performed telephone interviews to assess reasons for non-disclosure of kin contact information and to determine if these kin were now able to participate in the OFBCR. If the proband participant agreed to provide kin contact information, addresses were obtained over the phone or returned via a mailed list after the interview. Four hundred eighty five participants, with a total of 2308 eligible kin, were contacted by phone. One hundred forty seven participants agreed to kin involvement for selected kin. Two hundred thirty six kin addresses were obtained over the phone and 27 kin addresses have been returned by mail for a total of 263 addresses collected thus far. Reasons for refusal to provide kin contact information included 28% refused with no reason, 21% lost contact with kin, 17% kin not interested, 10% deceased/unwell/too old, 8% location/language barrier, 7% not willing to ask kin again, 3% don't get along with kin, 2% too busy, 4% other. We have demonstrated that some OFBCR proband participants that initially were unwilling to provide kin contact information for study enrollment purposes may reconsider this position over time.

Exacerbation of transcriptional inactivity leads to epigenetic silencing of a tumor suppressor gene. *M. Ren, S. Pozzi, G. Bistulfi, S. Rossetti, G. Somenzi, N. Sacchi.* Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY.

Resistance to the growth inhibitory action of retinoic acid (RA), the bioactive derivative of Vitamin A is common in human tumors. One form of RA resistance has been associated with aberrant DNA methylation and silencing of the retinoic acid receptor beta 2 (RARB2) gene, whose transcription is regulated by RA. Understanding why RARB2 is prone to aberrant epigenetic silencing in human cells is critical for both prevention and early treatment of RA-resistance in human carcinoma cells. Here we show that an exacerbation of RARB2 transcriptional inactivity leads to heritable RARB2 DNA methylation and silencing. Further, we show that RARB2 epigenetic silencing leads to the development of RA-resistance and distinct features of tumor progression. This study serves as the proof of principle that RARB2 epigenetic silencing is consequent to an exacerbated transcriptional inactivity. Supported by the DOD-IDEA Award DAMD17-02-1-0432 (NS).

Influence of glutathione-S-transferase (GSTM1, GSTP1, GSTT1) and cytochrome p450 (CYP1A1, CYP2D6) polymorphisms on numbers of basal cell carcinomas (BCCs) in families with the nevoid basal cell carcinoma syndrome (NBCCS). *R. Yang, R.M. Pfeiffer, A.M. Goldstein.* Dept DCEG, NCI, Bethesda, MD.

The nevoid basal cell carcinoma syndrome (NBCCS) is an autosomal dominant multisystem disorder with variable expression. NBCCS patients have varied susceptibility to basal cell carcinoma (BCC) development. Previous studies have demonstrated that polymorphisms of some metabolic genes encoding the cytochrome p450 (CYP) and glutathione-S-transferase (GST) enzymes influenced the numbers of BCCs in sporadic BCC cases. In this study, we genotyped and analyzed 152 members (69 affected and 83 unaffected) of 13 families with NBCCS for 7 polymorphisms in 5 metabolic genes including CYP1A1, CYP2D6, GSTM1, GSTP1, and GSTT1. GSTP1 Val^{105} and GSTP1 Val^{114} alleles were significantly associated with fewer BCC numbers (odds ratio $[OR]_{105}$ = 0.55, 95% confidence interval [CI], 0.35 to 0.88; OR_{114} = 0.20, 95% CI, 0.05 to 0.88). The Val^{105} allele demonstrated a dosage-dependent effect ($OR_{Ile/Val}$= 0.58, 95% CI, 0.34 to 0.88; $OR_{Val/Val}$= 0.34, 95% CI, 0.14 to 0.78). In addition, we observed fewer jaw cysts in carriers of the three p450 polymorphisms (CYP1A1m1, CYP1A1m2, and CYP2D6*4) ($OR_{CYP1A1m1}$ = 0.27, 95% CI, 0.12 to 0.58; $OR_{CYP1A1m2}$ = 0.25, 95% CI, 0.08 to 0.78; $OR_{CYP2D6*4}$ = 0.33, 95% CI, 0.18 to 0.60). Our data show that genetic variants might contribute to the variation in numbers of BCCs and jaw cysts observed in NBCCS families.

Identification of genetic modifiers in a large BRCA1 family. *R.E. Ellsworth[1], R. Leach[2], L.R. Hoffman[1], C. Snyder[3], H.T. Lynch[3].* 1) Windber Research Inst, Windber, PA; 2) Teneo Sciences, Bethesda, MD; 3) Creighton University School of Medicine, Omaha, NE.

Although mutations in BRCA1 and BRCA2 represent the primary lesions in hereditary breast and ovarian cancer (HBOC) families, these mutations are marked by incomplete penetrance, as 15-20% of carriers never develop either cancer. In addition, the expressivity of these gene mutations varies with manifestation in breast, ovary, or both breast and ovary. To identify additional genes associated with dictating tumor location, we have collected DNA samples from 52 members of a large six-generation HBOC family with an IVS16-581del1014 BRCA1 mutation. Over 10,000 genotypes were determined for each individual using the GeneChip Mapping 10K Array (Affymetrix, Santa Clara, CA). Disease modeling using artificial intelligence-based algorithms was performed using Exemplar 2.0.0 (Teneo Sciences, Bethesda, MD). Allele frequencies of several SNPs were significantly different between carriers with cancer and those without. SNPs on chromosomes 13q33 and 18p11 could be used to correctly classify carriers with breast cancer, a SNP on chromosome 2q31 effectively separated carriers with ovarian cancer, and a SNP on chromosome Xp11 reliably identified carriers with breast and/or ovarian cancer($P < 0.05$). Genes from these regions include the RAB6C gene on chromosome 2q31, the ligase 4 (LIG4) gene on chromosome 13q33.3, variations in which have been associated with a protective advantage against breast cancer, the EPB41L3 gene on chromosome 18p11, and the ubiquitously expressed transcript (UXT), which is overexpressed in a number of tumor cell lines. Models can thus be designed in which alone, mutations in BRCA1 are not sufficient to promote breast cancer, but interactions between these candidate genetic modifiers and BRCA1 provides an environment hospitable to tumor development. Confirmation of these results using data generated from other BRCA1 families and identification of causative mutations will provide more effective diagnostic tools for counseling mutation carriers and determining optimal treatment regimens.

Mosaicism confounds prenatal diagnosis of retinoblastoma: Exclusion of disease after linkage analysis predicted an affected fetus. *R.D. Clark[1], D. Rushlow[2], B.L. Gallie[2], S.O. Cox[3], A.L. Murphree[3].* 1) Division of Medical Genetics, Department of Pediatrics, Loma Linda School of Medicine, Loma Linda, CA; 2) Retinoblastoma Solutions, University Health Network, University of Toronto, Toronto, Canada; 3) Division of Ophthalmology, Retinoblastoma Program, Childrens Hospital Los Angeles, Los Angeles, CA.

We report a 2 generation family with retinoblastoma (Rb) in which undetected germline mosaicism led to misinterpretation of linkage analysis data for prenatal diagnosis.

A 37-year old pregnant G2 P1 female with a history of unilateral Rb at 21 months, presented for genetic counseling regarding the prenatal diagnosis of Rb in her fetus. She was the first affected member of her family although her only child had bilateral Rb. In 1998, RB1 gene sequence analysis, performed elsewhere, on the patients blood was normal and linkage analysis was done using polymorphic intragenic RB1 probes. In the current pregnancy, amniocytes expressed the at-risk RB1 haplotype and the patient was given a greater than 99% chance that her fetus was affected. RB1 mutation studies were then performed on her affected child, the patient, and her fetus.

The patients affected child had an RB1 mutation, R455X, in her blood. Using R455X-specific PCR, the patient was shown to be mosaic for this mutation. The amniocytes of the fetus did not show the R455X mutation. The newborn eye exam was normal.

Linkage analysis was misleading because, in the mosaic proband, some cells with the at-risk haplotype did not harbor the RB1 mutation. Mosaicism should be suspected when the first case in the family has unilateral Rb. For this reason, linkage analysis can be unreliable for the prenatal diagnosis of retinoblastoma in some families.

Duplications of the MSH2 and MLH1 genes in Hereditary Non Polyposis Colorectal Cancer (HNPCC) / Lynch syndrome. *S. Baert-Desurmont[1,2], S. Frerot[1], C. Martin[1,2], E. Bessenay[1], F. Charbonnier[2], S. Olschwang[3], Q. Wang[4], M-P. Buisine[5], T. Frebourg[1,2].* 1) Department of Genetics, Rouen University Hospital, Rouen, France; 2) Inserm U614, Faculty of Medicine, Rouen, France; 3) Department of Genetics, Institut Paoli Calmettes, Marseille, France; 4) Molecular Oncology, Centre Léon Bérard, Lyon, France; 5) Laboratory of Biochemistry and Molecular Biology, Lille University Hospital, France.

Hereditary Non Polyposis Colorectal Cancer (HNPCC) or Lynch syndrome results from germline mutations of the DNA mismatch-repair genes MSH2, MLH1, MSH6 and PMS2. The systematic screening for genomic rearrangements in 332 HNPCC families without MSH2 or MLH1 point mutations, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments), allowed us to report previously that genomic deletions of MSH2 and MLH1 are respectively involved in approximately 10 % and 4 % of the HNPCC families fulfilling Amsterdam criteria. We identified 22 and 15 distinct exonic deletions of MSH2 and MLH1, respectively. We have now detected, using QMPSF, 8 distinct (including 5 novel) genomic duplications of MSH2 and MLH1: 6 duplications of MSH2, affecting respectively exons 1-2-3, exons 5-6, exon 7, exons 7-8, exons 9-10, and exon 11, and 2 duplications of MLH1, involving exons 2-3 and exons 6-7-8. These duplications were confirmed by MLPA (Multiplex Ligation-dependent Probe Amplification). The recent reports highlighting segmental duplications and copy number variation in the human genome led us to check that these duplications affecting MSH2 or MLH1 did not correspond to polymorphisms. Although genomic duplications of MSH2 and MLH1 are less frequent that genomic deletions, their presence should be considered in HNPCC families without detectable point mutations and their detection can easily be performed using QMPSF.

Single cell gel electrophoresis (comet assay) to assess genomic instability in different esophageal pathologies. *Y. Ahuja[1], M. Vasavi[2], V. Bhavani[3], P. Shivani[2], K. Kishore[3], V. Kiran[2], Q. Hasan[2,3].* 1) VMRC, Hyderabad 500 004,India; 2) Dept of Genetics & Molecular Medicine, Kamineni Hospitals, L B nagar, Hyderabad 500 068, India; 3) Dept of Genetics, BMMRC, AC Guards, Hyderabad 500 004, India.

Cancer is a multistep process resulting from a series of genomic alterations that lead to the progressive malfunctioning of crucial mechanisms of cell growth, differentiation and death. Most human cancers are associated with genomic instability this was assessed in different esophageal pathologies using Single cell gel electrophoresis (SCGE) / Comet assay. 1ml of heparinised peripheral blood was collected from 124 individuals referred for endoscopy with upper GI tract symptoms. Clinical, personal and family history was collected. 63 samples with >85% cell viability by Trypan blue test were processed for SCGE analysis. Individuals were categorized into four groups based on clinical evaluation, endoscopic and histopathological reports into: 23 cases of cancer, 7 of premalignant lesions, 8 with inflammatory pathologies and 25 endoscopically normal individuals taken as controls. 40ul of blood was processed for comet assay by standard lysis, alkaline treatment and electrophoresis. 100 cells per patient were scored using the oculometer after silver staining. The mean percent of damaged cells was 37% in cancers, 30.7% in pre-cancers, 15.6% in cases with inflammatory esophagitis and 10.6% in controls. The number of damaged cells from controls to cancers was significant ($p<0.0001$). One-way ANOVA showed a significant increase in the comet tail length between the four groups ($p<0.005$) indicating a progressive increase in DNA damage from controls and esophagitis to precancers and cancers. DNA damage did not appear to have any association with smoking, tobacco chewing and alcohol consumption. Comet assay in peripheral blood reflects the DNA damage associated with pre-cancers and cancers of esophagus. Our study also indicates that the DNA damage seen was mostly due to the exposure to endogenous disease promoting agents in the tissue microenvironment rather than exogenous agents.

Genealogy and genetic evidence linking AAPC kindreds to an American founder. *D. Neklason[1,2], J. Stevens[3], N. Matsunami[3], B. Otterund[3], J. Barlow[1], R. Burt[1,4], M. Leppert[3].* 1) Huntsman Cancer Institute; 2) Oncological Sciences; 3) Human Genetics; 4) Medicine; University of Utah, Salt Lake City, UT.

We previously reported four independently ascertained attenuated familial adenomatous polyposis (AFAP) kindreds with an identical mutation in the APC gene (exon 4: 426_427delAT) (Spirio et al, 1993). We hypothesize that these four kindreds are descendents of a common ancestor from America. We continue to expand and phenotype two of these kindreds, 353 and 439 (Burt et al, 2004) and here provide genealogy and genetic data to support their common heritage. The 353 kindred is from Utah with more than 4000 descendents spanning 8 generations. 490 members have been studied and 145 are mutation positive. The founding parents were born in Massachusetts and New York in the 1790s and were part of the Mormon emigration to Utah in the 1850s. The 439 kindred is from upstate New York spanning 6 generations. 99 members have been studied and 36 are mutation positive. The founding parents were born in New York in the 1830s. Using genealogic resources, ancestors from both kindreds have been traced to the same Massachusetts town in the 1600s, however the common ancestor has not been identified. Using the Affymetrix GeneChip 10K SNP array, we have found that the two kindreds share an identical haplotype of 31 SNPs spanning 6.48Mb across the APC region. This genetic data provides convincing evidence that these two kindreds descend from a common ancestor. To our knowledge, this mutation has not been reported outside of the USA, suggestive of an American founder. This founder may also be the ancestor of the other two kindreds originally described, but this has yet to be determined.

Functional analysis of inherited genetic variants associated with hereditary colorectal cancer predisposition. *S. Perera, B. Bapat.* Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada.

Hereditary nonpolyposis colorectal cancer (HNPCC) is the most common form of inherited colorectal cancer. Germline mutations in the mismatch repair (MMR) genes lead to this autosomal dominant disorder, characterized by the development of cancers of the colon, endometrium, stomach, urinary tract, ovaries, small bowel and brain. 90% of known cases of HNPCC arise due to defects in the MMR genes *hMLH1* and *hMSH2*. Around 20-30% of MMR gene alterations reported to date are missense changes. In the absence of functional data, the pathogenic effects of these changes cannot be accurately interpreted. This poses problems for predictive genetics testing programs offered to HNPCC patients. Thus the aim of this project is to investigate the consequence of these alterations on the function of the protein and the efficiency of the MMR system. We have selected 5 unclassified variants in *hMLH1*: I19F, A128S, R265C, K618A and L749Q, based on their presence in functional domains, predicted effect and the evolutionary status of the respective amino acid residues. These alterations were created in plasmids containing wild type MLH1 cDNA by site-directed mutagenesis, and transiently transfected into the colon cancer cell line HCT116, which is deficient in hMLH1. Preliminary results indicate that both R265C and L749Q decrease the expression of hMLH1 compared to the wild type vector, however with R265C a more striking effect is seen. This novel observation will be verified by independent experiments. Quantitative RT-PCR assays are being used to determine the level at which the alterations affect the expression of the protein. Co-immunoprecipitation experiments are being carried out to address the possibility that these alterations disrupt interactions of hMLH1 with its partner proteins, and the effects of the alterations on the stability and turnover of the protein will be investigated using pulse chase assays. These studies will provide a better understanding of the function of MMR proteins and will help to decrease the ambiguity that arises in predictive genetic testing and counseling of HNPCC patients and their families.

Prostate Cancer Specific Clinical Data on African-American and Caucasian Males in Louisiana: Impact of Family History. *D.M. Mandal[1], S.L. Halton[1], J.J. Hunter[1], O. Sartor[2], J.E. Bailey-Wilson[3], W. Rayford[4].* 1) Dept Genetics, LSU Health Sciences Ctr, New Orleans, LA; 2) Stanley Scott Cancer Center, LSU Health Sciences Ctr, New Orleans, LA; 3) NHGRI/NIH, Bethesda, MD; 4) Dept of Urology, LSU Health Sciences Center, New Orleans, LA.

Prostate cancer is a heterogeneous disease, the exact causes of which are still unknown. There are several significant risk factors identified, including age, race and family history. African-American men have an incidence rate of prostate cancer almost two times greater than Caucasian American men and in addition, they are two to three times more likely to die from this disease. Studies examining the disproportionately higher incidence and death rate of prostate cancer among African-Americans indicate that this dire impact might be attributed to an earlier onset of the disease and delayed diagnosis. The purpose of this study is to compare clinical/pathological characteristics of men with familial and sporadic prostate cancer in African-American and Caucasian males. Clinical records were reviewed for 100 prostate cancer (approx. 40 African-American and 60 Caucasian) cases identified with positive family history from 30 families and the clinical characteristics, including age at onset, Prostate Specific Antigen (PSA) values at the time of diagnosis, Gleason scores and clinical stages were compared with an equal number of prostate cancer cases with no family history. All sporadic prostate cancer cases were verified for family history of the disease. Statistical analyses and a detailed account of our data resources will be presented comparing clinical and pathological characteristics of men in both races, in conjunction with the use of family history information. Preliminary analyses show that there is a significant difference in the age at onset between familial and sporadic prostate cancer cases both in African-American ($p=0.002$) and Caucasian ($p=0.01$) patients. The result of the study will allow us to understand the characteristics of the disease in different ethnic groups recruited from Louisiana.

Reclassification of 54 BRCA1 DNA sequence variants of uncertain significance as benign polymorphisms has positively affected test results for 1500 patients. *A.M. Deffenbaugh, D. Pruss, T. Judkins, T. Scholl, L.A. Burbidge, C.A. Frye, M. Frost, R. Iyer, J. Tazelaar, B.E. Ward, W.W. Noll.* Myriad Genetic Laboratories, Salt Lake City, UT.

Introduction: *BRCA1/BRCA2* genetic testing for hereditary breast/ovarian cancer is important in managing patients who may be at increased risk of cancer. Clearly positive or negative test results are usually obtained, but sometimes sequence variants of uncertain significance (UVs) are found, producing a clinically ambiguous test result. Efforts to gather additional information so that these variants may be reclassified as deleterious or benign are essential. All evidence currently available in the literature and in the Myriad database indicates that a person cannot carry biallelic deleterious mutations in *BRCA1*. Mouse studies indicate that absence of *Brca1* expression is embryonically lethal, and in more than 70,000 individuals tested, Myriad has never identified two deleterious mutations in *BRCA1* that are on opposite chromosomes. **Methods:** All *BRCA1* UVs identified as homozygous or *in trans* with a deleterious mutation through haplotype analysis or family testing were reclassified as genetic variants, favor polymorphism. If additional data were available, such as lack of co-segregation of the variant with cancer in families, variants were reclassified as polymorphisms. **Results:** 54 *BRCA1* variants previously classified as UVs were reclassified as favor polymorphism (31/54) or polymorphism (23/54). This has resulted in the reclassification of test results for 1505 patients and has reduced the percentage of patients tested for *BRCA1* and *BRCA2* who receive an overall test result of genetic variant of uncertain significance from 11% to 9.5%. The number of patients who carry only a *BRCA1* UV has decreased 43%. **Conclusion:** Reclassification of *BRCA1* UVs using the sole criterion that a UV identified *in trans* with a deleterious mutation is unlikely to be clinically significant has resulted in the clarification of genetic test results for more than 1500 patients. As data continue to accumulate regarding the clinical significance of UVs in *BRCA1* and *BRCA2*, additional reclassifications will be made.

The Norwegian founder mutation, BRCA1:1135insA, occurs on different haplotypes in ethnically diverse populations. *N. Hamel[1], T.M. Rudkin[2], M. Galvez[2], F. Hogervorst[3], J.J.P. Gille[4], P. Møller[5], J. Apold[6], W.D. Foulkes[1,2,7].* 1) Dept Medicine and Research Institute, McGill Univ. Health Centre, Montreal, QC, Canada; 2) Dept Human Genetics, McGill Univ., Montreal, QC, Canada; 3) Netherlands Cancer Institute, Amsterdam, Netherlands; 4) Dept Clinical Genetics, VU Univ. Medical Centre, Amsterdam, Netherlands; 5) Dept Cancer Genetics, Norwegian Radium Hospital, N-0310 Oslo, Norway; 6) Center of Medical Genetics and Molecular Medicine, Haukeland Univ. Hospital, Bergen, Norway; 7) Cancer Prevention Centre, Sir M.B. Davis-Jewish General Hospital, McGill Univ., Montreal, QC, Canada.

Analysis of the chromosomal background upon which a mutation occurs can be used to reconstruct the origins of specific disease-causing mutations. The commonly observed BRCA1 mutation, 1135insA, has been previously identified as a Norwegian founder mutation, but it has also been observed in individuals with other ethnic backgrounds. In the BIC database, the 1135insA mutation is the 12th most common frameshift mutation occurring in BRCA1. To determine whether all carriers of the mutation share a common ancestry, we performed haplotype analysis of carriers from breast and ovarian cancer families with several different ethnic origins. We used four polymorphic microsatellite repeat markers located within and adjacent to BRCA1 for haplotype analysis. We found that the mutation occurs on several, clearly distinct haplotypes. Divergent haplotypes can sometimes be explained by recombination events following the appearance of the mutation. However, such events are unlikely to account for our observations given the proximity of the intragenic markers tested. While recombination events could have occurred between two of the markers, our haplotype results are not consistent with this scenario. The DNA sequence surrounding the mutation includes a run of seven consecutive adenines that may be prone to slippage during DNA replication. This may create a hot-spot within BRCA1 where mutations are more likely to occur than elsewhere in the gene. Our results suggest BRCA1:1135insA is a recurrent mutation that should be included in all targeted mutation panels, irrespective of the ethnic origin of the individuals tested.

Characterization of a large germline deletion of the VHL gene: Alu-mediated mechanism underlying VHL rearrangements. *A. Casarin, M. Martella, R. Polli, E. Leonardi, L. Anesi, A. Murgia.* Pediatrics, Univ Padua, Padua, Italy.

Mutations of the VHL gene (3p25) are responsible of von Hippel-Lindau disease, an autosomal dominant familial cancer syndrome predisposing to the development of benign and malignant tumors, among which CNS and retinal hemangioblastomas, clear cell renal carcinomas and pheochromocytomas. At least 30% of the disease-causing mutations of the VHL gene are represented by large alterations. The identification of these mutations is not possible with commonly used PCR-based mutational scanning methods. Quantitative Southern blot analysis has been traditionally employed for the detection of complete or partial deletions and seemingly more complex rearrangements of this gene. With the combined use of quantitative Southern blot and Real-Time PCR analysis, developed as an alternative quantitative method for the detection of hemizygosity, we have studied 30 large alterations of the VHL gene. Aim of the study was to determine the exact nature of the mutations and possibly to characterize the boundaries of the deleted regions. The Real-Time PCR analysis demonstrated that all the VHL rearrangements detected by Southern blot were actually represented by large deletions. One of the samples was found to carry a deletion of about 2.2 Kb which included exon 2 and part of the flanking introns. A long-range PCR encompassing the deleted fragment showed that both the 5 and 3 break-points were located within Alu-repeats, present in a large number within the VHL coding sequence. This is the first characterization of the break-point junction of a large VHL gene deletion. Our data suggest that an Alu-mediated mechanism is likely to be responsible of the common occurrence of large alterations in the VHL gene.

Genomic rearrangements of BRCA1 and BRCA2 genes in Belgian families with breast and/or ovarian cancers. *P. Hilbert, F. Cavallin, M. D'Amico, Y. Gillerot.* Human Genetics Center, Inst de Pathologie et Genetique, Loverval, Belgium.

Germline mutations in BRCA1 and BRCA2 genes cause predisposition to breast and ovarian cancers. Standard mutation detection screening based on PCR are aimed at identifying coding or splice site mutations but miss large rearrangements of the genes. Such rearrangements account for 5 to 30 % of mutations of BRCA1 gene, depending on populations studied. The availability of MLPA technology (Multiple Ligation dependent Probe Amplification) now allows the easy, fast and unexpensive screening of families for single or multiple exon deletion or amplification. To determine the frequency of such rearrangements in our at risk population, we tested all our mutation-negative patients by MLPA for BRCA1 and BRCA2 genes. On a total of 158 families, 34 carried evident mutations in either BRCA1 (21) or BRCA2 (13) and 9 (respectively 6 and 3) carried a variant of undetermined significance. On the remaining 124 patients without significant mutation, we found 7 genomic rearrangements, exclusively in BRCA1. Six that had been previously described were confirmed by PCR: one duplication of exon 13, one deletion of exon 22 and 4 deletions of exons 8 to 13 . The last one, previously undescribed, is a deletion of exon 23 that we further characterized (c.IVS22+664_IVS24-162 del 2282). No deletion nor amplification in BRCA2 was identified. Large genomic rearrangement of BRCA1 hence represent 17 % of the mutations in our breast/ovarian cancer families and 23 % if we consider only BRCA1 mutations. Interestingly, our results, obtained on patients from the southern part of Belgium, differ significantly from those obtained by another Belgian group in the Northern part of the country (2 %). We confirm that the search for genomic rearrangement is necessary in the BRCA1 and 2 screening process.

Screening for APC mutations in the Iranian FAP patients. *M. Shahmoradgoli[1], O. Mueller[2], N. Kutzner[2], P. Rostami[1], H. Najmabadi[3], B. Noorinayer[1], M.R. Zali[1].* 1) Research Center for Gastroenterology and Liver Diseases, Taleghani Hospital, Shaheed Beheshti University of Medical Sciences, Tehran, Iran; 2) Max-Planck Institute for Molecular Physiology, Dortmund, Germany; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Germ-line mutations in the adenomatous polyposis coli (APC) gene are causative for familial adenomatous polyposis (FAP), a dominant inherited syndrome characterized by presence of multiple adenomatous polyps in the colon and rectum. In this study, we screened the coding region of APC gene for germ-line mutations in ten unrelated Iranian FAP patients. These patients showed classical FAP symptoms. Our study began with a non-radioactive protein truncation test (PTT) to screen all patients for protein truncating mutations in mutation cluster region (MCR) of the APC gene. Then, we analyzed all 15 exons of the APC gene in patients with negative PTT results by single-strand conformation polymorphism (SSCP) and by DNA sequencing. APC mutations were detected in five (50%) patients including three protein truncating and two missense mutations. Nonsense mutations found were C3925T (Q1303X), G3943T (E1309X) and C3962G (S1315X). The G3967C (E1317Q) and G2407A (G797S) were missense mutations detected in two other patients. Genotype-phenotype correlation has been also shown in our study. Furthermore, two novel silent polymorphisms, G4497A and A5898G, were found in our patients. Although we used a combination of PTT, SSCP and DNA sequencing techniques to screen coding region of the APC gene, no causative mutation has been found in five patients. Besides the possibility of missing some mutations due to imperfect sensitivity of SSCP in these patients, existence of mutations located outside the coding region of APC or involvement of other genes, should not be excluded. Based on our findings, APC mutations are responsible for at least 50% of FAP patients in Iran.

***FH* mutation analysis, enzyme activity, protein modeling and early functional study in hereditary leiomyomatosis and renal cell cancer.** *M. Pithukpakorn[1,2], M.H. Wei[2], O. Toure[2], G.M. Glenn[2], L. Middelton[2], M. Merino[2], B. Zbar[2], L. Neckers[2], W.M. Linehan[2], J.R. Toro[2].* 1) NHGRI, and; 2) NCI, NIH, Bethesda, MD.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is the autosomal dominant predisposition to the development of leiomyoma of the skin and uterus and/or renal cancer. We previously showed that mutations in fumarate hydratase gene (*FH*) are associated with HLRCC. With 56 families to date, we have identified 31 different germline *FH* mutations, of which 9 were novel. These 31 mutations consist of 20 missense, 9 frameshifts (3 insertions and 6 deletions), 2 nonsense and 1 splice site. To date our *FH* mutation detection rate is 93% (52/56) in families suspected of HLRCC. Sixteen families shared the R190H mutation and four families shared the R58X mutation. Renal tumors were found in 32% (18/56) of families. The *FH* mutations associated with these 18 families with renal tumors consisted of R58X (3 families), R190H (4 families), L89S, S102X, R190C, H 275Y, S376P, Q396P, c.111insA, c.780delGC, c.1162delA, c.1339delG, c.138+1G>C. *FH* mutations were associated with a spectrum of renal tumors. LOH at the *FH* gene locus was found in 83% of HLRCC renal tumors. This finding supported the role of *FH* as a tumor suppressor gene. We also report for the first time the FH activity in cytosolic and mitochondrial fractions in cell lines from HLRCC patients. Lymphoblastoid cells (n=13) and fibroblasts (n=4) from the individuals with HLRCC had statistically significantly lower FH activity than normal control cells ($p<0.05$). There was no difference in FH activity between normal controls and 15 cell lines from patients with VHL and BHD. FH activity in fibroblasts from HLRCC patients was as low as in patients with FH deficiency but their urine organic acids were normal. In addition, we present the three-dimensional atomistic model of the human FH. Using siRNA to inhibit FH activity in culture cells, we found 2/3 reduction of FH enzyme activity in fibroblasts. We recently found that cellular accumulation of fumarate impairs hypoxia inducible factor (HIF) prolyl hydroxylase and leads to stabilization of HIF, suggesting that the VHL-HIF pathway may play role in tumorigenesis in HLRCC.

Genetic Factors in African American Women with Breast Cancer. *T. Pal[1, 3], S. Vadaparmpil[1, 3], S. Narod[2], J. Betts[3], C. Miree[3].* 1) Department of Interdisciplinary Oncology, University of South Florida, Tampa, FL; 2) Center for Research in Women's Health, Toronto (Canada); 3) H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

BACKGROUND. Because a larger proportion of African-American women have early onset breast cancer, we hypothesized that a subset of these women may have a genetic cause of their increased risk, such as BRCA1 and BRCA2 (BRCA1/2).

METHODS. We are conducting a study investigating BRCA1/2 among African American breast cancer patients with a personal or family history suggestive of hereditary predisposition to breast cancer. To date, twenty-three women have been enrolled. The majority (n=9; 39%) were recruited from the Moffitt Breast Program physicians. Other sources of recruitment included: outside physicians (n=3; 13%), newspaper advertisements and brochures (n=3; 13%), FORCE organization/website (n=2; 9%), community or support groups referrals (n=4; 17%), and word of mouth (n=2; 9%). RESULTS. The average age of study participants and age at cancer diagnosis is 41 (SD=7.35) and 39 (SD=6.39), respectively. BRCA1/2 test results are currently available on 18 patients, and 1 (5.5%) was found to be a mutation carrier. Review of family history data showed that 9 (39%) had a first or second-degree relative with breast cancer, and 3 (13%) had a relative with ovarian cancer.

CONCLUSIONS. Our preliminary results suggest a small proportion of breast cancers in young African American women are due to the BRCA1/2 genes. In mutation carriers, family history characteristics may be similar to that seen in Caucasian patients. The oncology care setting may serve as an important point for identification and risk appropriate referral to genetic services for African American breast cancer patients.

Full mutational analysis of the Chk2 gene in high risk Jewish Ashkenazi women. *E. Friedman[1,3], Y. Leitman[1,3], T. Distelman-Menachem[1,3], R. Gershoni-Baruch[2].* 1) Oncogenetics Unit, Inst. Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Institute of Genetics, Rambam Medical Center, Haifa, Israel; 3) Sackler School of Medicine, Tel-Aviv University, Ramat-Aviv, Israel.

Germline mutations in BRCA1 and BRCA2 genes account for 20-40% of all familial breast cancer cases. The CHEK2 gene encodes a checkpoint kinase which is activated by ATM in response to DNA damage, and hence is a candidate gene for breast cancer susceptibility. The CHEK2*1100delC truncating mutation, originally described in a subset of Li-Fraumeni cases, was later reported in a subset of mostly European breast cancer families. The rate of the CHEK2*1100delC in the Ashkenazi population both in Israel and New York was reported to be 0.3%. To evaluate whether other variants of CHEK2 contribute to breast cancer predisposition in the Ashkenazi Jewish population we screened the entire coding region of CHEK2. Mutation analysis of the CHEK2 gene was performed using PCR followed by DGGE in high risk Jewish Ashkenazi women, none of whom was a carrier of the predominant Jewish mutations in BRCA1/BRCA2: 70 with breast cancer (average age of diagnosis 48.3 years, median 48.5) and 100 high risk asymptomatic individuals. Four previously described missense mutations were detected (R3W 1.2%, I157T 1.8%, R180C 0.6% and S428F 5%), one silent polymorphism (E84E 20.5%) and one novel missense mutation (Y424H 1.2%). Of the 10 carriers of S428F mutation, 8 were breast cancer patients (average age at diagnosis 50, range 41-57, median 51) and each had at least one other first degree family member affected with breast cancer, ovarian cancer was observed in a single pedigree. Of the remaining two healthy S428F carriers, one had a second degree relative affected with breast cancer and the other had a first degree relative affected with breast cancer and a second degree relative affected with ovarian cancer. The results of this study suggest that CHEK2 variants (other than 1100delC) may contribute to breast cancer susceptibility in Ashkenazi Jews.

Hypoxia-inducible factor 1 alpha gene expression in prostate cancer measured by quantitative reverse-transcriptase polymerase chain reaction. *C. Pipinikas[1], S. Nair[1,2], R. Kirby[2], N. Carter[1], C. Fenske[1].* 1) Medical Genetics and; 2) Urology Department,St. George's Univ. London,SW17,UK.

INTRODUCTION There is an urgent need for accurate diagnosis of prostate cancer (CaP). Hypoxia is associated with cancer formation. Hypoxia-inducible factor-1 alpha (HIF-1)mediates activation of genes involved in cell survival and apoptosis. These normal cellular responses also give tumour cells a survival advantage. Quantitative RT-PCR (qRT-PCR)was used to measure HIF-1 expression levels and detect tumour cells in peripheral circulation. **METHODS** RNA was extracted in quadruplet from blood taken from 164 patients,divided into 4 diagnostic groups, based on clinicopathological information: no evidence of malignancy (NEOM), localised CaP (LCaP), metastatic CaP (MCaP) and radical prostatectomy (RP). qRT-PCR was carried out using HIF-1 specific primers and a LightCycler (Roche). **RESULTS** Highly significant differences in HIF-1 expression were found between all patient groups, with the exception of that between the NEOM and MCaP patient groups.

Patient Group	NEOM(N=36)	LCaP(N=67)	MCaP(N=27)	RP(N=34)
Mean (×10-4)	1.77	260.0	1.9	6.5
Median (×10-5)	6.2	81.0	6.9	23.0

DISCUSSION We have shown that HIF-1 together with qRT-PCR may be used for accurate diagnosis of CaP. Results indicate that hypoxia plays a role in the initial stages of CaP formation (150-fold increase in HIF-1 expression levels between NEOM and LCaP; $p<0.0001$). HIF-1 is down-regulated at advanced stages of the disease ($p<0.0001$ between LCaP and MCaP) suggesting the role of an alternative mechanism in the metastatic stages of CaP formation. High levels of HIF-1 were found patients following surgery (RP group). Of these,a high proportion were shown to have positive margins,highlighting the need for continued monitoring and additional therapy.

Analysis of von Hippel-Lindau tumor suppressor gene mutations in clear cell RCC tumors using multiple platforms: an in-depth mutation screening strategy. *S. Lilleberg[1,2], K.B. Walters[2], Y. Shi[3], J.A. Durocher[2], W.-H. Chow[4], L.E. Moore[4], B. Zbar[5], G. Gerard[3], M.L. Nickerson[2].* 1) Discovery Services, Transgenomic, Omaha, NE; 2) Discovery Services, Transgenomic Gaithersburg, MD; 3) Research and Development, Transgenomic, Gaithersburg, MD; 4) Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 5) Laboratory of Immunobiology, NCI-Frederick, Frederick, MD.

Mutation of the VHL tumor suppressor gene has been implicated in the pathogenesis of clear cell renal carcinoma. A large case-control epidemiology study of kidney cancer is underway in Eastern Europe, which will, in part, examine how exposure history relates to the spectrum of mutations found in the VHL gene. In preparation for analysis of the VHL gene as part of this study, we rigorously examined Transgenomics independent mutation detection methodologies during analysis of the gene in a panel of patient tumor DNAs. Mutation analysis of the VHL protein coding region was performed on 28 patient tumors. Three methods of analysis were employed; denaturing high performance liquid chromatography (dHPLC), enzymatic digestion of PCR products with Surveyor Nuclease, and DNA sequencing. All platforms were able to detect point mutations, insertions, and deletions within the VHL gene. We found slight variation in sensitivity and specificity between the three individual approaches. Initial screening for mutations using Surveyor Nuclease and separation on a WAVE instrument followed by sequence characterization of variant positive amplicons allowed sequencing costs to be reduced considerably while maintaining 100% sensitivity. Integration of the 3 independent mutation detection platforms employed in this pilot study has the potential to expedite renal cancer research while reducing the cost of the analysis.

Genome-wide Expression Analysis of Breast Cancer in African-Americans: New Insights into Genetic Mechanisms. *L. Baumbach, L. Gayol, M.E. Ahearn, L. Nathanson, B. Morel, R. Bookman, F. Moffat.* Miller School of Medicine, University of Miami, Miami, FL.

As is well known, breast cancer (BC) is the most common cancer in American women, and numerous studies have reported an excess incidence and mortality in AA women <50 yoa. To further investigate the genetic basis of these observed differences, we have conducted a novel pilot study analyzing genome-wide expression differences in self-matched breast cancer and normal tissue from African-American (AA) women: two sporadic cases and three with a family history of BC. Study recruitment criteria were either a sporadic case <50 years old/dx. with BC or a high-risk familial case of BC, and no radiation or chemotherapy prior to enrollment. Tumor and normal tissue samples were obtained fresh from surgery. Total mRNA from tumor tissue and the corresponding self-matched normal tissue were labeled with either Cy3 or Cy5 dye and then hybridized to the Agilent Whole Human Genome arrays. Dye-Swap labeling was completed for validation of hybridization data. These data were analyzed using Significance Analysis of Microarrays (SAM) with an FDR1%. Data from self-matched tumor and normal tissue samples were compared between familial and sporadic cases and between individual women in these two categories. The analysis yielded more than twice as many over expressed genes (2852) in the familial cases than in the sporadic cases. There were also 1988 under expressed statistically significant genes in the familial cases and about 200 less of these genes in the sporadic cases. About 1/8 of the reported over expressed genes and 1/3 of the reported under expressed genes were shared between the familial and sporadic groups. Importantly, there are 11 significant genes that are under expressed in sporadic and over expressed in familial cases, and 10 significant genes that are over expressed in sporadic and under expressed in familial cases (FDR1%). Additional analyses, including hierarchical clustering and real-time PCR are underway. This study should provide important information concerning the genetic differences between AA women with familial or sporadic BC.

Hereditary Non-Polyposis Colon Cancer associated with a novel duplication mutation in the MSH2 gene encompassing exons 1 to 6. *B. Roa[1], L.H. Chin[1], B. Chong[1], T. Badger[2], P. Ward[1], H. Vance[3], A. Rajput[3], C. Le Vea[3], C. Farrell[3], M. Hegde[3].* 1) Medical Genetics Laboratories, Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Texas Tech University, Lubbock, Texas; 3) Roswell Park Cancer Institute, Buffalo, New York 14263.

Hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome is an autosomal dominantly inherited cancer syndrome characterized by malignancies of the colon and other sites. HNPCC results from germline mutations in DNA mismatch repair genes, primarily MSH2, MLH1 and to a lesser extent MSH6, PMS1 and PMS2. Identification of a germline mutation provides a molecular diagnosis in HNPCC patients. Sequence analysis can identify ~90% of germline mutations in the MSH2 and MLH1 genes. A proportion of HNPCC cases can be due to large gene rearrangements in the MLH1 and MSH2 genes which are refractory to PCR-based sequencing analysis. A founder mutation in MSH2 comprising of deletion of exons 1-6 has been reported to be one of the most frequent MSH2 mutations in North America. However, a reciprocal duplication has not been previously reported in HNPCC patients. We report on the identification of a novel duplication mutation encompassing exons 1 to 6 of the MSH2 gene. A Caucasian woman diagnosed with colorectal cancer at age 46 with a family history of colon cancer fulfilling the Amsterdam criteria was referred to our laboratory for MSH2 testing. Analysis on her colorectal tumor had shown high microsatellite instability on DNA testing, and absence of MSH2 and MSH6 expression on immunohistochemistry analysis. Sequencing did not identify a mutation in the MSH2 coding region. Analysis for gene rearrangements was performed using real time quantitative PCR, which showed duplication of MSH2 exons 1 to 6 with normal dosage of the remaining exons. This was corroborated by MLPA analysis. The exact endpoints have yet to be characterized to determine whether this novel duplication corresponds to the reciprocal recombination product of the MSH2 deletion founder mutation. Our data highlight the value of genomic rearrangement testing in the MSH2 and MLH1 genes as part of a comprehensive molecular diagnostic work-up for HNPCC.

New DHPLC based method using qasimonomoprhic mononucleotide repeats and pentaplex PCR for rapid and accurate MSI analysis. *M. Ravnik-Glavac, G. Berginc, D. Glavac.* Department of Molecular Genetics, Institute of Pathology, Medical Faculty, Korytkova 2, 1000 Ljubljana, Slovenia.

Microsatellite instability (MSI) is a phenomenon characterized by small deletions or insertions within short tandem repeats in tumour DNA compared to matching normal DNA. MSI analysis is becoming more and more important for detection of herditary non-polyposis colorectal cancer as well as for sporadic primary colorectal tumours with MSI high phenotype. Set of two monucleotide and three dinucleotide microsatellite markers called Bethesda panel was proposed by National Cancer Institute Workshop in 1997 to provide uniform criteria for MSI analysis. A second consensus meeting was held at 2002 where guidelines were revised and exclusive use of mononucleotide instead of dinucleotide markers was proposed due to their quasimonomorphic nature. Use of five quasimonomorphic mononucleotide markers eliminates ultimate need for analysis of germline DNA corresponding to tumour DNA. Here we report a new method for MSI analysis using denaturating high performance liquid chromatography (DHPLC). We analysed 980 newly diagnosed colorectal tumours and 145 normal samples. Five quasimonomorphic mononucleotide microsatellite markers including BAT-25, BAT-26 were amplified in a single multiplex reaction and analysed using DHPLC and capillary electrophoresis. We have shown that tested markers are quasimonomorphic in Slovenian population with frequences of polymorphisms 0,07%, 1,4 for BAT-25, BAT-26 respectively. 71 new MSI-H tumours were identified among. Overall, we developed a high-throughput, robust, accurate and cost-effective method for detection of MSI-H tumours in only nine minutes using DHPLC. Method is suitable for large scale studies as well as for daily use with smaller numbers of samples.

Linkage disequilibrium and founder *BRCA1* mutations: preliminary study in Ashkenazi Jews and other populations. *L.H.M. Pereira[1], M.A. Pineda[1], W.H. Rowe[1], L.R. Fonseca[1], M.H. Greene[2], K. Offit[3], N.A. Ellis[3], J. Zhang[1], A. Collins[4], J.P. Struewing[1,2].* 1) Lab of Population Genetics, &; 2) Clinical Genetics Branch, NCI, Bethesda, MD; 3) Memorial Sloan Kettering Cancer Center, New York, NY; 4) Human Genetics Division, University of Southampton, Southampton, UK.

We analyzed a dense set of SNPs in a 650kb region around *BRCA1*, a breast/ovarian susceptibility gene, in 5 populations, focusing on Ashkenazi Jews, a population with *BRCA1* founder mutations. We developed 143 SNP assays, of which 114 were polymorphic in at least 1 population. There were 84 intragenic (~ 1 SNP per kb) and 30 SNPs that flanked *BRCA1* (~ 1 SNP per 20kb). Subjects included 85 unrelated Ashkenazi Jews, 60 CEPH parents, and 48 each from African-Americans, Chinese-Americans and Mexican-Americans. Further, 6 unrelated 185delAG founder mutation carriers and their relatives were studied to define mutation-associated haplotypes from family data. We calculated pair-wise r^2 measures of LD using a modified version of LDSelect that does not assume Hardy-Weinberg equilibrium, estimated haplotypes using SNPHAP as implemented in Hapscope, determined haplotype block boundaries using Haploview, filtering SNPs with population-specific minor allele frequencies less than 5%, and calculated LDU length using LDMAP. The region analyzed shows long-range LD, falling primarily into 3 blocks among non-African populations. The entire *BRCA1* gene maps to a large block of at least 188kb that spans 95 markers (excluding a genome gap of arbitrary 100kb size). This block correlates completely with the largest LDSelect bin of SNPs correlated at $r^2 > 0.8$. The LDU map length among Ashkenazi Jews was 35% shorter than the CEPH map length. The 185delAG founder mutation occurs on the second-most frequent haplotype, representing 15% of chromosomes among Ashkenazi Jews, suggesting that a haplotype-based case-control association analysis would have been modestly enriched due to this founder mutation. Although in strong LD with the majority of markers studied as measured by D, owing to its relatively low frequency, the highest pair-wise r^2 for 185delAG was 0.04 with a SNP that mapped outside the large *BRCA1*-containing block, approx. 110kb downstream.

Multicenter study to determine the frequency of germline mutations in MSH6 among various groups of patients with colon cancer. *M.L. Butz, S.N. Thibodeau, Colon Cancer Family Registry.* Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Current testing strategies to identify germline mutations in the MSH6 gene in families suspected of HNPCC are dependent on the sensitivity of IHC staining and MSI testing. To determine the frequency of germline mutations in MSH6 among different groups of patients having colon cancer, we utilized a subset of patients who participated in the Colon Cancer Family Registry. Direct DNA sequencing of the MSH6 gene was performed on 337 germline DNA samples provided by 2 main groups of subjects: 109 whose cancers had high MSI (MSI-H) and showed loss of MSH6 protein expression, either alone or in combination with other mismatch repair (MMR) proteins; and 228 whose tumors were either low MSI (MSI-L, n=95) or microsatellite stable (MSS, n=133) with normal IHC. The MSH6/MSI-H group consisted of cases that had loss of protein expression (by IHC) for either MSH6 alone (n=33), MSH2 and MSH6 (n=57), or MSH6 along with other MMR proteins (n=19). Of the MSH6-only cases, alterations were identified in 19 and in 16 (48%) they were pathogenic nonsense/ins/del mutations. Among the 57 MSH2/MSH6 cases, there were 3 nonsense (1 of unknown clinical significance - UCS) and 2 missense (UCS) alterations. Of the MSI-L cases, 1 missense mutation (UCS) and a 3 UTR deletion (UCS) were identified. Among the MSS cases, 4 missense (UCS) and 4 novel insertion/deletion mutations (UCS) were identified. As expected, pathogenic mutations were identified primarily among the group demonstrating loss of MSH6 only by IHC. The overall prevalence of 48%, however, is lower than anticipated. Other mechanisms need to be considered in these cases. Of interest, several likely pathogenic mutations were identified among patients showing loss of MSH2/MSH6. Thus, in such cases, testing MSH6 should be considered when an MSH2 mutation cannot be identified. Among the MSS/MSI-L group, a higher than anticipated frequency of missense mutations of UCS were identified. The significance of these alterations is under investigation. In summary, IHC and MSI analysis provides an efficient strategy for identifying MSH6 germline mutations.

Expression phenotype of lymphoblastoid cell lines from carriers of the breast cancer-associated ATM mutation, 7271T>G (V2424G). *N. Waddell[1], J. Jonnalagadda[1], S. Grist[2], kConFab[3], M. Taylor[4], G. Suthers[2], K. Khanna[1], S. Grimmond[5], G. Chenevix-Trench[1].* 1) Queensland Inst Med Res, Brisbane, Australia; 2) South Australian Familial Cancer Service, Australia; 3) Peter MacCallum Cancer Institute, Melbourne, Australia; 4) University of Birmingham, UK; 5) Institute for Molecular Biosciences, Brisbane, Australia.

Heterozygous (ht) mutations in ATM (mutated in ataxia telangiectasia) have been associated with an elevated risk of breast cancer. We have reported one Australian breast cancer family in which ATM V2424G segregated with disease, and apparently acted as a dominant negative. To elucidate the consequences of this mutation, we expression profiled 5 wildtype (wt), 7 ht, and 3 homozygous (hom) LCLs from a Scottish and an Australian family using 19k oligo arrays, and found 60 significant differences between the genotypic groups. Cluster analysis revealed some discrete patterns of gene expression, including a large group of genes that are differentially expressed in hom and ht V2424G cells (compared to wt) and a small number differentially expressed in the hom cells (compared to wt and ht LCLs). We also evaluated the profiles of LCLs after exposure to ionizing radiation (IR) and identified a group of genes (over-represented in the DNA replication and cell cycle regulation pathways) that were differentially expressed in wt cells after IR, but not in hom or ht V2424G carriers. We validated the expression differences by RT-PCR in additional ht V2424G LCLs from one of two additional Australian breast cancer families that we have recently identified with the same mutation. We also found the same expression pattern in two other ht ATM LCLs with truncating mutations, suggesting a similar mechanism of action of V2424G and truncating mutations in ATM. We found no consistent cytotoxicity or abrogation of ATM kinase activity after IR in seven ht V2424G LCLs, compared to wt LCLs, but did find an increase in the number of chromosomal aberrations. These data suggest that the missense V2424G mutation, like truncating ATM mutations, act largely as a dominant negative in terms of the associated expression profiles and chromosomal aberrations.

Does Nonsense-mediated mRNA Decay explain the Ovarian Cancer Cluster Region of the *BRCA2* Gene? *S. Mazoyer[1], D. DeSilva[2], O.M. Sinilnikova[3], D. Stoppa-Lyonnet[4], S.V. Tavtigian[2], M.D. Ware[1].* 1) Laboratoire de Génétique Moléculaire, Signalisation et Cancer UMR5201 CNRS, Université Claude Bernard Lyon I, 69373 Lyon cedex 08, France; 2) International Agency for Research on Cancer, 69372 Lyon cedex 08, France; 3) Plate-forme Mixte de Génétique Constitutionnelle des Cancers Fréquents, Hospices Civils de Lyon / Centre Léon Bérard, 69373 Lyon cedex 08, France; 4) Service de Génétique Oncologique, Institut Curie, 75248 Paris cedex 05, France.

BRCA2 germline mutation carriers are at increased risk for breast and ovarian cancers. Mutations occurring in the Ovarian Cancer Cluster Region (OCCR) of *BRCA2* are linked to a higher risk of ovarian cancer and/or lower risk of breast cancer than mutations occurring outside this region. Most *BRCA2* germline mutations introduce premature termination codons (PTCs) that are likely to make their mRNAs targets of nonsense-mediated mRNA decay (NMD), a mechanism that detects and destroys PTC-bearing transcripts to prevent expression of truncated proteins. The PTC position in relation to downstream exon-exon junctions (EEJ) is an important factor in its recognition by NMD. Contradictory reports exist regarding the ability of NMD to recognize PTCs located far from the nearest 3 EEJ. The presence of the OCCR in the 4.9 kb exon 11 of *BRCA2* prompted us to investigate whether transcripts containing PTCs in this large exon avoided detection by NMD and whether this might contribute to the phenotypic difference associated with the OCCR. We observed a global reduction of 1.4 to 3.3-fold in the relative abundance of PTC-containing transcripts in lymphoblastoid cells of 18 truncating mutation carriers, regardless of the location of the PTC in the gene or its distance from the nearest 3 EEJ. We conclude that NMD is capable of recognizing PTCs up to 4.5 kb upstream of the nearest EEJ and that NMD-avoidance does not appear to be the biological mechanism behind the genotype-phenotype correlation associated with the OCCR.

Presence of complete NF1 gene deletion is not frequently associated with the development of malignant peripheral nerve sheath tumours (MPNSTs). *M. Upadhyaya[1], E. Majounie[1], G. Spurlock[1], S. Griffiths[1], S. Huson[2], G. Evans[2], R. Ferner[3].* 1) Dept Medical Genetics, Univ Wales Col Medicine, Cardiff, United Kingdom; 2) Medical Genetics, St Mary's Hospital,Manchester, uk; 3) Clinical Neurosciences, Guy's Kings and St Thomas' School of Medicine, London, Uk.

Neurofibromatosis type 1 (NF1) is an autosomal dominant disease with an incidence of about 1 in 3,500. NF1 is characterised by a variety of benign and malignant lesions, including café-au-lait spots, neurofibromas, pilocytic astrocytomas and malignant peripheral nerve sheath tumours (MPNSTs). An increased incidence of malignant peripheral nerve sheath tumours (MPNSTs) in NF1 patients with microdeletions has been reported. We have studied DNA from 32 NF1 patients with MPNSTs for NF1 gene constitutional mutations to ascertain whether complete NF1 gene deletions are more frequently predisposed to the development of MPNSTs. Patients were clinically evaluated in London, Manchester,Oxford and Cardiff. Complete mutation analysis was conducted using SSCP,dHPLC,FISH, deletion breakpoint PCR and MLPA. Mutations were identified in a group of 30/32 patients.The age at diagnosis of MPNSTs ranged from 16 to 64 years and half of these patients have since died. Of the 32 patients, 20 had high grade MPNSTs, 9 had low grade MPNSTs while no details were given for three patients. Of the 30 mutations, nonsense mutations were identified in seven patients, microdeletions in 7 patients, micro-insertion in 3 cases, missense mutations in 3, splicing alterations in six and exonic/multi-exonic deletions identified in 3 patients. The common 1.5 Mb large deletion was only identified in one individual. The NF1 mutations identified were distributed evenly across the gene . There is no apparent relationship between the mutation type and the observed clinical severity. The overall mutation detection rate in our series was 94%.Thirteen of these sequence changes are novel. Our results indicate that NF1 patients with a variety of constitutional mutations may develop MPNSTs. Analysis of a larger panel of MPNSTs is clearly warranted to determine the risk related to microdeletion in MPNST formation.

Global expression based classification of lymph node metastasis and extracapsular spread of oral tongue squamous cell carcinoma. *X. Zhou[1], S. Temam[2,3], B. Huang[1], M. Oh[4], N. Pungpravat[1], L. Mao[2], D.T. Wong[1,5].* 1) Dental Research Institute, School of Dentistry, University of California at Los Angeles, Los Angeles, CA; 2) Department of Thoracic/Head and Neck Medical Oncology, University of Texas, MD Anderson Cancer Center, Houston, TX; 3) Department of Head and Neck Surgery, Institut Gustave-Roussy, Villejuif, France; 4) Department of Biostatistics, School of Public Health, University of California at Los Angeles, Los Angeles, CA; 5) Jonsson Comprehensive Cancer Center; Molecular Biology Institute, University of California at Los Angeles, Los Angeles, CA.

Tumor metastasis is the dominant cause of death in cancer patients, including oral tongue squamous cell carcinoma (SCC) patients. However, the molecular and cellular mechanisms underlying tumor metastasis are still elusive. The identification of molecular markers associated with the metastatic process would help to understand biological mechanisms and facilitate the development of therapeutic interventions for oral tongue cancer patients. We performed global gene expression profiling on 11 lymph node metastatic (pN+) and 14 non-metastatic negative (pN-) SCC samples of tongue, and the matching normal tissues. Using stringent statistical criteria (fold difference >2, and $p<0.003$), a signature set of 99 genes was generated that can classify the pN+ and pN- cases with > 90% accuracy. These analyses also generated a second gene list that can provide superb classification power for extracapsular spread (ECS). ECS is considered as the most reliable clinical predictor of poor treatment outcomes of metastatic squamous cell carcinoma of the head and neck to regional lymph nodes. Expression profiling capable of predicting ECS phenotype has not been reported previously, so these results have high substantive significance. Our results were further validated using real-time quantitative PCR, as well as publicly available microarray datasets of metastasis and non-metastasis head and neck cancers from the Gene Expression Omnibus (GEO) database.

AGC repeat polymorphism in E2F-4 is associated with increased risk of gastric carcinoma. *L. Hu, Y. Yu, Y. Lu, W. Li, J. Ji, H. Xu, Q. Li, Z. Wang, Z. Zhu, B. Liu, Y. Lin, X. Kong.* Health Sci Ctr, Sibs, CAS, Shanghai, Shanghai, China.

E2F-4 protein is a member of the E2F family of transcription factors, playing an important role in DNA synthesis and cell cycle control. In its coding region, there is an AGC triplet repeat sequence, which has been reported to vary in some cancers. However, the characteristic of the AGC triplet repeat has never been detected systematically in gastric carcinoma. Here, we report four novel repeat variants in gastric carcinoma. Totally, 11 repeat variants and one SNP were detected in 20 of 85 tumors (23.53%), and among them 4 variants were detected in 9 of 11 MSI samples (81.82%). In healthy individuals, 3 variants were found in 7 out of 80 samples (8.75%). Overall, the AGC repeat polymorphisms occurred much more frequently in gastric carcinoma group than that in healthy (P=0.01, Odds Ratio was 3.21). The results demonstrated that people with AGC repeat variants had a higher risk of suffering gastric carcinoma than those without. Furthermore, immunohistochemical experiment revealed E2F-4 protein expression was obviously increased in diffuse-type gastric carcinoma than that in intestinal-type carcinoma and mixed carcinoma (P=0.017). All the results suggested E2F-4 AGC variants and increased expression maybe associated with predisposition and some clinical phenotype of gastric carcinoma.

The role of genes related to DNA methylation process as modifiers of BRCA1/2 gene penetrance. *M.A. Caligo[1], C. Pepe[1], E. Sensi[2], P. Aretini[2], L. Guidugli[1], G. Cipollini[2], E. Falaschi[1], E. D'Andrea[3], M. Montagna[3], P. Radice[4], A. Viel[5], G. Bevilacqua[1].* 1) Department of Oncology, Division of Pathology,University Hospital and University of Pisa,Italy; 2) MGM,Pisa,Italy; 3) Department of Oncology and Surgical Sciences, Oncology Section, Azienda Ospedaliera, Padua, Italy; IST-Genova c/o Department of Oncology and Surgical Sciences,Azienda Ospedaliera, Padua, Italy; 4) National Cancer Institute, Milan, Italy; FIRC Institute of Molecular Oncology, Milan, Italy; 5) Centro di Riferimento Oncologico IRCCS, Aviano Italy.

Significant variations in the level of risk associated with a mutation of BRCA1/2 genes have been highlighted, suggesting the existence of modifiers of gene penetrance. DNA methylation is an important mechanism of transcriptional regulation. Polymorphisms in enzymes involved in SAM (S-adenosylmethionine) metabolism, such as MTHFR (methylene tetrahydrofolate-reductase), MS (methionine synthase) and CBS (cystathionine beta-synthase) are good candidates for affecting the pattern of DNA methylation.The aim of the study is to investigate the role of genes related to DNA methylation process as possible modifiers of the BRCA1/2 gene penetrance. We genotyped 348 affected and 115 unaffected BRCA1/2 mutation carriers (of which 133 affected and 32 unaffected BRCA1-carriers and 215 affected and 83 unaffected BRCA2-carriers) and a control group. Four polymorphisms have been considered: C677T and A1298C for MTHFR gene, A2756G for MS gene and Ins68bp for CBS gene.The analysis has been performed by means of PCR-RFLPs. A Cox regression analysis on age of breast cancer onset showed that the BRCA1 carriers with the MTHFR gene 677T allele exhibited a lower age of onset of the breast disease (P=0,04 HR=1.73).The HR and the confidence limits were adjusted by provenience group and by year of birth (before and after 1960).Moreover the analyses were corrected for the familial aggregation.No effect on BRCA2 gene penetrance was observed.A MSP(Methylation-Specific PCR) analysis of the promoter region of BRCA1 gene in tumor samples will allow to test the effect of a low apport of the methyl-group donor SAM on gene inactivation.

Induction of renal tumourigenesis with elevated levels of somatic LOH in *Tsc1*$^{+/-}$ mice on a *Blm*-deficient background. *J.P. Cheadle, C. Wilson, S. Idziaszczyk, J. Colley, V. Humphreys, C. Guy, J. Maynard, J.R. Sampson.*
Institute of Medical Genetics, Cardiff Uinversity, Cardiff, S Wales, United Kingdom.

A Bloom (RecQ) deficient mouse model (*Blm*$^{m3/m3}$) has been shown to induce colorectal tumourigenesis when crossed with *Apc*$^{Min/+}$ mice (Luo *et al.* 2000). Here, we investigated whether *Blm*$^{m3/m3}$ mice could induce tumourigenesis in extra-colonic tissues by crossing with *Tsc1*$^{+/-}$ mice that are predisposed to renal cystadenomas and carcinomas (Wilson *et al.* 2005). Genotyping of offspring from *Tsc1*$^{+/-}$ *Blm*$^{+/m3}$ intercrosses showed that a ~24% excess of *Tsc1*$^{+/-}$ mice died before weaning (P= 0.016), in agreement with our previous study (Wilson *et al.* 2005). *Tsc1*$^{+/-}$ *Blm*$^{m3/m3}$ mice had significantly more macroscopic and microscopic renal lesions at 3-6 months compared to *Tsc1*$^{+/-}$ *Blm*$^{+/m3}$ mice (p=0.0003 and p=0.0203, respectively), and showed significantly increased levels of somatic LOH of the wild type *Tsc1* allele, as compared to *Tsc1*$^{+/-}$ *Blm*$^{+/+}$ mice (p<0.0001). *Tsc1*$^{+/-}$ *Blm*$^{+/m3}$ mice did not show significantly more renal lesions compared to *Tsc1*$^{+/-}$ *Blm*$^{+/+}$ animals; however, their lesions still showed significantly increased levels of somatic LOH (p=0.028). Renal lesions on a *Blm*-deficient background stained positively with anti-Phospho-S6 Ribosomal protein (Ser 240/244) indicating that these lesions develop through the normal pathway of *Tsc*-associated tumourigenesis. This work demonstrates the utility of the *Blm*-deficient mice for inducing renal tumourigenesis and the high levels (~82%) of LOH in the resultant tumours will help facilitate mapping of loci involved in tumour progression.

The contribution of BRCA1 and BRCA2 mutations to inherited ovarian cancer. *S.J. Ramus[1], P. Harrington[2], R.A. DiCioccio[3], B.A. Werness[4], K. Garlinghouse-Jones[5], I. Oakley-Girvan[5], C. Pye[2], I.J. Jacobs[1], A.S. Whittemore[5], B.A.J. Ponder[2], P.D. Pharoah[2], M.S. Piver[3], S.A. Gayther[1].* 1) Department of Gynaecological Oncology, University College London, UK; 2) Department of Oncology, University of Cambridge, UK; 3) Gilda Radner Registry at Roswell Park Cancer Institute, Buffalo, NY, USA; 4) Department of Pathology, Inova Fair Oaks Hospital, Fairfax, VA, USA; 5) Department of Health Research and Policy, Stanford University School of Medicine,CA, USA.

Three hundred families, from the UKCCCR and Gilda Radner ovarian cancer registries, containing at least two confirmed cases of epithelial ovarian cancer (EOC) in first-degree relatives were screened for coding mutations in the BRCA1 and BRCA2 genes and genomic deletion/rearrangement mutations in BRCA1. An affected individual from each family was first screened by SSCP/HA analysis. Abnormal variants were sequenced to identify the causative nucleotide change. Families in which no deleterious mutation was identified (174 families) were further analysed for genomic rearrangements of BRCA1 using MLPA. Functional BRCA1 mutations were identified in 111 families (37%), of which 10 were detected by MLPA; thus 9% of all BRCA1 mutations were large rearrangements. Of these, 5 were the same exon 13 amplification (a UK founder mutation). The remaining 5 rearrangements were previously unreported deletions of exon 2, exons 3-16, exons 8-13, exons 15-20, and exons 21-24. Functional BRCA2 mutations were identified in 25 families (8%). BRCA1/2 mutation prevalence correlated with the extent of ovarian and breast cancer in families. Of families with >2 EOC cases and at least one breast cancer case under 60 years, 86% had a BRCA1/2 mutation. Mutation prevelence was significantly less in families containing no breast cancer. Of 156 families containing 2 ovarian cancer cases, only 28% had an identifiable mutation compared to 64% of 58 families containing 3 or more EOC cases. These data indicate that BRCA1 and BRCA2 are the major EOC susceptibility genes; but that other susceptibility genes may also exist.

Multiplex PCR as sensitive method for *BRCA* founder mutation detection in formalin-fixed and paraffin-embedded (FFPE) tissue. *M.A. Adank[1,4], E. Brogi[2], F. Bogomolniy[3], E.A. Wadsworth[1], K.J. Lafaro[1], C. Yee[1], E.J. Meijers-Heijboer[4], N.D. Kauff[1], J. Boyd[1,3], K. Offit[1].* 1) Clinical Genetics Service, Memorial Sloan-Kettering Cancer Center (MSKCC), New York, NY; 2) Dept. of Pathology, MSKCC, New York, NY; 3) Dept. of Surgery, MSKCC, New York, NY; 4) Dept. of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands.

Statement of purpose: To determine the sensitivity and reproducibility of *BRCA1* and *BRCA2* founder mutation analysis in formalin-fixed and paraffin-embedded (FFPE) tissue so it can be offered in a clinical setting. **Methods:** DNA extracted from 161 coded, morphologically normal FFPE samples (from women who were previously genotyped on lymphocyte derived DNA by direct sequencing) were analyzed simultaneously for the presence of one of the three common Ashkenazi founder mutations in *BRCA1* (5382insC and 185delAG) and *BRCA2* (6174delT) with multiplex PCR followed by electrophoresis on denaturing polyacrylamide gels. **Results:** A total of 120 *BRCA* founder mutations (39 *BRCA2*6174delT*, 24 *BRCA1*5382insC* and 57 *BRCA1*185delAG*) and 40 wild type samples were detected, including 25 samples over 10 years old. Only one of the 161 morphologically normal FFPE tissue samples was excluded due to PCR-failure. There was a 100% sensitivity and concordance between DNA results of the 160 samples derived from archival FFPE tissue and fresh lymphocytes. **Conclusions:** The multiplex PCR method had 100% sensitivity in detecting 120 Ashkenazi *BRCA* founder mutations in a time-efficient way. This is the largest described comparative study on *BRCA* testing of FFPE tissue; prior studies have shown highly variable sensitivity of this approach. This method has high potential for clinical testing in dominantly inherited breast and ovarian families where the only affected women are deceased. By testing them it allows clarification of uninformative negative interpretations for a subset of unaffected probands, mitigating the need for intensified surveillance and/or risk-reducing surgery. This method may also be useful in other populations were founder mutations are the predominant mutations in *BRCA1* and *BRCA2*.

A high frequency of germline NF2 mutations detected with complementary mutation screening techniques. *A. Rohlin[1], J. Wahlström[1], L. Wiklund[2], M. Nordling[1].* 1) Clinical Genetics, Sahlgrenska University Hospital, Gothenburg, Sweden; 2) Dept of Neurology, University Hospital, Uppsala, Sweden.

Neurofibromatosis type 2 (NF2) is an autosomal, dominantly inherited tumor syndrome with high morbidity and mortality caused by mutations in the NF2 gene. Bilateral vestibular schwannomas are the most frequent manifestations of the disease, other manifestations are; central and peripheral nervous system schwannomas, cereberal meningiomas and ocular abnormalities. In about half of the patients the mutation occurs as a new-mutation i.e. the family does not show any heredity for NF2.

Since 2000 we provide genetic and clinical investigations for Swedish NF2 patients. Initially we use DNA sequence determination and Multiplex Ligation-dependent Probe Amplification (MLPA), to detect sequence variations and large deletions/duplications in the NF2 gene. In new-mutation cases, mosaics (i.e. the mutations are only present in a group or population of cells) are frequently encountered. If no mutation is found using initial DNA-sequence determination or MLPA the sample is analyzed with DHPLC (Wave system equipped with the HSX fluorescent detector) and /or SSCP to enhance detection of low-frequency mutation alleles in mosaic samples. To detect mutations causing aberrant splicing and to verify MLPA findings mRNA (cDNA) is analysed. Total loss of NF2 transcripts is also investigated using coding SNP polymorphism on cDNA. Mutations where detected in 20/31 (64%) of patients with verified NF2 disease, including two mutations not reported earlier. A genotype-phenotype correlation was observed in a mosaic case and in a patient carrying a splice-site mutation, both giving rise to milder disease.

Mutation screening in Juvenile Polyposis Syndrome. *R.E. Pyatt[1], R. Pilarski[2], T.W. Prior[1].* 1) Dept Pathology, Ohio State University, Columbus, OH; 2) Department of Internal Medicine, Division of Human Genetics, Ohio State University, Columbus, OH.

Juvenile polyposis syndrome (JPS) is an autosomal dominant cancer predisposition syndrome characterized by congenital anomalies, hamartomatous polyps in the colorectal and upper gastrointestinal regions, and the development of tumors in these tissues. The clinical diagnosis of JPS is often difficult due to the phenotypic overlap with other syndromes featuring hamartomatous polyps. Recently germline mutations have been identified in SMAD4 and BMPR1A, two members of the TGF- superfamily, which has aided in presymptomatic genetic testing. In this study, we describe the results from three years of molecular diagnostic screening for germline mutations in these genes. Seventy unrelated individuals referred to our lab for JPS testing were examined by direct sequence analysis of all coding regions and exon-intron boundaries in both genes. Mutations were identified in thirty percent of cases, with eleven percent in BMPR1A and eighteen percent in SMAD4. All mutation positive individuals were negative for cancer at the time of testing and a single case of pulmonary valve stenosis was the only congenital anomaly reported. A majority of mutations identified in both genes were novel including the first splice site alteration described in SMAD4. Based on the limited number of exons in either gene, low polymorphism frequency, and high frequency of frameshift or nonsense mutations identified, direct sequence analysis is an suitable methodology for mutation screening in JPS. The large number of unique mutations, the absence of mutational hotspots, and similar mutation frequencies between genes mandate that all coding regions and exon-intron boundaries must be examined.

Mutational screening of MLH1, MSH2, and APC genes in Chilean patients with hereditary colorectal cancer. *K. ALVAREZ[1], M. DE LA FUENTE[2], A. LETELIER[2], F. LEON[1], F. BELLOLIO[1], F. LOPEZ-KOSTNER[1], M.P. CARVALLO[2].* 1) Departamento de Cirugía Digestiva, Facultad de Medicina, P. Universidad Católica de Chile, Santiago, Chile; 2) Departamento de Biología Celular y Molecular, Facultad de Ciencias Biológicas, P. Universidad Católica de Chile, Santiago, Chile.

Two hereditary variants have been described in Colorectal Cancer: HNPCC (hereditary non polyposis colorectal cancer) caused by mutations at the MLH1 and MSH2 genes, and FAP (familial adenomatous polyposis) caused by mutations at the APC gene. In Chile there is an increase in the incidence of colorectal cancer in the last years. For this reason we proposed to study the MLH1 and MSH2 genes in HNPCC families, and the APC gene in FAP families. Four HNPCC families and seven FAP families were selected by standard criteria. All exons and intron-exon boundaries of the three genes were analyzed through Single Strand Conformation Polymorphism, Protein Truncation Test, and sequencing. In the HNPCC families we found one allelic variant, non described previously, IVS15+3A>T, and one mutation c.504insA in exon 6, both in the MLH1 gene. The c.504insA frameshift mutation causes a premature termination at the codon 171. In FAP families we found four mutations in the APC gene: c.790C>T (Q264X) in exon 7 in one family, c.3927_3931delAAAGA in exon 15 in two families, c.3941_3942delG in exon 15 in one family and c.3920T>A (I1307K) in exon 15, previously described for Ashkenazi-Jewish families. The first three mutations lead to premature translation termination, being the c.3927_3931delAAAGA, the most frequent mutation described in FAP patients. Mutations in IVS 15+3A>T in MLH1, c.790C>T in exon 7 of APC, and c.3941_3942delG in exon 15 of APC constitute novel germline mutations. This is the first mutational report in Chilean HNPCC and FAP patients. These three novel mutations contribute to the world genetic database. FONDECYT 1040827.

Screening of the ATM gene, and CHEK2 1100delC in 40 Chilean families with high risk to breast cancer. *M.P Carvallo[1], T. Tapia[1], A. Sánchez[1], C. Alvarez[1], S. Smalley[1], A. Letelier[1], M.C. Vallejos[1], M. Alvarez[2].* 1) Facultad de Ciencias Biologicas, P. Universidad Catolica de Chile, Santiago, Chile; 2) Centro de Cáncer, Facultad de Medicina, P. Universidad Católica de Chile, Santiago, Chile.

The major genetic factor for breast cancer high risk in families, is the presence of mutations in the BRCA1 or the BRCA2 gene. Several studies have shown that the prevalence of mutations among families is variable, and depends on the ethnic origin of the population analyzed. In a previous study in 54 Chilean families, we found that only 20% presented mutations in one of these genes. It has been mentioned that other low penetrance genes, like ATM and CHEK2, that are components of the ATM-dependent signalling pathway, as BRCA1 and BRCA2, may explain part of the hereditary predisposition to breast cancer. For ATM it has been shown that female heterozygous carriers for mutations in this gene have an increased risk of breast cancer. For CHEK2, one mutation 1100delC has been involved in predisposition to breast cancer for some populations. We performed a screening of the ATM gene in 40 non BRCA1 or BRCA2 patients from our previous study. We screened the 62 exons and intron-exon boundaries from the ATM gene for mutations, through SSCP and sequencing. We found five intronic polymorphisms (homozygous or heterozygous), with no significant differences in frequency between cases and controls. Three heterozygous missense mutations: c5557G>A (D1853N), c2572T>C (F858L), c5558A>T (D1853V) were also found. No significant difference was found in the frequency of the variant allele c2572C (F858L) between 40 cases and 50 controls. However the c5557A (D1853N) variant allele was significantly associated with an increased risk of developing breast cancer (allele A vs allele G OR 4.8, 95% CI 2.74-8.39 , P< 0.05) The other missense mutation c5558A>T was found in 1/40 patient and not present in 50 controls. These results provide evidence that the c5557A (D1853N) variant allele might be associate with familial breast cancer risk in Chilean families. The CHEK21100delC mutation was not found in patients neither in 200 controls, from the Chilean population. FONDECYT 1040779.

The High Cumulative Incidence of Cancer in Individuals with Blooms Syndrome Does Not Vary by Sex, Ethnicity, or Mutation Type. *A. Zauber[1], M. Sanz[2], W. Shi[1], J.L. German[3].* 1) Dept Epidemology/Biostatistics, Mem Sloan Kettering Cancer Ctr, New York, NY; 2) Molloy College Kellenberg Hall, Rm105 1000 Hempstead Ave POBox 5002 Rockville Centre, NY 11571-5002; 3) Weill Cornell Medical College 1300 York Ave New York, NY 10021.

Blooms syndrome (BS) is a rare recessively transmitted form of proportional dwarfism that predisposes to many types of cancer. The gene mutated in BS encodes a large nuclear protein known to have DNA helicase activity. 64 BS-causing mutations have been identified and characterized at the molecular level; they can be classified as to whether the peptide they encode enters/does not enter the nucleus. The product of one mutant allele, blm^{Ash}, an allele present in ~1% of Ashkenazi Jews and in all Ashkenazi Jews with BS, is among many that fail to enter the nucleus; in contrast, the products of 11 missense mutations and the 1 splice-site mutation examined so far, though demonstrably lacking in helicase activity, do assume a roughly normal (nuclear)distribution. The features and clinical courses of 238 individuals with BS, along with certain features of the causative mutations, have been entered into a recently developed ACCESS database,the Bloom's Syndrome Registry Database. From this database we determined (i) the cumulative incidence of cancer (CIC) and also whether the incidence of cancer varies with respect to (ii) sex, (iii) ethnicity, and, or, (iv) mutation type. The CIC was 10% by age 10, 23% by age 20, 45% by age 30, and 82% by age 40. (The cumulative mortality was also high, 74% by age 40, with most deaths due to cancer.) CIC was similar for males (49%) and females (40%) by age 30 (hazard ratio [HR]=1.0 and 95% Confidence Interval [CI] 0.7-1.5) and for Jews (46%) and non-Jews (43%) by age 30 (HR=1.1; CI 0.7-1.7). Also CIC was similar with respect to whether the mutant proteins were/were not nuclear localizing. Thus, different classes of known BS-causing mutations are implicated in BS's extraordinarily great risk of cancer, and that risk is no greater in one sex than in the other, nor in Jews than in non-Jews.

Genetic Analysis of Candidate Modifier Genes in BRCA1 and BRCA2 Mutation Carriers. *D.J. Hughes[1], I. Coupier[2], L. Barjhoux[1], V. Gaborieau[1], G. Lenoir[3], P. Brennan[1], D. Stoppa-Lyonnet[2], O.M. Sinilnikova[1,4].* 1) Unit of Genetic Epidemiology, International Agency for Research on Cancer, 150 cours Albert Thomas, 69008 Lyon, France; 2) Service de Génétique Oncologique, Institut Curie, 75248 Paris, France; 3) Institut Gustave Roussy, 94805 Villejuif, France; 4) Centre Léon Bérard, 69373 Lyon, France.

Characterisation of deleterious germline alterations in the BRCA1 and BRCA2 genes has provided a genetic approach to identification of high-risk women for breast and ovarian cancer. Despite the high overall lifetime risk of these cancers among mutation carriers, there is marked variation in risk both between and within families. However, the basis of these strong inter-individual risk differences is very poorly understood and may be partly explained by modifier genes that influence mutation penetrance. We are using association studies to assess the influence of biologically plausible candidate loci on the penetrance of BRCA1/2 mutations. An understanding of these modifying effects should help refine individual risk estimates and is also expected to be an efficient method to identify further susceptibility alleles in general, as variants within low penetrance predisposition genes are likely to have a larger risk modification effect in BRCA1/2 mutation carriers. Several potential genetic modifiers in BRCA1/2 carriers have been reported including a polymorphism in the 5UTR region of the RAD51 gene, and poly-glutamine coding variation in the AIB1 gene. We have analyzed these variants in our sample set of around 1200 BRCA1/2 mutation carriers. We have focused on variants from several DNA repair genes, as this seems the major pathway in which BRCA1 and BRCA2 operate, and from genes whose products interact with the BRCA proteins. A more extensive genetic analysis of two of these latter genes, BARD1 and ACCA which are located in the same genomic region as BRCA1, has also been undertaken. For none of these genetic variants did we find any evidence of a major breast cancer modifying effect. We did see some effects for ovarian cancer but believe this could easily represent false positives, due to the low number of these cases in our sample set.

Neurofibromas from NF1 patients retain neurofibromin expression. *T. Tucker, CJ. Brown, JM. Friedman.* Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada.

Neurofibromatosis 1 (NF1) is an autosomal dominant disease affecting 1 in 3500 people. Neurofibromas are the hallmark of NF1 and are classically divided into four groups based on occurrence and clinical behaviour: cutaneous, subcutaneous, nodular plexiform and diffuse plexiform. These benign tumours develop from peripheral nerves and are comprised largely of Schwann cells but may contain numerous fibroblasts, perineural cells, endothelial cells and mast cells. All classes of neurofibromas are generally believed to develop in accordance with Knudsons two-hit hypothesis, and, as expected, loss of heterozygosity (LOH) at the *NF1* locus has been demonstrated. However, only 30% to 50% of neurofibromas analysed have shown LOH, even in tumour-derived $S100^+$ (presumably Schwann cell) lines. The low percentage of observed *NF1* LOH is usually attributed to technical limitations of the LOH assay, which is not capable of identifying point mutations or epigenetic mechanisms that may inactivate the normal *NF1* allele, or to contamination of the neoplastic cells by non-neoplastic stromal. We have used dual-label immunofluorescence to demonstrate the expression of neurofibromin, the protein product of the *NF1* gene, in tissue from nodular and diffuse plexiform neurofibromas from individuals with NF1. Diffuse plexiform neurofibromas demonstrated clusters of $S100^+$ (presumably Schwann) cells interspersed with $S100^-$ cells. An average of 63% of the $S100^+$ cells also expressed neurofibromin. Nodular plexiform neurofibromas showed a more even distribution of $S100^+$ cells, the majority (73%) of which also expressed neurofibromin. These findings are not consistent with an obligate requirement of complete loss of NF1 function as a prerequisite for neurofibroma development. Rather, our observations, which join an increasing body of evidence in other inherited tumour predisposition syndromes, suggest that some neurofibromas may develop in haploinsufficient tissues without the need for a second hit at the tumour suppressor locus. Examining neurofibromin expression in each type of neurofibroma may provide further information on the pathogenesis of these clinically distinct tumours.

Identification and characterization of novel SNPs in CHEK2 in Ashkenazi Jewish men with prostate cancer.

W.D. Foulkes[1], L.Q. Chen[1], T. Kirchhoff[2], N. Hamel[1], S.V. Tavtigian[3], S. Kolb[4], P. Nelson[4], L. Hood[5], S.A. Narod[6], K.A. White[7], E. Ostrander[8], W.B. Isaacs[9], K. Offit[2], K.A. Cooney[7], J.L. Stanford[4], D. Friedrichsen[4]. 1) Dept Medicine, Div Med. Gen. McGill Univ., Montreal, QC, Canada; 2) Dept Medicine, Memorial Sloan Kettering Cancer Center, NY, NY; 3) Genetic Susceptibility Group, IARC, Lyon, France; 4) Public Health Sci. and Div. Human Biol, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Inst. Systems Biology, Seattle, WA; 6) Univ. Toronto, Toronto, ON, Canada; 7) Dept Int. Med.& Urol., Univ. Michigan, Ann Arbor, MI; 8) Cancer Genetics Branch, NHGRI, Bethesda, MD; 9) Johns Hopkins Medical Institutions, Baltimore, MD 21287.

To identify variants (q > 0.01), we re-sequenced all exons and intron-exon boundaries of CHEK2 in 75 Ashkenazi Jewish (AJ) individuals with prostate, breast or no cancer (n = 25 each). We identified 7 coding SNPs (5 are novel) that changed the amino acid sequence, resulting in R3W, E394F, Y424H, S428F, D438Y, P509S and P509L. We determined their frequency in probands from 77 AJ families collected by ICPCG members where 2 men were affected by prostate cancer and 1 affected man provided a DNA sample. Only 1 variant, Y424H was identified in more than 2 affecteds. Exon 11 was screened in 10 additional families for a total of 87 families with at least one affected genotyped. The Y424H variant occurred in 9 affecteds in 4 different families. In 1 family, all 3 affecteds had the variant. In another, 4 of the 5 affecteds carried the Y424H variant. For the other 2 families, only 1 affected out of 2 or 3 affecteds had this variant. Bioinformatic analysis showed that Y424H is a radical missense substitution that falls at a position that is invariant in vertebrate CHEK2 orthologs. Both SIFT and Align/GV-GD predict that this is a loss of function mutation. However, Y424H frequency was 8/709 in prevalent cases and 5/545 in controls (OR 1.23, 95%CI: 0.35-4.82, P =.79). These results suggest that CHEK2 has a minor role, if any, in prostate cancer susceptibility in the AJ population. However, for = 0.05 and a power of 80%, a study of > 9000 cases and > 9000 controls will be required to rule out an OR of 1.5 in association with Y424H.

Impact of the MDM2 SNP309 and TP53 Arg72Pro polymorphism on age of tumor onset in Li Fraumeni syndrome. *G. Bougeard[1,2], S. Baert-Desurmont[1,2], I. Tournier[1], S. Frerot[2], C. Martin[2], D. Stoppa-Lyonnet[3], C. Bonaiti[4], T. Frebourg[1,2].* 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Department of Genetics, Rouen University Hospital, France; 3) Department of Genetics, Institut Curie, France; 4) Inserm U535, Villejuif, France.

The Li-Fraumeni syndrome (LFS), which results from germline mutations of the TP53 gene, represents one of the most devastating genetic predispositions to cancer characterized by a wide spectrum of early-onset malignancies. Recently, the SNP309 (T>G variation) in the MDM2 gene, encoding a negative regulator of TP53, was shown to be associated with accelerated tumor formation in TP53 mutation carriers. The impact of the common TP53 Arg72Pro polymorphism on tumorigenesis remains controversial. We have therefore investigated the effect on tumorigenesis of these 2 polymorphisms in 61 germline TP53 mutation carriers. The mean age of tumor onset in patients homozygous for the MDMD2 SNP309 T allele was 29.9 years whereas it was 19.6 years in G allele carriers. This difference was significant ($p<0.05$). Patients homozygous for the TP53 Pro allele had a mean age of tumor onset of 34.4 years, which was significantly different from that observed in Arg allele carriers (21.5 years, $p<0.05$). We observed a cumulative effect of both polymorphisms since the mean ages of tumor onset in patients, with the MDM2 T/T and TP53 Pro/Pro genotype, and in patients, carrying at least one MDM2 G allele and at least one TP53 Arg allele, were clearly different (43 years versus 16.9 years, $p<0.02$).We did not detect any effect of these polymorphisms on the tumour type. Neither the MDM2 nor the TP53 polymorphism could explain in our series the incomplete penetrance of germline TP53 mutations observed in males. Our results confirm the impact on the age of tumour onset, in germline TP53 mutation carriers, of the MDM2 SNP309 G and TP53 72 Arg polymorphism, which represent the first modifier genetic factors identified in mendelian forms of cancer. However, detection of these polymorphisms should not modify the genetic counselling and clinical follow-up of LFS families with germline TP53 mutations.

Population-based estimates of breast cancer risks associated with the *ATM* gene variants 7271TG and IVS10-6TG from the Breast Cancer Family Registry. *S. Teraoka[1], J.L. Bernstein[2], M.C. Southey[3], M.A. Jenkins[3], E.M. John[4], J. Knight[5], I.L. Andrulis[5], R. Lapinski[6], G. Chenevix-Trench[7], A. Wolitzer[2], E.R. Olson[1], A.S. Whittemore[8], D. Seminara[9], J.L. Hopper[3], P. Concannon[1], Breast Cancer Family Registry.* 1) Benaroya Research Inst, Seattle, WA; 2) Memorial Sloan Kettering Cancer Ctr, NY, NY; 3) University of Melbourne, Melbourne, AUS; 4) Northern California Cancer Ctr, Fremont, CA; 5) Samuel Lunenfeld Research Inst., Toronto, CAN; 6) Mt. Sinai School of Medicine, NY, NY; 7) Queensland Inst. of Medical Research, Brisbane, AUS; 8) Stanford University School of Medicine, Stanford, CA; 9) National Cancer Inst., Bethesda, MD.

The *ATM* gene variants segregating in ataxia-telangiectasia families are associated with an increased breast cancer risk, but the contribution of specific variants has been difficult to estimate. Previous small studies suggested that two functional variants, 7271TG and IVS10-6TG, are associated with increased if not high risk. Using population-based samples we found that 7 of 3,743 cases (0.2%) and 0 of 1,268 controls were heterozygous for the 7271TG allele (P = 0.1). In cases, the allele was more prevalent in women who had an affected mother (odds ratio (OR) = 5.5, 95% confidence interval (CI) 1.2-26; P = 0.04) or delayed child-bearing (OR = 5.1, 95% CI 1.0-25.6; P = 0.05). Based on breast cancer history of first- and second-degree relatives of carrier cases, the estimated cumulative breast cancer risk to age 70 years (penetrance) was 52% (95% CI 23-86; hazard ratio = 8.6, 95% CI 3.1-23.6; P 0.001). In contrast, 13 of 3,757 cases (0.3%) and 10 of 1,268 controls (0.8%) were heterozygous for the IVS10-6TG allele (OR=0.44, 95% CI = 0.19-1.0; P = 0.05). This suggests that the rare *ATM* 7271TG variant is associated with a substantially elevated breast cancer risk, but the more common IVS10-6TG variant is not associated with increased risk. Since 7271TG is only one of many rare *ATM* variants predicted to have deleterious consequences, effective means of identifying and grouping these variants will be essential to accurately assess the contribution of *ATM* variants to individual risk and population burden of breast cancer.

Evaluation of pre-test probability models in identifying MLH1 and MSH2 mutations in HNPCC: A retrospective study. *K.W. Jasperson, K. Lowstuter, J.N. Weitzel.* Clinical Cancer Genetics, City of Hope , Duarte, CA.

Hereditary non-polyposis colorectal cancer (HNPCC) is an autosomal dominant syndrome characterized by a susceptibility to colorectal, endometrial, and other cancers. The accuracy of available models for predicting mismatch repair (MMR) mutation probability is unknown. The purpose of this study is to evaluate the Wijnen et al. (1998) pre-test probability model and the Myriad Genetics Laboratories, Inc. prevalence table (2004) at predicting the likelihood of a mutation in individuals undergoing genetic testing for HNPCC. A retrospective analysis was performed in 49 patients that were enrolled in an IRB-approved hereditary cancer registry. Patients were previously screened for germline mutations in MLH1 and MSH2. Sensitivity, specificity, and negative and positive predictive values were calculated for the Amsterdam criteria I and II, modified Bethesda guidelines, Wijnen model, and Myriad table. In addition, receiver operator characteristic (ROC) curves were calculated for the Wijnen model and Myriad table. Of the 49 individuals, 18 were found to harbor a germline mutation in MLH1 or MSH2. Using a 10.0% MMR gene mutation probability threshold, the Wijnen model and Myriad table performed poorly with both low sensitivities (55.6% and 60.0% respectively) and specificities (54.8% and 23.8% respectively). As expected, the Bethesda guidelines showed a high sensitivity (94.4%) and low specificity (12.9%), while the Amsterdam criteria I and II together had a sensitivity of (38.9%) and specificity of (71.0%). In addition, the calculated pre-test probabilities from the Wijnen model and Myriad table inadequately correlated with mutation prevelance, which is shown by the small areas underneath their corresponding ROC curves (0.616 and 0.400 respectively). The results of this study demonstrate that the neither the Wijnen model nor the Myriad table are sensitive or specific enough to be useful in a clinical setting at prediciting MMR mutations in individuals suspected of having HNPCC.

c-Myc over-expression of Ramos Burkitt's lymphoma cell line predisposes to oxidative stress and to free radicals induced damages *in vitro*. *M. Habel[1,2], D. Jung[1,2].* 1) Research & Development, Héma-Québec, Sainte-Foy, Québec, Canada; 2) Laval University, Sainte-Foy, Québec, Canada.

Burkitt's lymphoma is an aggressive B-cell neoplasm resulting from deregulated *c-myc* expression. We previously showed that proliferation of BL cell lines such as Ramos is markedly reduced by iron . Furthermore, this effect is mediated by a cell cycle arrest in G_2/M. It has been shown that iron induces expression of *c-myc* which regulates genes involved in iron metabolism. Over expression of *c-myc* and transient enhancement of its expression by iron could increase the expression of genes involved in iron incorporation, which could lead to an accumulation of intracellular free iron. Indeed, intracellular free iron catalyzes the formation of highly reactive compounds such as hydroxyl radicals and nitric oxide that damages macromolecular components of cells, resulting in apoptosis. Here, we have investigated whether cells with a high basal level of c-Myc were more likely to accumulate free iron and the possible involvement of free radicals in the response of Ramos cells to iron. Our results suggest that in Ramos cells, where c-Myc is expressed at a high level, *H-ferritin* expression is down-regulated, transferrin receptor expression is increased and ferritin translation is inhibited. These modifications resulting from the strong basal expression of c-Myc, and amplified by iron addition, lead to a disruption in homeostasis and consequently to growth arrest mainly by increasing the intracellular levels of peroxide/peroxynitrite and NO. Moreover, the addition of free radicals scavengers neutralized the iron-induced free radicals accumulation in Ramos cells. Additional experiments provided support for the involvement of ROS in the G_2/M blockade, whereas growth inhibition appear to be primarily mediated by NO. Furthermore, addition of an NO donor or H_2O_2 to Ramos cells generated effects which partially mimicked those induced by iron. Collectively, our results suggest that cells with high expression of c-Myc are predisposed to homeostasis disruption leading to oxidative stress and that free radicals act as effectors in the iron specific growth inhibition of BL cells observed *in vitro*.

Immortalization of normal esophageal epithelial cells by human telomerase reverse transcriptase or human papilloma virus gene E6E7: sequential cytogenetic and molecular genetic characterization. *Y. Jin[1], H. Zhang[2], C. Jin[1], Y.L. Kwong[2].* 1) Department of Clinical Genetics, University Hospital, Lund, Sweden; 2) Department of Medicine, the University of Hong Kong, Hong Kong.

Cell cultures of normal esophageal epithelium (NE) from four individuals were initiated and immortalized by the use of human telomerase reverse transcriptase (hTERT) alone or with the combination of human papilloma virus E6E7 in order to establish in vitro model to study the genetic alterations associated with cell immortalization and early neoplastic transformation of esophageal epithelium. All cell lineages transfected by a combination of hTERT and E6E7 could survive over crisis and eventually be immortalized, whereas only one of cell lineages transfected by hTERT alone could be immortalized. All these cell lineages were extensively characterized at different time-points before and after immortalization by sequential cytogenetic, molecular cytogenetic, and molecular genetic techniques. During early stage of crisis, there was a progressive increase of chromosomal aberrations in all cell lineages with the expression of E6E7, showing great genetic instability and cytogenetic divergence. Telomere association or dicentric chromosome was the major aberration types. In the later stage of crisis, all cells carried aberrations, but karyotypic picture tended to be more convergent. All cell lineages surviving over crisis had gain of chromosome 20 and/or increased copy number of 20q. By contrast, cell lineage immortalized by hTERT alone showed genetic stability throughout immortalization process. Molecular genetic investigations showed markedly deduction of expression level of RB and P53 after infection of E6E7 in all cell lineages. Cell lineage transfected only with hTERT had spontaneously downregulation of p16INK4a protein. In all cell lineages, the telomerase was consistently activated when cells approaching immortalization. Furthermore, Aurora A, which plays critical role in mitotic spindle checkpoint, was overexpressed in post-crisis cells immortalized by either method. Our findings indicate that different genetic mechanisms are involved in immortalization of NE cells.

Oncogenic Transformation by SEI-1 is Associated with Chromosomal Instability. *X.Y. Guan, D. Tang, L. Hu, D. Xie, J.S. Sham.* Dept Clinical Oncology, Univ Hong Kong, Hong Kong, China.

Amplification of SEI-1, a cell cycle regulatory gene at 19q13.1 is commonly detected in ovarian cancer, suggesting a role in the pathogenesis of ovarian cancer. In the present study, the oncogenic potential of SEI-1 was demonstrated by anchorage-independent growth and tumor formation in nude mice with SEI-1-transfected NIH 3T3 mouse fibroblast cells. Silencing of SEI-1 gene expression by small interfering RNAs (siRNAs) in ovarian cancer cell line SKOV3 could inhibit cell growth as well as colony formation on soft agar. Chromosomal alterations including the formation of double minutes were observed in tumor cells derived from SEI-1-transformed NIH 3T3 cells. Micronuclei formation, which is an indicator of nuclear abnormality and genomic instability, was markedly increased in SEI-1-transfected cells. These data suggest that the oncogenic role of SEI-1 might be mediated at least in part via an effect on genomic instability. Furthermore, overexpression of SEI-1 was associated with higher tumor grades and late FIGO stages in ovarian carcinomas. These data strongly suggest that SEI-1 plays an important role in the development and progression of ovarian cancer.

ADAM23, a Possible Tumor Suppressor Gene, is Frequently Silenced in Gastric Cancers by Homozygous Deletion or Aberrant Promoter Hypermethylation. *I.. Imoto[1,3], H. Takada[1,3], H. Tsuda[3,4], Y. Nakanishi[6], T. Ichikura[5], H. Mochizuki[5], F. Hosoda[3,7], S. Hirohashi[6], M. Ohki[7], J. Inazawa[1,2,3].* 1) Department of Molecular Cytogenetics, Medical Research Institute,Tokyo Medical and Dental University, Tokyo, Japan; 2) COE program for Frontier Research on Molecular Destruction and Reconstitution of Tooth and Bone, Tokyo Medical and Dental University, Tokyo, Japan; 3) Core Research for Evolutional Science and Technology (CREST) of Japan Science and Technology Corporation (JST), Saitama, Japan; 4) Department of Pathology II, National Defense Medical College, Tokorozawa, Japan; 5) Department of Surgery I, National Defense Medical College, Tokorozawa, Japan; 6) Pathology Division, National Cancer Center Research Institute, Tokyo, Japan; 7) Cancer Genomics Project, National Cancer Center Research Institute, Tokyo, Japan.

Array-based comparative genomic hybridization (CGH-array) has a powerful potential for high-throughput identification of genetic aberrations in cell genomes. We identified a homozygous loss of ADAM23 (2q33.3) in the course of a program to screen a panel of gastric cancer (GC) cell lines (1/32, 3.1%) for genomic copy-number aberrations using our custom-made CGH-array. Infrequent homozygous deletion of ADAM23 was also seen in primary gastric tumors (1/39, 2.6%). ADAM23 mRNA was expressed in normal stomach tissue, but not in the majority of GC cell lines without homozygous deletion of this gene. Expression of ADAM23 mRNA was restored to gene-silenced GC cells after treatment with 5-aza 2'f-deoxycytidine. The methylation status of the ADAM23 CpG island, which showed promoter activity, correlated inversely with its expression. Methylation of this CpG island was observed both in GC cell lines and in primary GC tissues; in primary tumors with a hypermethylated CpG island, expression of ADAM23 was lower than in adjacent noncancerous tissues. Moreover, restoration of ADAM23 in GC cells reduced their numbers in colony-formation assays. These results suggest that genetic or epigenetic silencing by hypermethylation of the ADAM23 CpG-rich promoter region leads to loss of ADAM23 function, which may be a factor in gastric carcinogenesis.

Molecular Dynamics Simulations of BRCA1-BRCT Reveal Effects of Mutations on Protein-Protein Interaction Sites. *C. Gough[1], T. Imanishi[2], T. Gojobori[2,3].* 1) Japan Biological Information Research Center, Japan Biological Informatics Consortium, Tokyo, Japan; 2) Biological Information Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan; 3) Center for Information Biology and DNA Data Bank of Japan, National Institute of Genetics, Mishima, Japan.

Mutations in the BRCT domain of BRCA1 (BRCA1-BRCT) are associated with increased risk of breast cancer. Cancer-associated mutations abolish BRCA1-BRCT's tumor suppressor function by disruption of interactions with other proteins such as the BACH1 helicase. Since concentrations of mutant BRCA1-BRCT *in vivo* are similar to that of the wild type, loss of function is not caused by diminished levels of folded protein, but likely is due to localized structural changes. To investigate this possibility, we performed molecular dynamics simulations on the three cancer-associated mutants A1708E, M1775R, and Y1853ter and on the wild type and the fully-functional variant containing the benign M1652I mutation, and analyzed the resulting backbone structures and fluctuation dynamics. The fluctuations were quantified with quasiharmonic analysis. The cancer-associated mutants exhibited backbone structure differences from the wild-type crystal structure, while the wild type and benign mutant remained close to the crystal structure. Structural differences were observed in BACH1-binding regions identified by published crystal structures and site-directed mutagenesis studies. In the cancer-associated mutants, the lowest-frequency, largest-amplitude quasiharmonic mode contained many widespread regions of large-amplitude fluctuations, in contrast to more localized amplitude peaks in the wild type and benign mutant. The lowest-frequency mode motions in the cancer-related mutants were qualitatively different from those in the wild type and M1652I mutant; the wild-type and M1652I motions consisted of concerted motions of structural elements, while those of the harmful mutants involved distortion of these elements. These mutation-induced structural and dynamic changes may be responsible for loss of BACH1 binding and tumor-suppressor activity.

Mammographic Density and Breast Cancer Risk in BRCA1 and BRCA2 Mutation Carriers. *A. Antoniou[1], G. Mitchell[2], R. Warren[3], S. Peock[1], J. Brown[1], R. Davies[4], J. Mattison[1], M. Cook[1], I. Warsi[3], T. Cole[5], J. Paterson[5], S. Hodgson[5], L. Izatt[5], F. Douglas[5], G. Evans[5], D. Eccles[5], R. Eeles[6], D. Easton[1].* 1) CR-UK Genetic Epidemiology Unit, University of Cambridge, UK; 2) Peter Macallum Cancer Centre, Melbourne, Australia; 3) Dept of Radiology, Addenbrookes Hospital, UK; 4) Royal Devon and Exeter Hospital, UK; 5) EMBRACE study collaborators; 6) Institute of Cancer Research, Royal Marsden Hospital, UK.

High breast density as measured on mammograms is a strong risk factor for breast cancer in the general population, but its effect in carriers of germline BRCA1 and BRCA2 mutations is unclear. We obtained mammograms from 206 female carriers of BRCA1 or BRCA2 mutations, 96 of whom were subsequently diagnosed with breast cancer, and 136 relatives of carriers who were themselves non-carriers. We compared the mammographic densities of affected and unaffected carriers and of mutation carriers and non-carriers, using a computer assisted method of measurement and visual assessment by 2 observers. Analyses were adjusted for age, parity, body mass index, menopausal status and HRT use. There was no difference in the mean percent density between non-carriers and carriers (difference 2.9% for BRCA1 and 0.3% for BRCA2). Among carriers, increasing mammographic density was associated with an increased risk of breast cancer (p-trend=0.024). The odds ratio (OR) for breast cancer associated with a density of 50% was 2.29 (95% CI:1.23-4.26; p=0.009). The OR did not differ between BRCA1 and BRCA2 carriers or between pre- and post-menopausal carriers. Our results suggest that the distribution of breast density in BRCA1 and BRCA2 carriers is similar to that in the general population. High breast density in carriers is associated with an increased risk of breast cancer, with the relative risk being similar to that observed in the general population. This is consistent with the hypothesis that genetic and other risk factors that influence mammographic density and breast cancer risk in the general population also influence breast cancer risk to a similar relative extent in carriers. Use of mammographic density could improve individual risk prediction in carriers.

The Clinical Breast Care Project: An important resource for studying breast cancer in African American women. *C.D. Shriver[1], V. Gutchell[1], L. Bronfman[1], L.A. Field[2], R.E. Ellsworth[2].* 1) Clinical Breast Care Project, Walter Reed Army Medical Center Washington , DC; 2) Clinical Breast Care Project Windber Research Institute Windber, PA.

The African American population is under-represented in tumor registries and clinical protocols. African American women (AAW) are affected with breast cancer at a younger age, tumor behavior is often more aggressive and survival times tend to be shorter. The Clinical Breast Care Project (CBCP) has developed a large tissue and blood repository from patients undergoing treatment for breast cancer, with previous history of breast cancer, counseled in the Risk Reduction Clinic, screened by routine mammography, or undergoing elective reductive mammoplasty. The success rate for recruitment of AAW is high; currently 24% of the 1,800 patients are African American, including 15% disease-free, 12% high-risk, 54% benign, 6% preinvasive and 13% invasive breast disease. More than 500 data fields regarding lifestyle choices, socioeconomic status, heath history and geography are collected from all participants, and all consenting individuals provide blood specimens for genomic and proteomic studies. Tissues are collected from all patients undergoing surgical procedures using protocols that preserve the macromolecules for downstream research applications. Factors such as education level, tobacco use, BMI, age at diagnosis, hormone receptor status, and BRCA1-like tumor characteristics differ significantly ($P<0.05$) between AAW and age- and stage-matched Caucasian women, reflecting differences seen in the general population. Thus, recruitment efforts in the CBCP have resulted in collection of well-annotated information and research-quality specimens from a large number of AAW. This resource is unique due to the number of quality samples, accompanying demographic information, equal-access to quality health care provided by the CBCP and will allow for the identification of biological and environmental factors associated with adverse clinical outcomes often seen in AAW with breast cancer.

Evaluation of the worldwide-largest HNPCC cohort genotype-phenotype correlations, evidence for a new genetic entity. *E. Holinski-Feder[1,2], E. Mangold[2], C. Engel[2], H.K. Schackert[2], M. von Knebel-Doeberitz[2], T. Goecke[2], J. Willert[2], H. Vogelsang[2], M. Grabowski[1,2], C. Pagenstecher[2], S. Krueger[2], M. Kloor[2], G. Moeslein[2], M. Loeffler[2], C. Tympner[2], P. Propping[2].* 1) Institute of Human Genetics, Ludwig-Maximilians-University Munich, Muenchen, Germany; 2) HNPCC Consortium Germany www.hnpcc.de.

Hereditary non-polyposis colorectal cancer (HNPCC) is one of the most frequent hereditary cancer syndromes defined by the fulfilment of the Amsterdam criteria. In 1999 a multi-centre study for the collection of HNPCC families aiming the further scientific workup was launched by the German cancer aid which resulted in the largest HNPCC cohort worldwide. So far, 2300 families meeting the Bethesda criteria, including 591 Amsterdam pedigrees have been documented. 470 pathogenic mutations in MSH2, MLH1 and to a minor extend in MSH6 have been found. Mutation analysis uncovered c.1489_1490insC in exon 13 of MLH1 and c.942+3A>T splicing defect in exon 5 in MSH2 covering app. 13% of all pathogenic mutations detected. Studies on genotype-phenotype correlation for 1381 tumors of 988 patients from 281 families within the MMR-deficient cohort revealed that MLH1 mutation carriers have a younger age of onset than MSH2 mutation carriers in regard of first cancer (41 vs. 44 y) and to first CRC cancer (42 vs. 46 y). The rate of CRC was higher in MLH1 versus MSH2 mutation carriers. The study cohort provides clinical and molecular evidence that the Amsterdam positive cohort includes two different genetic entities of hereditary CRC predisposition: 1)families with MMR-deficiency caused by mutations in DNA mismatch repair genes. 2)families with MMR-proficient tumors based on so far unknown genetic alterations. The main statistically significant clinical differences are the age of onset for all tumors observed (median 41 vs. 55 y, p 0,003), CRC (median 42 vs. 56 y, p 0,001), the localization of CRC tumor disease (p 0,006), the spectrum of associated tumors and disease progression. A different surveillance program for these families will be discussed. By analysis of chromosomal instability, the MMR-proficient cohort can be further subdivided.

Untangling the association between the androgen receptor and prostate cancer risk. *A. Helgason[1], J. Gudmundsson[1], A. Sigurdsson[1], D.N. Magnusdottir[1], P. Sulem[1], M. Jakobsdottir[1], J.P. Kostic[1], B.A. Agnarsson[2], K.R. Benediktsdottir[2], S. Lindstrom[3], F. Wiklund[3], H. Gronberg[3], G.V. Einarsson[2], R.B. Barkardottir[2], J. Gulcher[1], U. Thorsteinsdottir[1], L. Amundadottir[1], K. Stefansson[1].* 1) deCODE Genetics, Reykjavik, Iceland; 2) University Hospital,Reykjavik, Iceland; 3) Umea University, Umea, Sweden.

Variation in the androgen receptor (AR) gene has been identified by a number of studies as a risk factor in the development of prostate cancer (PrCa). However, inconsistent results have cast some doubt on the role of the AR in PrCa -risk. We used the HapMap data to explore the pattern of haplotype diversity in and around the AR gene. Our results show that the AR gene is contained within a large LD block characterized by extremely divergent haplotype clusters, with great frequency differences between the HapMap populations. Four SNPs can be used to define the three major haplotype clusters observed in the region. Two of these haplotypes showed a marginally significant excess in Icelandic PrCa patients. By examining the evolutionary context of two previously unreported AR intron microsatellites in the HapMap samples, we noted a single haplotype, defined by one SNP and one microsatellite, that tagged both of the at-risk SNP haplotypes. When tested in the Icelandic case-control cohort this haplotype was seen in statistically significant excess in cases (RR= 1.57, p = 0.0017), with RR= 1.75 in high grade cancers (p = 0.0101) and RR= 1.83 in early-onset cases (p= 0.0042). We report findings from a replication analysis in a set of Swedish PrCa cases and controls. The at-risk haplotype tags one of the three basic haplotype clusters in the AR LD block, which is common in individuals of African ancestry, relatively rare in European populations and very rare in East Asian populations. Haplotypes belonging to this cluster tend to have shorter alleles for the two tri-nucleotide repeats in exon 1, than those from other clusters. Our results indicate that it is not length variation in the tri-nucleotide repeats, but rather older haplotype variants that underlie the association between AR and PrCa risk, at least in populations of European ancestry.

Mutation frequencies for BRCA1 and BRCA2 in German breast cancer families indicate additional predisposing genes. *A. Meindl[1], M. Zaino[2], M. Brosig[2], R.K. Schmutzler[3], and German Consortium for Breast and Ovarian Cancer.*
1) Gynaecology and Obstetrics, Klinikum rechts der Isar, Munich, Germany; 2) Institute for Statistics and Epidemiology at the University, Leipzig, Germany; 3) Gynaecology and Obstetrics, Womens Hospital at the University, Cologne, Germany.

Purpose: In order to determine the mutation prevalence of the BRCA1 and BRCA2 gene for different famial risk constellations, we performed screening in 3081 affected females. Methods: Mutation screening was performed by either DHPLC, direct sequencing and application of the MLPA technique in affected females belonging to different risk groups. The latter technique was used to identify genomic deletions in the BRCA1 gene. Results: The highest mutation frequencies were detected in families presenting with breast and ovarian cancer (about 50%). Interestingly, a similar mutation rate was found in single females diagnosed for breast- and ovarian cancer. In families with three or more cases of breast cancer, two of them diagnosed before the age of 50, a mutation frequency of about 35% was observed. Even in families with 5 or more cases of breast cancer, including two premenopausal cases, the mutation frequency was only about 45%. High mutation rates for BRCA1/2 were also found in single females diagnosed before the age of 35 or in females diagnosed with bilateral breast cancer (approx. 20 or 30%, respectively). A low mutation prevalence (about 12.5%) was found for families with three or more cases of late onset breast cancer. Furthermore, even in families with five or more cases of breast cancer diagnosed after 50, the mutation prevalence is only about 15%. Conclusions: Based on our comprehensive screening results, we determined a cut off of 10% empirical mutation probability for offering genetic testing. Moreover, we demonstrated that families with multiple cases of late onset of breast cancer show a low prevalence of mutations in th BRCA genes. Finally, the existence of further predisposing genes is indicated by the lack of BRCA mutations in about 50% of families with multiple early- and/or late onset cases of breast cancer. Currently employed strategies to identify such genes will be discussed.

Prostate cancer and genetic susceptibility: a genome scan incorporating disease aggressiveness. *J.L. Stanford[1], S.K. McDonnell[2], D.M. Friedrichsen[3], E.E. Carlson[2], S. Kolb[1], K. Deutsch[4], M. Janer[4], L. Hood[4], E.A. Ostrander[5], D.J. Schaid[2].* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Res Ctr, Seattle, WA; 2) Mayo Clinic College of Medicine, Rochester, MN; 3) Divisions of Human Biology and Clinical Research, Fred Hutchinson Cancer Res Ctr, Seattle, WA; 4) Institute for Systems Biology, Seattle, WA; 5) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

Prostate cancer is a heterogeneous disease, both genetically and phenotypically. Linkage studies attempting to map genes for hereditary prostate cancer (HPC) have proved challenging, and one potential problem contributing to this challenge is the variability in disease phenotypes. We collected clinical data on 784 affected men with prostate cancer from 248 HPC families for whom a genomic screen was performed. Disease characteristics (i.e., Gleason score, stage of disease, diagnostic PSA level, death from prostate cancer before age 65) were used to classify affected men into categories of clinically insignificant, moderate, or aggressive prostate cancer. These phenotypes were then incorporated into the linkage analyses using both a dominant and recessive model of inheritance. In addition, subset analyses considered age at diagnosis, number of affected men per family and other stratifications to try to increase genetic homogeneity. Several regions of interest (heterogeneity LOD score, HLOD > 1.0) were identified in families with > 2 affecteds with more aggressive prostate cancer. Suggestive linkage was observed at chromosome 22q11.1 (Dominant model HLOD = 2.18) and the result was stronger (Dominant HLOD = 2.75) in families with evidence of male-to-male disease transmission. A second region at 22q12.3-q13.1 was also highlighted (Recessive model HLOD = 1.90) in the aggressive subgroup, as was a region on chromosome 18. These analyses suggest that using clinically defined phenotypes may be a useful approach for simplifying the locus heterogeneity problems that confound the search for prostate cancer susceptibility genes.

A genome wide linkage search for breast cancer susceptibility genes. *P. Smith[1], N. Rahman[2], M.R. Stratton[2], G.J. Mann[3], G.M. Pupo[3], P. Devilee[4], M. Southey[5], C. Szabo[5], D.E. Goldgar[5], D.F. Easton[1], BCLC, kConFab, CFRBCS.* 1) Public Health & Primary Care, University of Cambridge, Cambridge, UK; 2) Institute of Cancer Research, UK; 3) University of Sydney, Australia; 4) University of Leiden, Netherlands; 5) International Agency for Research on Cancer, Lyon, France.

Mutations in known breast cancer susceptibility genes account for a minority of the familial aggregation of the disease. To search for further breast cancer susceptibility genes, we performed a combined analysis of four genome-wide linkage screens, which included a total of 149 multiple case breast cancer families. All families included at least three cases of breast cancer diagnosed below age 60 years, at least one of whom had screened negative for BRCA1 and BRCA2 mutations. Evidence for linkage was assessed using parametric linkage analysis, assuming both a dominant and a recessive mode of inheritance, and using non-parametric methods. The highest LOD score obtained in any analysis was 1.80 on chromosome 4 (close to marker D4S392). Three further LOD scores over 1 (on chromosomes 2, 5 and 22) were identified in the parametric analyses and two (on chromosomes 2 and 14) in the non-parametric analyses. A maximum LOD score of 2.40 was found on chromosome 2p in families with four or more cases diagnosed below age 50. Nine LOD scores of >1.5 were obtained in individual families. These results suggest regions that may harbour novel breast cancer susceptibility genes, but indicate that no gene is likely to account for a large fraction of the familial aggregation of breast cancer.

SF-1 Overexpression in Childhood Adrenocortical Tumors. *B.R. Haddad[1], M.A.D. Pianovski[2], L.R. Cavalli[1], B.C. Figueiredo[2], S.C.L. Santos[1,2], M. Doghman[3], R.C. Ribeiro[4], E. Michalkiewicz[5], G. Zambetti[4], E. Lalli[3].* 1) Georgetown Univ., Washington, DC; 2) Federal Univ. of Parana, Curitiba PR, Brazil; 3) Institut de Pharmacologie Moléculaire et Cellulaire, Valbonne France; 4) St. Jude Children's Res. Hospital, Memphis TN; 5) Erasto Gaertner Hospital, Curitiba PR, Brazil.

We have recently shown that the SF-1 (steroidogenic factor 1) gene is amplified in pediatric adrenocortical tumors (ACT) (JCEM 90: 615-619, 2005). SF-1 encodes a transcriptional activator belonging to the nuclear hormone receptor superfamily and plays a pivotal role in the regulation of adrenal gland development and expression of steroidogenic enzymes. To assess whether SF-1 gene copy number increase translates into increased protein levels and to study the correlation between SF-1 expression and clinical parameters in ACT patients, SF-1 protein levels and gene copy number changes were measured in adrenocortical tumor specimens of 10 children, 6 girls and 4 boys, aged from 11 months to 11 years old. These children presented with only virilization (n=7) or virilization associated with Cushing syndrome (n=3). Histologically, 3 were adenomas and 7 carcinomas. All featured the R337H TP53 mutation, inherited from one of the parents, and loss of heterozygosity (LOH) at the TP53 locus in the tumors. We detected increased SF-1 gene copy number by FISH analysis in eight of the ten cases. Conversely, the SF-1 protein was overexpressed in all cases, compared to normal adrenal cortex; no significant correlation was found between SF-1 protein levels and gene copy number. Furthermore, no correlation existed with histological grade or with the clinical manifestation or evolution of the disease. These data allow us to propose the hypothesis that SF-1 protein overexpression may play an important role in driving ACT genesis and/or progression and that, in addition to gene amplification, epigenetic mechanisms may control SF-1 gene expression in pediatric ACT.

Association of a histological type of gastric adenocarcinoma with an interleukin 1 beta promoter polymorphism: Interaction involving *Helicobacter pylori* CagA. *B. Schneider[1], L. Lopez-Carrillo[2], M. Camargo[1], P. Correa[1], R. Sierra[1], R. Henry[1], J. Chen[3], J. Zabaleta[1], M. Piazuelo[1], L. Sicinschi[1].* 1) Dept Pathology, LSU Health Sciences Ctr, New Orleans, LA; 2) Mexico National Institute of Public Health, Cuernavaca, Morelos, Mexico; 3) Mount Sinai School of Medicine, New York, NY.

Gastric adenocarcinomas are classified histologically into two major types: intestinal, in which the tumor cells form glands; and diffuse, in which tumor cells grow independently. Both types have as risk factors gastric infection with *Helicobacter pylori*. The intestinal type is preceded by a series of premalignant lesions: gastritis, glandular atrophy, complete intestinal metaplasia, incomplete intestinal metaplasia, and dysplasia. Diffuse gastric cancer has less well-defined premalignant lesions.

In European populations, SNPs in the interleukin 1 beta gene (*IL1B*) promoter are associated with gastric cancer risk. To examine the effect of *IL1B* polymorphisms, and any association with tumor type, we examined 183 cases of gastric adenocarcinoma (53% diffuse) and 377 hospital-based controls, all from Mexico. We genotyped *IL1B* (-31 and +3954), interleukin 1 receptor antagonist (VNTR) and interleukin 10 (*IL10*, -592). We evaluated serologically each person for the presence of *H.pylori* and CagA (an *H.pylori* virulence determinant). In intestinal tumors only, among patients with CagA positive *H.pylori* infections, we found a significant association of *IL1B* (-31) CC genotype (OR 3.19, 95%CI=1.05-9.68), compared to *IL1B*-31TT carriers. A significant interaction was found for *IL1B*-31C and CagA status in intestinal-type tumors (p=0.023). The *IL10*-592CC genotype was associated with elevated risk of intestinal-type gastric cancer (OR, 2.20, 95%CI=1.04-4.65) compared with the AA genotype. No associations were found for diffuse tumors. The risk of intestinal-type gastric cancer is apparently modified by *IL1B* or some gene in tight linkage with it; this process is amplified by the presence of CagA. In contrast, the risk of diffuse gastric cancer is unrelated to the state of the marker.

Disruption of circadian gene expression in hepatocellular carcinoma. *J.G. Chang[1], K.T. Yeh[2], M.Y. Yang[3], T.C. Liu[3], S.F. Lin[3], W.L. Chan[1], S.J. Kuo[2].* 1) Dept Molec Med, China Medical Univ Hosp, Taichung, Taiwan; 2) Departments of Pathology and Surgery, Changhua Christian Hospital, Changhua, Taiwan; 3) Division of Hematology-Oncology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background and Aims: Circadian rhythm plays an important role in the regulation of digestive system. The human circadian rhythm is controlled by at least 9 circadian genes. The aims of this study are to understand the difference of these 9 circadian gene expression between hepatocellular carcinoma (HCC) tissues and non-tumor tissue, and to explore the mechanism resulting in the difference. Methods: we analyzed the expression of 9 circadian genes in 46 hepatocellular carcinomas (HCC) and paired non-cancerous tissues by real-time quantitative RT-PCR (qRT-PCR) and immunohistochemical methods and explore the mechanism of down-regulation of 9 circadian genes by direct sequencing and methylation PCR analyses. Results: The results showed that the expression levels of PER1, PER2, PER3, CRY2 and TIM were decreased in HCCs. The down-expression of these genes was not caused by genetic mutation, but parts (34.8%) of them were caused by promoter methylation. The down-expression of these circadian genes has no relationship with the expression of the cell cycle-control genes. Conclusions: The down-regulation of circadian genes results in disturbance of circadian rhythm in HCCs, which may disruption the control of the central pacemaker and benefit the survival of cancer cells and promoting carcinogenesis. Differential expression of circadian genes between non-cancerous and cancerous cells may provide a molecular basis for chronotherapy of HCC.

The Role of Inherited Variation in the Apoptosis Pathway in Colorectal Cancer Risk. *R.R. George[1], S. Brown[4], I.J. Adam[4], A.J. Shorthouse[4], T. Bishop[2], G. Smith[3], A. Cox[1].* 1) Genomic Medicine, University of Sheffield, Sheffield, Yorkshire, United Kingdom; 2) Cancer Research-UK Clinical Centre, St James' Hospital, Leeds, United Kingdom; 3) Biomedical Research Centre, Ninewells Hospital and Medical School, Dundee, Scotland; 4) Department of Colorectal Surgery, Northern General Hospital, Sheffield, UK.

Colorectal cancer (CRC) is the third commonest cancer affecting Western Countries. Although there are inherited forms of the disease, the majority of cases are not familial. Disease in these cases is caused by a combination of weak effects at several genes and exposure to environmental risk factors.

Apoptosis is an essential defence against hyperproliferation and aberations of this process are hallmarks of cancer[1].

We have carried out a population-based case-control study of CRC to investigate single nucleotide polymorphisms in key apoptosis genes: caspase-8 (D302H, T21914C, A50121G, G50258A), caspase-10(L522I) and death receptor-4 (R209T). The study is based on a previously described set of 352 cases and 590 controls from the North of England and Scotland [2]. Blood DNA was genotyped by 5 nuclease PCR (Taqman). We found that there was a significant difference in the CASP8 T21914C genotype frequency between cases and controls (p=0.039). Carriage of the CASP8 C allele was found to be protective for CRC(odds ratio 0.54 - 95% confidence interval 0.33,0.89). We are in the process of genotyping further SNPs in the CASP8 gene to fine map this association. Furthermore, we are undertaking a replication study in a group of Sheffield-based cases and controls.

Indentifying which aspects of the apoptosis pathway are relevant in CRC susceptibility could suggest new targets for treatment.

Germline Mutations in BRCA1 and BRCA2 from Korean Breast Cancer Patients by DHPLC. *D.G. Lee[1], B.Y. Kim[1], S.H. Han[2], K.R. Lee[1].* 1) Dept Human Genome, Seoul Medical Science Inst, Seoul, Korea; 2) Department of Internal Medicine, Ewha Womans University Medical Center, Seoul, Korea.

In Korea, the incidence of breast cancer has been increasing in recent years, such that it is now the most common female cancer. BRCA germline mutations cause a substantially increased lifetime risk of both breast and ovarian cancers. To investigate the presence of BRCA mutations in Korean breast cancer patients, we performed mutational analysis using DHPLC. From 2002 to 2005, we screened 370 breast cancer patients who were not selected on the basis of family histories and 167 individuals considered as not being at risk. We identified fourteen deleterious mutations: 10 frameshift mutations and 4 nonsense mutations. Among the 14 mutations, 3 novel BRCA1 (Q310X, 2167delA, 2478delG) and 3 novel BRCA2 (2487delT, 8662delGGA, R3384X) were identified in this study. We found that BRCA deleterious mutations were present in 19 of 370 patients (5.1 %). Three mutations (K467X, 3972delTGAG, R2494X in BRCA2) of the 14 deleterious mutations were detected in 7 of 19 patients, which were also identified in other studies for BRCA mutations in Korean population. Among the BRCA variants found in 370 patients, 7 BRCA1 variants (2201T, 2430C, 2731T, 3232G, 3667G, 4427C, 4956G) and 9 BRCA2 variants (203A, 1093C, 1342A, 1593G, 2457C, 3199G, 3624G, 4035C, 7470G) of high frequency were shown similar frequency in normal control group. Most of patients with deleterious mutations do not have a family history of breast cancer and observed only 4 patients with a family history of breast cancer. For immunohistochemistry, BRCA-associated tumors were shown to have more PR, p53, and less Her-2/neu positivity. Above findings were not in accordance with previous studies except Her-2/neu. In this study, we identified six novel BRCA mutations, and no recurrent founder mutations were observed, which are different from those of Ashkenazi Jew and other populations, but we found three mutations identified in other studies for Korean population. We suggest the fundamental data for large population-based studies to establish the frequency and significance of BRCA mutations in Korean breast cancer patients.

Thymidylate synthase polymorphism (6bp-deletion) frequency in breast cancer from Mexican population. *M. Gallegos Jr[1], N.C. Olivares[1], G. Morgan[2], A.M. Puebla[1], V. Peralta[1], L. Arnaud[1], G.M. Zuniga[1].* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Unidad de Radio Diagnostico, Hospital de Especialidades, CMNO, IMSS.

Thymidylate synthase (TS; EC 2.1.1.45) is an enzyme essential for the provision of a nucleotide required for both DNA synthesis and repair, to participate in the proliferating cells and also is an important target for a variety of chemotherapeutic drugs, including 5-FU. Thus, TS plays a major role in cancer therapy and possibly in cancer prevention. Genetic polymorphisms in the TS gene may result in altered enzyme function. This could affect cancer susceptibility as well as treatment efficacy and the toxicity of antifolate cancer therapeutics. To date, of the frequency of genetic polymorphisms in TS identified as 6-bp deletion in the 39-UTR of the TS gene are unknown in Mexican population. The frequency of this polymorphism was confirmed in breast cancer patient (n=136) and a control group (n=100) from Mexican population by polymerase chain restriction amplification/RFLP analysis. The genotype frequency of the 6-bp deletion was found to be 30% in the patients group and 15% en the control group (OR 2.3 [CI95% 1.1-4.8] p=0.015), heterozygote of 45% and 30% respectively and the wildtype of 40% in both groups. The 6-bp deletion showed association in breast cancer patients from Mexican population with a risk of 2.3 times more than control groups.

Most familial cancers appear to be heritable. *J. Lorenzo Bermejo[1], K. Hemminki[1,2].* 1) Division of Molecular Genetic Epidemiology, German Cancer Research Centre, Heidelberg, Germany; 2) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden.

Cancer is mainly an environmental disease, with a minor heritable etiology. The effects of common exposures shared by family members and heritable genes are reflected in the increased risks which have been observed for relatives of affected individuals. The present study investigated the contribution of shared environmental factors to the familial clustering of cancer. The acquired information was used to evaluate the feasibility of case-control studies on SNPs. We used the nationwide Swedish Family-Cancer Database and other published information. For example, the risk of lung cancer in the offspring of lung cancer patients was about twice higher than the risk in the general Swedish population. When published data on the heritability of smoking habits (0.5), the smoking prevalence (40%) and the odds ratio of lung cancer for smokers versus nonsmokers (20) were modeled, the relative risk of lung cancer attributable to smoking was 1.19. We show figures for the assessment of genetic parameters of most common cancer types. The results suggest that, in the absence of strong risk factors of cancer, most familial cancers are attributable to heritable genes. Unless established environmental risk factors are tested on proven candidate genes, the likelihood of a successful application of SNPs in gene-environment studies is small.

Transfection of in vitro-transcribed EGFP-mRNA into SK-N-AS and 293 cells shows major difference in the sensitivity to a nuclear compared to a cytoplasmic EGFP-variant. *K. Ejeskär[1,2], S. Fransson[1], F. Zaibak[2], P. Ioannou[2].* 1) Clinical genetics, Gothenburg university, Gothenburg, Sweden; 2) Murdoch Childrens Research Institute, Melbourne University,Parkville, VIC, Australia.

Good transfection efficiency and low toxicity are two important factors for reliable results in in vitro gene studies. Here we report a method for efficient transfection of in vitro transcribed mRNA into two different types of adherent cells, the neuroblastoma cell line SK-N-AS, and the transformed kidney cell line 293. By using newly trypsinized adherent cells in suspension and LipofectamineTM 2000 we can detect a transfection efficiency of 80-90% in both cell lines, and a cell viability of 90% in SK-N-AS and 60% in 293, 24 hours after transfection when using cytoplasmic enhanced green fluorescent protein (EGFP)-mRNA. We have also evaluated the different effects of the generally used EGFP that mainly localizes to the cytoplasm and nuclear EGFP, where the nuclear EGFP are significantly more toxic to the cells than the cytoplasmic EGFP. In order to develop a good null experiment for functional tests of nuclear proteins we have constructed a short non-functional mRNA including a nuclear localisation signal, and evaluated at what concentrations mRNA encoding nuclear proteins can be added without a general toxicity only depending on the fact that the protein are localised to the nucleus. For both SK-N-AS and 293 cells, a concentration of up to 100 ng mRNA in 105 cells, encoding a non harmful nuclear protein, does not affect the cells. We have developed an easy method for efficient delivery of in vitro transcribed mRNA into the adherent cell lines SK-N-AS and 293. This method is useful for functional screening of genes encoding both nuclear and cytoplasmic proteins.

Role of biomarkers in the development of breast cancer. *D.O. McDaniel[1], S. Bigler[2], W.H. Barber[1], A. Lewis[1].* 1) Dept Surgery, Univ Mississippi Medical Ctr, Jackson, MS 39216; 2) Dept Pathology.

This study is to identify genetic variants of the Cytochrome P450 (CYP) 3A4 gene that might be used as diagnostic biomarkers in studies of breast cancer susceptibility. Biochemical pathways involved in hormone metabolism have been implicated in the etiology of breast cancer and the CYP 3A enzymes are involved in such metabolisms. A transition of AG at position -290 of the CYP 3A4 gene has an effect on the level of gene transcription and has been associated with several disease conditions. We sought to determine the frequency distribution of this variant and its effect on gene expression in breast cancer. Patients undergoing lumpectomy, needle localization, simple mastectomy and modified radical mastectomy were recruited in this study. Clinical conditions including menopausal status, tumor stage, receptor status, previous breast cancer and family history were evaluated for genotype and phenotype association. Genotypes were detected by a PCR-base approach using SNP analysis of human CYP 3A4 gene. Expression levels of mRNA transcripts were determined by a semiquantitative RT-PCR. The homozygous AA allele was present with higher frequency (71.0%) in Caucasian (CAU) group as compared with African American (Af-Am) (29%) patients and controls (15%). Homozygous GG alleles were absence in CAU patients and the frequency was increased 4.8-fold in cancer patients as compared with controls ($p<0.05$). A vs. G genotypes were inversely associated with tumor staging in Af-Am patients. Patients with stage 0 tumors 50% carry the AA alleles as compared with 33% in stage II, whereas patients with stage II and III, 67 to 100% carry AG or GG alleles. The expression levels of CYP 3A4 transcript was higher in PBMCs of patients with benign tumors as compared to malignant tumors ($p<0.03$). In summary, the CYP 3A4 genotype demonstrated a remarkable interindividual variation between Af-Am and CAU patient populations, furthermore, Af-Am patients with homozygous GG genotype were at higher risk of developing cancer as compared with controls. Thus, the CYP 3A4 genotype analysis may predict likelihood of developing breast carcinoma, and might allow earlier detection of cancer.

Splicing defects in hereditary nonpolyposis colorectal cancer. *I. Tournier[1], A. Martins[1], C. Martin[2], J. Auclair[3], Q. Wang[3], M.-P. Buisine[4], S. Olschwang[5], T. Frebourg[1,2], M. Tosi[1].* 1) Inserm U614, IFRMP, Faculty of Medicine, Rouen, France; 2) Department of Medical Genetics, Rouen University Hospital; 3) Centre dOncologie Génétique, Centre Léon Bérard, Lyon, France; 4) Laboratoire de Biochimie et de Biologie Moléculaire, CHU Lille, France; 5) Institut Paoli-Calmettes, INSERM UMR 599, Marseille, France.

Hereditary nonpolyposis colorectal cancer (HNPCC)is the major form of hereditary colorectal cancer and results from constitutional mutations in mismatch repair genes, especially *MLH1* and *MSH2*. One of the current limitations of the molecular diagnosis of HNPCC results from the numerous missense or translationally silent mutations in these genes and from the difficulty of establishing simple functional assays for the corresponding proteins. Considering that some of these variants could be pathogenic by affecting splicing, our present goal is to optimise the detection of all splicing defects of *MLH1* and *MSH2*, including the characterisation of defects possibly affecting ESE or ESS elements. We have listed in France more than 120 distinct missense or translationally silent mutations of *MLH1* or *MSH2*. In order to evaluate the potential effect of these mutations on splicing, we have undertaken a parallel screening of these mutations using focused RT-PCR analysis of RNA obtained from patient peripheral blood and a functional assay of exon inclusion or exclusion. The latter is based on an expression construct, driven by a CMV promoter, into which exons 2 and 3 of the *SERPIN/G1* gene, separated by their natural intron, were inserted. In this assay, wild type and mutant exons are PCR amplified from patient DNA together with about 150 bp of flanking sequences, cloned into the intron of the expression construct and transiently transfected into HeLa cells. The effects of mutations on splicing are evaluated by RT-PCR analysis of the resulting mRNA and direct sequencing of the RT-PCR products. Several mutations located near the 3 exon boundaries, previously classified as missense, were found to be in fact splicing defects. Complete analysis of this cohort will provide an evaluation of the impact of mutations of these genes affecting ESE or ESS elements.

A new microarray-based diagnostic tool for resequencing the entire BRCA1 and BRCA2 genes. *M. Bonin Sr, O. Altug-Teber, F. Stutzmann, S. Poths, O. Riess.* Medical Genetics Department, Institute for Human Genetics, Tuebingen, Germany.

It has been 10 years since the BRCA1 gene was first identified. During this decade, genetic testing for breast cancer susceptibility has been incorporated into the practice of oncology. In this process, the identification of families at the highest hereditary risk for cancer has served as a model to test strategies for prevention or early detection of breast malignancies. Here we report the first microarray-based resequencing analysis of the complete BRCA1 and BRCA2 genes. For this purpose, we used the oligonucleotide-microarray technology and designed a CustomSeq-Array for the coding region of both genes. Twenty-five unrelated patients and control persons were analysed. All exons of each sample were amplified by PCR using specific primers, pooled, labelled, fragmented, and hybridised to the BreastCancer-CustomSeq array. In addition all samples were confirmed by conventional sequencing procedure. All analysed BRCA mutations could be detected by the new diagnostic system. The BreastCancer-Array provides base calls at more than 99.5 accuracy which is comparable to capillary sequencing. Replicate experiments demonstrated a reproducibility of more than 99.95%. We conclude that array-based sequencing technology has the capability to efficiently and cost-effectively generate large-scale resequencing data of genes. The technology is in particular applicable to large genes with numerous different mutations, like BRCA, but is also utilized for highly heterogenous diseases. Furthermore CustomSeq arrays deliver a complete sequence within 48 hours which opens a revolutionary new era of sequence-based diagnostics.

Genome-wide SNP association studies for interstitial lung disease in gefitinib (Iressa)-treated patients with non-small cell lung cancer. *T. Mushiroda[1], Y. Ohnishi[2], S. Saito[1], A. Takahashi[1], N. Kamatani[1,3], Y. Nakamura[1,2].* 1) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 3) Division of Genomic Medicine, Department of Applied Biomedical Engineering and Science and Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Drug-associated interstitial lung disease (ILD) is severe and sometimes fatal among non-small cell lung cancer (NSCLC) patients treated with gefitinib (Iressa). We conducted exploratory case-control association studies using gene-based 52,608 single nucleotide polymorphisms (SNPs) with 102 NSCLC patients receiving gefitinib (28 patients with ILD, 74 without) to identify genes susceptible to ILD. We observed associations with p-value of < 0.01 at 306 SNP loci calculated by allele frequency model ($p < 0.0001$, 3 SNPs; $p < 0.001$, 30 SNPs), at 129 SNP loci by dominant inheritance model ($p < 0.0001$, 1 SNP; $p < 0.001$, 5 SNPs), and at 293 SNP loci by recessive inheritance model ($p < 0.0001$, 1 SNP; $p < 0.001$, 28 SNPs). The predictive validation using a novel block sequential method is ongoing based on a nested case-control study in Japan run by AstraZeneca, and any positive results will be evaluated for clinical utility to guide gefitinib therapy.

Mutations in *FANCD2* are not prevalent in hereditary breast cancer families. *T. Scholl[1], K. Eliason[1], A. Carlson[2], R. Kalb[3], K. Neveling[3], H. Hoehn[3], H. Hanenberg[4], S.D. Batish[2], A. Parslow[1], H. King[1], B.C. Hendrickson[1], T. Judkins[1], M. Norton[1], D. Schindler[3], A.D. Auerbach[2].* 1) Myriad Genetic Laboratories, Salt Lake City, UT; 2) Laboratory of Human Genetics and Hematology, The Rockefeller University, NY; 3) Department of Human Genetics, University of Wuerzburg, Germany; 4) Department of Pediatric Oncology, Hematology and Immunology, University of Dusseldorf, Germany.

Fanconi anemia (FA) exhibits extensive genetic heterogeneity. Seven of the FA proteins (FANCA/B/C/E/F/G/L) form a nuclear FA core complex that activates the monoubiquitination of FANCD2, targeting FANCD2 into nuclear foci containing BRCA1, BRCA2/FANCD1 and RAD51. These functional associations between the *BRCA* and FA genes suggest a role for the FA pathway in the repair of DNA strand breaks and prompts the hypothesis that additional FA genes could also be responsible for hereditary breast cancer. Familial cancer histories in pedigrees from the International Fanconi Anemia Registry (IFAR) were examined for incidence of breast, ovarian, and pancreatic cancers. Six families with mutations in the *FANCD2* gene that appeared to contain especially high incidences of these cancers were selected for further study. Within these families, mutations in *FANCD2* did not appear to segregate in subjects affected with cancer in this ongoing study. In addition, direct DNA sequencing was employed in families with strong histories of breast/ovarian cancer to screen for mutations in the 9 exons of *FANCD2* which contained mutations in the IFAR pedigrees. This specimen set comprised 420 fully anonymous specimens derived from probands affected with breast/ovarian cancer prior to age 50 and also reported at least two relatives affected with breast/ovarian cancer that were previously shown to be negative for mutations in *BRCA1* and *BRCA2* as part of clinical genetic testing. No obvious pathogenic mutations in these regions of *FANCD2* were detected, although some missense variants of uncertain clinical significance were observed. These results support the conclusion that *FANCD2* mutations probably do not play a significant role in hereditary breast cancer.

Results of a *BRCA1/BRCA2* Mutation Screening Panel in 119 Women of African ancestry. *L. Gayol[1], M.E. Ahearn[1], T. Donenberg[2], B. Morel[1], J.F. Arena[2,3], L. Baumbach[1].* 1) Dept Pediatrics, Miller School of Medicine, University of Miami, Miami, FL; 2) FOBCC, Miller School of Medicine, University of Miami, Miami, FL; 3) National Cancer Institute, Washington, D.C.

Recent evidence from our laboratory as well as others, suggest that certain *BRCA1/BRCA2* mutations and variants appear to be either at increased frequency or specific to women of African ancestry (AA) at-risk for breast cancer. These observations have led to development of a screening panel for selected *BRCA1* and *BRCA2* mutations/variants in AA women. This panel is designed to detect 37 *BRCA1* mutations and unclassified variants, and 22 *BRCA2* mutations and unclassified variants, either previously detected in our laboratory, or found in a thorough review of all published English literature. The screening strategy is based on a combination of DNA sequencing and SSCP. Currently, the mutation-screening panel is comprised of five DNA sequencing reactions for *BRCA1*, and four DNA sequencing reactions for *BRCA2*, which together detect 86% of the mutations and variants, the remainder being detected by SSCP. In the 119 patients analyzed, only two deleterious (and recurrent) *BRCA1* mutations were detected: the founder mutation *BRCA1* 943ins10 and a splicing mutation *BRCA1* IVS13+1 G>A, both at a 3.3% frequency. In *BRCA2* gene, we detected just one rare deleterious mutation: 6828 del TT. A number of other recurrent missense mutations, unclassified variants and polymorphisms were also detected in both genes; three in *BRCA1* and six in *BRCA2*. In addition, five rare missense mutations were detected in one patient each. The frequency of these variants is being investigated. Based on these data, we are refining the mutation-screening panel for application to a population-based study.

Mutation screening of BRCA1 and BRCA2 in the Netherlands and Belgium: An overview of 9 years screening and identification of 1700 mutation positive families. *F.B.L. Hogervorst[1,2], H. Gille[2], A. van der Hout[2], G. Vink[2], M. Vreeswijk[2], P. Devilee[2], A. van den Wijngaard[2], R. Blok[2], D. Bodmer[2], M. Ligtenberg[2], H. Bruggenwirth[2], A. van den Ouweland[2], R. van der Luijt[2], K. Claes[2], G. Michils[2], E. Teugels[2], S. Wilcocx[2].* 1) Family Cancer Clinic, Dept Pathology, Netherlands Cancer Inst, Amsterdam, Netherlands; 2) The Dutch/Belgian working group on BRCA mutation screen of the Clinical Genetic centers.

In 1995 the DNA-diagnostic laboratories of the Dutch and Belgian Clinical Genetic Centres started DNA testing for BRCA1 and BRCA2. At present, BRCA1 and BRCA2 are completely screened either by a combination of PTT and DGGE/DHPLC or entirely by DGGE/DHPLC/Sequencing. In addition BRCA1 specific testing is performed by Multiplex Ligation-dependent Probe Amplification (MLPA). Up to March 2005, more than 10.000 families have been tested identifying 1700 mutation positive families: 1190 BRCA1 and 510 BRCA2 families. For BRCA1, 171 distinct pathogenic mutations have been identified. The TOP 10 mutations did account for almost 55% of the families. For BRCA2 173 distinct mutations were identified of which the majority (127) is found in only one or two families. The TOP 10 mutations account for 42% of the families. For both genes we identified regional and national founders. Recently, BRCA1 mutation screening has been improved by a novel method, called MLPA. This test allows rapid screening for rearrangements in the BRCA1 gene in a high throughput format. In addition to the genomic deletions of exons 13 or 22, more than 15 different deletions and duplications have been found. With the completion of the mutation scanning for both genes many so-called unclassified variants (UV's) have been reported. These are minor changes in the genes for which the relation with the genetic predisposition for breast/ovarian cancer still has to be established. For BRCA1, 148 different UVs have been identified in 241 families. For BRCA2 this is number is much larger: 247 different UVs in 481 families. As more than 80% of all different UVs have been reported only once or twice this clearly is a drawback in the elucidation of the pathogenic status of such variants.

The prevalence of *MSH6* mutations in North American patients receiving clinical genetic testing for HNPCC.

B.C. Hendrickson, A.P. Parslow, B. Wardell, J.T. McCulloch, K. Eliason, T. Judkins, A.E. Deffenbaugh, J. Tazelaar, W.W. Noll, B.E. Ward, S. Bhatnagar, T. Scholl. Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

The protein encoded by *MSH6* is involved in DNA mismatch repair and heritable *MSH6* mutations convey risk for colorectal cancer. It has been reported that mutations in *MSH6* may convey less risk than those in *MLH1* or *MSH2*, two other DNA repair genes associated with HNPCC. Mutations in *MSH6* may also be preferentially associated with other cancers, particularly endometrial cancer. It is difficult to estimate the importance of *MSH6* mutations in HNPCC since the prevalence that has been reported varies greatly between studies. This variation probably reflects biases due to the particular effects of *MSH6* mutations mentioned above combined with the criteria employed to select patients for particular research studies. Our objective is to determine the overall prevalence of *MSH6* mutations in North American patients undergoing clinical genetic testing for HNPCC.

A set of 381 specimens previously submitted for clinical genetic testing by direct DNA sequencing and Southern blot analysis of *MLH1* and *MSH2* were selected for this study. The initial testing had identified 64 deleterious mutations and 38 genetic variants of uncertain clinical significance in *MLH1* and *MSH2*. Of the remaining specimens, 279 had sufficient material for further analysis and were made fully anonymous for *MSH6* mutation screening. *MSH6* analysis included direct DNA sequencing for the entire coding region and consensus splice sequences adjacent to the exons. A total of six protein truncating mutations were detected, which would indicate an overall *MSH6* mutation prevalence of 2.2%, or 11.4% of all mutations detected in these samples. In addition, seven missense variants of uncertain clinical significance were detected.

Protein truncation testing to identify *BRCA1* and *BRCA2* variants of unknown significance that are splicing mutations. *J.K. Booker[1], L.R. Susswein[2], C. Skrzynia[3], N. Adams[4], J.P. Evans[2,3].* 1) Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC; 2) Genetics, University of North Carolina, Chapel Hill, NC; 3) Hematology Oncology, University of North Carolina, Chapel Hill, NC; 4) Moses Cone Regional Medical Center, Greensboro, NC.

Molecular genetic testing is increasingly sequence based, with the advantage of detecting rare mutations in addition to those that are more common and generally targeted by simpler mutation detection methods. While sequencing has advantages in the number of mutations that can be detected, it has the disadvantage of identifying all sequence variants, including benign polymorphisms and variants of unknown significance (VUS). VUS are, by definition, uninterpretable with regard to their contribution to the cause or risk of disease and present a complicated and unsatisfying result to patients, counselors and physicians. When a VUS is identified, clues to disease association can be found by looking at segregation of the variant with disease, and evolutionary conservation and degree of chemical change when an amino acid is altered, but this information is not definitive. Here we used the protein truncation test to evaluate the splicing consequences of one *BRCA1* missense mutation (5191 C>T, T1691I), one *BRCA2* silent mutation (459 T>G, T77T), and two *BRCA2* missense mutations (457 A>G, T77A and 9599 A>T, N3124I). Three of the four VUS were shown to be associated with a truncated protein. Sequencing of the cDNA used to generate the truncated protein demonstrated that the truncated protein resulted from abnormal mRNA splicing. Abnormal splicing was presumed to result from interruption of exonic splicing enhancers. Prediction of the exact splice product was not possible based on the exonic location of the variant, illustrating the need to look beyond the immediate flanking exons, when a splicing mutation is suspected. Characterizing a silent or missense mutation identified through sequencing as truncating with the protein truncation test can alter the interpretation from a VUS to a probable deleterious mutation and is thus an important adjunct to mutational analysis.

Contribution of BRCA1 and BRCA2 germ-line mutations to the incidence of breast and ovarian cancer in young Cypriot women. *A. Hadjisavvas[1], M. Loizidou[1], Y. Marcou[2], D. Papamichael[2], M. Televantos[3], G. Kalakoutis[3], K. Kyriacou[1].* 1) Electron Microscopy/Molecular Pathology, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus; 2) Oncology center Bank of Cyprus, Nicosia , Cyprus; 3) Makarios III Hospital, Nicosia, Cyprus.

In Cyprus, the contribution of the BRCA mutations to the population incidence of early-onset breast cancer was unknown. We carried out a mutational analysis of the BRCA1 and BRCA2 genes in 30 Cypriot women diagnosed with breast cancer before the age of 40 and 15 women diagnosed with ovarian cancer before the age of 60 irrespective of their family history. Genetic analysis was performed by PCR and DNA sequencing. We identified 5 pathogenic mutations in the BRCA genes, in 7 unrelated probands: 2 in BRCA1 (K614X and 5424delG) and 3 in BRCA2 (3758del4, 6310insA and 8984delG). Two out of the 5 mutations are novel (BRCA2 3758del4, 6310insA) and two were previously identified in Cypriot high risk families (BRCA1 5424delG and BRCA2 8984delG). The BRCA2 8984delG mutation was detected in three non-related breast cancer patients. Additionally, 2 new missense mutations were identified (BRCA1 H628Y and BRCA2 I2068L). In total, 5 out of 30 early-onset breast cancer patients carried a pathogenic BRCA mutation (20%) which is high in comparison to the expected 5-10%. This higher than expected frequency, may be a result of the presence of the already identified Cypriot founder mutation in the BRCA2 gene. Regarding the ovarian cancer patients, 2 out of 15 (13%) carried pathogenic BRCA mutation which is within the expected range. These results confirm that in the Cypriot population the BRCA2, rather than BRCA1 gene appears to play a more significant role in the breast cancer phenotype. This study has indicated that Cypriot women with early-onset breast cancer, irrespective of their family history, are a good predictor of being a BRCA mutation carrier.

Predicting *BRCA1* and *BRCA2* genotype by expression profiling after induced DNA damage:a novel approach for functional mutation detection? *Z. Kote-Jarai[1], L. Matthew[2], A. Osorio[1,3], I. Giddings[2], I. Locke[1,4], S. Shanley[1,4,5], R. Williams[6], C. Campbell[7], R. Eeles[1,4].* 1) Translational Cancer Genetics, The Institute of Cancer Research, Sutton, Surrey, UK; 2) Molecular Carcinogenesis, The Institute of Cancer Research, Sutton, Surrey, UK; 3) Department of Human Genetics, Spanish National Cancer Centre, Madrid, Spain; 4) Royal Marsden NHS Foundation Trust, London, UK; 5) Westmead Hospital, Sydney, Australia; 6) Pediatrics Oncology, The Institute of Cancer Research, Sutton, Surrey, UK; 7) Computational Intelligence Unit, University of Bristol, Bristol, UK.

Germline mutations in *BRCA1* and *BRCA2* predispose women to an increased risk of breast and ovarian cancer. Both genes have important roles in DNA damage repair and in gene expression regulation. We have studied the differential gene expression profiles after radiation-induced DNA damage in normal cells from *BRCA1/2* mutation carriers using high density microarray technology. Short-term primary fibroblast cultures were established from skin biopsies from healthy women: 10 *BRCA1* and 10 *BRCA2* mutation carriers, and 10 non-carrier control individuals. The cells were subjected to high dose ionizing irradiation (15 Gy) to induce DNA damage. We have used 15K spotted cDNA microarrays manufactured by the Cancer Research UK Microarray Facilities. For data analysis Significance Analysis of Microarrays (SAM), hierarchical clustering and the Support Vector Machine classifier (SVM) was applied. SAM and SVM identified the best genotype predictor features for *BRCA1* and *BRCA2* heterozygous genotype. The supervised class prediction model, SVM and leave-one-out (LOO) cross validation, performed with high accuracy (85-95%), *BRCA1* and *BRCA2* carriers could be clearly distinguished from non-carriers and from each other after radiation induced DNA damage. Without irradiation however no significant differences were found, providing further evidence that these genes have important roles in DNA damage responses. We propose that gene expression profiling could provide a novel functional mutation detection technique that could have important implications in the identification functionally important alterations in these genes.

Frequency of the mutation IVS14+IGA in the dihydropyrimidine dehydrogenase gene in cancer patients from Mexican population. *V. Peralta[1], MR. Flores[2], G. Morgan[3], L. Arnaud[1], E. Vargas[1], M. Gallegos[1].* 1) Div. Medicina Molecular, CIBO, IMSS, Guadalajara,, Jalisco, Mexico; 2) Departamento de Patologias, Hospital de Especialidades, CMNO, IMSS; 3) Unidad de Radio Diagnostico,Hospital de Especialidades, CMNO, IMSS.

The dihydropyrimidine dehydrogenase (DPD), is the first enzyme that takes part in the degradation of 5-fluorouracil (5FU), related to toxic effects in cancer patients that receive this antineoplasic as part of the chimeoterapeutic scheme. One of the most frequent mutations of the dihydropyrimidine dehydrogenase gene (DPYD), is the called IVS14+IGA, that results in a deletion of exon 14 by a change of G instead A in the splicing site GT '5 and as consequence a non functional protein. Objective: To determine the frequency of the mutation IVS14+IGA of the gene DPYD from Mexican cancer patients. Material and methods: We analized 102 DNA samples of cancer patients, from the Oncology Division of HE,CMNO, IMSS and 117 DNA samples as control group from general population of the West of Mexico. Results: The genotypic frequency was in Hardy Weinberg's equilibrium in the groups of study. The wild type genotype was observed in 88.2%; in the patients group, in comparison to 100%; of control group. The heterocygote genotype was observed in 10.8%, and homocygote for the mutation in 1%; in the patients group. When to compared the study groups were statistically significant difference (p=0.0001) with Odds ratio for 15.86 (95%CI 2.15-327). Conclusions: The mutation IVS14+IGA showed association in Mexican cancer group with a OR of 15.86 times major with regard to the normal genotype.

Increasing detection efficiency of microsatellite instabilities in colon carcinoma by applying a label-free method.

R. Salowsky[1], S. Baldus[2], N. Barta[2], M. Odenthal[2]. 1) Agilent Technologies, Waldbronn, Germany; 2) Institute of Pathology, University of Cologne, Cologne, Germany.

Microsatellite instability (MSI) is caused by a failure of the DNA mismatch repair system and occurs frequently in various types of cancer. Since MSI, associated with ca. 10 to 15 % of colorectal, gastric or endometrial carcinoma, impact clinical prognosis, MSI analysis is an important tool of molecular pathology. This study aimed to develop a simple and efficient procedure of MSI detection. 40 cases with no (27), low (l) or high (h) MSI (13), pre-identified by conventional fluorochrome-associated PAGE technology, were selected out of a panel of 150 patients with colon carcinoma. Microdissected non-tumor (N) and tumor (T) tissue areas of one or two 4 m-sections were de-paraffinized and DNA was extracted. Primer sequences recognizing the five microsatellite loci BAT25, BAT26, D5S346, D17S250, D2S123, were selected according to the recommendation of the 1997 National Cancer Institute-sponsored conference on MSI. Primer sets were applied in label-free duplex or single PCR assays for DNA amplification and amplicons were analysed by microfluidics based on-chip electrophoresis. In all 40 cases, chip linked microcapillary electrophoresis of the amplicons, arisen from tumor and non-tumor DNA, resulted in highly resolved, distinct patterns of each of the microsatellite loci. Label-free detection of MSI could be demonstrated by microsatellite loci-associated deviations in the electropherogram profiles of tumor and non-tumor material, and confirmed the prediagnosis of the MSI cases by conventional technology. Here, we present a simple and robust approach for MSI detection, which allows a label-free microsatellite analysis of uncharacterized microdissected tissue areas within 30 minutes.

Genetic basis of meningioma formation and progression is significantly different between men and women. *F.P. Nunes[1], I. Ahronowitz[1], A.O. Stemmer-Rachamimov[2], M. MacCollin[1].* 1) Molecular Neurofibromatosis Laboratory, Massachusetts General Hospital, Charlestown, MA; 2) Molecular Neuro-Oncology Laboratory, Massachusetts General Hospital, Charlestown, MA.

Meningiomas are common neoplasms of the brain and spinal cord with an annual incidence of 7.8 per 100,000 individuals. Interestingly, meningiomas are much more prevalent in women, with a female to male ratio of 2.3:1. We sought to determine if genetic differences might be associated with this disparity by studying 131 sporadic meningioma patients (91 women and 40 men) randomly selected from the Massachusetts General Hospital Neuro-Oncology Tumor Bank. Full record review included clinical data, radiology reports, and pathology reports. Loss of heterozygosity (LOH) at the neurofibromatosis 2 (*NF2*) locus was determined using polymorphic microsatellite markers on chromosome 22q. In addition, LOH of 1p, 10q, and 14q, previously shown to be associated with meningioma recurrence, was determined in a subset of 45 patients. Average age at surgery was similar between men (55.3 years) and women (57.5 years) in this cohort. Meningiomas of higher grades were more common in men (WHO grade II and III, 40%) than in women (32%, $p< 0.10$). *NF2* LOH was seen in 56% of cases, but was more often present in tumors from men (70% of cases) than in those from women (50% of cases, x^2 Test = 4.27, $p<0.05$). Interestingly, men with tumors lost at *NF2* had an average age at surgery of 52.9 years, versus 61.7 years in women ($p<0.05$). LOH of 1p, 10q, and 14q were seen in 7 (16%), 2 (4%), and 8 (18%) tumors, respectively, and were associated with *NF2* loss in 10 out of 13 cases. Losses of 1p and 14q were more common in tumors from men (21% and 20%) than women (13% and 17%), but this finding did not reach statistical significance. Our results show clear differences in the molecular biology of sporadic meningiomas from men and women. Our current work is focused on further understanding these differences with the hypothesis that this will explain the increased risk of women for meningioma development.

HLA DRB1 gene and cervical squamous cell carcinoma in Chinese. *T.Y. Chang[1], Y.C. Yang[1,2,4], Y.J. Lee[1,3,5], T.H. Su[2,4], C.W. Dang[1], H.F. Liu[1], C.C. Chu[1], M. Lin[1].* 1) Department of Medical Research; 2) Gynecology and Obstetrics; 3) Pediatrics, Mackay Memorial Hospital, Taiwan; 4) Mackay Medicine, Nursing and Management College; 5) College of Medicine, Taipei Medical University, Taiwan.

Cervical cancer is the second most common cancer in women in developing countries and the second most common cancer worldwide. Polymorphisms in human leukocyte antigen (HLA) genes have been implicated in the risk for cervical cancer. Association of HLA alleles, particularly class II, with cervical cancer in different ethnic populations has been documented. The association, however, is scarcely reported in Asian populations. We examined HLA-DRB1 gene frequency in 123 women with cervical squamous cell carcinoma (CSCC) and 298 healthy control subjects. All patients and control subjects were Chinese living in Taiwan. Genotyping of HLA-DRB1 gene was carried out by sequence-based typing. An increase in the frequency of the DRB1*1502 and a decrease in the frequency of the DRB1*12 were observed in patients, however, the differences were not statistically significant as compared to controls (P=0.06). Relevant studies on the association between HLA-DRB1 and CSCC were searched and retrieved from MEDLINE database and analyzed. The results from literature search demonstrated that DRB1*1001, DRB1*1101, and DRB1*1501 were associated with increased risks and DRB1*0301, DRB1*1301/02 were associated with decreased risks. Some literatures also showed that the frequency of DRB1*12 had decreased tendency in patients but without statistical significance. Given the literature results we could sensibly infer that DRB1*1502 might be an allele making some Chinese women more susceptible to CSCC. In addition, the trend of decreased frequency of DRB1*12 found in patients was in accordance with the published data. In conclusion, this is the first study investigating the association between HLA-DRB1 gene and CSCC in Chinese. Although the association between HLA and CSCC was unable to be confirmed in our population, the possibility of a very weak association still remains. Further studies by extensive genotyping of other polymorphic sites of the HLA genes in a larger dataset are necessary.

MYH Y165C and G382D mutations in hepatocellular carcinoma and cholangiocarcinoma patients. *L.M. Baudhuin[1], L.R. Roberts[2], F.T.B. Enders[3], R.L. Swanson[1], T.A. Mettler[2], I. Aderca[2], L.M. Stadheim[2], W.E. Highsmith[1].*
1) Division of Laboratory Genetics, Mayo Clinic, Rochester, MN; 2) Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN; 3) Division of Biostatistics, Mayo Clinic, Rochester, MN.

Purpose: Production of reactive oxygen species (ROS) during chronic inflammation has been implicated in the progression of liver diseases and carcinogenesis. Subjects with inflammatory liver disease and one nonfunctional allele of the base excision repair gene, MYH, may be more susceptible to progression to cancer due to MYH haploinsufficiency in repairing oxidative damage caused by ROS. Furthermore, a common area of loss of heterozygosity (LOH) in hepatocellular carcinoma (HCC) is at 1p34-36, which is near the chromosomal location of MYH (1p32.1-34.1). Here, we investigated the association of two common germline MYH mutations in patients with HCC and cholangiocarcinoma. **Methods:** DNA from patients with HCC (n=48) or cholangiocarcinoma (n=84) compared to non-cancerous controls (n=308) were genotyped by restriction fragment polymorphism analysis for the common Y165C and G382D mutations in MYH. Fisher's Exact Test was used to compare patient population data to control data. **Results:** There was no significant difference in MYH mutation carrier status between patients with HCC (1/48), cholangiocarcinoma (3/84), and non-cancerous controls (4/308). One patient with cholangiocarcinoma and a monoallelic MYH mutation also had inflammatory bowel disease. **Conclusions:** Patients with HCC or cholangiocarcinoma do not have an increased incidence of monoallelic germline MYH mutations predisposing them to disease. However, somatic and/or other germline MYH mutations involved in disease pathogenesis of HCC or cholangiocarcinoma cannot be ruled out. Further investigations are necessary to determine whether MYH mutations are involved in progression of inflammatory bowel disease.

Examination of the effect of MC1R gene variants on melanoma risk in CDKN2A mutation carriers across continents : A Melanoma Genetics Consortium (GENOMEL) study. *F. Demenais, for the Melanoma Genetics Consortium.* INSERM EMI-0006, Evry, France.

Melanocortin-1 receptor (MC1R) gene plays a key role in human pigmentation. MC1R polymorphisms have been shown to be associated with pigmentation phenotypes and with melanoma independently of skin type. Penetrance of CDKN2A, a gene predisposing to familial melanoma, was also found to be influenced by MC1R variants. We examined the effect of MC1R variants on melanoma risk in CDKN2A mutation carriers using data from 14 groups from Australia, Europe and North-America (the United States and Canada) that are part of The Melanoma Genetics Consortium. Logistic regression analysis was applied to the total sample of 768 CDKN2A mutation carriers (452 affected and 316 unaffected subjects) who were genotyped for MC1R and to subgroups of subjects according to geographical location (125 Australians, 450 Europeans, 193 North-Americans). Overall, the absolute number of MC1R variants carried, three common specific variants (R151C, R160W, V60L) as well as pooled RHC variants increased significantly melanoma risk : p-value being always less than 0.001, except for V60L and R160W for which p was equal to 0.02. A dosage effect of MC1R variants (2 variants conferring a higher risk than only one) was consistently observed across all three continents. When examining the effect of specific variants by continent, melanoma risk was always increased but significance was only reached in Australia and Europe for R151C (p0.01), in North-America for R160W (p=0.01) and in Australia for V60L (p=0.04). These effects of MC1R polymorphisms will be further evaluated by taking into account pigmentation characteristics and sun-related covariates.

***LHFPL3*, a Candidate Gene for Uterine Leiomyoma.** *T.S. Ptacek[1], C.Y. Song[1], C.L. Walker[2], S.M. Sell[1].* 1) Department of Nutrition Sciences, UAB, Birmingham, AL; 2) Department of Carcinogenesis, UTMDACC, Austin, TX.

Uterine leiomyoma (UL), a benign smooth muscle tumor of the uterus, is common among women of reproductive age. Although often asymptomatic, UL can cause serious health problems. Deletions on chromosome band 7q22 are common in UL. Recently, we reported a minimal 7q22 deletion interval defined by closely spaced microsatellite markers (Sell *et al.*, 2005). One marker, D7S2446, was deleted, and microsatellite instability (MSI) was observed at this maker. Based on the May 2004 human genome assembly, this interval contains two genes: the origin recognition complex 5-like (*ORC5L*) and lipoma *HMGIC* fusion partner-like 3 (*LHFPL3*) genes. The *ORC5L* gene has been previously studied as a candidate gene for UL in tumor samples with larger deletions (Quintana *et al.*, 1998). The *LHFPL3* gene is a member of a new family of *LHFP-like* genes. Another member, the *LHFP* gene, is a fusion partner with the *HMGIC* gene in lipoma (Petit *et al.*, 1999). In this study we used bioinformatics following a tiered approach (Ptacek and Sell, 2005) and expression analyses to examine the *LHFPL3* gene as a candidate gene for UL. The D7S2446 marker was positioned within the first intron of the *LHFPL3* gene. The human gene showed sequence identity with the mouse and rat (exon 1: >95%, exons 2 and 3: >80%) and the genomic organization was conserved across species. Analyses of the protein sequence identified four transmembrane helix domains, including a signature sequence for the peripheral myelin protein 22 (PMP22) Claudin family. Members of the PMP22 Claudin protein family participate in extracellular matrix formation, proliferation and differentiation. *LHFPL3* expression, assessed using RT-PCR and the Agilent 2100 Bioanalyzer, was either significantly increased or decreased in human UL compared to matched, normal myometrium (n=8 total; $P < 0.05$). Similar results were obtained using the Eker rat (UL, n = 8; normal myometrium, n = 4; $P < 0.05$). We conclude that the *LHFPL3* gene is a candidate gene for UL. Future studies will assess the possible molecular pathogenic roles of *LHFPL3* MSI and the observed distinct patterns of gene expression.

Polygenic models, association studies and bilateral breast cancer. *J. Peto[1,2], N. Johnson[3], O. Fletcher[1], C. Lombardelli[3], I. dos Santos Silva[1], A. Ashworth[3].* 1) EPH, LSHTM, London, United Kingdom; 2) Cancer-Research UK Epidemiology & Genetics Unit, ICR, Surrey, United Kingdom; 3) The Breakthrough Breast Cancer Research Centre, London, United Kingdom.

Bilateral breast cancers have important advantages for detecting susceptibility alleles in association studies. They provide considerably more power than unselected cases, and unlike cases with several affected relatives, they can be ascertained systematically through cancer registries. The proportions of bilaterals and unaffected controls who carry a susceptibility allele can thus be used to calculate unbiased risk estimates for the general population. Under a polygenic model in which many low-penetrance alleles interact to produce a wide spectrum of individual susceptibility, bilaterals and other familial breast cancer patients are at particularly high risk because on average they carry more susceptibility alleles than unselected cases. An allele that interacts synergistically with other (as yet unknown) alleles should therefore confer a high absolute risk among bilateral patients and their relatives. Findings based on the first 469 bilateral cases: Under a polygenic model, each allele should be more common and the absolute risk in carriers should be higher in bilateral than in unselected cases, and also in their relatives. The first degree relatives of our bilateral cases suffered substantially larger excesses of prostate cancer (SIR=2.4 95%CI 1.7-3.4) and breast cancer (SIR=3.5 95%CI 3.0-4.1 in women, 15.1 95%CI 4.9-35.4 in men) than relatives of unselected cases. CHEK2*1100delC, which is carried by about 1% of Caucasians, doubles the risk of breast cancer in women unselected for family history. Relatives of bilateral cases who were CHEK2*1100delC carriers had greatly increased risks for both breast cancer (SIR=12.1 95%CI 5.2-23.9) and prostate cancer (SIR=9.9 95%CI 1.2-35.7), suggesting that CHEK2*1100delC interacts with unidentified low penetrance polygenes. CHEK2 carrier status may be a clinically important determinant of absolute risk in women with bilateral disease or a strong family history of breast cancer.

Molecular Classification Of 39 Cancer Subtypes With A Gene Panel: Implications For Diagnosis Of Carcinoma Of Unknown Primary. *R.D. Patel, J. Murage, R.M. Desai, R.C. Salunga, S.S. Chu, X. Wang, R. Raja, X-J. Ma, M.G. Erlander.* Life Sciences, Arcturus Bioscience, Inc., Mountain View, CA.

Identifying the origin of a carcinoma of unknown primary (CUP) enables a physician to more effectively treat a CUP patient. Using current immunohistochemistry methods, the origin of only ~25% of CUPs is usually identified. Gene expression-based classifications have recently been shown to be highly successful in predicting the origin of cancer types. These previous molecular classifications of cancer types have been completed via whole-genome microarray-based gene expression profiling using frozen tissue. However, neither the use of whole-genome microarrays nor the assaying of frozen tissue is always practical in the real-world. Therefore, we have developed a gene panel amenable to PCR-based quantification utilizing formalin-fixed paraffin-embedded (FFPE) tissue for the prediction of the primary origin of metastatic cancers. A total of 497 cancers (training set: 75% primary, 25% metastatic) representing 39 cancer types were expression-profiled by a whole-genome array (Agilent). Following this, a bioinformatic strategy was used to identify a set of <96 genes for the prediction of the origin of 39 cancer types. A set of 87 genes (plus 5 reference genes) from the microarray data was identified as having the ability to predict the origin of 39 cancer types. To validate this set in-silico, 146 FFPE samples representing these 39 cancer types were used as a test set using real-time PCR, in which 83% sensitivity and 99% specificity was achieved. Subsequently, a PCR-based training and test database consisting of 339 frozen and 61 FFPE tumor samples was generated for 31 cancer types (a subset of the 39) and 85% sensitivity and 99% specificity was achieved. We have demonstrated that the primary origin of a large number of different cancer types can be predicted with a relatively small number of genes (87 genes/39 cancer types = ~2 genes/cancer type) using routine clinical samples. This approach should lead to an assay that is amenable for a clinical laboratory that utilizes 96-well PCR-based assays.

Strong evidence for linkage with prostate cancer at chromosome 17q in the University of Michigan Prostate Cancer Genetics Project pedigrees: Eighty-nine new pedigrees provide additional evidence for a chromosome 17q susceptibility locus. *E.M. Lange[1], C. Robbins[2], L.A. Ho[1], K.A. White[3], Y. Wang[1], W.B. Isaacs[4], K.A. Cooney[3].* 1) University of North Carolina, Chapel Hill, NC; 2) TGen, Phoenix, AZ; 3) University of Michigan, Ann Arbor, MI; 4) John Hopkins Medical Institutions, Baltimore, MD.

Previously, Lange et al. (Prostate, 2003) described a genome-wide linkage scan (GWS) for 175 prostate cancer pedigrees from the University of Michigan Prostate Cancer Genetics Project (UM PCGP). The maximum LOD score (2.36) using non-parametric linkage methods (the pairs allele-sharing statistic and Kong and Coxs exponential model) occurred at chromosome 17q between markers D17S798 and D17S1868 in near proximity to the breast cancer susceptibility gene BRCA1. Herein, we extended our analyses on chromosome 17q to include 12 additional microsatellite markers and 89 additional prostate cancer pedigrees with three or more confirmed prostate cancer cases. The additional markers marginally increased the LOD to 2.41 in the original GWS families, with the maximum LOD score occurring near the new marker D17S1788 in the same location as the peak in the original GWS. The 89 new pedigrees gave a maximum LOD score of 0.77 (p=0.03), which also occurred at marker D17S1788. Combining the original GWS pedigrees with the 89 new pedigrees resulted in a maximum LOD = 3.07 at D17S1788. There was evidence for linkage in both our Caucasian pedigrees (n = 242; LOD = 2.35 at D17S1788) and African American pedigrees (n = 19; LOD = 1.01 at D17S1868 and LOD = 0.45 at D17S1788). Finally, consistent with previous results, the maximum evidence for linkage occurred in the subset of pedigrees with four or more confirmed prostate cancer cases, LOD = 4.11 near D17S1868, approximately 7.5 cM distal to D17S1788. Two recent linkage studies that have combined pedigrees from different groups including our original GWS families (Gillanders et. al, 2004, JNCI; Xu et. al, 2005, AJHG) have implicated chromosome 17q as a candidate interval for a prostate cancer susceptibility locus. Neither of these studies included the corroborating data from these 89 new pedigrees.

Further evidence of linkage on chr5 in a large Tasmanian prostate cancer family. *J. McKay[1,2], L. Fitzgerald[1], A. Banks[1], K. Hazelwood[1], J. Brohde[3], G. Hannan[3], T. Dwyer[1,4], J. Dickinson[1].* 1) Menzies Ctr, Biochem, Univ Tasmania, Hobart, Tasmania, Australia; 2) International Agency for Research on Cancer, Lyon, France; 3) PHealth, CSIRO, Nth Ryde, Sydney, Australia; 4) Murdoch Research Institute, Melbourne, Victoria, Australia.

The Tasmanian familial prostate cancer study's purpose is to use large extended pedigrees from the Australian island state of Tasmania to attempt to understand the genetics of familial prostate cancer. Recently, we have used the HMA10K high density SNPchip to perform a genome wide scan in a 6-generation pedigree in which 18 cases of prostate cancer could be traced back to a common founding pair. Through this genome scan we identified evidence for linkage at the centromere of chromosome 5, an area noted by other prostate cancer studies. Using further genealogical research, we have identified a second 5-generation pedigree from the same geographical region of Southern Tasmania, in which 11 cases are able to be traced back to a common founding pair. Interestingly, one patient is present in both pedigrees via marriage. Founder mutations have been noted in Tasmania, and given the limited population of this area and presence of two large pedigrees, an undiscovered genealogical link between these families seemed plausible. Genotyping of both SNP and microsatellite markers showed some evidence consistent with linkage at chr 5 in this second large family. However, we were unable to find evidence of a common founding haplotype among these two pedigrees.

Evidence for Balancing Selection within an FHIT Intronic Region Implicated in Prostate Cancer. *Y. Ding, G.P. Larson, G. Rivas, L. Geller, C. Lundberg, C. Ouyang, T.G. Krontiris.* Dept Molecular Medicine, Beckman Res Inst, City of Hope, Duarte, CA.

Previously, we identified a locus for prostate cancer susceptibility at D3S1234 within FHIT (maximum LOD = 3.17, LODPAL) using a candidate gene-based linkage approach on 228 brother pairs (200 families) affected with prostate cancer. Subsequent association tests in Americans of European descent on 16 SNPs spanning approximately 400 kb surrounding D3S1234 revealed significant evidence of association for a single SNP (Pearson¡¦s ^{2} = 8.54, df = 1, p = 0.0035) within intron 5 of FHIT. Genotyping 40 tagging SNPs within a 30 kb region surrounding this SNP further delineated association of prostate cancer risk to a 10 Kb region. Population studies (13 Americans of European descent and 16 Yorubans) revealed strong signatures of balancing selection within the European population, but not within the African population. A sliding window analysis of resequencing data from individuals of European descent revealed a 13 Kb region of peaks and plateaus of Pi > 0.004 and Tajima¡¦s D > 2.0 (max. Pi = 0.0074, max. Tajima¡¦s D = 3.06, p < 0.001 under a standard neutral model). The elevated Pi and Tajima¡¦s D extends across three LD blocks, suggesting the possibility of multiple sites under selection. Decay of these D statistic elevations elsewhere suggests that population structure and past demographic events do not account for our result. Within the LD block associated with prostate cancer, the haplotype enriched in the control group is the most common haplotype in European descent (40%) compared to only 10% in the Yoruban population. In contrast, the putative risk haplotype is 28% in Americans of European descent and occurs as the most common haplotype (33%) within the Yoruban population. Our study, which suggests an important selectable function within intron 5, also represents an additional corroborative approach for gene-disease associations.

Assaying for Loss of Heterozygosity in Tumor Samples using Relative Fluorescent Quantitation on Capillary Electrophoresis Systems. *S. Karudapuram[1], L. Joe[1], A. Wheaton[1], T. McElroy[1], Y. Lou[1], A. Rico[2], C. Stemmer[3], A. Schneider[3], M-P. Gaub[3], M. Legrain[3], P. Oudet[3].* 1) Applied Biosystems, Foster City, CA; 2) Applied Biosystems, France; 3) Service de Biochimie et de Biologie Moléculaire, Hôpital Hautepierre, Strasbourg, France.

Several capillary electrophoresis based fragment analysis applications require comparison of peak heights across samples as a relative quantitation method. Screening for Loss of Heterozygosity (LOH), Microsatellite Instability (MSI) and detection of chromosomal deletions and duplications are typical examples of such applications. Optimized chemistries, a robust and reliable electrophoresis platform as well as accurate analysis software are all essential to the success of these assays. In this study we use a LOH assay to demonstrate relative quantitation using capillary electrophoresis. Microsatellite markers were run on the Applied Biosystems 3130*xl* Genetic Analyzer and peak heights were compared across paired samples from tumor and healthy tissues. Using GeneMapper v3.7 Software samples were identified as LOH candidates based on a threshold enabling rapid identification for downstream review. Our results highlight the 3130 Series Systems in conjunction with GeneMapper Software as an optimal solution for relative fluorescent quantitation assays.

Detection of ultra rare somatic mutations in p53 by Bi-PAP-A. *J. Shi, Q. Liu, S. Sommer.* Department of Molecular Genetics and Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA 91010-3000.

Detecting rare sequence variants in the presence of excess amounts of normal genomic DNA is central to i) early cancer detection; ii) cancer chemotherapy; iii) assessment of environmental mutagen exposure, and iv) prenatal diagnosis of paternally derived mutations within fetal cells in the maternal circulation. Bi-PAP-A (Bi-directional Pyrophosphorolysis Activated Polymerization Allele-specific Amplification) is a method that uses two opposing 3¢-terminal blocked oligonucleotides (P*s) with one nucleotide overlap at their 3¢ termini. The selectivity of Bi-PAP-A derives from the serial coupling of pyrophosphorolysis and DNA polymerization. Eighteen Bi-PAP-A assays were developed for the p53 gene. The sensitivity and specificity of each assay were tested using mutated and wild type DNA. Bi-PAP-A typically has a sensitivity of 1-2 molecules and selectivity greater than 10^7; in some cases, selectivity greater than 10^9 can be achieved. However, in the case of G:CA:T transitions and G:CT:A transversions, the selectivity is limited to about 10^4~10^5. Low selectivity is likely due to the deamination of cytosine during the amplification process and the presence of 8-oxo-dG in the genomic DNA, respectively. Efforts are under way to increase the selectivity of G:CA:T and G:CT:A, and to determine if Bi-PAP-A can be used to assay deamination of C and 8-oxo-dG damage in DNA. Five assays with high selectivity were used to detect rare somatic mutations in blood, enabling the detection of minimal residual disease at levels far below the sensitivity of conventional methods. The mutation frequency ranged from 10^{-7} to less than 10^{-8}. We conclude that Bi-PAP-A is a rapid and general method for detecting rare mutations although its selectivity may sometimes be limited by DNA damage.

Genetic and epigenetic alterations at chromosomal region 11p in sporadic Wilms tumors. *H. Soejima[1], Y. Satoh[2], Y. Kaneko[3], T. Mukai[1].* 1) Division of Molecular Biology and Genetics, Department of Biomolecular Sciences, Saga University, Saga, Japan; 2) Department of Urology, Saga University, Saga, Japan; 3) Research Institute for Clinical Oncology, Saitama Cancer Center, Saitama, Japan.

Chromosomal regions 11p13 and 11p15.5 are known to be loci for Wilms tumors. 11p13 is called the WT1 locus and 11p15.5, the WT2 locus. The *Wilms tumor 1* gene (*WT1*), which is mutated in a minority of Wilms tumors, is mapped to 11p13 (WT1 locus). It is known that the *WT1* mutation is significantly associated with the -*catenin* (3p21) mutation. 11p15.5 (WT2 locus) is a well-known imprinted region that is divided into two domains, *IGF2*/*H19* and *KIP2*/*LIT1*. Loss of imprinting (LOI) of *IGF2*, reduced expression of *KIP2*, and aberrant methylation of imprinting centers (ICs) and of gene promoter regions have been reported in Wilms tumors. However, it has not been clear whether or how the genetic and epigenetic alterations of these four loci *WT1*, -*catenin*, *IGF2*/*H19*, and *KIP2*/*LIT1* are associated. In this study, we performed analyses for loss of heterozygosity (LOH), gene mutation, gene expression, imprinting status, and DNA methylation on a total of 37 sporadic Wilms tumors. We found 10 tumors with only genetic alterations, which were 11p LOH, *WT1* mutation, and -*catenin* mutation, and 18 with only epigenetic alterations, which were LOI of *IGF2*, reduced expression of *KIP2* and *WT1*, and aberrant methylation of ICs and of *WT1* promoter. Five tumors showed simultaneously the both genetic and epigenetic alterations. Thirty-three tumors (89%) showed at least one of the alterations of the four loci, and 19 tumors (51%) had alterations of multiple loci. However, there was no tumor showing only the -*catenin* mutation at 3p21. The results indicate the genetic and epigenetic alterations of 11p are involved in a majority of sporadic Wilms tumors, and suggest that these alterations play an important role in Wilms tumorigenesis.

The role of mitochondrial complex II in hereditary neoplasia. *B. Battersby[1], S. Leary[1], T. Wai[1], G.H. Guercin[1], J. Green[2], E. Shoubridge[1].* 1) Human Genetics, MNI, McGill University, Montreal, Quebec, Canada; 2) Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

The mitochondrial respiratory chain is composed of five multimeric complexes required for aerobic ATP production. Complex II consists of four nuclear-encoded subunits: two membrane-bound subunits and two soluble subunits in the matrix of mitochondria. The complex functions in both the citric acid cycle, by oxidizing succinate to fumarate, and in the electron transport chain by transferring electrons from FADH2 to ubiquinone. Germline mutations in SDHB, SDHC, and SDHD have been identified in patients with hereditary head and neck paraganglioma and/or pheochromocytomas, suggesting that these proteins function as tumor suppressors. In the tumors, a somatic deletion of the wild-type allele results in a loss of complex II function, and activation of the hypoxia response pathway by stabilization of the transcription factor, HIF1-alpha. We have investigated the genetic basis for hereditary head and neck paraganglioma in a large Newfoundland pedigree and identified a novel mutation in SDHB that segregates with the disease. In tumor tissue, there is a loss of heterozygosity and a dramatic increase in the expression of HIF1-alpha target genes. Blue-native gel electrophoresis demonstrates that the mutant allele of SDHB prevents assembly of the mature holoenzyme, thereby eliminating complex II function in mitochondria. Mutations in the fourth subunit of complex II, SDHA, are associated with an autosomal recessive, early-onset, neurodegenerative disorder, called Leigh syndrome. It is currently unknown why the loss of complex II function in mitochondria can produce two very different clinical presentations. To investigate the mechanism behind these two pathologies, we used shRNA directed against the different complex II subunits to generate stable knockdowns that impair assembly of the complex. This genetic model system should allow us to identify the molecular mechanism of activation of the hypoxia response pathway and establish why only three of the four complex II subunits function as tumour suppressors.

Mitochondrial DNA G10398A polymorphism and risk of invasive breast cancer in African-American women.

A.R. Kallianpur[1], J.A. Canter[1], J.L. Haines[1], F.F. Parl[1], R.C. Millikan[2]. 1) Vanderbilt University Medical Center, Nashville, TN; 2) University of North Carolina, Chapel Hill, NC.

Mitochondria generate oxygen-derived free radicals that damage mitochondrial DNA (mtDNA) as well as nuclear DNA and in turn promote carcinogenesis. The mtDNA G10398A polymorphism alters the structure of Complex I in the mitochondrial electron transport chain, an important site of free radical production. This polymorphism is associated with several neurodegenerative disorders. We hypothesized that the 10398A allele is also associated with breast cancer susceptibility. African mitochondria harbor the 10398A allele less frequently than Caucasian mitochondria, which predominantly carry this allele. Mitochondrial genotypes at this locus were therefore determined in two separate populations of African-American women with invasive breast cancer and in controls. A preliminary study at Vanderbilt University (48 cases, 54 controls) uncovered an association between the 10398A allele and invasive breast cancer in African-American women, OR=2.90 (95% CI 0.61-18.3; P=0.11). We subsequently validated this finding in a large, population-based, case-control study of breast cancer, the Carolina Breast Cancer Study at the University of North Carolina (654 cases, 605 controls). African-American women in this study with the 10398A allele had a significantly increased risk of invasive breast cancer, OR=1.60 (95% CI 1.10-2.31; P=0.013). The 10398A allele remained an independent risk factor after adjustment for other well-accepted breast cancer risk factors. No association was detectable in white women (879 cases, 760 controls), OR=1.03 (95% CI 0.81-1.31; P=0.81). This study provides novel epidemiologic evidence that the mtDNA 10398A allele influences breast cancer susceptibility in African-American women. MtDNA polymorphisms may be underappreciated factors in breast carcinogenesis.

A heteroplasmic, not homoplasmic, mitochondrial DNA mutation promotes tumorigenesis via alteration in reactive oxygen species generation and apoptosis. *Y. Bai, J. Park, P. Hu, R. Xiang, D. Holstein, J. Lechleiter, S. Naylor.* Cellular & Structural Biol, Univ Texas Health & Sci Ctr, San Antonio, TX.

Mitochondrial alteration has been long proposed to play a major role in tumorigenesis. Recently, mitochondrial DNA (mtDNA) mutations have been found in various cancer cells. In this study, we have examined the contribution of mtDNA mutations to tumorigenesis with human cell lines carrying a frameshift mtDNA mutation on NADH dehydrogenase (respiratory complex I) subunit 5 (ND5) gene which was also identified in a colorectal cancer cell line. The anchorage dependence phenotype and tumor-forming ability of cells carrying wildtutype and mutant mtDNA were tested by growth assay in soft agar and subcutaneous implantation of the cells in nude mice. One cell line carrying the heteroplasmic ND5 mtDNA mutation showed significantly enhanced tumor growth, while cells with homoplasmic form of the same mutation inhibited tumor formation. We further provided evidence to suggest that these results might be mediated by alteration in reactive oxygen species (ROS) generation and apoptosis. Based on the data obtained, we propose that mtDNA mutations play an important role in tumorigenesis. Our working model for the role of mtDNA mutations in cancer development is as follows. In the initial stage, cancer cells are very mutagenic either because of a carcinogenic insult or the compromised repair mechanism and mtDNA is more likely to be mutated at this stage. Because of replicative advantage of the mutant mtDNA molecules, mtDNA mutations get enriched to certain level of heteroplasmy which would enhance tumor progression due to the elevated ROS generation which in turn activates the oncogenic pathways. In late stages of cancer, the cells are progressively adapted to a glycolytic metabolism because of the hypoxic environment. This may lead to the selection of cells in which the mutations makes mitochondrial function-independent, and therefore cells with homoplasmic mtDNA mutation may become predominant in tumors. However, when a homoplasmic status of some mtDNA mutations is reached, the host cells could be converted into non-tumorigenic cells because of the loss ATP production.

Identification of a tumor-associated germline mutation in the mitochondrial DNA that reduces cytochrome c oxidase activity. *M.E. Gallardo[1], R. Moreno-LosHuertos[2], M. Casqueiro[1], J. Silva[3], F. Bonilla[3], J.A. Enriquez[2], S. Rodriguez de Cordoba[1].* 1) Department of Inmunology, Centro de Investigaciones Biológicas, CSIC, Spain; 2) Department of Biochemistry and Molecular Biology, Universidad de Zaragoza, Spain; 3) Department of Medical Oncology, Hospital Universitario Puerta de Hierro, Madrid, Spain.

To identify genetic variants in the human mitochondrial DNA potentially associated to tumors we have fully sequenced the mtDNA of thirteen randomly selected cell lines derived from a variety of human cancers. Among several mtDNA mutations, we found two that are functionally relevant, 12240delC and 6267G>A. 12240delC alters the mitochondrial tRNASer(AGY) and 6267G>A causes the Ala122Thr substitution in the Cytochrome c Oxidase subunit I (CO I). Biochemical analysis of the original cell lines and the transmitochondrial cybrids generated by transferring mtDNAs to a common nuclear background, demonstrate that COX activity, respiration and growth in galactose are impaired by the 6267G>A mutation. 6267G>A was found twice in the cancer cell lines. Interestingly, the 6267G>A mutation was also found in one out of 15 breast cancer samples analyzed in this report and it has been described previously in one out of 15 pancreatic cancer cell lines and in one out of 260 prostate cancer samples, always associated to different mtDNA haplogroups. In contrast, the 6267G>A mutation was encountered only once in a compilation of 2,064 full mtDNA sequences from the literature and was not detected in 200 additional non-cancer mtDNA sequences from our laboratory. These findings indicate that the CO I missense mutation 6267G>A (Ala122Thr), impairs COX activity and is a recurrent mutation specifically associated with cancer. Based on the analysis of matched tumor/normal DNA pairs from cancer patients we propose that 6267G>A is a mtDNA germline mutation predisposing to cancer.

MtDNA sequence heterogeneity in single cells from leukemia patients. *Y.G. Yao[1], Y. Ogasawara[1], S. Kajigaya[1], J.J. Molldrem[2], R.P. Falcão[3], M.C. Pintão[3], J.P. McCoy[1], K. Keyvanafar[1], E.G. Rizzatti[3], N.S. Young[1].* 1) Hematology Branch, NHLBI, NIH, Bethesda, MD; 2) M.D. Anderson Cancer Center, Houston, TX; 3) University of Sao Paulo at Ribeirao Preto Medical School, Ribeirao Preto, Brazilã.

A high frequency of mtDNA somatic mutation has been observed in many tumors as well as in ageing tissues. Specific characteristics of malignant growths, especially generation of increased reactive oxygen species, may contribute to mitochondrial genetic alternations, leading to an increase in mtDNA heterogeneity among different cells. Conversely, rapid expansion of a clonal malignant cell population would act to either dilute mutations or to fix by genetic drift specific mtDNA changes, thus leading to lower overall heterogeneity. In this study, we analyzed the mtDNA control region sequence heterogeneity in single normal cells and individual blasts from leukemia patients, to address the mutation process in tumor cells and further to determine whether mtDNA be useful as a marker for monitoring disease progression and the presence of minimal residual leukemia. Among 1304 cells analyzed, we found a higher variance of the frequency of the single cells harboring mtDNA heterogeneity from the 13 patients (8.5% - 65.0%) compared to that of the 6 normal controls (36.6% - 44.1%). The 8 AML patients did not show a uniform pattern of heterogeneity in single blasts. One relapsed AML patient presented a complex shift of two different haplotypes in single cells, which might be the result of chemotherapy. Most mtDNA heterogeneity in single cells was caused by the C-stretch length mutations in the second hypervariable segment. Three patients showed high frequencies of heterogeneity at sites 189, 260, and insertion of the AC repeat at region 515-524, respectively, which could be considered as a marker for disease progression. Aging-dependent mutation accumulation observed in normal tissues was abrogated in leukemic blasts due to the blast expansion and crisis. Our results suggest that the somatic mutation processes in leukemia is complex, leading to deviations from normal level of heterogeneity due to either intrinsic aspects of leukemia pathophysiology and/or chemotherapy effects.

Major regions of mitotic recombination of heterozygous mice fibroblasts located on chromosome 8. *I.V. Tereshchenko, L. Serrano, C.L. Ayala, S. Bruse, J.A. Tischfield.* Department of Genetics, Rutgers University, Piscataway, NJ.

Mitotic recombination in somatic cells is a main pathway to the loss of heterozygosity (LOH) that may lead to cancer if tumor suppressor genes are involved. In present study the C57BL6 x 129S2 F1 mice heterozygous for the adenine phosphoribosyltransferase (Aprt) gene were used as a model for studying in vivo mechanisms of LOH. In ear-derived fibroblasts of forty mice, 192 of 239 (80%) DAP-resistant clones were attributable to physical loss of the wild-type Aprt allele. 116 of these clones were genotyped with SSR markers located 1 - 73 cM along chromosome 8. After making the most conservative correction for possible sib clones, more than half of clones exhibited a breakpoint in the 47 - 67 cM interval. We selected nine informative SNPs located in this 20 cM interval. We genotyped with a method that utilizes multiplex PCR, ligation chemistry, FlexMap microspheres, and the Luminex100 flow cytometer for efficient and robust SNP genotyping. We found an elevated frequency of mitotic crossovers in two regions within the 47 - 67 cM chromosomal interval. 43% of 30 breakpoints occurred in the 6-Mbp interval between 113.1 Mbp - 120.8 Mbp, and 20% in the 2-Mbp interval from 106.1 Mbp - 108.1 Mbp. Both of these frequencies represent more than the expected number of crossovers than would be predicted for these intervals based on meiotic map distances or a random distribution of crossovers based on DNA length. The details of sequence analysis of these target regions will be presented.

Simplified amplification approach for all exons and regions of interest for PTEN, ATBF1, and hMLH1/hMSH2 gene(s) followed by mutation detection using DHPLC. *B.L. Legendre[1], J. Zhu[1], G. Wu[1], J. Durocher[3], S. Lilleberg[2].* 1) Research & Development, Transgenomic, INC., Omaha, NE; 2) Translational and Clinical Research, Transgenomic, INC., Omaha, NE; 3) Translational and Clinical Research, Transgenomic, INC., Gaithersburg, MD.

Mutation detection by denaturing high performance liquid chromatography (DHPLC) has become a robust and accepted technology in screening for genetic variations, both germline and somatic, due to its high accuracy and sensitivity, high throughput, and low running costs. Screening of all exon sequences and other regions of interest of a particular gene for known and unknown mutations is important in the understanding of cancer development, treatment choices, treatment response and outcome monitoring. One current issue for mutation screening with DHPLC analysis is the lack of a simple, standardized protocol for the sample preparation and simultaneous amplification for all exons of the gene(s) of interest. In order to minimize the PCR amplification time and skill level needed, PCR-based 96-well plate assays were developed for numerous genes and their regions on interest which are prevalent in cancer screening, including PTEN (including the promoter region of exon 1, prostate cancer), ATBF1 (recently shown to be linked to prostate cancer), and hMLH1/hMSH2 (hereditary nonpolyposis colorectal cancer [HNPCC]). This technique involves identifying primers sets with similar annealing temperatures for all exons and regions of interest for a specific gene (PTEN, ATBF1) or set of genes which are associated with a particular disease (hMLH1/hMSH2 for HNPCC or ATBF1, PTEN, and hMLH1/hMSH2 for prostate cancer). These primers sets are then aliquoted into defined wells of the 96-well plates, allowed to dry, and then covered with a thin film. The plates are then stored at room temperature until use. In this study, we demonstrate the use of these gene specific (PTEN, ATBF1) or disease specific (hMLH1/hMSH2 for HNPCC) sample amplification assays followed by DHPLC analysis under partially denaturing conditions or DNASep-based HPLC analysis under nondenaturing conditions using SURVEYOR Nuclease.

Molecular diagnosis of CML (RT- PCR for bcr-abl gene)compared with cytogenetic diagnosis. *Z. Ataei Kachoei[1], L. Andonian[2], MT. Akbari[3], MR. Khorramizadeh[4], MA. Patton[5], M. Hashemzadeh Chaloshtori[6].* 1) Dept of medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; 2) Dept of Epidemiology and Biostatistics, School of Public Health, Tehran University of Medical Sciences, Tehran, Iran; 3) Dr Akbari Medical Genetic Lab, No 98, Taleghani Ave, Tehran, Iran; 4) Dept of Pathobiology, School of Public Health, Tehran University of Medical Sciences, Tehran, Iran; 5) Dept Medical Genetics , St Georges Hospital, Medical School, Cranmer Terrace, London, UK; 6) -Dept of Biochemistry and Genetics, School of Medicine, Shahrekord University of Medical Sciences, Shahrekord, Iran.

Chronic myelogenous leukemia (CML) is a clonal myeloprolifrative disorder of hematopoietic stem cells (HSC). The Pathologic hallmark of CML is the Philadelphia (ph) chromosome, which is a result of reciprocal translocation between long arms of chromosome 9 and 22 [t(9;22)(q34;q11)]. This translocation transposes Abl exon a2 into the M-bcr and in lees cases m-bcr-region so that hybrid gene has b3a2, b2a2 or e1a2 sequence. This study is a comparison between the results of molecular and cytogenetic tests for detection of ph chromosome for 29 patients in presentation of CML. Patients were referred to genetics laboratory by oncologists or hematologists according to the clinical diagnosis for CML and befor taking any drug. Altogether 23 patients were ph(+) by molecular test but 5 of them were cytogenetically ph(-). The result of both cytogenetic and molecular test for 2 cases was negative. Molecular study for 39 patients shows the different rate of b2a2 (7cases), b3a2 (9cases)and e1a2 (7 cases) fussions and coexpression of these fusious in some cases (b2a2 / b3a2 6 cases , e1a2 / b3a2 1case, b2a2 / b3a2 / e1a2 2 cases) .Odds ratio between molecular and cytogenetic test in this study is 1.3 . Keyword: CML , RT-PCR, Molecular diagnosis, Cytogenetic, Iran.

Novel microarray-based resequencing using pyrophosphate-activated polymerization (PAP). *Q. Liu, S.S. Sommer.* Dept of Molecular Genetics, City of Hope Ntnl Med Ctr, Duarte, CA.

The rate and cost of DNA resequencing limit molecular epidemiological analysis and clinical molecular diagnosis. Pyrophosphate-activated polymerization (PAP) is a novel technology for nucleic acid amplification and DNA sequencing. In PAP, DNA polymerase serially couples pyrophosphorolysis and polymerization using a 3 blocked nucleotide (P*). This serial coupling exhibits a high selectivity to mismatches along the length of the blocked oligonucleotide. Herein, this property is used for a resequencing microarray technology with an unparalleled signal to noise ratio, in which P*s are anchored to a surface and processed in a high throughput manner. For each nucleotide on the template strand, four P*s, one wildtype and three single base substitutions, were synthesized with identical sequence complementary to the template except at the 3' terminus, where ddAMP, ddTMP, ddGMP or ddCMP correspond to the wild type sequence and the three possible single base substitutions. For resequencing, a 20 nucleotide region of the human factor IX gene, a total of eighty P*s were synthesized. Then each was anchored onto one spot of a CodeLink microarray through a 5 amino linker. DNA samples of wildtype, single base substitution, micro-deletion and micro-insertion were examined. All sequences were called correctly. Thus, we demonstrate the feasibility of a high throughput microarray-based resequencing for detection of unknown mutations.

SCIMLA: Testing the lipophilic mutagen hypothesis of breast cancer (LMHOB). *E. Saleh, A. Bockholt, S.S. Sommer.* Dept Molecular Genetics, City of Hope, Duarte, CA.

Background:Breast cancer is the most frequent malignancy occurring in women. The origins of sporadic breast cancer are largely unknown. There is growing indirect evidence that mutagens in the environment and particularly of dietary origin may play a causative role in the etiology of breast cancer. Breast tissue has a unique architecture:small islands of cancer-prone cells surrounded by a sea of fat cells. Hypothesis:Breast tissue may be a preferential target for fat-soluble mutagens. Cancer-prone cells of breast tissue are hypothesized to be 1) particularly sensitive to fat-soluble mutagens originating in animal feed and 2) differentially susceptible to the type of fat consumed in the diet. In adulthood, adipocytes cannot replicate but they can concentrate the great diversity of lipophilic mutagens from meat products which derive from animal feed (lipophilic mutagen hypothesis of breast cancer LMHOB). We hypothesize that mammary mutation load (mutation frequency, pattern, and spectrum) differs dramatically among women, and that, the pattern of mutation in breast adipocytes and mammary cells correlate within an individual. Method:Single Cell Immunohistochemical Mutation Load Assay(SCIMLA)is a novel method to measure somatic mutation load in solid tissues. SCIMLA requires reporter genes in which missense mutations often cause protein accumulation. Single cells that are immunohistochemically positive for protein accumulation are microdissected from ethanol fixed and paraffin embedded tissues. The reporter gene is amplified from the single cell and sequenced for somatic mutation. Results:SCIMLA was used to test a first prediction of the LMHOB. Our observation of marked interindividual variation in mammary cell mutation pattern is consistent with LMHOB. Implications:The marked interindividual variation in mutation load among women requires explanation. Based on these data a mouse model is being used to examine directly the effect of dietary lipophilic mutagens on mutation frequency and pattern in mammary vs colon and lung epithelium. If LMHOB is correct monitoring the mutagen content of animal feed could be implemented to reduce the incidence of breast cancer.

Mutation screening of UBE4A, a homologue of the putative neuroblastoma tumour suppressor gene UBE4B. *H. Caren, A. Holmstrand, R.M. Sjoberg, T. Martinsson.* Department of Clinical Genetic, Gothenburg University, Gothenburg, Sweden.

Chromosome 11q and 1p are commonly deleted in advanced stage neuroblastomas and are therefore implicated to contain tumour suppressor genes involved in the development of neuroblastoma. The two UFD2 homologs, UBE4A and UBE4B, involved in the ubiquitin/proteasome pathway, reside in 11q and 1p respectively. UBE4B has previously been analyzed for mutations and one mutation (a mutation in splice donor site of exon 9; c.1439+1G>C) was found in one neuroblastoma tumor with fatal outcome. We now speculated that the homolog UBE4A could be an alternative way to tumorgenesis. The coding exons of UBE4A were therefore sequenced. One putative missense mutation (a 1028T>C, leading to a putative missense mutation, p.I343T, residing in exon 8) was found in one neuroblastoma tumor 20R8 and this was confirmed by sequencing in both directions. The change, an isoleucine (unpolar) to threonine (polar) was situated in a highly conserved amio acid region. In adition two novel variants were also found in intronic sequences of UBE4A. Both the UBE4A and the UBE4B genes are implicated in the ubiquitin proteasome pathway by encoding proteins that are homologues of the yeast protein Ufd2. One could speculate that the proteins generated from UBE4B and UBE4A are involved in protecting the cell from environmental stress and that inactivation of either of them could contribute to malignancy.

Mutation and LOH analyses of cell cycle genes in skin melanoma: cyclin D1, p53, p21, p16, p15, and Rb1. *J. Durocher, C. Wasserburger, J. Hempel, D. Foster, M.L. Nickerson, S.L. Lilleberg.* Translational and Clinical Res, Transgenomic, Omaha, NE.

The transition from phase G1 to S of the cell cycle is controlled by sequential activation of cyclin/Cdk complexes (Cyclin-dependent kinases). Active cyclin/Cdk complexes phosphorylate and inactivate members of the retinoblastoma protein (Rb) family, which are negative regulators of G1 and S-phase progression. This leads to the induction of E2F-regulated gene expression and cell proliferation. Cdk inhibitors directly bind to and interfere with cyclin/Cdk complexes, and negatively regulate cell cycle progression. The TP53 tumor suppressor gene and Cdk-inhibitors such as CDKN1A, CDKN2A, and CDKN2B are altered and thus aberrantly regulated in different types of tumors. In order to investigate the role of the genes involved in the control of G1/S phase cell cycle progression in human melanomas, we determined the spectrum of mutations in TP53, CCND1, CDKN1A (p21), CDKN2A (p16), CDKN2B (p15), and RB1 genes in primary and metastatic melanomas and melanoma cell lines. Sixty (60) melanomas and 12 melanoma cell-lines were analyzed utilizing an in-depth scanning strategy that consists of heteroduplex-based mutation detection by DHPLC and Surveyor Nuclease with the WAVE System. Results will be presented suggesting that these genes are involved in melanoma tumorigenesis, although at low frequencies. Other tumor suppressor genes that may be informative of the mechanism of tumorigenesis in skin melanomas will also be discussed.

Mutations Screening in BRCA1 /2 Genes in Non -Ashkenazi Women. *A. Elimelech[1], M. Sagi[2], C. Shochat[1], S. Korem[1], D. Levi[1], L. Kaduri[2], A. Nissan[2], T. Peretz[2], D. Bercovich[1,3].* 1) human genetic, migal, kiryat -shmona, Israel; 2) Department of Human Genetics, Dept. of Surgery 2 and Department of Oncology, Hadassah University Hospital, Jerusalem; 3) Tel Hai Academic College, Israel.

Increased knowledge of breast cancer genetics has improved the possibilities to predict the risk for developing breast and ovarian cancer. In Israel, genetic testing and screening of women at high risk is done at present only for the founder mutations, according to the ethnic origin: in Ashkenazi -185delAG and 5382insC in the BRCA1 gene, and 6174delT in BRCA2, for Yemenite Jews- the mutation 8675delAG in BRCA2 and in Persian Jews - the 3053T>G in BRCA1. For other non-Ashkenazi Jewish women and for Arab women, no common mutations predisposing to breast cancer were found. Using DHPLC mutation detection technique we screened 12 Israeli Arabs or non-Ashkenazi Jewish women with breast cancer and significant family history and 6 controls, for mutations in the BRCA1/2 genes. Our goal was to screen the full sequences of the two genes in order to find all cancer causing mutations and/or sequence variations that could be modifiers alleles to breast cancer. Screening 31 fragments covering the 24 exons of the BRCA1 gene revealed three mutations, which can be suspected as deleterious. Of the three, one was found in non-Ashkenazi Jewish women, novel mutation P1812A in exon 23 (were also found in two affected sisters). Two mutations were found in Israeli Arabs: E1373X in exon12 and M1652I in exon16. The E1373X mutation was found in four affected family members. By screening 40 fragments covering the 27 exons of BRCA2, 3 mutation was found, one of them on a codon 1646del4 (5164del GAAA) in exon 11d, for a woman with no mutation in the BRCA1, which was previously reported (in the (Breast Cancer Information Core (BIC) -NHGRI). In the BRCA1gene, a total of 17 DNA alterations were found: 1 nonsense, 8 missense, 4 IVS, 1 5UTR and 3 silent. The complete sequence variations for each participant in both genes will be presented. Screening these mutations in large populations of non-Ashkenazi women can add private or common mutations in non-Ashkenazi Jews or Israeli Arabs, and will help developing new screening programs for these populations.

***EGFR* Mutation Status and Pathological Features of Primary Lung Cancers.** *K.E. Finberg, J. Beheshti, E.J. Mark, A.J. Iafrate.* Department of Pathology, Massachusetts General Hospital, Boston, MA.

Somatic mutations in the kinase domain of the epidermal growth factor receptor (*EGFR*) have been detected in a subset of patients with pulmonary adenocarcinoma and correlate with clinical responsiveness to the tyrosine kinase inhibitors gefitinib and erlotinib. Here we correlate adenocarcinoma subtype and *EGFR* mutation status in 130 primary lung cancers. DNA was isolated from microdissected tissue, and the nucleotide sequence encoding the kinase domain (exons 18-24) of *EGFR* was analyzed by PCR and capillary gel electrophoresis. Heterozygous *EGFR* mutations predicted to alter the coding sequence were identified in 24/130 (18.5%) tumors. Of the previously reported mutations associated with clinical response to gefitinib, the 2573T>G mutation in exon 21 (resulting in L858R) was detected in 7 tumors, while 12 tumors harbored in-frame deletions within exon 19. 27/130 tumors analyzed were bronchioloalveolar carcinomas (BACs) or adenocarcinomas with bronchioloalveolar features; of these 27 tumors, *EGFR* mutations were detected in 9 tumors (33%), consistent with prior reports of a high prevalence of BAC among tumors with *EGFR* mutation. All of these 9 tumors were of the non-mucinous histologic subtype. In contrast, 10 of the 18 BACs or adenocarcinomas with bronchioloalveolar features that did not have *EGFR* mutation showed mucinous differentiation. Thus, in BACs or adenocarcinomas with bronchioloalveolar features, the presence of mucinous differentiation was a negative predictor of *EGFR* mutation (^{2}=5.74 with Yates' correction, df=1, p=0.02). There was no correlation between BAC histological subtype, or other adenocarcinoma histologic subtype, and specific *EGFR* mutations. Prior work has demonstrated a high frequency of *KRAS* mutation in mucinous-type BAC, and recent study has shown that lung tumors refractory to gefitinib or erlotinib often have *KRAS* mutations and that these tumors lack *EGFR* mutation. Thus, our data suggest the possibility that in BACs mucinous differentiation may correlate with refractoriness to EGFR kinase inhibitors.

Ultra-Deep Sequencing of EGFR from Lung Carcinoma Patients Reveals Low Abundance Drug Response Mutations. *M. Egholm[1], E. Nickerson[1], R. Thomas[2], G. Turenchalk[1], B. Desany[1], M. Ronan[1], S. Hutchison[1], J. Knight[1], L. Du[1], J. Leamon[1], J.M. Rothberg[1], T. Tengs[2], J.F. Simons[1], M. Meyerson[2].* 1) 454 Life Sciences, Branford, CT; 2) Dana-Farber Cancer Institute, Boston, MA.

A current challenge in oncology is the detection of cancer causing and chemotherapy responsive mutations in clinical samples that may contain only a small sub-population of tumor-derived cells. Mutation detection by Sanger sequencing is typically restricted to mutations present at 20% abundance or greater.

Here we report high-sensitivity mutation detection using a new high-throughput DNA sequencing technology with the ability to simultaneously sequence 200,000-400,000 templates, in excess of 100 bases each, within 4 hours. The massive over-sampling enables mutation detection below 1% without *a priori* knowledge of the mutations. We have demonstrated the utility of the technology by studying mutations in the epidermal growth factor receptor (EGFR), associated with tumorigenesis and response to tyrosine kinase inhibitors in non-small cell lung cancer (NSCLC). We examined the mutational status of exons 18-21 of EGFR in over twenty NSCLC patients. Overlapping PCR products covering the five target exons were simultaneously sequenced to 1000-fold coverage per template. Our data revealed low abundance mutations, including base-pair substitutions, deletions and insertions associated with disease and drug-response, not formerly detected with Sanger sequencing. In a pre-therapy pleural effusion sample from a patient with strong initial drug response, a drug-sensitizing 18 base-pairs deletion was detected at 0.28%. Sequencing of a post-therapy sample taken after relapse determined that the deletion was present at 2.5% and, consistent with the clinically observed loss of drug response, also revealed a drug-desensitizing mutation, T790M, at 2.0%.

Our data demonstrate fast and accurate identification of cancer-associated mutations from complex samples at a sensitivity and speed that is unprecedented. The rapid mutation detection can aid in critical decision making regarding course of treatment and potentially affect patient outcome.

Cooperation between tumor suppressor genes: accelerated tumorigenesis in a child with constitutional mutations in the *p53* and *PTEN* genes. *S.E. Plon[1], H.V. Russell[1], J.G. Nuchtern[1], J.Y. Kim[1], M. Hegde[1], M.B. Bhattacharjee[1], J. Hicks[1], C. Eng[2], L.L. Wang[1].* 1) Depts of Pediatrics, Surgery, Pathology, and Molecular and Human Genetics, Baylor College Medicine, Houston, TX; 2) Human Cancer Genetics Program, The Ohio State University, Columbus OH.

Studies of sporadic cancers suggest that inactivation of *p53* and *PTEN* tumor suppressor genes are mutually exclusive events. However, mouse models heterozygous for both *p53* and *Pten* mutations demonstrate accelerated tumor development comparable to *p53* homozygous null mice, demonstrating that haploinsufficiency at both loci may cooperate in tumorigenesis. Here we describe a four-year-old girl who inherited a *PTEN* missense mutation, L112V, from her father and a *p53* hotspot mutation, R282W, from her mother. The paternal history is consistent with Cowden Syndrome (CS) with macrocephaly, lipomas and thyroid disease. The probands mother and sister, both heterozygous for the *p53* mutation, were diagnosed with cerebellar astrocytoma and medulloblastoma, respectively. The proband displays clinical features of CS including macrocephaly, multiple lipomas and hemangiomas. However, her tumor spectrum is not typical of either CS or Li Fraumeni syndrome and includes: metastatic neuroblastoma (*MYCN* non-amplified) at age 7 months, anaplastic juvenile granulosa cell tumor of the ovary at age 16 months, pleomorphic xanthoastrocytoma of the left temporal lobe at age 3 years, and liposarcoma of the pelvis, metastatic to bone and lung, at age 4 years. Cytogenetic analyses of the neuroblastoma, ovarian and brain tumors revealed different abnormalities including hyperdiploidy, acquisition of trisomy 21, and telomeric association of chromosome 15. Thus, the accelerated and unique pattern of tumors in this child suggests cooperation between the *p53* and *PTEN* gene products to maintain genomic stability. Studies to confirm this hypothesis are underway utilizing cell lines established from family members. More generally, studies of sporadic human tumors that focus on inactivation of both copies of a tumor suppressor gene may not appreciate the contribution of haploinsufficiency at two different tumor suppressor loci to tumorigenesis.

MSI colorectal cancer is characterized by decreased expression of CDK2-AP1. *Z. Yuan[1], A. Bennett[2], T. Sotsky Kent[2], A. Miller[2], T.K. Weber[1, 2].* 1) Department of Molecular Genetic; 2) Surgery, Albert Einstein of College of Medicine,NY.

Background: We have demonstrated Cyclin Dependent Kinase2 -Associated Protein 1 (CDK2-AP1) expression is significantly decreased in microsatellite unstable (MSI) CRC cell lines (Yuan et al., 2003). Recently, we observed a novel del T alteration in a microsatellite-like sequence of CDK2-AP1 associated with its decreased expression in MSI CRC. We also observed siRNA inhibition of CDK2-AP1 expression associated with increased colon cell proliferation and decreased apoptosis (Yuan et al., 2005). In this study we: 1) Employed multiple MMR deficient systems to study MMR modulation of CDK2-AP1 expression. 2) Utilized MASS spectrometry analysis of purified CDK2-AP1 protein complexes to investigate the mechanism of CDK2-AP1 regulation of cell growth and apoptosis.**Materials and Methods**: mRNA and protein expression of CKD2-AP1 were determined in MSH2 knockout mouse embryonic stem (ES) cells vs MSH2 wild type mouse ES cells and a MLH1 knockout mouse vs a MLH1 wild type mouse using real-time RT-PCR and Western blot assays. CDK2-AP1 protein expression was analyzed in 50 human CRC tissues (43 MSS/7 MSI) using tissue microarray assays. CRC CDK2-AP1 protein complexes were purified using a tandem affinity purification (TAP) system. Purified CDK2-AP1 protein complexes were characterized using MASS Spectrometry. **Results**: CDK2-AP1 mRNA and protein expression were significantly decreased in MMR knockout mouse ES cells and mouse knockout models using real-time RT-PCR and Western blot assays. In tissue arrays, CDK2-AP1 expression was significantly decreased in 6/7 human MSI CRCs. Interestingly, 14 candidate proteins including cell growth and apoptosis control elements, were identified as components of the CDK2-AP1 protein-protein complex by MASS Spectrometry. **Conclusion**: These results support and expand our novel published observations of a relationship between MMR deficient CRC and decreased CDK2-AP1 expression. CDK2-AP1 protein complex analysis identified a number of candidate mediators of CDK2-AP1 modulation of cell growth and apoptosis. These results further support an important role for CDK2-AP1 in the initiation and progression of MMR deficient CRC.

Altered Expression of the Early Mitotic Checkpoint Gene *CHFR* in Breast Cancers: Implications for Tumor Suppression. *L.M. Privette[1], M.E. Gonzalez[1], A.E. Erson[2], E.M. Petty[1].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Biology, Middle East Technical University, Ankara, Turkey.

Introduction: Every three minutes, a woman in the United States is diagnosed with breast cancer. Many of the genetic changes that occur in breast cancer lead to defects in cell cycle checkpoint regulation. The early mitotic checkpoint gene *CHFR* (Checkpoint with FHA and Ring Finger) delays mitotic entry and aids in the survival of normal cells in response to microtubule stressors like nocodazole and paclitaxel. This suggests that CHFR expression may have prognostic value for cancer patients, yet little is known about this recently discovered gene.

Methods and Results: We analyzed Northern and Western blots to determine if CHFR expression was altered in breast cancer cell lines. Results indicated that CHFR mRNA and protein expression was lower in 12 of 25 cell lines when compared to immortalized mammary epithelial cells. Similar results were noted in ovarian cancer cell lines. When mammary epithelial cells expressing low levels of CHFR were retrovirally transduced with a *CHFR* construct, both an immortalized (HPV 4-12) and a cancer cell line (Hs578t) showed reduced growth kinetics and had a decrease in the mitotic index, with and without nocodazole treatment. Importantly, expressing *CHFR* in the breast cancer cell line, Hs578t, resulted in a dramatic five-fold decrease in invasion through a Matrigel matrix. Immunofluorescence also indicated that CHFR colocalizes with F-actin at the edge of the cytoskeleton. Preliminary tests to lower *CHFR* expression by RNAi indicate that epithelial cells have a higher mitotic index and also show some cytoskeletal defects.

Discussion: Together, these results suggest that low *CHFR* expression contributes to rapid growth and unregulated progression into mitosis whereas over-expressing *CHFR* lowers the growth rate and invasiveness of some breast cell lines. These results have implications for oncogenesis and begin to characterize *CHFR* as a tumor suppressor gene. Since *CHFR* expression is associated with a cellular response to paclitaxel, further characterization of *CHFR* could have great clinical impact.

Analysis of a human septin gene, *SEPT9v1*, in mammary cells suggests novel oncogenic properties. *E.M. Petty, M.E. Gonzalez, L.M. Privette, E.A. Peterson, J.L. Loffreda-Wren.* Int Med/Hum Gen, Univ Michigan Med Ctr, Ann Arbor, MI.

Introduction: Fourteen human septin genes have been described in the past 10 years but their diverse functional roles await elucidation. Septins are members of an evolutionarily conserved GTP-binding family of proteins that localize to cytoskeletal filaments. They are implicated in cellular functions ranging from apoptosis to vesicle trafficking and associated with disorders ranging from Alzheimer's disease to cancer. We cloned *SEPT9* from a region of 17q25 allelic imbalance in cancer cells while others discovered it as an MLL fusion partner in leukemia cells. It is 96% identical to *Sept9/Sint1*, a proto-oncogene identified in murine lymphomas and mammary tumors. *SEPT9* is essential for normal cytokinesis.

Methods/Results: Upon finding *SEPT9* amplification and increased mRNA and protein expression of specific SEPT9 variants in the majority of breast cancer cells studied, we developed *in vitro* models to examine the consequences of *SEPT9* variant expression. Analysis of stable retrovirally transduced *SEPT9v1* expression in mammary epithelial cells revealed altered cell morphology, accelerated growth kinetics, enhanced foci formation, increased cell motility, higher invasive potential, dissociation of alpha-tubulin microfilaments, bi-nucleated giant cells, nuclear mis-localization, elevated mitotic indices, and significant aneuploidy when compared to control cells. While *SEPT9v2* and *SEPT9v4* variants also demonstrated high expression in some breast cancer cells, ectopic expression of *SEPT9v2* did not alter cellular phenotypes and *SEPT9v4* changes were less striking than those observed with *SEPT9v1*.

Discussion: Our data suggest that targeted expression of certain *SEPT9* variants, specifically *SEPT9v1*, may contribute to genomic instability and alter cellular proliferation, motility, and architecture, thus driving malignant progression in mammary epithelial cells. Further *SEPT9* analysis will deepen our understanding of novel septin-associated molecular pathways relevant to oncogenesis. Knowledge of *SEPT9's* functional roles in cancer may have prognostic and therapeutic implications.

Somatic microindels. *S. Sommer[1], K. Gonzalez[1], K.A. Hill[1,2], K. Li[1], X. Li[1], W.A. Scaringe[1,3], J. Wang[1].* 1) Dept Molecular Genetics, City of Hope, Beckman Res Inst, Duarte, CA; 2) Dept of Biology, The University of Western Ontario, London, ON CANADA; 3) Bionformatics Group, Dept. of Molecular Genetics, City of Hope National Medical Center, Duarte, CA.

Microindels are infrequent mutations, often resulting in protein truncations. Little is known of the mutational mechanisms of microindels, and analyses are limited to the germline. Our database of 6,016 independent somatic mutations in Big Blue mice permits the first detailed analyses of 30 somatic microindels and direct comparisons with features of 795 pure microinsertions/microdeletions. Each microindel is unique. Microindel frequency shows no age, gender, or tissue specificity. Microindels have a similar frequency in mouse tumors and normal tissues, consistent with a similar endogenous contribution of microindels in cancer. 1-2 microindels (1 bp inserted and 2 bp deleted) are the most common. In microindels, deletions tend to be larger than insertions. The size distribution of deletions or insertions in microindels decays more slowly than for pure microinsertions/microdeletions. Many insertions in microindels do not repeat the adjacent nucleotides, while 97% of pure microinsertions do. Mouse somatic microindels and human germline microindels display many similarities, consistent with similar processes in mouse, humans, germline, and soma. Functionally, 13% of either somatic or germline microindels are in-frame, causing a minor change in protein size, which can play a crucial role in protein-tinkering in oncogenesis and evolution. Somatic microindels in Big Blue account for 17% of protein-tinkering expansions and 5% of protein-tinkering contractions. Analysis of somatic microindel sequences suggests heterogeneous mechanisms. Some seem to arise by error-prone processes such as the recruitment of error-prone polymerases at replication-blocking adducts. It is estimated that a human adult carries roughly 1.6 trillion somatic microindels (20% 1-2 microindels) with the potential to predispose to cancer.

The human single-strand DNA binding protein RPA rapidly associates with DNA breaks in vivo. *I. Pasic[1,2], M.S. Meyn[1,2,3].* 1) Genetics & Genomic Biology, Hospital for Sick Children, Toronto, ON; 2) Molecular & Medical Genetics, Univ of Toronto, Toronto, ON; 3) Paediatrics, Univ of Toronto, Toronto, ON.

Human replication protein A (RPA) is a heterotrimeric single-stranded DNA-binding protein involved in DNA replication, recombination, and repair. In response to genotoxic insults such as -radiation, the 34kDa RPA2 subunit of RPA becomes phosphorylated at multiple serine and threonine residues. This response is, in part, dependent on the DNA damage response kinases ATM and DNA-PKcs. Phosphorylation promotes interactions between RPA and DNA repair proteins and shifts RPA away from a role in DNA replication. However, it is unclear whether RPA phosphorylation affects its ability to interact with damaged DNA.

To answer this question and better understand the role of RPA in the initial response to DSBs, we studied the recruitment of endogenous RPA and GFP-tagged RPA2 to the sites of laser microbeam-induced double-strand DNA breaks (DSBs) in human fibroblast nuclei. We can detect DSB-associated RPA foci 15 minutes and 1 hour post-irradiation. In contrast to ?-H2AX, RPA foci are small and punctate, reflecting tight spatial localization of RPA with damaged DNA.

The initial association of GFP-tagged wild type RPA2 with DSBs can be detected <2 seconds post-irradiation. This association is largely unchanged by RNAi-mediated depletion of DNA-PKcs in wild type or ATM-deficient human cells. However, the proportion of nuclei with damage-induced RPA foci 15 and 60 minutes post-irradiation is reduced in ATM-deficient fibroblasts and by specific RNAi-mediated depletion of DNA-PKcs in wild type and ATM-deficient fibroblasts. In addition, we find that the association of GFP- RPA2 with DSBs is decreased in NBS1-deficient human fibroblasts. Taken together, these findings implicate DNA damage kinases and the MRE11/NBS1/RAD50 complex in the interaction of RPA with DSBs and suggest that phosphorylation is required for the persistent association of RPA with damaged DNA but not for RPAs initial interactions with DSBs.

DOES BRCA2 HETEROZYGOSITY RESULT IN HAPLOINSUFICIENCY IN HUMAN BREAST CELLS? *R. Bruchim, L. Quenneville, C.L. Panasci, W. Foulkes, R.S. Aloyz.* LDI. JGH, Montreal, qc, Canada.

Heterozygous carriers of mutations in the BRCA2 gene have a high risk of developing breast cancer. In these individuals, BRCA2 appears to act as a tumor suppressor gene, in that loss of the wild type allele (LOH) is frequently observed within tumors, leading to loss of BRCA2 function. BRCA2 protein has a critical role in DNA repair via homologous recombination and cytokinesis. We established a breast epithelial cell line (B28) derived from tumor tissue of a woman who developed an invasive ductal breast cancer and carries the truncating mutation BRCA2:5578delAA. Sequence analysis of the tumour shows only the mutated allele, whereas B28 retains heterozygosity at BRCA2. The mutation results in a truncated BRCA2 protein lacking the Rad51 association domain and the nuclear localization signal. Consistently, full length BRCA2 is detected in B28 cells and BRCA2 and Rad51 foci are detected in these cells after Cisplatin treatment. The cytokeratin (CK) expression profile of B28 cells suggests that the cells display a basal epithelial phenotype. Briefly, all the cells expressed HMW keratins (1, 5, 10 and 14), EGFR and IGF-1R. Moreover, 60% of the cells expressed CK 8/18, CK5/6 and p63. No staining for ER/PR, CK19 and SMA was detected. Additionally, 5-10% of the cells were positive for vimentin. In the present communication we report that B28 cells are more sensitivity than HNME cells and CAPAN-1 (human pancreatic deficient BRCA2 cell line) to Cisplatin, Etoposide and Taxol. Interestingly late passages of B28 cells are more sensitive to DNA damaging agents at early passages than at late passages. In contrast there is not significant difference in the sensitivity to Taxol between early and late passages of B28 cells. To our knowledge this is the first report suggesting that BRCA2 heterozygous cells display a phenotype regarding the sensitivity to chemotherapeutic agents. This is probably due to the fact that lymphocytes from carrier patients or engineered mouse cells have been utilized to assess BRCA2 haploinsuficiency in heterozygous cells.

The BARD1 Cys557Ser variant confers susceptibility to breast cancer in carriers of BRCA2 999del5 and increases risk for multiple primary breast tumors. *S.N. Stacey[1], P. Sulem[1], A. Helgason[1], J. Gudmundsson[1], O.T. Johannsson[2], J.T. Bergthorsson[1], L. Amundadottir[1], U. Thorsteinsdottir[1], A. Kong[1], J. Gulcher[1], K. Stefansson[1].* 1) deCODE Genetics, Reykjavik, Iceland; 2) Dept of Oncology, LSH, Reykjavik, Iceland.

BRCA1 protein exists predominantly as heterodimers with a related protein, BARD1. Some pathogenic BRCA1 mutations disrupt the function of the BRCA1/BARD1 complex. Recently a missense BARD1 variant, Cys557Ser, was reported at increased frequencies in breast cancer (BC) families. We investigated the BARD1 Cys557Ser variant in a population-based sample of 1232 Icelandic BC patients and 703 controls. We then used the Icelandic national genealogy to study the relationships between the Cys557Ser variant and familial clustering of BC. Cys557Ser was present at an allelic frequency of 0.025 in BC probands unselected for family history and 0.016 in controls (risk ratio= 1.61, p=0.036). The frequency was 0.034 (risk ratio= 2.24, p=0.018) in a high-predisposition group of probands defined by family history, early onset and multiple incidences of primary BC. The frequency of the variant allele amongst carriers of the common Icelandic BRCA2 999del5 mutation in the high-predisposition group was 0.059 (risk ratio= 3.93, p=0.034). In contrast to BRCA2 999del5 carriers, BARD1 Cys557Ser carriers did not drive familial clustering of BC on their own. However, Cys557Ser carriers were at a more than 2-fold risk of subsequent primary breast tumors after the first BC diagnosis. Lobular and Medullary BC were over-represented in Cys557Ser carriers. An excess of ancestors of contemporary carriers lived in a single county in the southeast of Iceland. Most carriers shared a microsatellite haplotype suggestive of a founder event. The variant occurred on a single SNP haplotype background in the HapMap CEPH sample of Utah residents, suggesting a single ancient origin for common forms of the variant. Our findings suggest that BARD1 Cys557Ser is an ancient pathogenic variant that can confer risk for single and multiple primary breast cancers in combination with other known or unknown predisposition genes.

Associations between the Glutathione S-Transferase Pi (*GSTP1*) Ile104Val polymorphism and lung cancer: a meta-analysis of published studies. *C.S. Hoffman, C.L. Avery, K.E. North, D.A. Canos, A.F. Olshan, C. Poole.*
Department of Epidemiology, University of North Carolina, Chapel Hill, NC.

Lung cancer is the leading cause of cancer-related deaths in the US and has been directly associated with cumulative smoking exposure. The detoxification of smoke in the lung is a multi-step process in which the GST family of proteins, particularly *GSTP1*, plays a role. Multiple studies have examined the association between the Ile104Val (A>G) variant and lung cancer. A systematic review and meta-analysis was conducted to describe the state of the literature, with the goal of informing decision making and future research. We examined evidence of publication bias, evaluated the consistency of results overall and with regard to study characteristics, and estimated summary estimates when warranted. Published studies were obtained from Pubmed, OMIM, Biosys, and ISI Web of Science between May, 2004-June, 2005 and supplemented with citations from retrieved articles. Results were abstracted by two independent extractors and unadjusted odds ratios (OR) were calculated for three genotype contrasts (AG, GG, and AG/GG versus AA). We evaluated a dominance effect (AG/GG versus AA), as estimated odds ratios for this contrast were available for all 22 studies. There was evidence of funnel plot asymmetry (log rank test p=0.05, regression test p=0.2) and the trim and fill analysis imputed five hypothetically unpublished results. This reduced both the homogeneity test p-value (0.02 to <0.001) and the random-effects summary odds ratio estimate (OR = 1.11 to OR = 1.02). Funnel plot symmetry test p-values were higher within geographic strata, with OR estimates of 1.09 (95% CI: 0.97, 1.22) and 1.02 (95% CI: 0.91, 1.14) in the European and North American strata, respectively. Studies conducted in Asia produced higher and more heterogeneous odds ratio estimates than studies conducted elsewhere and did not support a summary measure. There was not compelling evidence of a consistently strong effect of the *GSTP1* polymorphism on lung cancer risk. Our future work will involve analyses that distinguish between one and two copies of the G allele and the evaluation of interaction by smoking.

Variable expression and activity of taxane-metabolizing enzymes in ovarian tumors as a potential mechansim of taxane resistance. *J. DeLoia[1], W. Zamboni[2], J. Jones[1].* 1) Dept OB/GYN/RS, Univ Pittsburgh, Pittsburgh, PA; 2) Molecular Therapeutics and Drug Discovery Program, UPCI, Pittsburgh, PA.

Objective: Current firstline chemotherapy for ovarian cancer consists of carboplatin combined with either paclitaxel or docetaxel. Disposition of carboplatin is determined by renal clearance, while the taxanes are metabolized by cytochrome P450 (CYP450) enzymes. Although the majority of taxane metabolism occurs in the liver, recent data has shown that some solid tumors express CYP450 enzymes in the tumors themselves. The objective of this study was to determine whether ovarian tumors express genes regulating cellular efflux and subsequent metabolism, and whether histology, grade or stage correlated with expression. Methods: Gene expression of CYP2C8, CYP3A4/A5 and the ABC transporter ABCB1 was determined in 56 primary epithelial ovarian tumors. Cells were grown from seven tumors and exposed ex vivo to paclitaxel (PAC) and docetaxel (DOC) for up to 24 hours. PAC and DOC concentrations were measured in the media by an LC-MS assay. Results: Results from this analysis demonstrate that ovarian cancer cells do express functional taxane-metabolizing enzymes. Such expression appeared to enhance the ability of cancer cells to metabolize DOC. Specifically, the PK of DOC was correlated with the ratio of CYP4A5 to ABCB1 gene expression, thus representing a novel mechanism of chemotherapy resistance. There was no relationship between PAC PK parameters and gene expression. Unlike hepatic expression, these genes were not induced by exposure to drug. Conclusions: Knowledge of inter-individual variation in CYP450 enzyme tumor expression and activity may influence the individualization of chemotherapy, by avoiding agents that are rapidly metabolized and selecting agents that are not.

Association of polymorphisms of dopamine receptor/transporter genes with risk of non-small cell lung cancer. *D. Campa[1,2], S. Zienolddiny[1,3], R. Barale[2], A. Haugen[3], F. Canzian[1].* 1) International Agency for Research on Cancer, 69372 Lyon Cedex 08, France; 2) Department of Science for the Study of Man and Environment, University of Pisa, Pisa, Italy; 3) Department of Toxicology, National Institute of Occupational Health, P.O. Box 8149 Dep., 0033 Oslo, Norway.

Tobacco smoking is the most important cause of lung cancer, however less than 20% of smokers develop lung cancer, suggesting that genetic factors play a role in the etiology of lung cancer. Dopamine receptor/transporter genes may be of interest in assessing NSCLC risk .Dopamine has been shown to inhibit the growth of several types of malignant tumors in mice, and this activity has been variously attributed to inhibition of tumor-cell proliferation and stimulation of tumor immunity. In addition, the dopamine concentration in malignant tumors is reported to be significantly reduced compared with that of normal control. Moreover, the neurotransmitter dopamine inhibits angiogenesis induced by VPF/VEGF. Angiogensis has an essential role in many important pathological settings including tumors. Dopamine strongly and selectively inhibits the vascular permeabilizing and angiogenic activities of VPF/VEGF. Dopamine exerted this role through dopamine receptors, inducing endocytosis of VEGF receptor 2, which is critical for promoting angiogenesis, thereby preventing VPF/VEGF binding, receptor phosphorylation and subsequent signaling steps. To evaluate the lung cancer genetic susceptibility we used an oligonucleotide microarray based on the arrayed primer extension (APEX) technique, The APEX technique consists of a sequencing reaction primed by an oligonucleotide anchored with its 5' end to a glass slide and terminating one nucleotide before the polymorphic site. The extension with one fluorescently labeled dideoxynucleotide complementary to the template reveals the polymorphism. A total of 26 oligonucleotides were designed to flank 13 SNPs of DRD2, DRD4 and DAT1 genes. A case-control study, on a total of 861 individuals of norwegian origin, showed that a 2 to 4-fold increased lung cancer risk is associated with DRD2, DRD4 and DAT1 genes
Keywords:dopamine lung cancer, SNPs.

Association of MLH1 and MSH2 Polymorphisms and Colorectal Cancer Risk: A Population-Based, Case-Control Study of Canadian CRC Cases. *M. Mrkonjic[1], S. Raptis[1], J. Knight[1], D. Daftary[1], B. Younghusband[2], S. Gallinger[1], R. Green[2], J. McLaughlin[1], B. Bapat[1].* 1) Samuel Lunenfeld Research Inst, University of Toronto, Toronto, Ontario, Canada; 2) Memorial University, St.John's, NFLD, Canada.

Colorectal cancer (CRC) is a complex disease attributed to the interplay between genetic and environmental risk factors. The most commonly inherited form of CRC is hereditary nonpolyposis colorectal cancer (HNPCC); an autosomal dominant syndrome marked by tumors expressing genome-wide microsatellite instability (MSI) and caused by germline mutations in the mismatch repair (MMR) genes. Mutations in two MMR genes, MLH1 and MSH2, account for ~85% of cases among confirmed HNPCC patients. A number of single nucleotide polymorphisms (SNPs) in MMR genes have been identified, but little is known about the role of most of these SNPs in CRC. We hypothesize: A) that some MMR SNPs affect functional variation in MMR and contribute to CRC susceptibility and B) that the role specific MMR SNPs play in the development of CRC may vary by population. Specifically, a founder population with a high incidence of CRC, such as Newfoundland, may have a limited set of SNPs, which will have a greater population attributable risk compared to a more diverse population such as Ontario. We performed a case-control study and looked at associations between candidate SNPs and family history, MSI status, age of onset and location of the CRC tumors. The analysis was performed using lymphocyte DNA isolated from over 1000 CRC cases and 1000 controls from Ontario, as well as 500 cases and 350 controls from Newfoundland. Selected SNPs were genotyped using TaqMan assay. Statistical analyses of the selected MLH1 SNPs- I219V (p=0.73), -93G>A (p=0.17), IVS14-19A>G (p=0.70) indicated no significant association with the overall incidence of CRC. IVS14-19, however, was confirmed to be in linkage disequilibrium with I219V. MSH2 SNP G322D was significantly associated with family risk among CRC cases (p=0.02). Analysis of MSH2 promoter SNP -118T>C is currently in progress. Characterization of such SNPs in MMR genes will help to enhance our understanding of CRC development.

Localization of Breast Cancer Susceptibility Loci by Genome-Wide SNP Linkage Disequilibrium Mapping. *T. Kirchhoff, N.A. Ellis, N. Mitra, T. Ye, S. Chuai, H. Huang, K. Nafa, K. Offit.* Dept Medicine, Mem Sloan Kettering Cancer Ctr, New York, NY.

Five to 15% of incident breast cancer (BC) cases and only half of the hereditary BC cases result from mutations in putative cancer susceptibility genes such as *BRCA1* and *BRCA2*. Attempts to map other BC susceptibility genes by linkage analysis have been hampered by genetic heterogeneity, decreased penetrance, and chance clustering. We are utilizing an association approach to localize BC genes, using genome-wide panels of single nucleotide polymorphisms (SNPs) and taking advantage of the genetic enrichment of susceptibility alleles in high-risk cases. Our ascertainment was focused on the Ashkenazi Jewish (AJ) population because it was established from a small number of founders and consequently the regions of increased linkage disequilibrium (LD) flanking the founder mutations are usually large (>1 million bases). With Affymetrix GeneChip arrays, we genotyped 8,487 SNPs in 3 sets of AJ BC cases: a validation set of 27 BC cases, all of whom carried the *BRCA2*6174delT* founder mutation, a field set of 19 BC cases from male BC kindreds, which simulated conditions for finding new genes, and a test set of 57 probands from BC kindreds (4 or more cases/kindred), in which mutations in *BRCA1* and *BRCA2* had been excluded. To identify associations, we compared the frequency of genotypes and haplotypes, respectively, in cases versus controls by the Fishers exact test and a maximum likelihood ratio test. In the validation set, we demonstrated the presence of a region of LD on *BRCA2*6174delT* chromosomes that spanned over 5 million bases. In the field set, we showed that this large region of LD flanking *BRCA2* was detectable despite the presence of heterogeneity in the sample set. Finally, in the test set, two regions of increased interest ($p<10e-5$) were identified on chromosomes 15 [TSC582885-TSC948257] and 9 [TSC181069-TSC1555460], and a third region ($p<10e-3$) emerged that had been identified previously by linkage analysis on chromosome 8. These results demonstrate the feasibility of the genome-wide association design and provide insights into optimizing its application.

Identifying Associations Between SNPs In Cell Cycle Control Genes And Susceptibility To Ovarian Cancer. *S. Gayther[1], H. Song[2], S. Ramus[1], R. DiCioccio[3], L. Quaye[1], E. Hogdall[4], C. Hogdall[4], I. Jacobs[1], D. Easton[2], B. Ponder[2], A. Whittemore[5], S. Kruger Kjaer[4], P. Pharoah[2].* 1) University College London, UK; 2) University of Cambridge, UK; 3) Roswell Park Cancer Institute, Buffalo, USA; 4) Institute of Cancer Epidemiology, Danish Cancer Society, Denmark,; 5) Stanford University School of Medicine, USA.

BRCA1 and BRCA2 are responsible for the majority of families containing multiple cases of epithelial ovarian cancer. However, high-risk susceptibility genes are responsible for less than 30% of the excess familial ovarian cancer risks, which suggests other ovarian cancer susceptibility genes exist. The remaining risk may due to combinations of several common alleles of moderate/low risk, rather than other rare high-risk genes. We have used a SNP tagging candidate gene approach to look for associations between single nucleotide polymorphisms (SNPs) in three ovarian cancer case-control studies from Denmark, the UK and USA. These studies comprise ~1,500 cases and 2,500 controls. We chose to look for disease associations in genes involved in cell cycle control because there is extensive evidence for a ubiquitous role of cell cycle genes (e.g. p53, RB, p16) in cancer development generally and ovarian cancer specifically. So far we have genotyped 51 SNPs in 13 genes (CCND1, CCND2, CCND3, CCNE1, CDK2, CDK4, CDK6, CDKN1A, CDKN1B, CDKN2A, CDKN2B, CDKN2C, RB1, p53). Genotype distributions were close to those expected under Hardy-Weinberg equilibrium. Genotype frequencies in cases and controls, stratified by study, were compared using a likelihood ratio test in a logistic regression model. For 46 SNPs, we detected no significant differences in genotype frequency between cases and controls. Two associations with $P < 0.05$ and three associations with $P < 0.01$ were seen for SNPs in CCND1, CDK6 and CDKN1B. In summary, we have found evidence that common variants in cell-cycle control genes are associated with increased ovarian cancer risk. In order to validate the role of these genes in ovarian cancer, it will first be necessary to confirm these results in even larger series of ovarian cancer cases and to identify the causative functional variants.

***CHEK2* I157T associates with colorectal cancer risk.** *O. Kilpivaara[1], P. Alhopuro[2], P. Vahteristo[2], L.A. Aaltonen[2], H. Nevanlinna[1].* 1) Dept OB/GYN, Helsinki Univ Ctr Hosp, Helsinki, Finland; 2) Dept Medical Genetics, University of Helsinki, Helsinki, Finland.

CHEK2 is a serine/threonine kinase which takes part in various cellular functions regulating cell cycle progression, apoptosis, and DNA damage repair. CHEK2 is activated in response to DNA double strand breaks and it then phosphorylates various substrates including p53, BRCA1, and CDC25A. *CHEK2* germline mutations have been identified, first in breast cancer patients, and then also in patients with other types of cancer. The two most studied variants, 1100delC and I157T show statistically significant associations with breast and prostate cancer. Very recently, it was suggested that *CHEK2* I157T variant confers an elevated risk also for colon, kidney, and thyroid cancers as well as for non-Hodgkin lymphoma (Cybulski C. *et al.* AJHG, 2004). We have here studied the effect of *CHEK2* I157T on colorectal cancer predisposition in Finland. A total of 973 colorectal cancer patient samples were successfully analyzed for *CHEK2* I157T variant. The mutation frequency among population-based series of colorectal cancer cases was 7.8% (76/973), which is significantly higher than in Finnish population controls (5.3%), OR=1.5, 95% CI 1.1-2.1, p=0.008). Furthermore, the carrier frequency among familial colorectal cancer cases was 10.4% (14/135 OR=1.5, 95% CI =1.1-3.7 p=0.01). Our results are in agreement with the previously observed association between *CHEK2* I157T and colon cancer and suggest that *CHEK2* I157T is a risk allele for colorectal cancer in the Finnish population.

Germline Mutations in the PTEN promoter affect autoregulation of its expression through interaction between PTEN and p53. *Y. Tang*[2,3,4], *C. Eng*[1,2,3,4,5,6,7]. 1) Clinical Cancer Genetics Program; 2) Human Cancer Genetics Program; 3) Comprehensive Cancer Center; 4) Department of Molecular Virology, Immunology and Medical Genetics; 5) Division of Human Genetics; 6) Department of Internal Medicine, The Ohio State University, Columbus, OH 43210, USA; 7) Cancer Research UK Human Cancer Genetics Research Group, University of Cambridge, Cambridge CB2 2YZ, UK.

PTEN is a tumor suppressor with dual phosphatase activity and mutations of its gene, PTEN, have been associated with many sporadic cancers and heritable neoplasia syndromes including Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS). In the present study, we demonstrate that cell lines from CS and BRRS patients with germline PTEN promoter mutations in the vicinity of the p53 binding motifs have altered p53 regulation. This appears to be due to reduced PTEN stability and decreased PTEN-p53 interactions. By utilizing luciferase reporter assay and ectopic expression system, we demonstrate that PTEN is able to autoregulate its expression through the stabilization of p53. We further show that PTEN enhances p53 transactivation, a relationship which requires the interaction between PTEN and p53, and which is PTEN phosphatase-independent. Our data provide clues to better understand the regulation of PTEN expression and the possible mechanisms of the pathogenesis of the subset of CS individuals with germline promoter variation and who lack mutations in the PTEN coding region and splice sites. This mechanism also holds for those sporadic tumors that lack intragenic mutations but have hemizygous deletion of PTEN, which includes the promoter region as manifested by loss-of-heterozygosity of 10q markers.

EGFR Mutations in Japanese lung cancer patients: A retrospective study of 198 cases and examination of a novel therapeutic application using siRNA targeting _EGFR_. *S. Yamanaka[1,2], M. Sato[2], R. Fujisaki[1], A. Sakukrada[2], T. Kondo[2], A. Horii[1].* 1) Dept Molecular Pathology, Tohoku Univ School of Med, Sendai, Japan; 2) Department of Thoracic Surgery, Institute of Development, Aging, and Cancer, Tohoku University.

We collected 198 surgically resected lung cancers and analyzed mutations in *EGFR*, *KRAS*, *TP53*, and *ERBB2*. Eighteen of them had been treated with gefitinib. Mutations in *EGFR* were found in 35 cases; all of them were adenocarcinoma (33%; 35 of 106 cases with adenocarcinoma), and females accounted for 74%. No tumors harbored mutations in both the *EGFR* and *KRAS* genes, but 10 of the 35 tumors harbored both *EGFR* and *TP53*. *ERBB2* mutations were less frequent. Mutations of *EGFR* were well associated with a positive response to gefitinib; all the patients with *EGFR* mutations except two cases without lung lesions showed clinical PR. We then performed in vitro studies to validate the gefitinib treatment for lung adenocarcinoma. Cells with *EGFR* mutations were very sensitive to gefitinib, and those with *KRAS* mutations were quite resistant. We further examined siRNA-mediated knockdown of *EGFR* and found that the effects were quite similar to those of gefitinib. Our present results imply that (i) mutation analyses of *EGFR* and *KRAS* provide valuable information about whether or not apply treatments targeting against EGFR and the selection of dosage for such treatments, and (ii) siRNA-mediated knockdown may be effective in treating cases of acquired resistance to gefitinib.

Cytologic, molecular and proteomic analysis of breast ductal fluid from *BRCA1* and *BRCA2* gene mutation carriers and controls. *I. Locke[1,2], Z. Kote-Jarai[1], E. Bancroft[2], M. Le Bihan[3], P. Osin[1,2], A. Nerurkar[1,2], C. Isacke[1], G. Gui[1,2], L. Izatt[4], G. Pichert[4], R. Eeles[1,2], The Carrier Clinic Collaborators.* 1) Institute of Cancer Research, Sutton, UK; 2) Royal Marsden Hospital, London, UK; 3) St George's Hospital Medical Biomics Centre, London, UK; 4) Guy's Hospital, London, UK.

Aim: To evaluate the ductal approach for risk assessment in *BRCA1/2* families. Methods: We recruited 53 women from *BRCA1/2* families (21 *BRCA1*, 20 *BRCA2* and 12 non-carriers) for nipple aspirate fluid (NAF) collection from their healthy breasts. Ductal lavage (DL) was attempted in a subgroup of 35 women. Two slides, produced using the Shandon cytospin technique, were Giemsa-stained for cytologic assessment. Free DNA was extracted from the DL supernatant (DLS) using a DNeasy Tissue Kit (Qiagen). Loss of heterozygosity (LOH) analysis of free DNA from 34 ducts was performed by fluorescence-based PCR amplification of 7 *BRCA1/2* microsatellite markers. The methylation status of a panel of genes was investigated using a multiplexed methylation-specific PCR technique. Proteomic profiling of NAF and serum from carriers and controls was performed on three array surfaces and analysed by SELDI-TOF mass spectrometry with data interpretation using Biomarker Wizard software (Ciphergen). Results and Conclusions: NAF was obtained from 30% *BRCA1* carriers, 45% *BRCA2* and 30% of controls. At least one breast duct was cannulated in 80% of NAF producers but only 27% of non-NAF producers. Overall 65% of cytology slides were deemed adequate for diagnosis. Two *BRCA* carriers were found to have epithelial cell atypia (C3) in the absence of clinical or radiological findings suspicious of malignancy. No controls thus far have had atypia. We found high levels of LOH, but reproducibility was not consistent. *Cyclin D2* and *RAR* genes were found to be uniformly unmethylated. Cu-IMAC30 array surfaces were found to give the most data-rich proteomic spectra for NAF. Peaks discriminating healthy carrier and control breasts were found and are being evaluated as biomarkers of risk.

Associations with family history of cancer in a population survey. *M. Scheuner[1], P. Yoon[1], S. Coughlin[2], T. McNeel[3], N. Breen[4], A. Freedman[4].* 1) Office of Genomics and Disease Prevention, CDC; 2) Division of Cancer Control and Prevention, CDC; 3) IMS, Inc; 4) Division of Cancer Control and Population Sciences, NCI.

Few population-based studies have investigated associations between personal and family history of cancer. Using the 2001 California Health Interview Survey data, we describe associations between cancer family histories and breast, prostate and colorectal cancer. Of the 55,513 respondents, 34.4% reported a cancer family history. Personal history of any cancer was reported by 8%; 0.5% had colorectal, 2.4% of females had breast, and 1.5% of males had prostate cancer. Odds ratios were calculated by comparing cancer family histories for respondents with and without breast, prostate and colorectal cancer, adjusting for demographic factors. Family history of breast cancer, and family history of ovarian cancer were associated with breast cancer (OR=2.0, 1.6-2.5 and OR=1.8, 1.1-3.1, respectively). Associations with breast cancer were higher when family histories included breast and ovarian (OR=4.7, 2.1-10.4), breast and melanoma (OR=2.3, 1.1-5.0) or breast and prostate cancer (OR=2.6, 1.5-4.4). Family history of prostate cancer was associated with prostate cancer (OR=3.2, 2.1-4.8). Stronger associations with prostate cancer were observed when family histories included ovarian and melanoma (OR=25.4, 4.1-158), breast and melanoma (OR=14.8, 4.0-55), breast and ovarian (OR=9.7, 2.4-39) or prostate and colorectal cancer (OR=4.5, 1.3-15.6). Family history of colorectal cancer was associated with colorectal cancer (OR=2.3, 1.5-3.4), and associations were also found given family histories of ovarian and cervix (OR=14.9, 7.2-31.2) or colorectal and breast cancer (OR=2.5, 1.1-5.4). Our results show similar associations to those found in case-control studies with a 2 to 3-fold increase in breast, prostate and colorectal cancer given a family history. This suggests population-based, self-reported data are useful in assessing familial risk. Certain combinations of cancer family histories display associations of similar or greater magnitude. Recognizing these familial patterns may have implications for risk assessment.

MyGenerations:A computerized family history risk assessment tool for the public. *S.M. O'Neill, W.S. Rubinstein.*
Dept Medical Genetics, Evanston NW Healthcare, Evanston, IL.

Family history is a risk factor for many chronic diseases, but systematic collection of family history is not practiced routinely in health care settings. When collected, the information is often not interpreted, and management is not targeted to calculated risk levels. Integrated tools that assess risk based on family history data, and other personal risk factors, could be of value to clinicians, patients, and researchers. We have developed an interactive touchscreen computer program called MyGenerations which obtains family cancer history and performs breast cancer risk assessments. The program produces a printed pedigree, calculated risks for breast cancer and BRCA mutations, and risk-tailored prevention/screening messages. We are currently adding risk assessment algorithms for several other cancer syndromes. MyGenerations kiosks are installed in our hospital lobby, cancer center lobby, and mammography suite. In the first 11 months, 737 users tried the program. Of the 577 users (78%) who continued past the login screens, 344 (47%) completed all segments of the program. The average time for completion was 9.5 minutes (range 2 to 78). In this population, 12% had some form of cancer, but BRCAPRO mutation risk was generally low. Only 1.2% were classified as high risk (>8%) and 2.3% as moderate risk (3% -8%). However, among unaffected women, 23% had a Gail 5-yr risk above the 1.67% threshold. Survey questions at the end were answered by 280 people (81% response rate). Most found the program easy to use (88%) and said they would definitely recommend it to friends (74%). While 66% said they would definitely show their printed family history tree to their family, only 39% said they would show it to their physician. We designed the program so users could remain anonymous. Only 33 (9%) of the users who completed the program chose to provide identifying contact information. MyGenerations is well accepted by users and enables them to record their own family history of disease, learn about their risks, and receive information about actions to take. However, further research is needed to determine the barriers to sharing the information with physicians.

Evaluation of *RAD50* in Familial Breast Cancer Predisposition. *J. Tommiska[1], S. Seal[2], A. Renwick[2], R. Barfoot[2], L. Baskcomb[2], H. Jayatilake[2], J. Bartkova[3], J. Tallila[1], M. Kaare[1], A. Tamminen[1], P. Heikkilä[4], D.G. Evans[5], D. Eccles[6], K. Aittomäki[7], C. Blomqvist[8], J. Bartek[3], M.R. Stratton[2,9], H. Nevanlinna[1], N. Rahman[2], Breast Cancer Susceptibility Collaboration (UK).* 1) Dept. Obstetrics and Gynecology, HUCH, Helsinki, Finland; 2) Institute of Cancer Research, Sutton, UK; 3) Danish Cancer Society, Copenhagen, Denmark; 4) Dept. Pathology, HUCH, Finland; 5) Dept. Medical Genetics, St Marys Hospital, Manchester, UK; 6) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton; 7) Dept. Clinical Genetics, HUCH, Finland; 8) Dept. Oncology, HUCH, Finland; 9) Cancer Genome Project, The Wellcome Trust Genome Campus, Hinxton, Cambs, UK.

The genes predisposing to familial breast cancer are largely unknown, but five of the six known genes are involved in DNA damage repair. RAD50 is part of a highly conserved complex important in recognising and repairing DNA double-strand breaks. Recently, a truncating mutation in the *RAD50* gene, 687delT, was identified in two Finnish breast cancer families. To evaluate the contribution of *RAD50* to familial breast cancer we screened the whole coding region for mutations in 435 UK and 46 Finnish familial breast cancer cases. We identified one truncating mutation, Q350X, in one UK family. We screened a further 544 Finnish familial breast cancer cases and 560 controls for the 687delT mutation, which was present in 3 cases (0.5%) and 1 control (0.2%). Neither Q350X nor 687delT segregated with cancer in the families in which they were identified. Functional analyses suggested that *RAD50* 687delT is a null allele as there was no detectable expression of the mutant protein. However, the wild-type allele was retained and expressed in breast tumors from mutation carriers. The abundance of the full-length RAD50 protein was reduced in carrier lymphoblastoid cells, suggesting a possible haploinsufficiency mechanism. These data indicate that *RAD50* mutations are rare in familial breast cancer and either carry no, or a very small, increased risk of cancer. Altogether, these results suggest *RAD50* can only be making a very minor contribution to familial breast cancer predisposition in UK and Finland.

DC-SIGN Haplotypes are Associated with Risk of Prostate Cancer in Afro-Caribbeans of Tobago. *Y. Li[1], J. Martinson[2], C.H. Bunker[3], A.L. Patrick[4], R.E. Ferrell[1].* 1) Human Genetics; 2) Infectious Diseases and Microbiology; 3) Epidemiology, University of Pittsburgh, Graduate School of Public Health; 4) Tobago Regional Hospital, Scarborough, Tobago.

Epidemiology and genetic epidemiology studies suggest a role for chronic inflammation in the etiology of prostate cancer. Several candidate prostate cancer susceptibility genes (MSR1, RNASEL, TLRs) are involved in innate immunity and inflammation. DC-SIGN is a promiscuous C-type lectin receptor, expressed on macrophages, dendritic cells and B cells of the innate immune system, which capture and process foreign antigens for presentation to the adaptive arm of the immune system. To assess the impact of DC-SIGN variation on prostate cancer risk in the high risk population of Tobago, we report an exhaustive interrogation of the DC-SIGN promoter region in a case/control study. Cases and controls were identified through a population based screening study in Tobago men, ages 40-79 years. 1.8 Kb of the proximal 5'-flanking region of DC-SIGN was resequenced in 153 cases and 172 controls. Haplotypes were estimated using the PHASE software package. Association was assessed by chi square analysis. We identified 26 single nucleotide polymorphisms, six of which had a minor allele frequency >7.5% (-2267G>A, -1567A>T,-1326C>T,-336C>T, -201C>A, -139T>C). Six site haplotypes were estimated and there was significant evidence of association (p=0.01) between haplotypes and prostate cancer. Haplotype GATTCC was more frequent in controls (17% vs. 2%) and haplotype GACTCC was more prevalent in cases (17% vs. 7%). This association was not explained by any single SNP. The association of haplotypes at the DC-SIGN locus and prevalent prostate cancer suggests a role for infection in the etiology of prostate cancer in the high risk population of Tobago.

Prevention of lung adenocarcinoma induced by benzo[a]pyrene in GNMT transgenic mice. *Y.M. Chen[1], S.P. Liu[1], J.H. Hung[1], F.Y. Li[2], T.F. Tsai[3].* 1) Inst Public Health; 2) Department of Pathology; 3) Department of Life Science, School of Life Science, Natl Yang-Ming Univ, Taipei, Taiwan.

Glycine N-methyltransferase (GNMT), also known as a 4S-polycyclic aromatic hydrocarbon (PAH)-binding protein, is a protein with multiple functions which including a) catalyzing glycine to sarcosine in the one-carbon metabolism pathway; b) affecting DNA methylation level through regulating the concentration of S-adenosylmethionine (SAM), a general methyl group donor for DNA MTs ; c) serving as a binding for Benzo[a]pyrene (BaP), preventing the BaP-DNA-adducts formation by BaP. We used mouse phosphoenolpyuvate carboxykinase promoter to establish a human GNMT transgenic (TG) mouse model to study the interaction between GNMT and BaP. The GNMT-TG mice were bred with HBV large surface antigen transgenic (LS-TG) mice to generate the following three groups: A, GNMT-TG mice; B, GNMT-LS double TG mice; and C, wild type (Wt) mice. Male mice from three groups were challenged with BaP (375£gg/7g body weight) intraperitoneally. Seventy-eight weeks after the challenge, the mice were sacrificed. In terms of lung tumor, the results showed that 3/4 mice of group C developed lung adenocarcinoma, but only 2/4 mice of groups A and 1/6 of B developed lung adenocarcinoma. Therefore, there were only two nodules in group A and B, respectively, but 9 nodules developed in group C. It indicated that over-expression GNMT in liver may play a protection role for lung tumor formation. This study is helpful for elucidating the role of GNMT in the tumorigenesis of lung which has important implications in the development of strategies for the prevention, diagnosis and treatment of lung cancer.

Increased Tumor Frequency in Individuals with Isolated Hemihyperplasia and Molecular Alterations at 11p15.

C. Shuman[1, 2], L. Steele[1, 2], A. Smith[1], P. Ray[1, 2], E. Zackai[3], M. Parisi[4], C. Clericuzio[5], A. Meadows[6], T. Kelly[7], D. Tichauer[1], J.A. Squire[8], R. Weksberg[1, 2]. 1) Div Clin & Met Gen, Dept Paed Lab Med, Research Ins, Hosp Sick Children, Toronto; 2) Dept Mol & Med Gen, Univ Toronto; 3) Div Hum Gen & Mol Biol, Childrens Hosp of Philadelphia; 4) Dept Med Gen, Univ Washington, Seattle; 5) Ped-Div Dysmorph/Clin Gen, Ped-Div Dysmorph/Clin Gen, Univ New Mexico Sch Medicine, Albuquerque; 6) Div Onc, Childrens Hosp of Phil; 7) UVA Health System, Dept of Ped Gen, Charlottesville, VA; 8) Ont Cancer Inst, Dept Lab Med & Pathobiology, and Dept Med Biophysics, Univ Toronto.

Isolated hemihyperplasia (IH) refers to asymmetric overgrowth of single or multiple organs or regions of the body. Recent reports document molecular alterations in 11p15 in individuals with IH, including paternal uniparental disomy (UPD) [Shuman et al., 2002; Grundy et al., 1991] and more recently methylation alterations at KCNQ1OT1 and H19 [Martin et al., 2005] but they do not report on the frequency of tumors in molecular subtypes of IH. We report here on the frequency of tumors in 51 patients with IH. Blood samples and when available skin and/or tumor tissue were obtained. Molecular alterations were detected at 11p15 in 11/51 patients: 8 (16%) with UPD, 3 (6%) hypomethylation at KCNQ1OT1 and 0 with hypermethylation at H19. Of the 8 patients with UPD, 4 had tumors (3 hepatoblastoma, 1 Wilms tumor); 0/3 patient with hypomethylation at KCNQ1OT1 had a tumor. Of the remaining 40 with no molecular alterations, 6 had tumors (3 Wilms tumor, 2 neuroblastoma, 1 adrenocortical adenoma). The 50% frequency of tumor development in patients with IH and UPD was significantly higher than the 15% frequency in those with IH and no molecular alteration detected (Fishers exact test p = 0.047, OR 5.67). Of note, the high overall frequency of tumors in the study population (19.6%) likely reflects a bias in ascertainment of patients with IH being referred for genetic testing. Our data demonstrate that patients with IH and tumors have molecular alterations known to increase tumor risk and highlight the importance of implementing molecular testing and tumor surveillance for all patients with IH.

Severe Pfeiffer syndrome (PS) and Antley-Bixler syndrome (ABS) : Clinical and molecular evidences for differential diagnosis. *M. Gonzales[1], S. Heuertz[2], J. Martinovic[3], S. Delahaye[1], P. Loget[4], M. Le Merrer[2], A. Verloes[5], A. Bazin[3], J. Bonaventure[2].* 1) Fetal Pathology Unit, Hosp Saint Antoine, Paris, France; 2) INSERM U393, Necker Hospital, Paris, France; 3) Laboratoire Pasteur-Cerba, Cergy-Pontoise, France; 4) Centre Hospitalier du Mans, Le Mans, France; 5) Clinical Genetics Unit, Genetic Dept, and INSERM U676, Robert Debre Hospital, Paris, France.

PS and ABS are rare skeletal disorders characterized by severe craniofacial malformations and limb abnormalities. While PS is an AD disease, the mode of inheritance of ABS, originally described as AD, has been challenged, when a heterozygous mutation in the FGFR2 gene was reported to produce an ABS-like phenotype, suggesting that ABS could be genetically heterogeneous. We present here a series of 5 fetuses obtained after TOP following ultrasound detection of skeletal anomalies suggestive of severe non syndromic craniosynostosis. Clinical and radiological examination of fetuses following interruption revealed craniosynostosis with midface hypoplasia, frontal bossing, proptosis and variable anomalies of the axial and appendicular skeleton evocative of severe PS or ABS. Two of these patients had dysplastic ears, slender fingers with arachnodactyly, marked femoral bowing and radio-humeral synostosis. No FGFR2 mutations were identified in these cases but homozygous and compound heterozygous mutations in the cytochrome P450 oxydoreductase (POR) gene were found, supporting the clinical diagnosis of ABS. Out of the three other foetuses, two had elbow ankylosis and none of them exhibited femoral incurvation. Broad halluces were visible in two cases in the absence of arachnodactyly. All three foetuses had tracheal cartilaginous sleeve and fusions of cervical and/or lumbar vertebrae. The recurrent S351C FGFR2 mutation was detected in all three cases. Based on these findings, we suggest that severe PS would be the most likely diagnosis in these patients. The absence of tracheal cartilaginous sleeve and vertebral defects in patients carrying POR mutations indicate that these clinical signs are cardinal for the differential diagnosis of severe PS versus ABS.

Update on the dup(22q) syndrome and expansion of the clinical phenotype. *S.J. Hassed, J. Lee, S. Li, J.R. Seely.*
Dept Pediatrics/Genetics, Univ Oklahoma Medical Ctr, Oklahoma City, OK.

Since our first description of the dup(22q) syndrome in 2002 in a family with a relatively mild phenotype, we and others have reported several patients and families with this duplication. As more individuals with the dup(22q) are reported, the clinical phenotype has expanded. This condition is expected to be complimentary to the 22q deletion syndrome that encompasses the conditions previously referred to as velocardiofacial syndrome (VCFS), di George syndrome, and Shprintzen syndrome. The dup(22q) may be as common as the deletion, but recognized less frequently due to a less well defined phenotype and the standard laboratory technique of analyzing metaphase cells. It has been suggested that all FISH studies be evaluated by scanning of interphase cells in addition to the usual metaphase cells, since duplications are much less obvious on metaphase spreads. It is expected that, as this change in laboratory protocol becomes standard, the dup(22q) syndrome phenotype and incidence will be elucidated. We report an 11-month-old male with infantile spasms beginning at five months. EEG was consistent with a seizure disorder, but not characteristic for hypsarrhythmia. Normal studies included MRI, chromosome analysis (46,XY), amino and organic acids, and ophthalmological consult. Prior to the onset of seizures, development was reportedly normal. Psychomotor development has slowed markedly. Seizures are controlled with Klonopin. The mother reportedly had seizures beginning at 18 months that resolved. There are minor dysmorphic features, which resemble the mother. Two males on the maternal side of the family are reported to have congenital heart defects and learning disabilities. FISH analysis of 22q revealed ish dup(22)(q11.2q11.2)(TUPLE1X3) for the patient. FISH analyses on the family are pending. We suggest further expansion of the 22q duplication syndrome to include infantile spasms.

Raising Awareness About Birt-Hogg-Dube Syndrome. *D. Kostiner, C. Miranda, A. Holt.* Dept. of Medical Genetics, Kaiser Permanente PC, Portland, OR.

Birt-Hogg-Dube syndrome (BHD) is an autosomal dominant condition that predisposes to fibrofolliculomas (small, firm, dome-shaped, papules), trichodiscomas (tumors of the hair discs), and acrochordons (skin tags). Associated findings can include spontaneous pneumothoraces, lung cysts, colonic polyps, and renal tumors. Features typically present in adulthood and show variable expression. The condition is likely underdiagnosed since most physicians have not heard of it and since many patients do not come to dermatologic attention. Molecular testing can detect 80% of mutations. We present the cases of two patients to raise awareness of BHD since the pulmonary, renal, and colonic manifestations can cause morbidity and mortality. Pt. #1 is a 53-year-old man with multiple fibrofolliculomas confirmed by biopsy, several flat skin tags, and hyperkeratosis of the hair follicles. The lesions first appeared in his 30s. Screening CXR and sigmoidoscopy were normal. His father had fibrofolliculomas and benign renal cysts and his PGM had fibrofolliculomas. He was offered molecular testing for BHD, but declined for fear of insurance discrimination. Pt. #2 is a 57-year-old man with multiple fibrofolliculomas confirmed by biopsy, unilateral pneumothorax at age 23, and right renal hypodensity found on screening CT. His mother had characteristic skin changes and a pneumothorax in her 50s. Molecular testing showed a deleterious duplication in exon 9 of the BHD gene. Follow-up care will include a repeat renal CT and screening colonoscopy. Discussion: Although patients are bothered by the skin findings of BHD for cosmetic reasons, the internal manifestations are far more dangerous. We recommend screening CXR, colonoscopy, and renal scan at time of diagnosis and periodically thereafter, and offering of molecular testing to at-risk relatives when the probands mutation is known. Educating primary care physicians about BHD might increase referrals to dermatologists, and thus increase overall rates of diagnosis.

VACTER ASSOCIATION. *C. Martinez-Cruz[1,2], A. Garcia-Huerta[3], M. Diaz-Garcia[3], N. Lopez-Trinidad[3], G. Garcia-Sanchez[3].* 1) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 2) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México; 3) Servicio de Genética.Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación.México, D.F. e-mail gsanchezg03@yahoo.com.mx.

VATER is a mnemonically useful acronym for vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial dysplasia. This combination of associated defects was pointed out by Quan and Smith (1972) Nearly all cases have been sporadic, with no recognized teratogen or chromosomal abnormality. VACTER association features overlapping those of Townes-Brocks syndrome and branchiootorenal syndrome. Case report. We report a Mexican male patient 14 -year- old with VACTER association. The parents of the patient are not consanguineous and the family history was negative for VACTER association. At 15 days of age he had undergone surgery for imperforate anus, he has bilateral radial hypoplasia, a bifid thumb on the right and preaxial polydactyly on the left side. Echocardiography at 6-month- old showed coarctation of the aorta. Left small, dysplastic ear, hearing impairment onset before 2 years old. The audiogram at 14 years old shows sensorineural profound hearing impairment. X-rays revealed Klippel-Feil type II (Vertebral fusion of C2-C3 and C5-C6). He has gastroesofagic reflux and mental retardation. Nowadays he is becoming aggressive. The kidneys were normal on ultrasound. Genetic molecular exam is in process.

150 Patients with Facio auriculo vertebral spectrum. *A. Garcia-Huerta[1], L.M Rosales-Olivares[2], M. Diaz-Garcia[1], N. Lopez-Trinidad[1], C.F. Martinez-Cruz[3,4], R. Baez-Reyes[5], G. Garcia-Sanchez[1].* 1) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación. México, D.F; 2) Servicio de Cirugía de Columna, Centro Nacional de Rehabilitación/Ortopedia. Mexico, D.F; 3) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 4) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México; 5) Servicio de Genetica,Departamento de Investigacion. Instituto Nacional de Perinatologia, Mexico, D.F.E mail gsanchezg03@yahoo.com.mx.

Facio auriculo vertebral spectrum (FAV) is a disorder with variable expression that mainly involves structures developed from first and second branchial arches as well as ocular, vertebral, cardiac, renal and neurological anomalies. FAV has a heterogenous etiology: vascular disruption, lack of interaction of mesenchyme with neural crest cells and teratogens, among others. Some chromosomopathies have been described in patients with FAV, and recently a MSX gen mutation is suggested. This study with 150 patients with FAV shows the clinical findings: microtia: 99%, meatal atresia: 78.7%, facial asymmetry: l4% preauricular tags; l2.7% and submucous cleft palate:l6%. We also found cardiac anomalies in l.2%. No patient had ocular, renal or neurological anomalies, but vertebral malformations were present in l3.9%. Our patients had severe hearing loss: 59.4%, mainly conductive type; 64.3%. In 150 patients with FAV: 61% were sporadic cases. In 26%, they had recessive pattern of inheritance and 13% were dominant. We discuss the high frequency of adverse factors during early pregnancy: hemorrhages, medical administration or infections. The impact in reproductive conduct in parents of a child with FAV and the importance of searching minimum expression of FAV in all the family members.

CHARGE association. Mother and daugther. *N. López Trinidad[1], C.F. Martinez-Cruz[2,3], M. Diaz-Garcia[1], A. Garcia-Huerta[1], G. Garcia-Sanchez[1].* 1) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación. México, D.F; 2) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 3) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México. E-mail gsanchezg03@yahoo.com.mx.

CHARGE association is characterized by coloboma, it is bilateral or unilateral, affecting the iris, retina and/or disc. Visual loss varies according to size and location of the coloboma. Heart defects are conotruncal anomaly, aortic arch anomaly, isolated septal defects are uncommon. Choanal atresia is bilateral or unilateral. Retarded growth and development. The diagnosis of mental retardation must be made with caution in anyone who has impaired hearing and/or vision. Hearing loss may cause language delay, while blindness impairs motor skills and genital hypoplasia. Although the most consistent features are still those prefixed bye the letters CHARGE, additional abnormalities frequently occur, these include facial palsy, renal abnormalities, orofacial clefts and tracheoesophageal fistulas. This association overlaps some features with Schprintzen and Cat eye syndrome. We report a female 17 years old patient with bilateral hearing loss, present at birth, language and psychomotor delayed. She shows short stature, facial asymmetry, hypertelorism, small auricles and nose and flat philtrum, absent uvula, thoracic asymmetry, scoliosis, multiple nevus, cardiac murmur, cubitus valgus, hypoplasic phalanges of thumbs. She also had swallow impairment. She had undergone a palatoplasty at 2 years old and fundoplasty at 3 years old. Her mother had facial asymmetry, scoliosis; small auricles, broad thumbs. We did not find any ocular anomalies on the patient or her mother. We discuss the minimum expression of CHARGE association in the mothers patient.

Osteogenesis imperfecta type I. *S. Juarez-Garcia[1], L. Hernandez-Gomez[2], C.F. Martinez-Cruz[3,4], R. Baez-Reyes[5], G. Garcia-Sanchez[6].* 1) Instituto de la Comunicación Servicio de Neuropsicologia Infantil.Humana/Instituto Nacional de Rehabilitación; 2) Instituto de la Comunicación Servicio de Audiologia. Humana/InstitutoNacional de Rehabilitación; 3) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 4) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México; 5) Departamento de genetica.Instituto Nacional de Perinatologia, Mexico. D.F E; 6) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/InstitutoNacional de Rehabilitación.E. mail gsanchezg03@yahoo.com.mx.

Osteogenesis imperfecta (OI), often referred to as "brittle bone disease", is a heritable disorder characterized in most instances by either qualitative or quantitative abnormalities in the synthesis of the most important component of the bone matrix, type I collagen. Sillence in 1979 proposed a classification based on clinical, radiographic and genetic criteria, that quickly was adopted worldwide: Type I is the mildest form, with occasional fractures before puberty, minimal deformity and normal stature. Large families from that group were used to demonstrate linkage with COLlAl and COLlA2. In type II, the most severe (lethal) form, fractures in utero lead to pulmonary insufficiency and perinatal death. In type III, frequent fractures causing progressive deformities, short stature, and triangular face are characteristic. In type IV, deformities and dwarfism are present, but are less severe.We report a female patient 39-year-old, right hearing loss anset at 15-year-, left hearing loss onset at 20-year-old with slowly progression.Tinnitus alltime, Several bone fractures in the infancy. Exposition to noisy environment for 9 years, chicken pox and measles in the infancy.The pedigree shows two brothers with osteogenesis imperfecta. Physical exam: Prognatism, eyes with blue sclera. Opalescent teeth. Audiogram: Mixed severe bilateral hearing loss. Timpanogram: curves As of Jerger bilateral. Stapedial reflex: absent bilateral response.Caloric test with bilateral hyperreflexia.

Wildervanck syndrome. Report of three Mexican patients. *M. Diaz-Garcia[1], C.F. Martinez-Cruz[2,3], A. García Huerta[1], R. Baez-Reyes[4], N. Lopez-Trinidad[1], G. Garcia-Sanchez[1].* 1) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación. México, D.F; 2) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 3) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México; 4) Servicio de Genetica, Departamento de Investigacion.Instituto Nacional de Perinatologia, Mexico, D.F. E-mail gsanchezg03@yahoo.com.mx.

The Wildervanck syndrome is a rare disorder characterized by a triad of features including congenital deafness (sensorineural, conductive, or mixed); fused cervical vertebrae (Klippel-Feil anomaly),and abduction and/or adduction (Duane syndrome). Occasional abnormalities include mental retardation, growth deficiency, cleft palate, ear abnormalities, etc. This syndrome may be responsible for at least 1%; of deafness among females; the deafness has been shown by radiologic studies to be due to a bony malformation of the inner ear and/or anomalies of the ossicular chain. The etiology is unknown. The disorder is almost limited, to females, raising the question of sex-linked dominance with lethality in the hemizygous male. We present three cases of Wildervanck syndrome. Patient 1: a 7-year-old male child with right hemifacial microsomia, right microtia, low occipital hairline. Bilateral abduction and adduction normal (Duane type I). Nystagmus, uvula bifida, submucous cleft palate and short neck. Audiometric study showed, sensorineural hearing loss, bilateral and profound. Ear CT scan, revealed Mondini malformations. Radiography of spine showed a congenital fusion of C2 and C3 vertebrae, thoracic hemivertebrae, scoliosis, and spina bifida occulta (Klippel-Feil type III). MRI of cervical spine showed continuity of the vertebral body of C2 and C3. Patient 2: a 16-year-old female with low occipital hairline; abduction and adduction, bilateral (Duane type 3). Low-set ears, mandible with left hypoplasia, broad short neck. Audiometric testing showed sensorineural hearing loss, bilateral and profound. Ear CT scan, revealed a Mondini dysplasia. Radiography study reveled fusion of C2-C7 vertebrae, scoliosis of C6 to C7 and alteration on T2. Patient 3: is a 10-year-old female with unilateral abduction on the right eye (Duane type I). Low-set ears and hypoplasics helix, hypoplasica uvula, short broad neck with limited move; probable spina bifida occulta. Radiography study will be discussed. The audiogram showed sensorineural hearing loss, bilateral and profound.

Waardenburg syndrome: Differentiation between types and risks of deafness. *E. Pardono, J.F. Mazzeu, K. Lezirovitz, R.M.P. Nascimento, M.T.B.M. Auricchio, R.C. Mingroni-Netto, P.A. Otto.* CEGH, Depto de Genética e Biologia Evolutiva, IB-Universidade de São Paulo,Brazil.

The Waardenburg syndrome (WS) is clinically characterized by craniofacial dysmorphims, pigmentation defects (irides, skin and hair) and congenital sensorineural deafness. Since the penetrance rate of the telecanthus trait in WSI is high but incomplete, the clinical diagnosis of the variant (WSI or WSII) in isolated affected individuals without telecanthus is troublesome. We present the results of a study performed in 41 patients with WSI, 33 having the type II and 18 of them being isolated cases without telecanthus. From all these patients, 17 craniofacial measurements were obtained. We developed also a method that enables the estimation of frequencies of the eight cardinal signs used for the diagnosis of the condition, based on a total sample (containing our and literature cases) of 502 affected individuals with WSI and 154 with WSII and derived discriminant functions to separate individuals affected by one of the two variants. Discriminant analysis based on the frequencies of the eight cardinal signs can improve the correct separation of WSI patients without telecanthus from those presenting WSII: deafness is the most important characteristics for the diagnosis of the WSII in patients without telecanthus;the presence of defects of fusion of the medial region of the face (synophrys, nasal root hyperplasia, and lower lacrimal dystopia) favors the hypothesis of WSI. The discriminant function based on four ocular measurements (inner and outer intercanthal, interpupillary and lower interlacrimal distances), combined to four other measurements (nose interalar distance, mean length and width of ear, face height), perfectly classifies patients affected by one of the WS variants. We prepared also a table for use in the genetic counseling of WSI and WSII, that lists the risks of deafness for the offspring of carriers of the two conditions. Two new mutations in the PAX3 gene were found in ten, investigated propositi with WSI: the substitution c.142 G>T on exon 2 (48G>C) and the deletion c.764-776del(TTACCCTGACATT) on exon 5. Financially supported by CNPq/PRONEX and CEPID/FAPESP .

Groll-Hirschowitz Syndrome.Two unrelated Mexican families. *G. Garcia-Sanchez[1], M. Diaz-Garcia[1], A. Garcia-Huerta[1], N. Lopez-Trinidad[1], C.F. Martinez-Cruz[2,3].* 1) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación. México, D.F; 2) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 3) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México. E-mail:gsanchezg03@yahooo.com.mx.

Hirschowitz et al. (1972) described 3 sisters, from a sibship of 6, who had progressive nerve deafness beginning at ages 8, 3 and 9 years and becoming complete or nearly complete by ages 10, 5 and 18 years, respectively. Vestibular function remained normal. Progressive sensory neuropathy without peripheral trophic changes was also present. Tachycardia and loss of the carotid sinus reflex may indicate involvement of the cardiac vagus. Involvement of the vagus nerve led to progressive loss of gastric motility. Two of the sisters were demonstrated to have multiple diverticula with jejunoileal ulceration from which the eldest sister died at age 18 years. Malabsorption of fat and intestinal loss of serum protein occurred. A surviving sister had marked acanthosis nigricans. Potasman et al. (1985) reported 2 sisters with the same or a similar disorder. The parents were first cousins. Peripheral nerve biopsy showed demyelinization. The patients died at ages 31 and 20 years, their disorder having manifested itself at age 24 and 13 years, respectively. We report two unrelated families with two sisters affected in each one. First family: The eldest maternal half sister apparently hearing, because her language development was normal, since 18 months of age, when she died due to abdominal pain, vomiting and diarrhea. The youngest maternal half-sister referred with hearing impairment, apparently prelingual. At 7 months of age she had undergone surgery for abdominal pain, vomiting and diarrhea. After surgery she is still vomiting and she has abdominal pain sometimes. The audiogram at 3 years old shows sensorineural bilateral profound hearing impairment. Second family: The eldest sister was referred as deaf-mute, died at 14 years old by abdominal pain. The youngest sister is referred with hearing impairment apparently prelingual and at 2 years old had undergone surgery for strong abdominal pain. Audiogram at 6 years old shows sensorineural bilateral profound hearing impairment. All patients reported with this syndrome and our patients are female. It is an X dominant linked syndrome?

Evaluating the frequency that babies with *GJB2*-related hearing loss pass newborn hearing screening. *C.G. Palmer[1], A. Martinez[1], M. Telatar[1], N. Shapiro[1], M. Fox[1], B. Crandall[1], Y. Sininger[1], W.W. Grody[1], L.A. Schimmenti[2].* 1) UCLA, Los Angeles, CA; 2) U of Minnesota, Minneapolis, MN.

GJB2/GJB6 hearing loss variants are a common cause of mild to profound nonsyndromic sensorineural hearing loss (NSNHL). There currently is limited knowledge on the postnatal and early infancy period of *GJB2*-related hearing loss, raising questions about the age of identification of babies with *GJB2*-related hearing loss vis a vis newborn hearing screening (NHS). We present results on 63 infants/toddlers with apparent NSNHL from a longitudinal study in which NHS, audiology, and *GJB2/GJB6* status are analyzed. Genomic DNA was collected from the infants by buccal brush and subjected to complete *GJB2* sequencing and assay of del(*GJB6*-D13S1830). 19 infants (30%) were identified as having two *GJB2* or a combination of *GJB2/GJB6* hearing loss variants, and 2 of these infants (10.5%) passed NHS. 44 infants had 0 or 1 *GJB2* hearing loss variant, and 4 (9%) passed NHS. There was no significant relationship between NHS result and presence of 2 or 0/1 *GJB2/GJB6* hearing loss variants (F.E. p=1.0). Of the 2 infants with *GJB2*-related hearing loss who passed NHS, one has V37I/V37I genotype and was diagnosed at 21m with mild-mod sloping SNHL and the other has 35delG/167delT genotype and was diagnosed at 2m with profound SNHL. Of the 4 infants with non-*GJB2*-related hearing loss who passed NHS, 2 are heterozygous for 35delG (data available on one showed profound SNHL), one has V27I polymorphism and severe-profound SNHL, and one has no variants and a unilateral severe SNHL. These results suggest that newborns with two *GJB2* hearing loss variants are as likely to pass NHS as those with 0 or 1 variant, however larger samples are needed to confirm this finding. These results also suggest that *GJB2*-related hearing loss may have a variable age of identification, either due to a mild congenital phenotype that is more likely to be missed by NHS, a progressive phenotype, or a postnatal onset. Genetic studies in conjunction with NHS can provide the empirical data needed for elucidating the postnatal and early infancy detection period of *GJB2*-related hearing loss and for determining the timing of genetic testing.

Distribution of mutations associated with sensorineural hearing loss in a minority population. *J. Neil[1], J. Lu[2], S. DiMauro[2], S. Shanske[2], B. Morrow[3], A. Shanske[1].* 1) Center for Craniofacial Disorders, Childrens Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, New York; 2) Laboratory of Molecular Neurogenetics, Columbia University, New York, New York; 3) Department of Molecular Genetics, Albert Einstein College of Medicine, Bronx, New York.

Approximately 50% of sensorineural hearing loss (SNHL) is attributed to genetic causes, the majority being non-syndromic. Mutations in many autosomal loci and several in mitochondrial DNA (mtDNA) have been identified. The mutation spectrum is known to vary by population, though little is known about the distribution in minority populations, including African Americans and Hispanics. Fifty charts of patients with non-syndromic SNHL referred to The Craniofacial Center were reviewed. Data regarding ethnicity, GJB2 (connexin-26) studies, mtDNA analysis (nucleotides 1555, 7445 and 3243, and the 12S rRNA gene) and CT scans of the temporal bones were collected. Fifteen of 48 patients tested for connexin-26 mutations were heterozygous for a known autosomal recessive mutation (35delG common mutation, 167delT or T101C), a benign polymorphism (G79A) or indeterminate changes (A503G, A670C or G380A). No patient had the A1555G or T7445C mtDNA mutations that have been associated with SNHL. Of the 31 patients with CT scan results, two had enlarged vestibular aqueducts, one of whom has a G79A polymorphism. Distribution by ethnicity identified one of nine American Blacks with G79A; one of eight Dominicans with A670C; two of two Guyanese with G380A; one Pakistani from a consanguineous family with G380A; two of nine Puerto Ricans with A503G (one also had an mtDNA mutation in the 12S rRNA gene, C1465T), a father and son with 35delG, one with G79A; and two of two Mexicans with G79A. A child with both 35delG and 167delT was of Brazilian, Jewish and Irish descent and an individual with T101C was of Sicilian, Italian and Irish descent. Our data suggest that specific mutation frequencies may vary by population. The high frequency of indeterminate nucleotide changes suggests that some may be pathogenic. We plan to validate these observations in a large prospective population study. We can then begin to correlate genotype with phenotype.

Hearing Loss in the Genetics Clinic. *E. Prijoles, R. Gallagher, M. Manning, L. Hudgins.* Dept of Pediatrics, Div of Medical Genetics, Stanford University, Stanford, CA.

With the advent of the newborn hearing screen, more children with congenital hearing loss are identified, and an underlying etiology is sought. We report our experience in evaluating patients with hearing loss and provide recommendations. Chart review of 76 patients referred for hearing loss was performed; those with known diagnoses were excluded. Thirty (39%) were nonsyndromic and 46 (61%) were syndromic. Of the nonsyndromic patients, 20 had connexin 26 testing: 3 (15%) had 2 disease-causing mutations, 6 (30%) had one mutation, and 4 (20%) had recognized polymorphisms. A connexin 30 deletion was found in 1 of 5 patients tested. Four chromosome aberrations were detected: del 18q (2), dup 4q35 (1), and 13;14 translocation (1). A mother and son with features suggestive of an ectodermal dysplasia had a dominant connexin 26 mutation consistent with KID syndrome. Five had genetic testing for Pendred due to inner ear malformations on CT; all were negative. LT1 and LT5 for Jervell and Lange-Nielsen were also normal in an individual with prolonged QT. Other diagnoses included: peroxisomal disorders(2), BOR syndrome(2), Usher syndrome(1), Charcot-Marie-Tooth disease(1), and isolated unilateral developmental defect of the inner ear(1). Identifying an etiology of hearing loss can be challenging. A definitive diagnosis was made in only 20% of our patients. The paucity of definitive diagnoses may be due to ascertainment bias, e.g. those with obvious diagnoses were referred with a specific diagnosis (and excluded) or not referred at all. In summary: 1) Individuals with hearing loss and developmental delay should have a chromosome analysis, 2) Testing for del 18q should be performed in patients with small auditory canals, 3) Consider peroxisomal disorders in patients with seizures, and 4) A good clinical evaluation is still the best tool in directing other studies such as renal ultrasound and EYA1 for BOR, ERG for Usher, and CMT testing for those with an abnormal neurological exam. Hopefully, genetic testing for hearing loss will continue to improve, so we can offer more accurate prognostic information and recurrence risk counseling in the future.

DNA sequence variations in *GJB2*, encoding Connexin 26: extreme allelic heterogeneity, variable carrier rates, and ethnic stratification of alleles. *R. Alford[1], HY. Tang[1], P. Fang[2], P. Ward[2], E. Schmitt[2], S. Manolidis[3], J. Oghalai[1], B. Roa[2].* 1) Otorhinolaryngology & Communicative Sciences; 2) Medical Genetics Laboratories, Molecular and Human Genetics; Baylor College of Medicine, Houston, TX; 3) Otolaryngology-Head & Neck Surgery, Columbia University, New York, NY.

Mutations in *GJB2* cause hearing loss with or without skin disease. DNA sequencing of *GJB2* in a cohort of hearing impaired patients and a multi-ethnic control group is reported. Among 610 cases, 42 DNA sequence variations were identified in the coding region of *GJB2* including 20 previously identified mutations, 8 polymorphisms, 3 unclassified variants (G4D, R127C, V163V), 1 controversial variant (V37I), and 10 novel variants (G12C, N14D, V63A, T86M, 313_326del, L132V, R134W, D159D, 592_600del_ins17, 647_650del). Sixteen sequence variations were identified among cases in the non-coding region of *GJB2* including 1 mutation, 2 polymorphisms, and 13 novel variants. Two dominant syndromic mutations were detected among cases. A diagnosis of *GJB2*-associated deafness was confirmed for 60 cases (9.8%). Heterozygous mutations were found in 38 cases (6%). Molecular diagnosis was complicated in 30 cases (5%) by the identification of unclassified, novel or controversial sequence variations. In addition, 294 control subjects from 4 ethnic groups were sequenced for *GJB2*. Thirteen sequence variations in the coding region of *GJB2* were identified among controls including 2 mutations, 6 polymorphisms, 2 unclassified variants (G4D, T123N), 1 controversial variant (V37I), and 2 novel variants (R127L, V207L). Nine sequence variations were identified among controls in the non-coding regions adjacent to *GJB2* exon 2. No control was homozygous for a mutation in *GJB2*. Of particular interest among controls were the variable carrier rates and stratification of alleles among ethnic groups, and the complexity of genotypes among Asian controls, 47% of whom carried 2 to 4 DNA sequence variations in the coding region of *GJB2*. The V37I allele occurred among Asian controls at a frequency of 0.076. These data provide new information about carrier rates for *GJB2*-based hearing loss in various ethnic groups and suggest that the V37I variant is a polymorphism.

Occipital Horn Syndrome in Brothers with a Missense Mutation in the ATP-binding domain of ATP7A. *J. Tang*[1], *S. Robertson*[2], *S.G. Kaler*[1]. 1) Unit on Pediatric Genetics, Laboratory of Clinical Genomics, NICHD/NIH, Bethesda, MD; 2) Department of Paediatrics and Child Health; Dunedin School of Medicine. University of Otago Dunedin NEW ZEALAND.

The clinical spectrum of Menkes disease includes a range of neurological severity, from the classical form that features seizures, severe developmental delay and death by 3 years of age, to occipital horn syndrome (OHS, X-linked cutis laxa or Ehlers-Danlos type IX). Occipital exostoses provide a distinctive radiographic feature in this latter condition, and slightly subnormal intelligence or signs of autonomic dysfunction (e.g., frequent syncope) are the only apparent neurologic abnormalities. While many mutations resulting in classical Menkes disease have been described, the literature contains fewer than ten reports of phenotype-genotype correlations for OHS. These all reflect milder molecular abnormalities, especially involving "leaky" splice junction mutations that impair but do not eliminate proper mRNA splicing. Only two missense mutations (G892D, A1325V) have previously been reported in this phenotype. Here, we report two brothers aged 5 and 14 years with somewhat distinct clinical phenotypes which are each consistent with occipital horn syndrome. In contrast to the two other missense defects producing OHS phenotypes, which do not involve important functional domains of ATP7A, the molecular defect in these brothers (N1304S) lies within the ATP-binding domain of the molecule. While functional analyses are necessary to formally demonstrate the point, the patients' mild phenotypes indicate that the N1304S substitution does not completely disrupt ATP-binding and the consequent ability to transport copper. This finding expands our knowledge of the structure-function relationships for ATP7A and genotype-phenotype correlations in OHS.

C-reactive protein and homocysteine levels in Prader-Willi syndrome. *N. Kibiryeva, D.C. Bittel, U. Garg, M.G. Butler.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, feeding difficulties, hypogonadism, small hands and feet, mental deficiency, behavioral problems, hyperphagia leading to obesity in early childhood and a paternal 15q11-q13 chromosome deletion in the majority of subjects. Whether the obesity associated with PWS contributes to an increased risk for diabetes and cardiovascular disease is unclear. To date there have been no studies confirming an associated risk of cardiovascular disease relating to obesity in PWS, nor of circulating biomarkers known to be predictive of cardiovascular disease. Therefore, we measured the levels of C-reactive protein (CRP) and homocysteine (HCY), both biomarkers for cardiovascular disease, using commercially available immunoassays from Diagnostic Products Corporation (DPC) on a cohort of PWS and comparison subjects. The means and standard deviations for CRP and HCY in eight nonobese comparison subjects were similar to established means and standard deviations reported by DPC from healthy adults. The mean circulating CRP concentration for 29 PWS subjects (14 females, 15 males; mean age 24.6 +/- 11.6 years; mean body mass index (BMI) 35.9 +/- 11.9) was 1.03 +/- 0.88 mg/dL and the mean HCY value was 5.76 +/- 3.35 umol/L. The mean CRP concentration for 23 nonsyndromic obese subjects (17 females, 6 males; mean age 32.7 +/- 12.5 years; mean BMI 34.6 +/- 5.9) was 0.88 +/- 1.07 mg/dL and the mean HCY value was 6.52 +/- 1.86 umol/L. The reported mean value for CRP was 0.26 +/- 0.30 mg/dL from 100 healthy adults and the mean HCY value was 7.82 +/- 1.8 umol/L from the DPC data. The CRP and HCY values were not significantly different between the PWS and obese subjects. However, CRP levels were significantly higher in both PWS and obese subjects relative to the reported DPC data ($p < 0.001$ for both) but HCY levels were lower in the PWS and obese subjects compared to the DPC data ($p < 0.001$ and 0.01, respectively). Moderately increased levels of CRP (between 0.3 and 1.0 mg/dL) are reportedly associated with cardiovascular disease suggesting both the PWS and obese groups are at an increased risk.

A new camptodactyly syndrome with lens subluxation and vascular features in two Mexican siblings. *J. Garcia-Ortiz[1], D. Garcia-Cruz[4], M.O. Garcia-Cruz[3], Z. Nazara[3], J. Sanchez-Corona[2].* 1) Division of Genetics, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) Division of Molecular Medicine, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 3) UMAE, CMNO-IMSS, Guadalajara, Jalisco, Mexico; 4) CUCS-University of Guadlajara, Guadalajara, Jalisco, Mexico.

Camptodactyly, a permanent non-traumatic flexion contracture of one or more proximal interphalangeal (PIP) joints of the fingers, is an isolated or syndromic feature; more than 60 distinct camptodactyly entities have been described. Here we report two brothers of 31 and 29 year-old that were seen at the Clinical Genetics service due to lens subluxation, asymmetric face, prominent supraciliar arches, deep nasofrontal angle, low nasal root protrusion, broad and beaky nose, long philtrum, downturned corners of the mouth, retrognathia, ears with hypoplastic anthelix and scapha and a groove in the lobe, wide neck, shoulders with promient trapezium; upper extremities with camptodactyly of fingers 3-5 in left hand, tapered fingers 3 and 4 with thickening of the volar surface, cubital deviation of fingers 3-5, thenar and hypothenar hypoplasia, limited abduction of the thumb; right hand showed similar features but more severe camptodactyly and prominent metacarpophalangeal joint of the thumb were observed; lower extremities with increased volume of the right ankle and presence of an old hypopigmentated scar, bilateral hallux valgus. Ophthalmological evaluation revealed anterior segment with nasal superior subluxation of lens in both eyes and central corneal thickening and a small central opacity in the right eye. Angiologic evaluation revealed varicosities in the lower limbs. Laboratory examination including karyotype, tests for metabolic defects gave normal or negative results. Differential diagnosis included Marfan, Ehlers-Danlos, Weill-Marchesani, Freeman-Sheldon, Tel-Hashomer camptodactyly and camptodactyly-arthritis-coxa vara-pericarditis syndromes. The striking skeletal, ocular and vascular features found in these two siblings are distinguishable from previously reported camptodactyly syndromes that we propose would be considered a new clinical entity.

Foramen Magnum and Cervical Vertebral Abnormalities in CDX2. *D. Myles Reid[1,2], J. Kingdom[1], A. Toi[1], D. Chitayat[2,3].* 1) Dep. of Obstetrics and Gynecology; 2) The Prenatal Diagnosis and Medical Genetics Program; Mount Sinai Hospital; 3) Div. of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Chondrodysplasia punctata, Conradi-Hunermann Type (CDPX2) is a rare, X-linked dominant condition characterized by asymmetric shortening of the long bones, cataracts; facial flattening with hypoplastic nasal bone in infancy, scoliosis, alopecia, joint contractures, and skin lesions. The condition is associated with mutations in the EBP gene on Xp11. We report a female neonate with CDPX2 who was born at 39 weeks gestation.Parents are healthy and non-consanguineous. Fetal U/S performed at 19 and 20 weeks gestation demonstrated normal growth and segmentation abnormality in the thoracic spine. Fetal MRI at 23 weeks gestation showed a mild alignment abnormality of the spine with kyphosis centered at the thoracolumbar spine. A repeat fetal U/S at 35 weeks gestation showed asymmetrical shortening of all the long bones. There were mild epiphyseal ossifications and a segmentation error or additional ossifications centers along the spine with mild kyphosis of the thoracolumbar junction.At birth the face was asymmetrical with the right side being more prominent than the left. The upper limbs were mildly asymmetric and thyere were streaks of hypopigmentation on the face, trunk and limbs. Cataract was present in the right eye. Stippling was detected on skeletal survey and there were limitations in finger movements. CT scan showed a tight craniocervical junction with what appeared to be compression by the cartilaginous arch of C1. MRI detected a narrowing of foramen magnum and narrow AP dimension of the cervical canal at C1 level consistent with spinal stenosis.The canal was narrowed by approximately 50%. The incidence of a narrow foramen magnum and cervicomedullary compression in cases with CDPX2 need to be further investigated since it can result in neurological problems, leading to disabilities in locomotion, communication, learning as well as sudden death.Early clinical and MRI evaluations may be necessary since early recognition, and immediate decompression can be performed safely to avoid serious complications.

Association between ADRA2A genotypes and Bone Density in Female Schizophrenic Patients with Exposure to Atypical Antipsychotics. *T. Lan[1,2,3,4], M. Lee[6], H. Chiu[2,5], T. Hu[2], F. Chu[7], H. Sun[8], C. Shu[9].* 1) Inst Genetics, Natl Yang-Ming Univ, Taipei, Taiwan; 2) Psychiatry, Yu-Li Hospital, DOH, Hualien, Taiwan; 3) Division of Mental Health and Substance Abuse Research, NHRI, Taipei, Taiwan; 4) Inst Human Genetics, Tzu-Chi Univ, Hualien, Taiwan; 5) Psychiatry, Natl Yang-Ming Univ, Taipei, Taiwan; 6) Department of Psychiatry, Yi-Lan Hospital, DOH, Yi-Lan, Taiwan; 7) Clinical Biochemical Laboratory, Tao-Yuan Hospital, DOH, Tao-Yuan, Taiwan; 8) Department of Psychiatry, Tao-Yuan Psychiatric Center, DOH, Tao-Yuan, Taiwan; 9) Bureau of Medical Affair, DOH, Taichung, Taiwan.

A lower bone density is suspected prevalent among female schizophrenia patients. This study is to explore the association of bone density in female schizophrenic patients and ADRA2A gene. This is a multi-center, investigator-initiated, naturalistic study project. Here we enrolled 90 female inpatients meeting DSM-IV criteria for schizophrenia or schizoaffective disorder from two psychiatric hospitals in Taiwan. Bone density indicated in BUA was measured for all subjects by using QUS-2 over calcaneal bone. Descriptive data of age, sex, height, body weight, medical or surgical past history, activity level, smoking and the antipsychotics used in the past two years were collected. Four candidate genes including ADRA1A, ADRA2A, ADRB3, HTR2A have been genotyped by PCR or DHPLC. After controlling for gender, age, smoking status, education year, BMI, daily energy intake, and the other 3 genotypes, the absolute regression coefficient of BUA for an individual female with one more allele C(1291) is -5.922.68 (p-value =0.030). After further stratified by their previous treatment of antipsychotics, this association was only held in those taking atypical antipsychotics (p-value =0.020). It is suggested that the SNP C1291G in ADRA2A gene is significantly associated with bone density in our female schizophrenic patients.

Clinical follow up of five patients with Rothmund Thomson: Importance of osteosarcoma. *C.R.L. Silva, D.R. Bertola, L.M.J. Albano, V. Odone, C.A. Kim.* Pediatrics, Instituto da Criança, São Paulo, Brazil.

Rothmund Thomson Syndrome (RTS) is a genodermatosis characterized by poikiloderma in sun exposed areas, premature aging, sparse hair, thin browns and eyelashes, micro or anodontia, juvenile cataracts and skeletal abnormalities. A helicase family gene (RECQL4), whose mutations have being related to RTS phenotype, was described in a group of patients. RTS is divided in: Type I without osteosarcoma; and Type II with increased risk to develop osteosarcoma and mutations in RECQL4 gene. We report on the natural history of 5 patients followed between 1995-2005, with RTS clinical diagnosis, according to Wang (2001) criteria. All cases were sporadics and from healthy and nonconsanguineous parents. The clinical diagnosis was made between 1y11mo and 29y8mo (mean=9y8mo). They were followed for about 4.8 years and their current ages range from 3y3mo to 30y7mo. The main findings were: poikiloderma in face, thorax and extremities (5/5 - 100%); thin eyelashes (5/5 - 100%); short stature (4/5 - 80%); skeletal abnormalities (4/5 - 80%); microcephaly (2/5 - 40%). None of them developed either cataract or skin cancer. Only one patient presented at 11 years of age osteosarcoma in the left tibia and received chemotherapy for a year without satisfactory response, requiring limb amputation. Poikiloderma injury in precocious ages is the main criteria for the clinical suspicion of RTS. Osteosarcoma occurs in the second decade of life, in up to 30% of the affected patients, and skin cancer occurs in 5% at any age, although earlier than in general population. Thus, a clinical and laboratorial follow up of these patients is extremely important to prompt detection of skin and bone cancers. Molecular study has been shown helpful to identify patients with risk of osteosarcoma.

Sprengel's deformity associated with Klippel Feil Syndrome in a Mexican patient. A report case at the Hospital Para el Niño Poblano. *C. Gil[1,7], J.M. Aparicio[2,7], M. Barrientos-Pérez[3], E. Landini-Maldonado[4], W.B. San Martín[5], F. Guzman-Serrano[1], K. Sanchez-Ortega[1], M. Gil-Barbosa[6], L.A. Gonzalez-Salazar[7], R. Tenorio-Sánchez[7], C.F. Salinas[8].*
1) Pediatric Estomatology; 2) Medical Genetics; 3) Endocrinology; 4) Orthopaedics; 5) Maxilofacial Surgery; 6) Direction, Hospital para el Nino Poblano, Puebla, Mexico; 7) Estomatology, Benemerita Universidad de Puebla, Mexico; 8) Craneofacial Genetics, Medical University of South Carolina, U.S.A.

INTRODUCTION. Eulenberg first described the Sprengel deformity in 1863. Sprengel then described 4 patients of upward displacement of the scapula in 1891. In 1912, Maurice Klippel and Andre Feil were independently the first to describe Klippel-Feil syndrome. They described patients who had a short neck, increased range of motion in the cervical. PROBLEM. Sprengel deformity is a complex anomaly associated with malposition and dysplasia of the scapula with muscle hypoplasia or atrophy, which causes disfigurement and limitation of shoulder movement. Whether Klippel Feil is caracterized by cervical fusion with movement limitations. FRECUENCY. Sprengel deformity is the most common congenital malformation of the shoulder with a male-to-female ratio of 3:1. Meanwhile, the incidence of Klippel-Feil syndrome is unknown. CLINICAL CASE. A Mexican male with unilateral elevation of right scapula short neck; a low posterior hair line; limitation of movement with congenital cervical sinostosis, cleft palate and a dismorfic phenotipe was estudied. CONCLUSIONS. The hallmarks of Sprengel are shoulder asymmetry and restriction of shoulder abduction. The scapula is hypoplasic. However cervical fusion and short neck is frecuently observed in Klippel Feil syndrome. An unusual presentation of Klippel-Feil syndrome was observed in this study, a patient two-year-old boy with multiple associated congenital anomalies that included short neck; a low posterior hair line; limitation of movement with congenital fusion cervical vertebrae (triad seen in 50% of the patients with KF. The patiente also has unilateral elevation of right scapula (seen in 20-25% of Sprengel).

A New Case of Fibula Agenesis and Oligodactylia Asocciated to Hypospadias and Cryptorchid Testes. *P.L. Paez*[1], *J.C. Prieto*[1,2]. 1) Instituto de Genetica Humana, Bogota, Colombia; 2) Hospital la Victoria, Genetica, Bogota Colombia.

We present a new case of a three year-old boy born in Chaparral (Tolima, Colombia) of non consanguineous parents presents with oligodactylia of hands and feet, bilateral fibula agenesis, bilateral talus deformity of feet, grade II hypospadias and bilateral cryptorchid testes. As this combination has been unpublished before, we believe that this is a new syndrome. The patient was the products of the mother's fourth unterm 34-week pregnancy and cesarean delivery. Prenatal ultrasonographic study showed inespecific dwarfism. There was evident oligodactylia of hands and feet, bilateral fibula agenesis, bilateral talus deformity of feet, grade II hypospadias and bilateral cryptorchid testes at birth. No delayed psychomotor development. No familiar history. R banding karyotype was normal: 46 XY. Roentgenologic findings are: bilateral fibula agenesis, tibial bilateral antecurvatum, delayed bone maduration on carpogram (bone age of two years), right hand: oligodactylia, fifth finger agenesis, thirth methacarpian hypoplasia, fifth finger clinodactylia; left hand: clinodactily and middle phalanx of second finger, bilateral oligodactylia of feet (fourth and fifth fingers agenesis), hypoplasic tarsal bones. Aplasia or hypoplasia of the fibula can occur as an isolated finding or as part of a syndrome. One of the commonest forms is Fibula aplasia/hypoplasia which is associated with short stature, mesomelic shortening, tibial aplasia/hypoplasia, talus or equinovarus deformity, toe hypoplasia and ocasionally fémur hypoplasia. Another condition is Fibula agenesis with oligodactylia and camptomelia which is characterized too for tibial aplasia/hypoplasia, clinodactylia, ectrodactylia, methacarpian agenesis, limb reduction and femur is usually not shortened. All these cases are sporadic and no mendelian inheritance mechanism have been found. No preview literature evidence of association between fibula agenesis, oligodactylia and hypospadias with cryptorchid testes has been reported.

Identification of a major recombination hotspot in short patients with SHOX deficiency. *G. Rappold[1], N. Sabherwal[1], K. Jantz[1], R. Roeth[1], N. Muncke[1], W.F. Blum[2], G.B. Cutler[3], K. Schneider[1].* 1) Inst Human Genetics, Univ Heidelberg, Heidelberg, Germany; 2) Lilly Research Laboratories, Eli Lilly and Company, Bad Homburg and University Childrens' Hospital, Giessen, Germany; 3) Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana, USA.

Aside from the influence exerted by environmental and internal factors, growth is orchestrated by a large number of different genes. One of them, SHOX, is believed to play a major role since defects in this homeobox-containing short stature gene on the sex chromosomes lead to syndromal (Léri-Weill, Langer and Turner syndrome) or idiopathic short stature. We have analysed 118 independent patients with Léri-Weill dyschondrosteosis and 1,500 patients with idiopathic short stature for deletions encompassing SHOX. Deletions were detected in 34% of the patients with Léri-Weill dyschondrosteosis and 2% of the patients with idiopathic short stature. For 27 patients with Léri-Weill dyschondrosteosis and 6 with idiopathic short stature, detailed deletion mapping was carried out. Analysis was performed by polymerase chain reaction (PCR) using pseudoautosomal polymorphic markers and fluorescence in situ hybridisation (FISH) using cosmid clones. Here we show that the identified deletions vary in size, yet the vast majority (73%) of patients tested share a distinct proximal deletion breakpoint. We propose that the tandem repeat sequences present within this proximal deletion breakpoint hotspot region predispose to recurrent breaks. Based on the prevalence of this deletion breakpoint in idiopathic short stature (1%), SHOX deletions are estimated to occur in roughly 1:2,000 in the total population. This implies that the recurrent deletion breakpoint identified in this study may represent one the most frequent known deletion breakpoint leading to disease. Together, mutations in the SHOX gene are seen in 3% of patients with idiopathic short stature and 60% of patients with Léri-Weill dyschondrosteosis.

Growth charts for weight, height and other anthropometric measurements in children with skeletal dysplasias.

J.E. Hoover-Fong[1,2], J. McGredy[1,3], K.J. Schulze[1,3], H. Barnes[2], C.I. Scott[4]. 1) Johns Hopkins University, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Greenberg Center for Skeletal Dysplasias, Baltimore, MD; 3) Bloomberg School of Public Health, Baltimore, MD; 4) AI DuPont Hospital for Children, Wilmington, DE.

Accurate assessment of growth parameters in skeletal dysplasias patients is problematic with current growth curves. Most were constructed from a small number of patients with a paucity of longitudinal data. Furthermore, data were compiled from multiple clinical settings using potentially non-standardized observational methods, and the curves were derived from very basic parametric analysis. Of clinical significance, weight-for-age norms are currently unavailable, despite significant negative orthopaedic, neurologic and general health sequelae caused by unrecognized and untreated obesity in this patient population. We have collected extensive, longitudinal anthropometric data from medical records of patients with a variety of skeletal dysplasias. The majority of the data were from patients with achondroplasia (n=334), with >2000 datapoints for height, weight and head circumference. Other skeletal dysplasias considered include hypochondroplasia, spondyloepiphyseal dysplasia congenita, diastrophic dysplasia, and Morquio syndrome. Patients were born between 1931 and 2004, and all anthropometric measurements were obtained by a single observer (Scott). Gestational age and birth weight, length and head circumference were also analyzed for each skeletal dysplasia type. Percentiles (5, 25, 50, 75, and 95th) were estimated across the age continuum for each growth parameter using a moving 6 month window. Percentiles were then smoothed using a quadratic, penalized smoother. This improves upon previous approaches for generating growth curves by taking advantage of the longitudinal nature of the data, thereby improving the precision of the percentile estimates. New growth charts constructed from these data conform to the current CDC curve structure for average stature individuals, with one chart for each anthropometric parameter for ages 0-36 months and another for 2-20 years.

Absence of MMP2 Mutations in Idiopathic Multicentric Osteolysis with Nephropathy in 2 American Boys. *D. Wenkert[1], S. Mumm[2], S.M. Wiegand[2], W.H. McAlister[3], M.P. Whyte[1,2].* 1) Research Center, Shriners Hospt, St Louis, MO; 2) Dept Med &; 3) Radiol, Wash U Sch Med, St. Louis, MO.

In 2001, Saudi Arabians with multicentric osteolysis and arthritis syndrome were found to have mutations of the gene encoding matrix metalloproteinase 2 (MMP2) (Nat Gen, 2001, 28:261). They suffered crippling arthritis, subcutaneous nodules, and osteoporosis with carpal-tarsal destruction called Nodulosis-Arthropathy-Osteolysis Syndrome (NAO) (OMIM #605156).

We report 2 unrelated Caucasian boys with idiopathic multicentric osteolysis (IMO) and nephropathy without MMP2 mutation. Elsewhere, each had been diagnosed with Juvenile Rheumatoid Arthritis (JRA) and had received NSAIDs, prednisone, gold, and methotrexate with minimal effect. Patient 1 crawled on knees and elbows at 1 yr of age. X-rays showed "delayed bone age". Flares of pain and limited motion of feet, wrists, elbows, and perhaps knees persisted despite JRA treatment. After IMO was diagnosed, pamidronate was administered for 1 yr. After referral at age 8, mild proteinuria developed over the next 1/2 yr. Osteolysis was treated with oral alendronate. Patient 2, referred at age 7, presented at age 2 1/2 with a limp. Originally evaluated for muscle disease, he was diagnosed with JRA at age 3. He had pain and swelling of wrists and ankles. IMO was diagnosed at age 5 following elbow, knee, and shoulder contractures and bony erosions. Proteinuria and progressive renal disease led to kidney transplantation at age 17. All 13 exons and adjacent mRNA splice sites of the MMP2 gene were amplified by PCR, using genomic DNA. Amplicons were sequenced in both directions, using the same PCR primers. Sequencing chromatograms were inspected and sequences aligned using VectorNTI AlignX software. No MMP2 mutations were detected.

Originally diagnosed as JRA, early clinical clues to IMO included aggressive symmetric involvement of wrists and ankles prior to the involvement of other joints, x-ray reading of delayed bone age, and negative serologies. Mutational analysis supports the clinical impression that IMO represents a disease distinct from NAO.

Clinical study of five patients with Trichorhinophalangeal syndrome. *L.M.J. Albano, T.B. Brasil, M.B. Moreira, C.R.L. Silva, D. Bertola, C.A. Kim.* Genetics Unit, Inst Da Crianca, Hosp das Clinicas, Sao Paulo, Brazil.

Trichorhinophalangeal syndrome (TRPS) is an autosomal dominant disorder, characterized by sparse scalp hair, bulbous nose tip, long flat philtrum and protruding ears and skeletal abnormalities, such as cone-shaped epiphyses at the phalanges, hip malformations, and short stature. There are 3 subtypes. Type I and II share the above characteristics, but type II differs from type I because of mental retardation and exostosis. In type III we observe normal development, absence of exostosis, but a severe brachydactyly. The responsible genes are located at the 8q.24. We studied 5 TRPS patients from healthy and nonconsanguineous parents. All cases (100%) had sparse hair, bulbous nose, prominent ears and high nasal bridge. In four of them (80%) we found: thin upper lip, elongated facies, displastic ears and ulnar deviation of the fingers. In three patients (60%), sparce eyelashes, long philtrum and recurrent infections were present. Only two of them (40%) had fragile nails and development delay. Abnormalities in the radiographic study were presented in all of them, especially cone-shaped epiphysis (80%). G-banded karyotype showed a deletion in the 8q.24.1 region in only one case presenting typical findings of TRFS II plus cleft lip and palate and preaxial polydactyly in the right hand. Preaxial polydactyly as well as cleft palate was previously described in association with TRFS II. Once this subtype is considered a contiguous gene syndrome with deletion of TRPS1 and EXT1 genes, the presence of these anomalies in our TRPS II patient reinforces the fact that these associations could be not fortuitous and raises the possibility of the presence of other gene(s) responsible for them located in this region.

Cone-rod dystrophy and spondylometaphyseal dysplasia. *B. Hall.* Greenwood Genetic Center Greenwood, SC.

In 2004 Walters et al. (Am J Med Genet 129A:265) reported 8 cases of spondylometaphyseal dysplasia (SMD) who also had cone-rod dystrophy or were suspected of having cone-rod dystrophy. Three of their cases were mixed sex siblings and one of the isolated cases was the product of first cousin mating. They noted the rarity of occular and non-bony abnormalities in SMD. The radiological features of platyspondyly, characteristic vertebral body shape, irregular cupped metaphyses, bowed long bones, and rhizomelia were felt to be different from other well-established disorders with SMD. I present MZ Black twins born to consanguineous parents one had negative FGFR3 testing, with "probable cone-rod" dystrophy and similar SMD as the cases reported by Walters et al.

The female twins were born at 34 weeks gestation to a 32 year old G2P3 mother who was a distant cousin to the 42 year old father. Twin 1 was 1497g and 38cm and twin 2 was 1391g and 36.8cm, respectively. Genetic evaluation at 4 months revealed both twins to be short with flat facies and bowed, disproportionately short limbs. Twin 2 had a disproportionately large head. At 10 months, achondroplasia was suspected, but both girls were noted to have nystagmus and skeletal x-rays showed ovid vertebrae and more irregular metaphyses than expected for achondroplasia. By 2 years of age non-specific retinal abnormalities were noted and cone-rod dystrophy was suspected. Twin 1 requires glasses. Both girls are developmentally normal.

The twin girls reported herein further support Walters et al contention that there is a specific SMD and cone-rod dystrophy syndrome with probable autosomal recessive inheritance.

Swallowing dysfunction in Stuve-Wiedemann syndrome. *J.R. Corona-Rivera[1,2], P. Coello[2], E. López[2], H. Silva[2], J. Hernández[2], A.M. de León[2].* 1) Instituto de Genética Humana Dr. Enrique Corona, CUCS, Universidad de Guadalajara; 2) División de Pediatría, Hospital Civil de Guadalajara Dr. Juan I. Menchaca, Guadalajara, Jal., México.

Stuve-Wiedemann syndrome (SWS) is an autosomal recessive skeletal dysplasia mostly considered to have an early lethality. We describe a female infant with SWS who suffered multiple life-threatening events. Cause of death or morbidity in SWS is discussed. She was the second child of healthy second cousin Mexican-gypsy parents. After birth, respiratory distress and severe episodes of hyperthermia and apnea were observed. Evaluation at 8 months of age showed weight 4200g (-5.7 SD), length 56 cm (-5.8 SD), short wide nose, hypolacrimation, lack of corneal reflexes, smooth tongue, bowing of the long bones, camptodactyly, overlapping fingers, hearth murmur, hypotonia and reduced patellar reflexes. On X-ray showed osteoporosis, bowing of the long bones with abnormal trabecular pattern, wide metaphyses and scoliosis. Electromyography showed absence of sympathetic skin response. She showed absence of reaction after intradermic injection of histamine and myosis after instillation of methacholine. Echocardiography revealed pulmonary hypertension. On examination of barium swallow showed aspiration of oropharyngeal secretions. Esophagic aperistalsis was found on manometry. Results of cranial CT scan, abdominal ultrasound, metabolic screening test and karyotype were normal. At two months of age, despite nasogastric feeding, she showed repeated pulmonary aspirations and required an esophagectomy and feeding gastrostomy. An ectopic thyroid gland was found at surgery. After these measures, no one event of aspiration pneumonia was experienced. Also, oxygen dependence, temperature instability, reduced sweating and pain sensations, and spontaneous fracture of the radius, were observed on evolution. Since our patient had symptoms of dysautonomia as well as evidence of esophageal dysfunction on manometry and barium swallow, we propose that swallowing dysfunction could be a dysautonomic manifestation of SWS. Early surgical management in infants with SWS could prevent morbidity or inclusively early death.

Cranioectodermal dysplasia: hepatic manifestations in two unrelated children. *C.H. Gonzalez[1], C.Y Utagawa[2], N. Zannon-Collange[2], M.R. Passos-Bueno[1], F. Sarquis-Jahee[1].* 1) Dept Genetics & Evol Biology, Inst de Biociencias - USP, Sao Paulo, Brazil; 2) Clinical Genetics, Pediatric Neurosurgical Division, Hospital Santa Marcelina, São Paulo, SP, Brazil.

Cranioectodermal dysplasia (CED) also known as Seusenbrenner Syndrome, is an autosomal recessive condition characterized by craniofacial and skeletal anomalies and by ectodermal dysplasia. There are 15 cases described in the literature including 4 pairs of brothers and a set of monozygotic twins. Manifestations of ectodermal dysplasia are variable. All the patients presented dolichocephaly and most of them, rhizomelia. The skull is scaphocephalic with sunostosis of the sagittal suture. Several children have died from chronic renal failure. Heart defect and short thorax were also observed as well as growth deficiency, delayed psychomotor development, microcephaly and abnormal calcium homeostasis. We have studied two unrelated children affected by CED. Patient 1 is a 9-year-old boy, the first child of healthy and non-consanguineous parents. Patient 2 is a 8-year-old girl born from a consanguineous couple. Both patients presented doliocephaly, prominent sagittal suture, frontal bossing, fine, sparse and slow-growing hair, peculiar facies with mongoloid slanting of the palpebral fissures, epicanthic folds, sparse eyebrow and long philtrum. The thorax was narrowed and at the hands brachidactyly and partial cutaneous syndactyly were observed. Joint laxity and hyperelasticity of the skin were also seen. In both patients sinostois of the sagittal suture was diagnosed and they were submitted to a neurosurgical procedure. Microdontia was observed during the follow-up. Both children also presented progressive hepatomegaly with ascites since 4 years of age. Patient 1 also had renal manifestations and his diagnosis was parenchimatosal nephropathy. His liver biopsy revealed moderate septal fibrosis. Patient 2 has no renal problem and her liver biopsy was not perfomed. We believe that the hepatic involvement observed in these two cases offer further evidence that the complete phenotype of CED was not described yet.

A new distal arthrogryposis syndrome characterized by plantar tendon contractures: clinical analysis of a large Utah kindred. *D.A. Stevenson[1], A. Rutherford[2], K. Swoboda[3], M. Bamshad[1,2].* 1) Dept Pediatrics, Univ of UT, SLC, UT; 2) Dept of Human Genetics, Univ of UT, SLC, UT; 3) Dept of Neurology, Univ of UT, SLC, UT.

Distal arthrogryposis (DA) syndromes are caused by mutations in genes (i.e., TNNI2, TNNT3, MYH7, and TPM2) encoding components of the contractile apparatus of fast-twitch myofibers. Accordingly, phenotypic and molecular characterization of DA syndromes is providing novel insights about the mechanism by which defects of contractility cause congenital contractures. We characterized a large three-generation Utah family in which plantar tendon shortening was transmitted among 13 affected individuals in an autosomal dominant pattern. Contractures were not evident at birth but became apparent in early childhood with the onset of walking. Indeed, plantar tendon shortening was commonly manifest as toe-walking, and required surgical palliation (i.e., tendon lengthening) in 8 cases. Contractures of hips, elbows, wrists, and fingers were variable among affected individuals and of modest severity. No affected individuals had clubfeet, hip dislocation, or clenched fists. All affected individuals had normal neurological and ocular exams, and normal stature. Creatine phosphokinase levels, magnetic resonance imaging of the lower leg and ankle, electromyograms and electrocardiograms on selected individuals were also normal. This disorder meets the diagnostic criteria for a DA but is distinct from all other DAs and appears, to our knowledge, to be unique. A genome-wide linkage scan to identify candidate loci is underway.

Amelogenesis Imperfecta (AI) and Nephrocalcinosis: further delineation of a rare or unrecognized syndrome. *I. Bailleul-Forestier[1,2], M. Molla[2], G. Zanni[3], D. Griffiths[5], B. Llanas[6], Ch. Loirat[7], D. Lacombe[5], A. Berdal[2], A. Verloes[3,4].* 1) Dpt Stomatology, Robert DEBRE Hospital, Paris; 2) INSERM U714; 3) Clinical Genetics Unit, dpet of Genetics, Robert DEBRE Hospital, Paris; 4) INSERM U676; 5) Dpt of Medical Genetics. Pellegrin University Hospital, Bordeaux; 6) Dept of Paediatric Nephrology, Pellegrin University Hospital, Bordeaux; 7) Dept of Paediatric Nephrology, Robert DEBRE Hospital, Paris, France.

AI is a clinically and genetically heterogeneous group of disorders of enamel development. Enamel defects can occur in isolated or syndromic forms. Mutations in genes encoding for enamel matrix proteins (Amelogenin X, Enamelin, Ameloblastin ...) have been identified respectively in XLR and AD families with apparently non-syndromic AI. The AI-Nephrocalcinosis (AIN) or renal-enamel syndrome is an AR condition with only few reported cases in the literature. Renal symptoms include progressive nephrocalcinosis without any apparent abnormality in calcium metabolism that could lead some patients to renal failure in the adulthood. At present no mutation have been identified in this syndrome. Albumin, osteopontin, calbindine-D28k and calcium sensing receptor could be proposed proteins. These four proteins are involved in calcium metabolism, in tooth and kidney physiopathology, and are expressed in both teeth and kidney cells. We report two consanguineous families and three sporadic cases of AIN. Generalized enamel hypoplasia of both primary and permanent dentition was present in all affected patients. In two families delayed or absent molar eruption and microdontia were noted. None of the patients had impaired renal function. In one sibship, nephrocalcinosis was only present in 1/3 AI patients. As nephrological screening of AI patients is not systematically done in AI, the incidence of this syndrome could be underestimated, and the risk of renal failure overestimated. As early diagnosis may lead to a better renal prognosis, all children with AI should at least have one renal ultrasonography performed to exclude nephrocalcinosis, and this examination should be repeated through infancy, as the natural history and age of onset are not known.

A new clinical finding in the Richieri-Pereira type of Acrofacial Dysostosis. *L.O. Dewes[1,2], V.R Philipsen[1,2], M.B. Golbert[1,2], R.S. Wachholz[1,2], C. Deutschendorf[1,2], R. Giugliani[1,2], J.C.L. Leite[1,2].* 1) Medical Genetics Service, Hosp Clin P Alegre, Porto Alegre , RS, Brazil; 2) Faculdade de Medicina,Universidade Federal do Rio Grande do Sul,Porto Alegre, RS.

We present a female newborn, from a 37-week pregnancy, who is the first child of a consanguineous couple without previous family history of congenital malformations. The mother was 24 years old and had na uneventful pregnancy. The patient was born through a cesarian section, weighting 2340 g, with a length of 44 cm and a head circumference of 32 cm. Apgar score was 8 on the first minute. Mother reported the use of folic acid during the first trimester. The physical examination showed severe micrognatia, palpable mobile collarbone and a median mandibular cleft. The radiological study showed mentus agenesia, congenital pseudoarthrosis of the right collarbone, deformities in the distal extremity of the left humerus, acetabular dysplasia and bilateral hip sub-luxation, bilateral clubfoot, hypoplasia pf the first metacarpus and fusion of the fourth and fifth metacarpi, bilaterally. The Richieri-Pereira form of Acrofacial Dysostosis has 16 known and only 9 of them published until 1999, 8 had been born in Brazil and one in France. All the brazilian cases had Portuguese ancestry, and a founding effect is suggested by the authors. It is characterized by short stature, Pierre-Robin sequence, congenital clubfoot, pre- and post-axial anomalies in hands and mandibular cleft. Some children may present malformations of the larynx. Its an autossomal recessive condition, and the mental development of the affected patients is within normal limits. In the present case, the clavicular hypoplasia raises the suspicion of an association with cleidocranial dysplasia, an autosomal dominant condition characterized by clavicular hyplopasia or agenesia, open fontanels, supranumerary teeth, short stature, and other changes in skeletal development of the affected individual. Cleidocranial dysplasia is the result of a mutation involving the CBA1 transcription factor in cromossome. The clavicular hypoplasia may be a new, yet to be described finding in the syndrome. DNA samples were sent for analysis.

Expanding the phenotypic spectrum of cerebro-costo-mandibular syndrome. *S. Purandare[1], N. UNANUE[3], K.L. Ciprero[1], L. Medne[1], M. Guttenberg[2], E.H. Zackai[1].* 1) Division of Human Genetics and; 2) Department of Pathology and; 3) Clinical Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Cerebro-costo-mandibular syndrome (CCM) is characterized by posterior rib gap defects, and Pierre Robin sequence. Growth retardation and development delay are common. The mortality is over 50% in the first year of life due to hypoxia. The inheritance pattern and the expressivity are variable. We report a patient whose findings of micrognathia, cleft palate and posterior rib gaps were consistent with CCM syndrome. The patient presented with small low set ears, bifid uvula, small narrow chest, lung hypoplasia, abnormal clavicles, absent ossification of the sternum, 11 ribs pairs, right ventricle dilatation, small left subclavian artery and bilateral inguinal hernia, all findings reported in CCM syndrome. In addition the patient was noted to have clenched hands, short proximal upper and lower extremities, bilateral 5th finger clinodactyly, small nails and full 4-5 toe syndactyly. Since the first description of CCM, over 60 patients (Megier, et al) have been reported and limbs defects (clinodactyly, contractures of the large joints, hypoplasia of radius, ulna and phalanges, cutaneous syndactyly) are unusual. A role for genes affecting chondrogenesis is suggested due to costal, palatal, and limb involvement. The presence of limb defects seen in our patient has not previously been reported and expands the phenotypic spectrum of CCM.

Lowry-Wood syndrome in two new patients. *P. Blanchet, C. Coubes, J. Puechberty, V. Cacheux, G. Lefort, P. Sarda.*
Medical Genetics Center, Arnaud de Villeneuve Hospital and University of Montpellier 34295 France.

Lowry-Wood syndrome (LWS) is a rare disease characterized by multiple epiphyseal dysplasia, microcephaly, mild short stature, mental retardation and congenital nystagmus. This condition is probably inherited as an autosomal recessive trait. Presently, the gene defect of this disorder is not known. To date only 7 patients have been described with the characteristic features of this syndrome. We report two new cases in two different families. The first boy, 10-years-old, is the only infant born of non-consanguineous parents. At birth, he presented intrauterine growth retardation (height: 41cm, weight: 1960g and OFC: 30cm for 36 weeks' gestation). Postnatal short stature (-4.5SD) and microcephaly (-2.8SD) were confirmed, associated with mental retardation and chronic bronchopathy. Multiple epiphyseal dysplasia was present on skeletal X-rays. The second case concerns a first boy, 14-years-old, born after three normal sisters from non-consanguineous parents. At term weight and OFC were normal but height was 46cm. The boy developed psychomotor retardation, microcephaly (-3SD), seizures and short stature (-4SD). Additional findings included bronchial dilatations of left lower lobe which were surgically corrected and precocious puberty. The two boys had no growth hormone deficiency. Hormonal treatment was administered to the first infant but was relatively inefficient (+1SD on 6 years). At the young age of these patients, no congenital nystagmus and no other major visual problems were present. These two new observations confirm the classical phenotype of patients with Lowry-Wood syndrome and suggest that large expressivity is present in this syndrome.

Opitz C (trigonocephly) syndrome in a boy with reciprocal translocation t(3;18)(q13.13q12.1). *Y. Chinen[1], T. Kaname[2], K. Yanagi[2], K. Naritomi[2].* 1) Dept Pediatrics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 2) Dept Medical Genetics, Univ Ryukyus Sch Medicine, Okinawa, Japan.

Opitz trigonocephaly C syndrome (OTCS) is a multiple congenital anomaly syndrome characterized by trigonocephaly, mental reterdation, typical facial appearance, redundant skin, joint and limb abnormalities and visceral anomalies. Several reports on the patients suggest that there is heterogeneous condition of the OTCS.
We report on a patient with clinical features of OTCS having a de novo translocation. The proband was 5-month-old at first visit with trigonocephaly, high-arched palate, thick and irregular alveolar ridge, hypotelorism, long philtrum, redundant nuchal skin, and hypotonia. His CT-scan on the head shows agenesis of corpus callosum. The clinical features and facial appearance in the patient are consistent with the OTCS. High resolution G-banding analysis revealed that he had a balanced translocation t(3;18)(q13.13q12.1) de novo.
These findings suggest that there is a possibility of a new locus responsible for OTCS on 3q13.13 or 18q12.1.

Fibrodysplasia Ossificans Progressiva: Middle-Age Onset with Poor Response to Aggressive Immunosuppressive Therapy. *S.J. DiMartino[1], E.F. DiCarlo[1], A.L. Boskey[1], M.P. Whyte[2,3].* 1) Hospt Special Surgery, New York, NY; 2) Wash U Schl Med, St. Louis, MO; 3) Shriners Hospt, St Louis, MO.

Fibrodysplasia ossificans progressiva (FOP) features ectopic bone formation and congenital malformation of great toes. The gene defect is unknown with no established treatment. Early lesions present as warm, erythematous, and tender nodules. Histology shows proliferating fibroblasts with sparse inflammatory cells. Lesions then ossify by an endochondral process. Ossification typically develops before 15 yrs of age (avg 3-5 yrs). A woman with FOP first developed ectopic ossification at age 47 yrs. Symptoms began with progressive pain, redness, warmth, and swelling over a scapula. CT showed asymmetric thickening of muscles and fascial planes, but no ectopic bone. Biopsy revealed proliferating fibroblasts with scattered inflammatory cells. Prednisone, 60 mg/d, was started for suspected inflammatory fasciitis. Symptoms improved, but returned during steroid taper on the posterior thorax, flank, and chest. Despite high-dose corticosteroids, immunosuppressives, and alendronate early on, ectopic bone deposition progressed rapidly. Methylprednisone (24 mg BID), methotrexate (max dose: 25 mg/wk), and alendronate (35 mg/wk) seemed to improve symptoms. Subsequently, however, these worsened, and methotrexate was discontinued due to non-efficacy (total treatment: 14 wks). On high dose steroids and alendronate, new larger lesions developed during trials of azothiaprine (max dose: 125 mg/d, total treatment: 10 wks) and mycophenolate mofitil (max dose: 1 g BID, total time of treatment: 10 wks). CT, 13 mo after FOP onset, showed many regions of ectopic bone in fascial planes of the thoracic, abdominal, and pelvic walls. She had the typical hallux valgus deformity of FOP. Our patient demonstrates that FOP may present well into adulthood when progression may seem inexplicably rapid despite intervention with high-dose steroid, immunosuppressive, and bisphosphonate therapy. It is important to recognize an adult-onset FOP because early diagnosis can help avoid harmful procedures (e.g. biopsy or surgical excision typically exacerbates the disorder) and unnecessary treatment.

Olliers disease (multiple enchondromatosis) associated with neuroblastoma and congenital cataract. *H. Fryssira[1], M. Moschovi[2], D. Tsoumas[2], F. Tzortzatou-Stathopoulou[2], A. Mavrou[1].* 1) Dept Medical Genetics, Ag Sophia Child Hosp, Athens, Greece; 2) Oncology Unit 1st Department of Pediatrics, Athens University School of Medicine, Athens, Greece.

Olliers disease (multiple enchondromatosis,OMIM 166000) is a non-hereditary mesodermal dysplasia that affects the metaphyseal ends of tubular bones causing multiple enchondromas. We report on a 6.5-year old girl with congenital cataract, neuroblastoma and Olliers disease. Cataract of the right eye was diagnosed at the age of 5 months and laboratory investigation for a metabolic disorder or congenital infection was negative. At the age of 12 months she developed a palpable mass in the right adrenal gland which was surgically removed and biopsy showed that it was a neuroblastoma. She received seven cycles of chemotherapy with OJEC (Vincristine, Etoposide, Cyclophosphamide and Carboplatinum). When the patient was 15 months old a slight length discrepancy and deformity of the rib cage were noted and x-rays of the pelvis and lower limbs showed widespread lytic abnormalities affecting the metaphyses, diaphyses and epiphyses of the long bones, as well as the iliac wings and pubic ramai. Multiple calcific foci were seen within these lesions. There was apparent cortical destruction but overall the appearances were in keeping with multiple enchondromatoses. No phleboliths were visible which made Olliers disease more likely than Maffucci syndrome. An MRI of the brain showed a skull base mass involving the clivus, petrous apices, sella and both cavernous sinuses which displaced the carotid artery. The most likely diagnosis included that of an enchondroma and follow up imaging was recommended in order to distinguish it from a chondrosarcoma. It is reported in the literature that approximately 30% of patients with Olliers disease will develop a secondary malignant bone neoplasm, most likely chondrosarcoma, but the possibility of developing other malignancies is low. We believe that the case described here is the first to be reported in which Olliers disease is associated with neuroblastoma and congenital cataract.

Mechanic and genetic component of congenital hip dislocation: an association study for analysing the implication of candidate genes. *K. Rouault[1], V. Scotet[1], F. Dubrana[2], B. Fenoll[3], F. Gaucher[4], D. Tanguy[5], C. Yaccoub[6], C. Férec[1].* 1) INSERM U613, Brest, France CHU Morvan, Brest, France University, Brest, France; 2) Department of orthopaedic surgery, CHU La Cavale Blanche, Brest, France; 3) Department of paediatric surgery, CHU Morvan, Brest, France; 4) Department of orthopaedic surgery, Hotel Dieu, Pont L'Abbé, France; 5) Department of physical medecine, Centre de Perharidy, Roscoff, France; 6) Department of orthopaedic surgery, CH Cornouaille, Quimper, France.

Congenital dislocation of the hip (CDH), which is one of the most common skeletal congenital anomalies, is a public health matter because of its high frequency, the severe functional handicap induced if it is not treated early and its natural evolution towards hip osteoarthritis. This disease presents a mechanical component linked to the pregnancy and delivery conditions, but the ethnical predispositions and the familial aggregation observed suggest that it also presents a genetic component. We set up an association study in the area of Finistère (western Brittany, France) where CDH is particularly frequent in order to study the implication of candidate genes. In a first step, we described the epidemiological characteristics of our cohort of patients. To date, 213 CDH patients have been recruited and the cohort is composed of 92.5% of women (n=197 - sex-ratio: 1:12). The pathology was bilateral in 59.0% of cases and when it was unilateral, it affects as often the left than the right hip (50.6 vs 49.4%). Breech presentation was documented in 157 patients and was observed in 12.0% of them, among whom 52.6% were delivered by caesarean. In this cohort, 13.5% of the patients had a high birthweight (4kg) and 5.3% were postmature babies (42 weeks of gestation). CDH affected the first child of the family in 41.1% of cases and three patients were part of multiple pregnancies. On clinical aspects, a postural anomaly was observed in 10.8% of patients. Hyperlaxity was also present in 10.8% of them and femoral antetorsion in 23.4%. This study will report the preliminary results of the first association study made on CDH and will highlight the role of candidate genes in this complex disease.

Deactivating Germline Mutations in LEMD3 Cause Osteopoikilosis and Buschke-Ollendorff Syndrome, but Not Melorheostosis. *S. Mumm[1], D. Wenkert[2], W.H. McAlister[3], X. Zhang[1], M.P. Whyte[1,2].* 1) Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO; 2) Ctr Metab Bone Dis & Mol Res, Shriners Hospitals, St Louis, MO; 3) Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO.

In 2004, heterozygous loss-of-function mutations in the LEMD3 gene were shown to be a cause of osteopoikilosis (a benign, autosomal dominant, skeletal dysplasia featuring multiple hyperostotic lesions symmetrically throughout the skeleton) and Buschke-Ollendorff syndrome (BOS) (a benign, autosomal dominant disorder combining osteopoikilosis with disseminated connective tissue nevi). In some of these families, unusually large areas of dense bone were called melorheostosis which typically refers to a troublesome sporadic skeletal dysostosis characterized by asymmetrical flowing hyperostosis of the cortex of long bones often with overlying soft tissue abnormalities. Others had proposed that melorheostosis results from a second, post-zygotic, somatic mutation in the putative osteopoikilosis gene. We investigated patients representing 9 families with sclerosing bone disorders where LEMD3 represented a candidate gene abnormality: 1 osteopoikilosis, 2 BOS, 2 melorheostosis, 1 reported with both osteopoikilosis and melorheostosis, and 3 additional patients with bone dysplasias. Genomic DNA, isolated from blood lymphocytes, was amplified by PCR and sequenced for all the coding exons and adjacent splice site regions for the LEMD3 gene. We did not study melorheostosis lesional tissue. A heterozygous nonsense mutation (T1433A, L478X) was found for the osteopoikilosis patient, and a heterozygous nonsense mutation (C1323A, Y441X) and another heterozygous mutation (insertion or deletion in exon 1) were found in the 2 BOS patients. Likewise, a heterozygous nonsense mutation (C1963T, R655X) was detected for the patient with osteopoikilosis and "melorheostosis". However, no LEMD3 mutations were detected for any other patient, including the 2 patients with classic melorheostosis. We conclude that osteopoikilosis and BOS are caused by heterozygous deactivating LEMD3 mutations, however, melorheostosis remains of unknown etiology.

Hypochondroplasia: FGFR3 gene mutation analysis in Indian pedigrees and possible genetic heterogeneity. *P.S. Gambhir[1], R. Uppala[2], U. Ratnamala[2], R. Meda[2], S. Nath[3], J.V. Solanki[4].* 1) Department of Pediatrics, B. J.Medical College , Pune, Maharashtra, India; 2) Green Cross Blood Bank & Genetics Research centre, Paldi, Ahmedabad,; 3) Arthritis & Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) Department of Animal Genetics & Breeding, Veterinany college, Anand, India.

Hypochondroplasia (HCH; OMIM 146000) also called genetic dwarfism is the most common type of skeletal dysplasia in humans. It is characterized by short stature, micromelia, lumbar lordosis, short and broad bones. The skeletal features of hypochondroplasia are comparable to that of achondroplasia but milder, and these two are considered to be allelic. It occurs at a frequency of approximately 1:30,000 births. Mutations in the FGFR3 gene at chromosome 4p16.3 are associated with HCH. A total of 29 loss-of-function mutations or missense mutations have been detected in FGFR3 and over 95% of patients were identified with a common mutation (Gly380Arg) in the gene (Nat Genet. 1995 10:357-9). We analyzed the FGFR3 gene coding regions from three independent large HCH families and 27 sporadic cases of Indian origins and confirmed the presence of G380R mutation only in 9 sporadic patients. No other pathogenic mutations were identified in the FGFR3 gene-coding region in all the remaining patients including three large families with autosomal dominant mode of inheritance. Clinical and radiographic findings were recorded for all the studied individuals. Absence of mutations in FGFR3 and exclusion of large families to the 4p16.3 region by linkage analysis indicates genetic heterogeneity within HCH. Our data also support the previous reports that HCH is clinically and genetically heterogeneous (J. Med. Genet. 33: 749-752, 1996; J. Med. Genet. 32: 492-493, 1995. Systematic genome-wide linkage analyses is in progress to map the elusive locus responsible for HCH in the present Indian families.

Split-hand/foot malformation with long bone deficiency (OMIM 119100) in a large inbred Arab family with an apparent autosomal dominant inheritance and reduced penetrance: Clinical and Genetic analysis. *M. Naveed[1], M.T. Al-Ali[1], S.K. Murthy[1], S.AH Ali[1], N. Al-Khaja[1], S.K. Nath[2], S. Deutsch[3], A. Bottani[3], S.E. Antonarakis[3], U. Radhakrishna[3].* 1) Center For Arab Genomic Studies (CAGS), PO Box 22252, Dubai, United Arab Emirates; 2) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, 825 N.E. 13th Street, Oklahoma City, USA; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

Hereditary developmental anomalies of the upper and/or lower extremities in humans occur in 1:500 to 1:1000 newborns. We have studied a very large six-generation inbred Arab family with multiple severe limb anomalies resembling OMIM 119100, the gene of which is at present unknown. The pedigree consists of 138 individuals including 22 (14 males/8 females) affecteds. Of these, 18 had tibial hemimelia (THM) usually on the right side. The expression of the phenotype was variable and ranged from bilateral to unilateral THM with or without foot anomalies, syndactyly, oligodactyly and split-hand (in one female). The mode of inheritance appears to be autosomal dominant with reduced penetrance. There were also ten consaguineous marriages observed in this pedigree. This also could suggest a recessive mode of inheritance with pseudodominance due to high frequency of the mutant allele. Candidate loci for the described syndrome include the Langer-Giedion syndrome (LGS; 150230) on 8q24.1, Split-hand/Foot malformation 3 (SHSF3; 600095) on 10q24, GLI3 morphopathies (GLI3; 165240) on 7p13, Sonic Hedgehog; (SHH; 600725) on 7q36. In addition bilateral tibial hemimelia and unilateral absence of the ulna was previously observed to co-segregate with deletion of 8q24.1. Two-point linkage analysis and haplotype data did not show the involvement of the above regions in this family. Cytogenetic and FISH analysis for the critical loci on 8q24.1, 10q24, 7p13 and 7q36 also did not show any abnormality. Genomewise linkage analysis is in progress to map the elusive locus and provide a target for positional cloning.

ARC syndrome in two patients with no mutation in VPS33B. *T. Tohma[1], K. Yanagi[2], I. Nakazato[3], T. Kaname[2], K. Naritomi[2].* 1) Dept Pediatrics, Okinawa Prefectural Naha Hosp, Okinawa, Japan; 2) Dept Med Genet, Univ Ryukyus Sch Med, Nishihara, Okinawa, Japan; 3) Dept Pathology, Okinawa Prefectural Naha Hosp, Okinawa, Japan.

ARC syndrome (OMIM 208085) refers to an association between arthrogryposis, renal tubular dysfunction, and cholestasis. Autosomal recessive inheritance is suggested and the *VPS33B* gene has been reported as responsible for the syndrome. We report on two female patients from one Japanese family with typical phenotypes of ARC syndrome. Patient 1: This girl was third child of healthy, no consanguineous parents. She admitted to our NICU because of constipation and vomiting after birth. She was noted to have hypotonia, arythrogryposis, ichtyosis and renal tubular acidosis. She developed cholestatic jaundice and anemia including thrombocytopenia, and died at the age of 6 month. Patient 2: The female sibling of patient 1 appeared similar symptom but it was milder than her sisters. The liver histology of both patients was characterized by lobular cholestasis and giant cells. Immunostaining with polyclonal antibody to CEA showed diffuse distribution in cytoplasm of the hepatocytes.

Direct sequencing analysis for all the exons (23 exons) in the *VPS33B* gene for both patients defined that they had no mutation in the gene. Besides, semi-quantitative RT-PCR revealed the level of *VPS33B* expression in the patients in B cells and liver were the same as in normal control.

Thus, we conclude that the patients affected with ARC syndrome have no mutation in *VPS33B* and there is heterogeneity of the syndrome.

Frontometaphyseal dysplasia: Phenotypic diversity and correlations with mutations in *FLNA*. *S. Robertson, Otopalatodigital Syndrome Spectrum Disorders Clinical Collaborative Group.* Dept Pediatrics, Otago Medical Sch, Dunedin, New Zealand.

The otopalatodigital syndrome spectrum disorders (OPDSD) are a group of phenotypically related conditions characterised by a skeletal dysplasia and variable extra-skeletal malformations. Approximately two thirds of individuals with an OPDSD diagnosis have an identifiable mutation within the X-linked gene *FLNA*, although this proportion differs depending on the diagnosis. Frontometaphyseal dysplasia (FMD), a condition belonging to the OPDSD group, is characterised by a skeletal dysplasia and respiratory tract, cardiac and genitourinary malformations. In contrast to other OPDSDs, mutations underlying this diagnosis are dispersed over more than one mutation hotspot within *FLNA*. We describe the molecular and clinical analysis of 20 individuals with frontometaphyseal dysplasia. Mutations underlying this phenotype were found in 10/22 individuals analysed and were observed to cluster in four hotspots within *FLNA*. Mutations were predicted to lead to amino acid substitutions within the actin binding domain, filamins repeats 9-10, 14-16 and 22-23. Males with typical phenotypes were identified with mutations in the three most 5' hotspots whereas only females have been observed with mutations predicting substitutions near the C-terminus of the protein. In two families with mutations within exon 22 (in addition to one previously reported in the literature with a mutation in exon 29), a severe male perinatal-lethal phenotype was noted. A skeletal dysplasia, cardiac anomalies and ureteric and urethral stenosis were the cardinal components of this phenotype. Markedly skewed X-inactivation patterns were noted in all females with an identifiable *FLNA* mutation, whereas a substantial proportion of females with no such mutation identifiable, including one familial instance, did not demonstrate such skewing. We therefore propose that FMD may exhibit locus heterogeneity.

An Unusual Presentation of Central Ray Deficiency in Manitoba Patients-A Dilemma for Classification. *A.M. Elliott[1], M.H. Reed[1,2,3,4], J.A. Evans[1,3,4].* 1) Department of Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, MB, Canada; 2) Department of Radiology; 3) Department of Pediatrics and Child Health; 4) Children's Hospital, Winnipeg, Manitoba, Canada.

Objective: We performed a clinical epidemiologic study of central ray deficiency (Split Hand Foot Malformation/SHFM, cleft hand/foot) of the Manitoba population. This study was conducted i) to determine the birth rate of SHFM and ii) to perform a classification of patients who met the inclusion criteria.

Methods: One hundred and sixty-four patient files were reviewed. The majority of patients were provided by the Section of Genetics and Metabolism of the Childrens Hospital.

Results and Discussion: In total, 43 patients met the inclusion criteria, resulting in a birth rate of 1 in 19 784. There were 26 females and 17 males. Twenty-nine patients had typical SHFM and 3 had atypical SHFM. There were 11 remaining patients who did not fit neatly into either group and comprised a distinct group, difficult to classify. Within this cohort, we identified 7 patients who had SHFM with extensive cutaneous syndactyly. Various classifications have been proposed for SHFM. Typical versus atypical SHFM was originally differentiated by Lange (1937). Atypical SHFM is usually sporadic and is commonly represented by a deficiency of the three central rays with a web or small nubbins in place of the deficient digits. Typical SHFM usually shows a central V-shaped cleft, more than one limb may be affected and there may be a positive family history. The 7 unclassified Manitoba patients had monomelic involvement, and in all cases it involved an upper limb (2 showed right- and 5 showed left-sided involvement). These 7 patients comprised 16% of our total affected population and represent an intriguing subpopulation. Their phenotype is not representative of either typical or atypical SHFM and has not been well recognized in the literature. We discuss the difficulties with classification and genetic counselling of SHFM patients and emphasize the importance of detailed clinical and radiographic evaluations of these patients and family members.

Expansion of the phenotype of X-linked hypophosphatemic rickets. *A.L. Shanske, J. Neil, M. Markowitz.* Ctr Craniofacial Disorders, Children's Hosp Montefiore, Albert Einstein College of Medicine, Bronx, NY.

X-linked dominant hypophosphatemic rickets (XLH)is the most common form of hereditary rickets.Children exhibit growth retardation,deformities of the lower extremities and radiographic evidence of rickets.In 1995, mutations in the *PHEX* gene on Xp22.2-p22.1 were found to cause XLH.We recently examined a mother and son with XLH with the Chiari malformation, syringomyelia, symmetric multiple craniosynostosis, ricketic radiographic changes and unique bony changes suggestive of a skeletal dysplasia.MG was the 3500 gm product of a term uneventful pregnancy born to unrelated West Indian parents.His mother, maternal grandmother, maternal half-aunt and her 2 sons all have XLH.An MRI at 5 months revealed hydrocephalus and a Chiari I malformation.A diagnsosis of XLH was made at 2 years and he was begun on a regimen of vitamin D and phosphate.His physical examination at 8 years revealed a short stigmatized delayed youngster whose height was 103.3 cm(<5%), weight 21.7 kg (5%), and HC was 52.5 cm (50%).He had turribrachycephaly, frontal bossing,malar flattening and exophthalmos.He had anterior bowing of the distal radii,flexion contractures of the elbows,bowing of the femora and tibia,notching of the inner maleolus,and a waddling gait.He had normal calcium and PTH levels,elevated alkaline phosphatase and depressed phosphate.A 3D CAT scan showed synostosis of all sutures and significant signs of increased intracranial pressure.A renal ultrasound revealed nephrocalcinosis.A skeletal survey showed in addition to ricketic changes and osteomalacia,diffuse metaphyseal fraying and cupping and widening of the physis,generalized platyspondyly and mild endplate sclerosis,pars interarticularis fractures and L4-L5 retrolisthesis.A survey of the literature indicates an incidence of craniosynostosis of 13% and of Chiari malformation of 44% in patients with XLH.Our patients have additional non-rachitic skeletal changes not previously reported.We plan to perform *PHEX* mutation analysis and suspect that although more than 140 mutations in the *PHEX* gene have been identified, a new allele may be found in this family.Alternatively,XLH in this family may be caused by a novel X-linked gene.

The Influence OF Speech And Family History on Mood Symptomatology and Autism Spectrum Disorders. *A.V. Hall[1], R.K. Abramson[1], S.A. Ravan[1], H. Cope[2], J. Gilbert[2], M.L. Cuccaro[2], H.H. Wright[1], M. Pericak-Vance[2].* 1) Dept Neuropsychiatry, Univ South Carolina Sch Med, Columbia, SC; 2) Duke University Center for Human Genetics, Durham, NC.

Objective:To determine if family history of mood disorders and level of language ability impacts parent report of mood symptoms in children with Autism Spectrum Disorders(ASD). **Design/Methods**:Subjects were drawn from a genetic study of ASD,(n=187 Autistic Disorder(AD); n=46 Aspergers Disorder(AS)). Diagnoses were confirmed by medical records, clinical evaluation, the Aspergers Syndrome Diagnostic Scale and the ADI-R. ADI-R Question 19 was used to group by level of language. The variables were sleep problems and family history of mood disorder from the research chart, and Hyperactivity(ABC-H),Irritability(ABC-I), and Inappropriate Speech(ABC-IS)subscale scores from the parent completed Aberrant Behavior Checklist-Community(ABC-C). AD and AS group analyses were performed separately. **Results and Conclusions**: *AD Group*: Using Discriminant Function Analysis(DFA), sleep difficulties, ABC-H and ABC-I scores were combined to create a new factor of irritable mood symptoms(IMS). Factor loadings were: ABC-I=.588, ABC-H=-.157, and sleep difficulties=.156. There was no main effect for family history with 2x2 ANOVA. There was a significant main effect for speech ($F(1,186)=9.0869$, $p=.003$). These findings suggest parents rate verbal children with AD higher on the IMS factor than nonverbal children, and speech is important in parents ability to recognize mood symptoms. *ASD Group*: Using DFA, sleep difficulties, the ABC-H and ABC-I scores, and two questions from the ABC-IS scale on the ABC-C were combined to create a new factor of mood related symptoms (MRS). The factor loadings were: ABC-H=.915, ABC-I=.721, ABC-IS=.678 and sleep difficulties=.405. There was a significant main effect for family history by one-way ANOVA ($F(1,45)=4.487$, $p=.04$). Children with ASD and a family history of mood disorders may be at a higher risk of having mood related symptoms than those children without a family history of mood disorders. Further investigation of the potential role for mood symptoms in ASD is needed.

Lissencephaly with marked pontocerebellar hypoplasia: clinical and molecular analysis of two affected sisters. *N. Ishihara[1,2], K. Yamada[2], Y. Yamada[2], Y. Okumura[3], M. Futamura[3], N. Wakamatsu[2].* 1) Deparment of Pediatrics, Kamo Hospital, Toyota, Aichi, Japan; 2) Department of Genetics, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Aichi, Japan; 3) Department of Neonatology, Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan.

Lissencephaly is a group of clinically and genetically heterogeneous brain malformations characterized by a smooth cerebellar surface and agyria with or without pachygyria. Here, we present two affected sisters with a rare type of lissencephaly accompanied by marked pontocerebellar hypoplasia. One patient was a Japanese female born from healthy non-consanguineous parents. She was born at 39 weeks and 5 days gestation without any complications. At birth, her weight was 2936 grams and she had microcephaly (head circumference was 29.5 cm). Her APGAR score was 9 after 1 minute. When she was transferred to our hospital, myoclonus was observed in her face and body. Multifocal partial seizures occurred frequently, which were uncontrollable with anticonvulsants. She died 41 days after birth. The other patient was her sister born at 37 weeks and 6 days gestation. She also presented with a similar clinical course and died 36 days after birth. Brain CT and MRI of both patients showed lissencephaly without thickening of the cortical gray matter and severe pontocerebellar hypoplasia, but the cerebral atrophy was more severe in the younger patient. They also had ocular nerve atrophy. The high-resolution G-banded karyotype of both patients was normal. We performed a Southern blot analysis using cDNA of known causal genes of lissencephaly, such as *LIS1* and *RELN*, as probes but no deletion was found in either case. Sequence analysis of all exons and exon/intron boundaries of *RELN*, *DAB1* and *POMT1* revealed no gene mutations. These results indicate that the disease was likely caused by the mutation of a gene not yet identified as a cause of lissencephaly.

Autosomal Recessive Lower Motor Neuron Disease with Childhood Onset: Clinical study and genetic mapping to chromosome 1p36.3 in an African family. *I. Maystadt[1], D. Leclair-Richard[2], B. Estournet[2], A. Barois[2], F. Renault[3], M.C. Routon[4], M.C. Durand[5], A. Munnich[6], C. Verellen-Dumoulin[2], L. Viollet[2,6].* 1) Centre de Génétique Humaine, Université Catholique Louvain, Bruxelles, Belgium; 2) Service de Neuropédiatrie, Hôpital Raymond Poincaré, Garches, France; 3) Service d'Explorations Fonctionnelles, Hôpital Trousseau, Paris, France; 4) Service de Neuropédiatrie, Hôpital Saint Vincent de Paul, Paris, France; 5) Service d'Explorations Fonctionnelles, Hôpital Raymond Poincaré, Garches, France; 6) INSERM U393. Génétique Médicale, Hôpital Necker Enfants Malades, Paris, France.

Lower Motor Neuron diseases (LMND) form a wide spectrum of rare sporadic and hereditary neuromuscular disorders, characterized by progressive degeneration of the motor neurons of the spinal cord. We reported here the clinical picture of a severe familial childhood onset LMND in a large inbred African pedigree, with autosomal recessive inheritance. First symptoms occurred at the age of 2 to 3,5 years. At the age of 5 years, most of the patients presented a real Gowers sign, a symmetrical atrophy of scapular muscles, bilateral equinus feet and retracted fingers Facial muscles were preserved. All tendon reflexes were abolished and diagnosis of motor neuron disease was suspected on neurological assays, showing muscle denervation with normal motor and sensory nerve conduction velocities. Conversely to classical childhood onset spinal muscular atrophies, no predominance of weakness between proximal and distal muscles was noted. The generalized muscle atrophy rapidly worsened and walking ability was lost at the age of 7,5 to 8,5 years. Severe scoliosis with hyperlordosis occurred during childhood and respiratory function progressively decreased, requiring assisted ventilation by tracheotomy at the age of 15 to 17 years. Genetic analysis in this pedigree allowed us to exclude the SMN gene (5q13.3) and to map the causing mutation in a 3,9 centimorgan interval between loci D1S508 and D1S2633 on chromosome 1p36.3 (Zmax=3,79 at locus D1S253). This study broadens the spectrum of hereditary childhood onset LMNDs and opens the way towards the identification of a novel gene involved in motor neuron degeneration.

Meckel-Gruber syndrome in a fetal case with a 1p35-pter deletion and a 14q32-qter duplication inherited from a maternal balanced translocation. *C. Thauvin-Robinet[1], P. Callier[2], N. Laurent[3], N. Marle[2], T. Rousseau[4], P. Sagot[4], F. Huet[1], L. Faivre[1], F. Mugneret[2].* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Laboratoire de Cytogenetique, CHU Le Bocage, Dijon, France; 3) Laboratoire d'Anatomie-Pathologie, CHU Le Bocage, Dijon, France; 4) Maternite, CHU Dijon, France.

Meckel-Gruber syndrome is an autosomal recessive disorder characterized by a combination of renal cysts and variably associated features including developmental anomalies of the central nervous system (typically occipital meningoencephalocele), hepatic ductal dysplasia and cysts, and polydactyly (postaxial in most cases). Additional anomalies (microphtalmia, cleft palate, ear defects, cardiac, intestinal, and genital anomalies) are frequent. In few cases, there is a only a binary combination of either encephalocele or polydactyly with polycystic kidneys. Genetic heterogeneity has been demonstrated by the identification of three loci on chromosomes 8q24, 11q13 and 17q21-24. We report on a fetal case (15 WG) with cleft palate, encephalocele, bilateral club feet, enlarged bladder and multicystic kidneys, compatible with Meckel-Gruber syndrome. Liver histology could not be studied because of autolysis. Fetal chromosome analysis showed a maternally inherited unbalanced translocation between the short arm of chromosome 1 and the long arm of chromosome 14, resulting in 1p35-pter deletion and 14q32-qter duplication (46,XY,der(1),t(1;14)(p35,q32). Since chromosomal breakpoints have not been previously implicated in Meckel-Gruber syndrome, this observation would be interesting for the identification of other genes responsible for Mecker-Gruber syndrome or encephalocele.

Psychiatric phenotype in Triple X Syndrome. *O. Caluseriu[1,2], E.W.C. Chow[2,3], A.S. Bassett[2,3].* 1) Dept Genetics & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) University of Toronto, Toronto, ON, Canada.

Triple X Syndrome is a chromosomal abnormality with a variable pattern of CNS involvement including learning difficulties and psychiatric illness in adults (Harmon, 1998). Psychotic features are not considered part of the phenotype, although sex chromosome anomalies may have an increased prevalence in schizophrenia (SZ) (Bassett et al, 2000). We present two adult women with Triple X Syndrome and psychosis: one with full syndrome and one mosaic. Patient 1, was 31 y old, of Caucasian origin, ambidextrous, with minimal physical anomalies and history of ventricular septal defect, atrial septal defect, patent ductus arteriosus, delayed puberty, hypothyroidism, ovarian cysts, learning disabilities, alcohol and drug abuse. She had a history of psychotic symptoms (visual and auditory hallucinations) starting at age 10 y, and later onset of depression and self-injurious behavior. She was formally diagnosed with schizoaffective disorder and treated at age 28 y. The karyotype was 47, XXX and FISH for 22q11.2 deletion was negative. Patient 2, was 43 y old, of Chinese origin, with asymmetric face, borderline MR and dysarthria. She was diagnosed with SZ at age 25 y. She had no history of seizures although EEG suggested subcortical white and cortical grey matter dysfunction in both lateral fronto-temporal areas. The karyotype showed 47, XXX [33]/46, XX [23] in lymphocytes and a ratio 1:3 in favour of the triploid line from buccal swab. A possible association between schizophrenia and sex chromosome aneuploidies is difficult to interpret given the random pattern of X inactivation and mosaicism. Genetic variation (e.g., HOPA polymorphisms), imprinting disruption (Latham, 2005), gene dosage effects and molecular regulatory processes affecting gene expression (Birchler et al, 2005) are possible mechanisms for the implication of sex chromosomes aneuploidies in the susceptibility to SZ.

Angelman syndrome from infancy to old age. *M. Philippart[1], B. Minassian[2].* 1) Semel Institute for Neuroscience and Human Behavior, Mental Retardation Research Center, UCLA, David Geffen School of Medicine, NPI C9-848,760 Testwood Plaza, Los Angeles, CA.90024-1759; 2) The Hospital for Sick Children, University of Toronto, 555 University Ave, Rm 6536B, Toronto ON M5G 1X8 Canada.

Twenty cases (14 females, 6 males, aged 2 to 74 years) of Angelman syndrome were followed for an average of 10 years (1-21). Thirteen had 15q11-13 deletions, 2 uniparental disomy, 2 UBE3A mutation, one inverted dup (15) marker, and two no anomalies. Psychomotor level was around 8-15 months, stable for up to 40 years. CT scans were normal in 8; 3 had mild ventriculomegaly and 3 cerebellar atrophy. The youngest were overweight. Behavior problems were uncommon. Seizures first occurred from 1 to 3 years of age. The oldest patient (15q11-13 deletion case) never had seizures. CCTV-EEG telemetry revealed epileptiform discharges in three who had normal EEGs, never had clinical seizures. Most had 1.5 to 2.5 Hz spike and waves. Most were tried on multiple AEDs. While Valproate was sometimes effective it caused problems in water balance, plasma albumin and osmolality, low blood glucose, without identified endocrine anomalies. Two developed heart failure with cardiomegaly. The younger children resembled Rett syndrome without failure to thrive and Prader-Willi with less hypotonia. Their exuberant personality was a main asset, leading to overestimation of social skills and tolerance of hyperactivity. Hand function was limited to simple manipulations; none could perform a 2-step command. Tremor was common. Ambulation remained precarious until age 61 in one and was lost in many older patients. Dystonia was minimal before middle age; 2 had Parkinsonism precipitated by Metoclopramide. Gastrointestinal problems were common. Happiness is the hallmark recognized by Angelman. Exuberance better describes their emotional state, giving them a drive to cope without the usual behavior difficulties commonly associated with mental retardation. The term puppet alluded to motor immaturity at the toddler level, the highest milestone attained in these patients. Clinical variability is wide within a narrow range of developmental skills throughout life.

A Japanese case of novel immunodeficiency-malformation syndrome. *N. Norimatsu[1], T. Kondoh[1], Y. Uehara[2], N. Miyake[1], M. Moriuchi[1], N. Tominaga[1], K. Tsuruda[3], H. Kanegane[4], K. Tashiro[5], S. Kamihira[3], H. Moriuchi[1].* 1) Depts of Pediatr, Nagasaki Univ Hosp, Nagasaki, Japan; 2) Dept of Pediatr, Nagasaki Memorial Hosp, Nagasaki, Japan; 3) Dept of Lab Med, Nagasaki Univ Hosp, Nagasaki, Japan; 4) Dept of Pediatr, Toyama Med Pharm Univ, Toyama, Japan; 5) Ctr for Mol Biol Genet, Kyoto Univ, Kyoto, Japan.

Congenital immunodeficiencies are occasionally associated with abnormalities in other organ systems. We here report a novel immunodeficiency and multiple anomalies in a 15-year-old Japanese boy. At birth, his brain computed tomography did not show any abnormality, and height, weight and head circumference were normal, but he developed severe and progressive growth retardation and microcephaly thereafter. Since 18 months old, he has had recurrent respiratory and skin infections. He underwent left lung resection because of refractory infection at 10 years of age. The histological study of the hilar lymph nodes revealed the absence of B-lymphocytes and primary/secondary follicle formation. Flow cytometric analyses revealed markedly reduced CD19+ cells in the peripheral blood in contrast with substantial number of CD19+ cells in the bone marrow. In addition to severe short stature and microcephaly described above, he also had multiple anomalies such as characteristic facies, multiple arythrogryposis, severe mental retardation, epilepsy, progressive brain atrophy, congenital bilateral cataract, progressive optic nerve atrophy, retinitis pigmentosa, Fanconi syndrome, micropenis, severe osteoporosis, and prolonged reaction of primary teeth. His chromosomal tests revealed normal karyotype, 46, XY. FISH analysis in 22q11.2 and OCLS regions as well as sequencing of his BTK, Oct-2 and OBF-1 genes revealed no abnormality. Functional expression of CXCR4 and SDF-1 was normal. Our case is clearly distinct from immunodeficiency-malformation syndromes previously reported, particularly in B-cell defect characterized by a lack of recruitment of mature B cells from the BM to periphery, as well as a combination of systemic involvement. We are currently investigating molecular mechanisms of the pathogenesis of this patient.

Correlation of phenotype and expression of four genes between breakpoints BP1 and BP2 in Prader-Willi syndrome. *M.G. Butler, N. Kibiryeva, D.C. Bittel.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is a genetic disorder that results from loss of paternally expressed genes from the 15q11-q13 region. The major features include hypotonia, mental deficiency, behavior problems, hypogonadism and hyperphagia leading to obesity. A paternal 15q11-q13 deletion is found in about 70% of PWS subjects, maternal disomy 15 (UPD) in 25% and an imprinting defect in 3%. The typical deletion is classified as Type I (TI) or Type II (TII) depending on involvement of two proximal breakpoints (BP1 or BP2). The TI deletion involving BP1 is 500 kb larger than the TII deletion involving BP2. We previously reported that TI individuals generally had a more severe phenotype compared with TII or UPD subjects, such as greater self-injury and obsessive-compulsive behavior, deficits in adaptive behavior, reduced reading and math skills and poorer visual integration. Four genes (*NIPA1, NIPA2, GCP5, CYFIP1*) located between BP1 and BP2 are deleted in TI individuals and implicated in poorer outcomes. We examined the expression of these genes by quantitative RT-PCR in eight TI PWS subjects (4 male, 4 female) and nine TII PWS subjects (3 male, 6 female) and found reduced but detectable expression in TI compared to TII subjects supporting biallelic expression. Correlations between gene expression C_T values and multiple behavioral, cognitive and visual integration measurements showed overlapping correlations of expression levels specifically with *NIPA2* [e.g., significant positive correlations between *NIPA2* expression and: adaptive behavior (SIB social interaction and communication index, $r = 0.83$, $p < 0.001$); cognitive ability (Woodcock-Johnson reading and math clusters: $r = 0.57$, $p = 0.02$ and $r = 0.58$, $p = 0.02$, respectively); visual-motor integration (VMI raw and standard scores, $r = 0.61$, $p = 0.01$ and $r = 0.65$, $p = 0.007$, respectively)]. *NIPA2* is conserved in vertebrates and widely expressed with transmembrane domains suggesting receptor or transporter function. Our data suggest that *NIPA2* may be important in influencing neurodevelopment and function deserving further study.

A Controlled Family Study of Attention Deficit Hyperactivity Disorder and Gilles de la Tourettes Syndrome. *E. Stewart[1], C. Illmann[1], D. Geller[1], J. Leckman[2], R. King[2], D. Pauls[1].* 1) Psychiatry, Harvard Medical School, Charlestown, MA; 2) Psychiatry, Yale University, New Haven, CT.

Objective: Although ADHD is commonly comorbid with GTS, it is unclear whether these disorders have a common genetic etiology. This study examines familial relationships between DSM-IV GTS and ADHD in mutually-exclusive groups of GTS+ADHD, GTS-only, ADHD-only and controls. **Method:** This was a direct-interview, case-control family study of 692 first-degree biological relatives of 75 GTS+ADHD, 74 GTS-only, 41 ADHD-only and 49 control probands. Age-corrected prevalence rates, odds ratios and comorbidity patterns of GTS, ADHD and OCD among relatives were estimated from blinded best-estimate diagnoses. **Results:** GTS and ADHD were more prevalent among relatives of probands with those specific disorders versus control relatives (p0.001). In the GTS-only group, although ADHD occurred at higher than control rates (p=0.03), ADHD-GTS in relatives (p=0.82) was not increased. In the ADHD-only group, GTS-ADHD was not increased (p=0.18). ADHD+GTS rates in relatives were elevated in all case groups (p0.03). Comorbid GTS predicted ADHD in relatives (p<0.001), comorbid ADHD predicted GTS in relatives (p<0.001) and comorbid OCD predicted both ADHD (p=0.002) and GTS (p<0.001) in relatives. **Conclusions:** Relatives of individuals with either ADHD or GTS are at increased risk for those same disorders in addition to comorbid ADHD+GTS. In familial forms of ADHD and GTS, their comorbid presence among relatives appears to be etiologically related rather than coincidental. However, the rates of GTS and ADHD alone are not consistent with the hypothesis that the same etiologic factors are acting in both disorders. Comorbid OCD may be a useful marker of ADHD cases related to GTS.

Microarray analysis in a second reported case of 18p11.2 monosomy in a psychotic patient. *C.M. Drazinic[1], B.A. Pletcher[3], H. Zheng[1], M.W. State[1,2].* 1) Child Study Center, Yale University, New Haven, CT; 2) Department of Genetics, Yale University, New Haven, CT; 3) Center for Human and Molecular Genetics, UMDNJ-New Jersey Medical School, Newark, NJ.

Microarrays provide an efficient way to map breakpoints in patients with chromosomal copy number abnormalities. In a recent report, microarrays were used to map 18p11.23 monosomy and 5p14.1 trisomy breakpoints in a female with dysmorphic features, short stature, mental retardation, and psychosis (Drazinic et al., 2005). Here we describe a second female with isolated 18p monosomy, who also presents with dysmorphic features, short stature, mental retardation, and psychosis. The patient's genomic DNA was analyzed using a GeneChip Human 50K XbaI 240 Array (Affymetrix), consisting of 58,960 single nucleotide polymorphism (SNP) probes with an average spacing of 46.5 kilobases. Fluorescence in situ hybridization (FISH) confirmed the deletion, using probes from bacterial artificial chromosomes (BAC's) of an RP-11 library. The patient's G-banded karyotype was read as 46, XX, del(18)(p11.2), with a deletion similar to the 18p monosomy derivative chromosome described in the previous report. Using the 50K SNP array, the 18p deletion breakpoint in this case mapped telomeric to the 14.9 megabase position, in band 18p11.21 (May 2004 freeze; http:genome.ucsc.edu). This breakpoint maps approximately 0.5 Mb away from the centromeric band 18p11.1, which begins at 15.4 Mb (May 2004 freeze; http:genome.ucsc.edu). While microarrays can be used to rapidly approximate the breakpoints in patients with unbalanced karyotypic abnormalities, these cytogenetic variations need to be confirmed with alternative methods such as FISH. Case reports and linkage analyses have implicated the short arm of chromosome 18 in patients with psychosis. The presence of two independent cases with both 18p11.2 monosomy and psychosis suggests that further investigations need to be conducted to determine the relative contributions of candidate genes on 18p to the psychosis phenotype.

Natural History of Aicardi Syndrome. *V.R. Sutton[1], M.A.K Glasmacher[2], T.N. Eble[1], B.J. Hopkins[1], R.A. Lewis[1], D. Park Parsons[2], I.B. Van den Veyver[1].* 1) Baylor College of Medicine, Houston, TX; 2) Aicardi Syndrome Newsletter, Louisville, KY.

Aicardi syndrome is a rare neurodevelopmental disorder characterized by agenesis of the corpus callosum, other developmental brain abnormalities, chorioretinal lacunae and severe seizures. Current clinical knowledge is derived from small case series that focus on these major defects. A detailed questionnaire covering information on general health, organ systems and family history was sent to 216 families of children with Aicardi syndrome to expand our knowledge of this disorder and to uncover previously unrecognized features of Aicardi syndrome. Of the 80 completed returned surveys, 75 met inclusion criteria and were further analyzed. The ages of children with Aicardi syndrome ranged from 5 months to 32 years (mean: 86 months). There was one boy with a 47,XXY karyotype, all others were girls. The growth in Aicardi syndrome is normal during early childhood and slows between ages 7 (weight) and 9 (height) with final weight and height reaching a mean at the 5th centile with a normal body mass index (BMI). Growth curves superimposed on standard CDC growth curves were constructed and will be presented. A Kaplan-Meier survival curve is presented and reveals the median age of survival was 18.5 years, which is more favorable than previously reported. We confirmed the high prevalence of chorioretinal lacunae (96%), agenesis of the corpus callosum (95%) and severe complex seizures (99%). There was a wide variety of seizure types and seizures were generally very difficult to control with a large range of medications and therapies having been tried. Vigabatrin or a vagus nerve stimulator provided the most satisfactory seizure control although most individuals were on multiple medications and no antiepileptic monotherapy was clearly the best treatment. The most common complication after seizures was gastrointestinal dysfunction, present in >90%. The results from this survey contribute new information on Aicardi syndrome that will benefit clinical management and patient counseling. The collected data are also of value for phenotype-driven research towards its underlying cause.

Candidate gene analysis in 4 families with CDAGS syndrome (craniosynostosis, delayed fontanel closure, cranial defects, anal and genital anomalies and skin eruption) mapping to chromosome 22q. *R. Mendoza-Londono[1, 2], D.A. Scott[1], E. Lammer[3], R. Watson[4], A. Hatamochi[5], D. Napierala[6], P. Hermanns[1], B.B. Roa[1], M.R. Hegde[1], D.W. Stockton[1], B. Lee[1, 6].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Childrens Hospital Research Institute, Oakland, CA; 4) Our Ladys Hospital for Sick Children Crumlin, Dublin, Ireland; 5) Dept. of Dermatology, Dokkyo University School of Medicine, Japan; 6) Howard Hughes Medical Institute, BCM, TX.

CDAGS syndrome is a rare genetic condition characterized by craniosynostosis, delayed closure of the fontanel, cranial defects, clavicular hypoplasia, anal and genitourinary malformations and skin eruption. We have identified 7 patients in 4 families from different geographic regions and ethnic backgrounds with this phenotype. This is an autosomal recessive condition that brings together apparently opposing pathophysiologic and developmental processes, including accelerated suture closure and delayed ossification. Selected candidate genes including RUNX2, CBFB, MSX2, ALX4, TWIST1, and RECQL4 were screened for mutations by direct sequencing of their coding regions, and for microdeletions by FISH. No mutations or microdeletions were detected in any of the genes analyzed. A genome wide screen yielded the maximum estimated LOD score of +2.38 for markers D22S283 and D22S274 on chromosome 22q12-q13. Expression microarray analysis was used to identify candidates for differentially expressed genes between fibroblast from affected individuals compared to normal controls. Genes located in the area of linkage that were significantly down regulated were sequenced. To date we have excluded mutations in the coding regions of RBM9, DDX17 and ATF4. We hypothesize that the gene defect in CDAGS exerts novel context-dependent regulation of multiple signaling pathways, including RUNX2 during osteoblast differentiation and craniofacial morphogenesis.

Hereditary neuropathy with liability to pressure palsies: clinical manifestations do not fit the name. *M. Sabatelli[1], M. Zollino[2], M.L. Mereu[1], F. Madia[1], A. Conte[1], G. Loria[1], R. Lecce[2], G. Neri[2], P. Tonali[1].* 1) Neurologic Institute, Catholic University, Rome, Italy; 2) Medical Genetics Institute, Catholic University, Rome, Italy.

Hereditary neuropathy with liability to pressure palsies (HNPP) is an autosomal dominantly inherited disease of peripheral nerves associated with a 1.5-megabase deletion on chromosome 17p11.2-12 containing the PMP22 gene. Recurrent mononeuropathies manifesting as transient episodes of weakness or sensory loss, often preceded by minor trauma, are considered the clinical hallmark of this condition. However a minority of patients have been described disclosing atypical phenotypical pictures, including symmetric chronic polyneuropathy, brachial plexopathies, Guillain-Barrè syndrome, chronic mononeuropathies. With the purpose of characterizing the phenotype of HNPP we evaluated both the clinical picture and neurophysiological findings in 34 patients from 24 unrelated families, disclosing chromosome 17p11.2-12 deletion. A total of 11 patients (32%) presented with classic episodes of transient mononeuropathy related to trivial nerve trauma. In the remaining 23 patients (68%) the clinical picture was different, including chronic mononeuropathy (4 carpal tunnel syndrome and 5 ulnar compression at the elbow) in 9 patients, a Charcot-Marie-Tooth phenotype in 7, a Guillain-Barrè-like pattern in one patient, chronic sensory polyneuropathy in 2. One patient presented with generalized weakness, another one with acute recurrent brachial plexopathy. The last 2 patients were asymptomatic. In all patients electrophysiological studies showed generalized neuropathy with moderately slowed conduction velocities, more obvious over entrapment sites. Our data show that the neurological phenotype associated with 17p11.2 deletion is very heterogeneous and that classic recurrent focal neuropathy, largely accepted as distinctive of this condition, is not the most frequent clinical presentation. Peculiar electrophysiological findings appear to be more reliable than clinical examination for selection of patients to be tested genetically.

Neurofibromatosis -1 is associated with a high incidence of migraine in both sexes. *K. Gardner[1,2], C. Roche[2], P. Duzenli[2], M. Amjhad[2], A. Goldstein[2], G. Alper[2], C. Kammerer[3].* 1) Dept Neurology, Veteran's Administration Pittsburgh Healthcare System; 2) Dept Neurology, Children's Hospital of Pittsburgh; 3) Dept Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Background: Headache (HA) is a well-recognized complaint in NF1 patients. Prior studies conflict regarding frequency of HA's in Neurofibromatosis 1 (NF1). One study suggested a reverse incidence of migraine with aura (MA) and migraine without aura (MOA) and more tension than migraine. Another study suggested a lower than expected incidence of all headache types; both studies used modified 1988 International Headache Society (ICHD-I) diagnostic criteria for HA and/or relied partially on questionnaires. Methods: We evaluated 70 probands and 88 total subjects from an NF clinic and confirmed NF1 diagnosis using the 1997 NIH consensus criteria. We used a structured, validated interview to note all headache features and types according to ICHD-I criteria. General and neurological exams, scans, and medical records were reviewed to identify nonprimary headache causes with questionnaire for headache triggers, etc. Results: Fifty-six percent (0.560.05) of probands (24/43 females and 15/27 males, p>0.95 sex difference) had migraine compared to a general population prevalence 16.5% while 19 percent (8/43 females and 5/27 males) had migrainous headache not meeting criteria, I.H.S. 1.7. Eighteen females and 8 males had episodic tension (TN) with one or more migrainous features and only 5 females and 1 male had typical episodic TN. There were 20 females and 9 males with 1 HA type, 14 females and 10 males with 2 HA types, 5 females and 3 males with 3 HA types, 2 females and 1 male with 4 HA types, 2 females with 5 HA types. Overall 34 percent had MOA (10 males, 14 females) and 20 percent had MA (4 males, 10 females) as their most severe HA. Females had 3 and males 1 secondary headache, not all tumor related. Conclusion: Migraine prevalence is higher than expected and equal in both sexes among NF1 clinic patients compared to general population prevalence studies. Multiple headache types are common and most have one or more migrainous features, including those meeting criteria for episodic tension.

Macrocephaly-cutis marmorata telangiectatica congenita: Further delineation of a clinically distinctive overgrowth syndrome. *J.T.C. Shieh, H.E. Hoyme.* Division of Medical Genetics, Department of Pediatrics, Stanford University, Stanford, CA.

Macrocephaly-cutis marmorata telangiectatica congenita (M-CMTC, OMIM 602501) is a syndrome characterized by macrocephaly, overgrowth, cutis marmorata, facial nevus flammeus, syndactyly or polydactyly, and hydrocephalus. We describe a patient with the key features of M-CMTC who has linear ear creases and an adrenal mass. The patient was born at 39 weeks gestation with a head circumference of 37cm and weight of 3685g. In the newborn period, mottling of the extremities prompted an echocardiogram and a head CT scan, both of which were unrevealing. At 2 months of age, the patient was referred for genetics evaluation for facial angiomata. She had macrocephaly, cutis marmorata, bilateral linear ear creases, facial dysmorphism, and hypotonia. A faint reticular purplish patch was present on the right half of the face, and hemangiomas were present on the back. At 5 months of age, an MRI revealed hydrocephalus and CSF shunting was performed. Additional findings included small hands, loose skin and lower extremity asymmetry. A diagnosis of M-CMTC was made. Because of a potential risk of malignancy in this overgrowth syndrome, the patient underwent screening abdominal ultrasounds, and a soft tissue mass was detected. Subsequent MRI demonstrated an adrenal mass that is currently being investigated. M-CMTC is of unclear etiology and pathogenesis. In the index patient, high resolution chromosome analysis and FISH for subtelomeric rearrangements were normal. Methylation analysis of H19 and LIT1 were unremarkable. FISH for NSD1 deletion was normal. M-CMTC is a clinically distinctive disorder, and the presence of linear ear creases contributes a new finding to the M-CMTC phenotype. Our case supports the need for patients with M-CMTC to be screened for potential malignancies. Further studies, however, are needed to elucidate the genetic etiology underlying this disorder.

Cognitive and language deficits among children with chronic neuronopathic Gaucher disease. *R. Schiffmann[1], O. Goker-Alpan[2,3], E. Wiggs[1], M. Eblan[2,3], E. Sidransky[2,3].* 1) DMNB/NINDS, NIH, Bethesda, MD; 2) NSB/NIMH, NIH, Bethesda, MD; 3) MGB/NHGRI, Bethesda, MD.

The advent of enzyme replacement therapy (ERT) has decreased mortality and morbidity in Gaucher disease(GD). Although ERT has resulted in fewer systemic complications, neurologic involvement is not impacted. Chronic neuronopathic (type 3) GD presents with diverse neurologic features between infancy and early childhood. We reviewed cognitive and speech testing in 32 children with type 3 GD on ERT. Diagnostic screening for mutations identified L444P/L444P as the most common genotype, and other mutations included G377S, N188S, and recombinant alleles. Wechsler Intelligence Scales demonstrated discrepancies between verbal and full scale IQ/DQ, with higher verbal IQ scores and weaknesses in processing speed, visual-spatial and perceptual organization skills. This gap increased upon sequential testing, with more gains in verbal areas. Despite relative verbal strengths, speech delays, especially expressive, frequently occurred. More than 60% of subjects had below average intellectual skills, and 13% had severe impairment. The degree of intellectual deficits concurred with neurologic involvement, and patients with recurrent seizures and ataxia received the lowest scores. Cognitive decline occurred in four with myoclonic epilepsy, and two were diagnosed with autism. On ERT, the systemic manifestations were usually mild, and no correlation was observed between the IQ scores and residual enzyme activity or genotype. While cognitive and speech problems are common in children with type 3 GD, the degree of impairment may be under-recognized, as the deficits are often compensated by verbal strengths. The visual-spatial weaknesses and cases of autism may correlate with the known hippocampal and parietal cortex involvement in GD. Neurodevelopmental screening should be part of routine medical care in GD, and remediation strategies for these patients might focus on their verbal strengths.

SCA17 in Italy: A molecular study in a large cohort of familial and sporadic ataxic patients. *C. Gellera[1], R. Fancellu[1], A. Castucci[1], G. Giaccone[2], P. Soliveri[3], F. Taroni[1], S. Di Donato[1], C. Mariotti[1].* 1) Dept. of Biochemistry & Genetics, Istituto Neurologico Besta, Milano, Italy; 2) Dept. of Neuropathology, Istiuto Neurologico Besta, Milano, Italy; 3) Dept. of Neurology, Istituto neurologico Besta, Milano, Italy.

Autosomal dominant spinocerebellar ataxias (ADCAs) are a heterogeneous group of neurodegenerative disorders characterized by progressive cerebellar ataxia associated with other neurological features. At present, more than twenty SCA (spinocerebellar ataxia) loci have been identified and twelve disease-genes. In 7 disease-genes the molecular lesion is an expanded CAG repeat sequence within the coding region. SCA17 is caused by a CAG/CAA expansion in the gene encoding the TATA-binding protein (TBP). We screened for SCA17 expansion 174 subjects with cerebellar ataxia, including 34 sporadic and 140 familial cases. The cases presenting an autosomal dominant trait (n=96), repeat expansions in the SCA1, 2, 3, 6, 7 have been excluded. An additional group of 79 subjects with suspected Huntington disease, who were negative at the molecular test has also been screened. Expanded allels with >= 45 CAG repeats were found in 11 affected individuals and in three presymptomatic subjects from 7 unrelated Italian families. Two patients were sporadic cases, four patients (2 families) had familial spinocerebellar ataxia, while 5 patients (3 families) had positive family history for movement disorder. Eight out of 14 subjects carried 45 CAG repeats, one patient carried 46 repeats, while 5/11 individuals had expansions larger than 50 repeats. All mutated subjects in each family carried the same size of CAG expansion, that resulted stable during parent to offspring transmissions. In our patients the age at onset ranged from 19 to 55 years. In 4/11 patients, the onset was characterized by cerebellar gait ataxia and limb incoordination, while in the remaining cases, the onset was characterized by behavioral disturbances, psychosis or mild choreic movements. Our data confirm that CAG expansion in the TBP gene can be associated with variable clinical features ranging from Huntington disease-like phenotype to familial spinocerebellar ataxia.

Clinical and molecular correlations in FXTAS. *F. Tassone[1], C. Greco[2], R. Berman[3], R.M. Martin[3], P.H. Schwartz[4], E.J. Becker[1], J. Papazian[5], S. Bacalman[5], L. Li[1], R.J. Hagerman[5], P.J. Hagerman[1].* 1) Department of Biochemistry and Molecular Medicine, University of California, Davis, School of Medicine, Davis, CA; 2) Department of Pathology, University of California, Davis, Medical Center, Sacramento, CA; 3))Department of Neurosurgery, University of California, Davis, School of Medicine, Davis, CA; 4) Childrens Hospital of Orange County Research Institute, Orange, CA; 5) M.I.N.D. Institute, University of California, Davis, School of Medicine, Davis, CA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurological condition, characterized by intention tremor, gait ataxia, parkinsonism, and cognitive decline. Brain imaging reveals generalized brain atrophy and white matter disease, particularly involving the middle cerebellar peduncles (MCP). Global cerebral atrophy, marked Purkinje cell dropout, and the presence of ubiquitin-positive neural intranuclear inclusions represent the main neuropathological features of FXTAS. Although it is clear that FXTAS is associated with premutation alleles, the precise relationship between the disease manifestations and the size of the repeat is not known. To address this issue, we have studied the association between CGG repeat number, FMR1 mRNA levels, and several clinical measures, including age of onset of symptoms, of ataxia, and of tremor, in a group of 38 male premutation carriers (mean age 59.4 6.6 year) affected by FXTAS. Statistical analysis showed a significant association between the number of CGG repeats and age of onset of symptoms (p=0.02), although no association was observed between age of onset of symptoms and FMR1 mRNA levels. Neuropathological studies, based on 11 males who died with FXTAS, showed a strikingly significant correlation (p0.01) between the number of intranuclear inclusions and the number of CGG repeats in several brain regions, including cortical gray matter and hippocampus. A significant correlation was also found between increasing number of CGG repeats and decrease in age of death (p0.01). Our findings suggest a role of the CGG repeat expansion as a prognostic indicator of both clinical and neuropathological involvement in FXTAS.

Pre- and post-natal imaging of familial primary microcephaly with simplified gyral pattern and tentative linkage to *ASPM* (MCPH5). *M. Abramowicz[1], M. Cassart[2], C. Donner[3], P. Van Bogaert[4], J. Desir[1].* 1) Dept Genetics, Hosp Erasme - ULB; 2) Dept Radiology, Hosp Erasme - ULB; 3) Dept Obstetrics & Gynecology, Hosp Erasme - ULB; 4) Dept Pediatric Neurology, Hosp Erasme - ULB, Free University of Brussels, Belgium.

Autosomal recessive primary microcephaly (MCPH) is characterized by a congenitally small but normally formed brain, and nonprogressive mild-to-moderate mental retardation. It is genetically heterogeneous with at least seven loci, and four genes identified so far. It is unclear whether the phenotype described as primary microcephaly with simplified gyral pattern relates to mutations of the same genes as MCPH. We report on a consanguineous family of Morroccan origin who consulted during a second pregnancy for microcephaly detected at 26 weeks gestation. The first child, a girl aged 5 years, presented MCPH with a head circumference at -7SD, a normal physical examination, a normal psychomotor development, and a hyperactive behavior with moderate mental retardation. She had had two episodes of seizures in the past which were not treated. MRI of the brain showed a simplified gyral pattern with a clear anterior > posterior gradient, where the frontal lobes were small and squared-off. The fetus, a male, had two serial brain MRIs in utero which showed short and hypoplastic frontal lobes as in the proband sister, with diffuse albeit anterior > posterior simplification of the gyral pattern. At birth his HC was 31 cm, with an otherwise normal physical and neurological examination. A third, postnatal MRI showed persistance of the same brain anomaly. Microsatellite markers of the *ASPM* locus were found homozygous and concordant in both sibs, with no evidence of linkage to the reelin gene nor to other MCPH loci. To our knowledge this is the first pre- and postnatal imaging study of autosomal recessive microcephaly with simplified gyri, the first description of an anterior > posterior gradient in this condition, and its first tentative association with *ASPM*.

The cholesterol transporter ABCG1 may contribute to the accelerated onset of Alzheimers Disease in Down Syndrome. *G.H. Tansley, B.L. Burgess, J. Chan, C.L. Wellington.* Pathology and Lab Medicine, UBC, Vancouver, BC, Canada.

Alzheimers disease (AD) is a neurodegenerative disorder affecting 80% of the population over 85 years of age. Extracellular deposits of aggregated amyloid beta peptides (A) are a neuropathological hallmark of AD, and factors that accelerate A production or impede its clearance may affect the onset or progression of AD. Intracellular cholesterol levels are known to regulate the production of A peptides. The cholesterol transporter ABCG1 is highly expressed in brain and maps to chromosome 21q.22.3 in the critical region for Down Syndrome (DS). Notably, individuals with DS typically manifest with AD in their 30s, suggesting that overexpression of genes such as ABCG1on chromosome 21 may accelerate AD pathogenesis. HEK cells stably expressing amyloid precursor protein (APP) containing the Swedish mutation (APPswe) were transiently transfected with an ABCG1 cDNA or empty vector. Cholesterol efflux assays were used to confirm ABCG1 activity, A peptides were measured by ELISA, and intracellular APP levels were determined by Western blot. Secretase activity was quantified by a fluorogenic assay. ABCG1 mRNA levels were determined in DS, AD, and control brain by quantitative PCR. We show that ABCG1 is overexpressed by 2-fold in DS frontal cortex compared to control and AD brain ($p<0.001$). HEK-APPswe expressing ABCG1 display a 1.2 fold increase in cholesterol efflux ($p<0.001$), confirming ABCG1 function. Moroever, cells expressing ABCG1 secrete 70% more A peptides within a 6h period compared to control cells ($p<0.001$). By 32h, approximately 3-fold more A peptides are secreted from ABCG1-expressing compared to control cells ($p<0.001$). Western blots show no difference in APP levels, indicating that the increase in A secretion cannot be accounted for by an increase in APP expression. Finally, both ABCG1-expressing cells and DS brain show a selective decrease in -secretase activity ($p<0.01$). Our results demonstrate that excess ABCG1 is present in DS brain and enhances A production. These observations suggest that ABCG1 may alter cholesterol metabolism in DS brain and contribute to the accelerated onset of AD neuropathology in DS individuals.

A new case of Megalencephaly and Perisylvian Polymicrogyria with Postaxial Polydactyly and Hydrocephalus: MPPH syndrome. *M. Colombani[1], M. Chouchane[2], G. Pitelet[4], L. Morales[5], JP. Pinard[5], L. Lion-François[4], C. Thauvin[1], F. Huet[1], L. Guibaud[3], L. Faivre[1].* 1) Departement of genetics, children hospital, Dijon, France; 2) Departement of pediatrics, Dijon, France; 3) Departement of radiology, Debrousse hospital, France; 4) Departement of pediatrics, Debrousse hospital, France; 5) Departement of pediatrics, Beaune hospital, France.

We report a new case of polymicrogyria, polydactyly, hydrocephalus with mental retardation. This 1 year-old girl was first child of healthy non-consanguineous parents. When she was born at 39 WG, weight was 3670g (+3 DS), length 53cm (+2 DS) and OFC 37cm (+4 DS). Family history was unremarkable. Ultrasound scan at 24 WG showed mild ventricular dilatation with unique ombilical artery and dacryocystocele. Clinical examination showed post axial polydactyly at the right hand and both feet, and axial hypotonia with hypertonic arms and legs. Facial dysmorphism inclued macrocephaly with proeminent forehead, dacryocystocele, hypertelorism, telecanthus, depressed nasal bridge, bulbous nose, large jaws with a small mouth. Standart cytogenetic examination was normal. At 8 months of age, weight was +3 DS, length + 1.5DS and the OFC +4 DS. She could not sit because of an opisthotonos attitude, but had no major feeding difficulties. Contact was satisfying. Echocardiography and renal ultrasond were normal, but brain magnetic resonance imaging showed the persistance of ventricular dilatation and polymicrogyria predominantly on frontal region. Electroencephalogram did not show any seizures. Occular evoked potentials were normal whereas abnormal ear conduction was noted. Advanced bone age was significant (2 ½ years at 8 months of age). In conclusion, we report another observation with MPPH similar to the five patients described by Mirzaa and al. (Neuropediatrics 2004;35:353-359), although a predominantely anterior distribution of the polymicrogyria. From this observation, we can postulate that macrosomia at birth was found in 5/6 cases and might be a major feature of this syndrome. Also, dacryocystocele might be a rare associated feature. The mode of inheritance of this syndrome remains unknown since there was no significant family history.

CDKL5/STK9 mutations in two unrelated females with early-onset infantile spasms. *M. Rio[1], D. Louesdon[1], N. Bahi-Buisson[2], P. Plouin[2], A. Munnich[1], J.P. Bonnefont[1].* 1) Department of Medical Genetics and INSERM U393, Hosp Necker-Enfants Malades, Paris, France; 2) Department of Neuropediatrics, Hosp Necker-Enfants, Paris, France.

Truncating and missense mutations of the X-linked cyclin-dependent kinase-like 5 gene (CDKL5/STK9) have been recently shown to cause a severe phenotype of early-onset infantile spasms, global developmental arrest, and severe mental retardation or a Rett syndrome-like phenotype (Kalscheuer et al. 2003, Weaving et al. 2004 and Tao et al. 2004). Here, we report two unrelated females with severe early-onset infantile spasms ascribed to CDKL5 mutations. The two girls developed infantile spasms in the first month of life after a normal pregnancy and delivery. Both patients had normal growth parameters for height, weight and head circumference. They did not show stereotyped hand movements or hyperventilation episodes. Severe psychomotor retardation was noted during infancy but their clinical course was different thereafter. Indeed, patient 1, now aged 3.5 years, showed generalized hypotonia and motor retardation in the first months of life. Seizures discontinued at 20 months but her development was very slow, and she was unable to sit unaided at 3.5 years. Sequencing analysis of CDKL5 coding regions showed a two bp deletion in exon 16 (c.2323-2324 del GA) leading to a stop codon at position 799 of the cDNA (p.E775fsX799). Patient 2, now aged 7 years , could sit unaided at the age of 16 months, started to walk at 3.5 years and say her first words at 2 years. Seizures remained very difficult to control and she developed intractable seizures during childhood. At 5 years of age, she showed developmental regression and lost her verbal and motor abilities. Sequencing analysis of CDKL5 coding regions showed a two bp deletion in exon 18 (c.2635-2636 del CT) leading to a stop codon at position 908 (pL879fsX908). These findings emphasize the extreme severity and precocity of infantile spasms, the absence of acquired microcephaly, and the broad variability of the clinical outcome associated with CDKL5 mutations.

Brain MRI findings in a fœtus carrying an oligophrenin-1 (OPHN1) mutation and in his carrier mother. *F. Mochel[1], N. Boddaert[2], P. Sonigo[2], M. Rio[1], N. Philip[3], F. Brunelle[2], C. Beldjord[4], P. de Lonlay[5], A. Munnich[1], S. Lyonnet[1].* 1) Service de Génétique and INSERM U393, Hopital Necker-Enfants Malades, Paris, France; 2) Service de Radiologie Pédiatrique, Hopital Necker-Enfants Malades, Paris, France; 3) Département de Génétique, Hopital La Timone, Marseille, France; 4) Laboratoire de Génétique Moléculaire, Hopital Cochin, Paris, France; 5) Service des Maladies Métaboliques, Hopital Necker-Enfants malades, Paris, France.

The oligophrenin-1 gene (OPHN1) maps to Xq12 and encodes a Rho-GTPase-activating protein highly expressed in fœtal brain. OPHN1 mutations have been recently involved in X-linked mental retardation with cerebellar hypoplasia (Billuart et al 1998, Philip et al. 2003). Male patients usually present with psychomotor retardation of variable severity, hypotonia, epilepsy, awkward gait and strabismus in infancy. Minor facial dysmorphism has been also noted, including deep set eyes and a prominent chin (Philip et al. 2003). In all reported patients, brain MRI showed evidence of cerebellar abnormalities, namely large cisterna magna, cerebellar hypoplasia and/or cerebelloschisis (additional cerebellar fissure). Here, we report two affected brothers presenting with moderate psychomotor retardation (IQ=78), with infantile hypotonia and slight facial dysmorphism. One patient also had strabismus and EEG anomalies. Brain MRI of the affected sibs showed similar cerebellar abnormalities with medial vermian hypoplasia and cerebelloschisis. Brain MRI of their mother also evidenced diffuse vermian atrophy and cerebelloschisis. Interestingly, a foetal MRI performed at 30 weeks of pregnancy for the second sib retrospectively showed a large cisterna magna with partial vermian hypoplasia. Based on the association of mental retardation with vermian abnormalities in two male patients, we screened for mutations in OPHN1. Deletions of exons 16 to 19 were found in both patients, and in their phenotypically normal carrier mother. Therefore, brain MRI findings may help diagnosing OPHN1 mutations in male patients with mental retardation. The visualisation of such a MRI pattern in an affected foetus, as well as in an at risk mother, may also contribute to genetic counselling.

Paraoxonase-1 Gly192Arg and Leu55 Met, and Paraoxonase-2 Ser311Cys polymorphisms and risk for sporadic Amyotrophic Lateral Sclerosis. *A. Slowik[1], B. Tomik[1], D. Partyka[1], W. Turaj[1], J. Pera[1], T. Dziedzic[1], D.A. Figlewicz[2], A. Szczudlik[1].* 1) Dept Neurology, Jagiellonian Univ, Krakow, Poland; 2) Dept Neurology, University of Michigan, Ann Arbor, MI.

INTRODUCTION: The human paraoxonase (PON) gene family consists of three members, PON1, PON2, and PON3, which are located adjacent to each other on chromosome 7. These enzymes protect LDL from oxidation and play a role in detoxification of organophosphate insecticides, pesticides, neurotoxins and arylesters. The activity of PON1 is modulated by Gln192Arg and Leu55Met polymorphisms, and PON2 by Cys311Ser polymorphism. Amyotrophic lateral sclerosis (ALS) is an adult-onset fatal neurodegenerative disorder involving motor neurons in the brain and spinal cord. Epidemiological studies suggest that exposure to environmental toxins may be a risk factor for the development of sporadic ALS. AIM: We have investigated a possible association between PON1 and PON2 polymorphisms and the risk of sporadic ALS. METHODS: 168 patients with sporadic ALS and 437 healthy controls were studied. The definite or probable diagnosis of ALS was established according to El Escorial Criteria (1998). Paraoxonase polymorphisms were studied by PCR and restriction enzyme digestion. RESULTS: The Arg/Arg genotype of PON1 gene is overrepresented in ALS cases as compared to their controls [cases: Gln/Gln 47.6%; Gln/Arg 40.4%; Arg/Arg 12.0% vs. controls: Gln/Gln 54.9%; Gln/Arg 38.2%; Arg/Arg 6.9%, $p<0.049$]. Genotypes with Cys allele of PON2 gene are overrepresented in cases as compared to their controls (cases: Cys/Cys 10.2%; Cys/Ser 42.8%; Ser/Ser 47% vs. controls: Cys/Cys 6.9%; Cys/Ser 35.5%; Ser/Ser 59.6%; $p=0.005$). The significant differences between ALS cases and controls are also found in the PON1 Gln192Arg ($p=0.03$) and PON2 Cys311Ser ($p=0.004$) alleles distributions. The PON1 Leu55Met genotype and allele distributions do not differ between ALS cases and controls. CONCLUSIONS: PON1 Gln192Arg and PON2 Cys311Ser polymorphisms influence the risk for sporadic ALS. These results support the hypothesis that genotype-dependent differences in sensitivity to environmental chemicals may play a role in the development of ALS.

A Novel PTPN11 mutation in an infant with Noonan syndrome (NS) and juvenile myelomonocytic leukemia (JMML). *G.C. Gowans[1], A. Asamoah[1], S.P. Ahuja[2], J.H. Hersh[1].* 1) Genetics Unit, Ped, WCEC, Univ Louisville, Louisville, KY; 2) Pediatric Heme-Oncology Unit, Ped, Univ Louisville, Louisville, KY.

Noonan syndrome (NS) is an autosomal dominant condition characterized by short stature, facial dysmorphism, a short and/or webbed neck, thorax deformations, heart defects and cryptorchidism in males. In 2001, missense mutations of the PTPN11 (protein tyrosine phasphatase, nonreceptor type 11) gene on chromosome 12 encoding protein tyrosine phosphatase (PTP) SHP-2 explained 30 - 50% of cases clinically diagnosed as NS. Mutations in PTPN11 have also been found to be present in LEOPARD/multiple lentigines syndrome, Noonan-like multiple giant cell lesion syndrome and cardiofacialcutanous syndrome. It has been previously reported that somatic mutations in PTPN11 account for 34% of nonsyndromic juvenile myelomonocytic leukemia (JMML). JMML has been rarely reported in NS. Germline mutations in PTPN11 have been found in most cases of NS with JMML. We describe an eleven month old Caucasian male infant with clinical features of NS and a mild case of JMML. Sequence analysis revealed the presence of a heterozygous single base change of C T in exon 13 of the PTPN11 gene (CCC CTC). This mutation is predicted to change the normal proline amino acid to a leucine at amino acid 491 of the protein. Mutations affecting this codon (P491S) have been reported previously. The P491L missense mutation is a novel mutation not previously reported for NS or JMML. We review the myeloproliferative and myelodysplastic conditions reported in NS.

Prolonged survival in generalized arterial calcification of infancy is associated with hypophosphatemia and renal phosphate wasting. *F. Rutsch[1], B. Lorenz-Depiereux[2], N. Ruf[3], G. Ciana[4], Z. Mughal[5], C. Loirat[6], J. Davies[7], P. Nürnberg[8], T. Strom[2], D. Schnabel[9].* 1) University Children's Hospital, Muenster, Germany; 2) National Research Center for Environment and Health, Neuherberg, Germany; 3) Max-Delbrueck Center for Molecular Medicine, Berlin, Germany; 4) Childrens Hospital, Trieste, Italy; 5) St. Marys Hospital Manchester, UK; 6) Hôpital Robert Debré, Paris, France; 7) University Hospital of Wales, Cardiff, UK; 8) Cologne Center for Genomics, University of Cologne, Germany; 9) Children's Hospital, Charité University Hospital, Berlin, Germany.

Generalized infantile arterial calcification (GACI, OMIM 208000) is caused by mutations of *ENPP1* encoding for E-NPP1 (EC 3.1.4.1). This cell surface enzyme regulates soft tissue calcification by generating inorganic pyrophosphate (PP_i), a solute that serves as an essential physiologic inhibitor of hydroxyapatite deposition. Most affected children die within the first year of life and factors leading to prolonged survival in some patients are unknown. PP_i and inorganic phosphate have mutually antagonistic roles in tissue mineralization. We hypothesized that hypophosphatemia may balance against pathologic effects of deficient E-NPP1 mediated PP_i generation and may be associated with prolonged survival. We measured serum phosphate and renal tubular phosphate reabsorption (TmP/GFR) levels in 7 surviving patients with GACI older than two years carrying *ENPP1* mutations and in one surviving patient without identified *ENPP1* mutations. Furthermore, in those patients with abnormal phosphate levels, we amplified all 22 *PHEX* and 3 *FGF23* exons by PCR using intronic primers. PCR products were sequenced bidirectionally. 6 of 7 patients with *ENPP1* mutations and the one patient without a mutation had serum phosphate levels below 0.9 mmol/l (normal: 1.38 - 2.01 mmol/l) and TmP/GFR levels below 0.9 mmol/l (normal: 1.45 -2.26 mmol/l). No pathogenic *PHEX* or *FGF23* mutation was found. Hypophosphatemia due to renal phosphate wasting is associated with prolonged survival in GACI and may compensate the phenotype. Renal phosphate wasting is not caused by mutations in *PHEX* or *FGF23* in GACI patients.

Familial thoracic aortic aneurysms/dissections with patent ductus arteriosus: Perhaps a novel locus. *V.T. Tran-Fadulu, J.H. Chen, H. Pannu, A.L. Lafont, D.M. Milewicz.* Internal Medicine, Med Gen, The University of Texas-HSC, Houston, TX.

Thoracic aortic aneurysms and dissections are important causes of sudden death, and are the 13th most common cause of death in the U.S. Familial cases account for 20% of all TAAD cases. Familial thoracic aneurysms and dissections (TAAD) is an autosomal dominant condition with reduced penetrance and variable expression. Four loci predisposing individuals to TAAD have been mapped to 5q13-14 (TAAD1), 3p24-25 (TAAD2), 11q23.2-q24, and most recently 15q (TAAD3). We have identified 290 families with predominately ascending aortic aneurysms leading to type A dissections. Four of these families had a unique presentation involving both type A aortic disease and patent ductus arteriosus (PDA). None of the four families exhibit features of Marfan syndrome, Ehlers-Danlos syndrome, vascular type or Char syndrome. Affected individuals in these families exhibit a predisposition to dissection and aortic enlargement. Aortic dilation in these families can also occur distal to the sinuses of Valsalva. Linkage analyses revealed that the aortic disease in these families was not linked to any of the known loci for familial TAAD. Familial TAAD with PDA has rarely been described in the literature, and is likely to be a heritable genetic disorder, unlinked to any of the known TAAD loci. Of the four families with this unique phenotype, there were a total of 20 affected individuals with either TAA or TAAD. A total of five cases of PDA were observed; three of which were associated with ascending aneurysms or type A dissections. Two cases were observed in individuals who are asymptomatic of TAAD. The large number of individuals with PDA compared to the incidence of 1 in 2000 in the general population, as well as its co-segregation with TAA/TAAD suggests the presence of a rare novel locus, yet to be mapped, is responsible for this unique phenotype.

Investigation of 7q11.23 microdeletion in supravalvular aortic stenosis. *N. Abdelmoula[1], B. Gargouri[1], I. Trabelsi[2], S. Kammoun[2], A. Amouri[3], T. Rebai[1].* 1) Lab of Histology, university of Medicine, Sfax, Tunisia; 2) Dep pf Cardiology, EPS Hedi Chaker, Sfax, Tunisia; 3) Lab of Cytogenetics, Pasteur Institute, Tunis, Tunisia.

Supravalvular aortic stenosis is a congenital heart disease caused by deletion, mutation or disruption of the elastin gene at 7q11.23. It may occur as an isolated disease or as part of a complex developmental disorder such as Williams Beuren syndrome. A spectrum of elastin gene mutations has been identified in isolated SVAS. 7q11.23 microdeletions have been described in 95 per cent of WBS patients. However, of all WBS individuals proven to be hemizygous for elastin gene, only 50 per cent had documented SVAS. In the present study, we have screened 7q11.23 microdeletion by fluorescence in situ hybridization in eight patients suffering from congenital heart disease and in whom cardiac evaluation confirm the diagnosis of SVAS. FISH studies were carried out using Williams Syndrome Region probe. No chromosomal aberrations was shown by conventional cytogenetic analysis whereas 7q11.23 microdeletion was detected by FISH in three patients (37.5 per cent). Deleted patients were two males and one female aged of 16, 6 and 5 years. WBS was suspected on the basis of dysmorphic facies or neurobehavioral phenotype in 4 patients. Diagnosis was confirmed for only three of them. In the remainder 4 children with isolated SVAS, 7q11.23 microdeletion was absent. Our study confirms the diagnostic usefulness of elastin gene deletion analysis by FISH and provides further evidence that the typical WBS phenotype is associated very often with 7q11.23 deletion. We concluded that screening of 7q11.23 microdeletion must be done for all patients with SVAS because establishment of WBS in the neonatal period and infancy can sometimes be difficult. Detection of the 7q11.23 deletion by FISH is a sensitive confirmatory test and should be performed routinely to facilitate genetic counselling, family screening, and formulation of a long-term management plan for the patient. If no deletion is found in SVAS patients, mutational studies within the elastin gene should be performed to establish a phenotype-genotype correlation.

Microdeletion 22q11.2 in contruncal heart disease. *G. Bochra[1], NB. Abdelmoula[1], I. Trabelsi[2], R. Smiti[3], S. Kammoun[2], A. Amouri[3], T. Rebai[1].* 1) Lab. of Histology, University of Medicine, Sfax, Tunisia; 2) Dep. of Cardiology, EPS Hedi Chaker, Sfax, Tunisia; 3) Lab. of Cytogenetics, Pasteur institute, Tunis, Tunisia.

Conotruncal heart defects that account for 50-60% of all congenital heart malformations are known to have a strong genetic component and constitute a cardinal component of branchial arch syndromes, such as DiGeorge and velocardiofacial syndromes. 22q11.2 microdeletions associated with the majority of these syndromes, occur in a high percentage of syndromic conotruncal heart defects and those associated with minor extracardiac abnormalities. A possible strategy for early detection of such syndromes is routine screening for 22q11 microdeletion in all patients with conotruncal heart disease. The purpose of this study was to evaluate whether this strategy is preferable to testing on clinical suspicion. At the south of Tunisia, 26 patients with unselected conotruncal heart disease were tested using fluorescence in situ hybridation and two probes LSI DiGeorge N25 (D22S75) region probe N25/ARSA and LSI DiGeorge/VCFS region probe TUPLE1/ARSA. Cardiac phenotypes were:, regular tetralogy of Fallot (9), irregular tetralogy of Fallot (10), double outlet right ventricule (3), transposition of great arteries with interrupted aortic arch type B (1), pulmonary atresia with ventricular septal defect with malalignment of the conal septum (2), pulmonary valve atresia (2). One deletion was identified in a 1.5-years old boy who have a regular tetralogy of Fallot associated with only some dysmorphic features. Based on this study, only 3.8 per cent of conotruncal heart diseases have 22q11 microdeletion. This prevalence is very low, in comparison to previous studies. We conclude that routine FISH testing for 22q11 microdeletion in conotruncal heart disease should be done in newborn infants with conotruncal defect or associated at least with one additional manifestation of DiGeorge or velocardiofacial syndrome phenotype.

Normal cardiac anatomy in an infant with trisomy 18 and trisomy X (48,XXX,+18). *J.C. Shores[1], G.L. Barnett[2], C.W. Yu[2], C.A. Friedrich[2].* 1) Pediatric Cardiology,; 2) Medical Genetics, Univ. Mississippi Medical Ctr., Jackson, MS.

An infant with dysmorphic features was found to have a karyotype of 48,XXX,+18 in 21 of 21 blood cells. She was born at term via C-section after failing induction. Examination revealed length and weight less than the 10th percentile for term, a large, open fontanelle extending to the level of her eyebrows, a narrow bi-temporal diameter, small, lowset ears with crumpled pinnae, widely-spaced nipples, small palpebral fissures, an asymmetric mouth, overlapping fingers, contractures of the hips and digits, and adduction of the feet with intact passive range of motion. Cranial ultrasound revealed a 3 mm choroids plexus cyst. Ophthalmologic exam revealed non-specific retinal pigmentary retinopathy. Renal ultrasound showed Grade 1 hydronephrosis. Echocardiogram revealed a small PDA, no VSD or ASD and no valvular abnormalities. She was seen again at 4 months and 7 months, when she was not yet crawling and had trouble swallowing baby food. No sleep apnea has been noted. This patient is apparently unique in that she has trisomy for both chromosome 18 and the X chromosome. She also does not have many typical manifestations of trisomy 18. The prenatal sex ratio is 0.9 although in live born infants the sex ratio is 0.63, suggesting strong prenatal selection against trisomy 18 males. It is unknown whether the additional X chromosome has any effect on the severity of findings expected with trisomy 18. Several studies (Vanpraagh et al, 1989; Musewe et al, 1990; Balderston et al, 1990) have shown up to 90% of trisomy 18 patients have unusual congenital heart defects including double outlet right ventricle and polyvalvular disease. Again, it is unknown what effect trisomy X has on the expression of trisomy 18. Cytogenetic study of a second tissue (e.g., fibroblasts) has been offered to the patients mother to evaluate the possibility of X chromosome mosaicism.

Familial thoracic aortic aneurysms and dissections: Clinical complications, response to interventions, and survival. *J.H. Chen[1], V.T. Fadulu[1], M. Willing[3], D. Aguilar[1], T. Bryson[1], B. Neichoy[1], A. Estrera[2], S. Safi[2], C. Anh[1], D.M. Milewicz[1].* 1) Int Med, The University of Texas-HSC, Houston, TX; 2) Cardiothor Vasc Surg, The University of Texas-HSC, Houston, TX; 3) Ped, The University of Iowa Hospitals and Clinics, Iowa City, Iowa.

Familial thoracic aortic aneurysms leading to type A or B dissections (TAAD) is inherited in an autosomal dominant manner with decreased penetrance and variable expression. Although there have been three loci mapped for the condition, there has been no comprehensive analysis of the phenotype of families with familial TAAD. A cohort of 155 families with 2+ members with TAAD was assessed for the cardiovascular features, inheritance and survival rates. The cohort of 4941 people were recruited since 1992. At risk individuals were urged to get aortic imaging. 811 family members scored as affected based on the presence of ascending/descending aortic disease. Visual inspection of pedigrees confirmed autosomal dominant inheritance in 49.7% of families. More males were affected (65.8%), suggesting that decreased penetrance is more apparent in women. 90.6% of deaths were due to TAAD. Survival rate in men was 51.7 years (SD=17.7), and in women 53.5 (SD=19.8). 42.1% of affected patients presented with death due to aortic disease. 71 affected people presented with dissection managed medically, and the remaining 399 individuals presented with aortic dilation; with 50% of these detected with dilation after entry into our study and subsequent imaging. Variable expression of TAAD was evident by the age at aortic dissection ranging from age 13-87 years and aortic dilation ranging from 2-85 years. 55.5% of families had vascular disease extending beyond the ascending aorta. Abdominal aortic aneurysms and peripheral vascular aneurysms/dissections were more prominent in men, while cerebral and carotid aneurysms/dissection were more prominent in women. 47 families in the cohort (30.3%) had 1+ members with cardiac abnormalities such as BAV, PDA, and cardiac septal defects. The potential influence of pregnancy on presentation of disease was evaluated. Average time from last parturition to presentation for all women was greater than 20 years.

Fetal Hypoplastic Left Heart Sequence (HLHS) extracardiac and CNS abnormalities. *M. Thompson[1], A. Many[1,2], S. Keating[1], E. Jaeggi[4], J. Smallhorn[4], D. Chitayat[2,3].* 1) Dept. of Pathology and Lababoratory Medicine &; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; 3) Division of Clinical and Metabolic Genetics &; 4) Division of Cardiology, Dept. of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Objective: To provide information on the incidence and type of extracardiac abnormalities in general and CNS abnormalities in particular detected in fetuses with HLHS. Methods: Cases, prenatally diagnosed with HLHS between 1995-2005 were evaluated. Most cases were assessed by both detailed fetal ultrasound and echocardiography. Results: Of 63 cases with HLHS detected prenatally, 31 cases had a thorough autopsy at our institution. Of the 31 autopsies, 30 pregnancies were terminated and one had an IUFD. Of the 31 autopsies, 6 had chromosome abnormalities and in 3 the analysis failed (2 had isolated HLHS and one had extracardiac, non-CNS abnormalities). Of the remaining 22, three had CNS abnormalities: one had Dandy-Walker malformation and other abnormalities, one had absence of olfactory bulbs and tracts, absence corpus callosum, retrocerebellar cyst and ventriculomegaly and one had Dandy-Walker variant and corticoneural migration abnormality. Of the remaining 19, 11 had isolated HLHS and 8 had other non-CNS abnormalities. Conclusion: Extracardiac abnormalities are common in HLHS detected prenatally. CNS abnormalities were detected in 3/25 (12%) of the chromosomally normal fetuses.

A Novel RASA1 Mutation Associated with Vein of Galen Malformation. *D. Chitayat[1,2], G.H.B. Maegawa[1,2], H. Sroka[1,2], L. Boon[4,5], N. Revencu[4], P. Clapuyt[6], M. Vikkula[4], S. Blaser[3].* 1) Prenatal Diagnosis & Medical Genetics Program, Mount Sinai Hospital &; 2) The Hospital for Sick Children, Department of Pediatrics, Division of Clinical & Metabolic Genetics &; 3) Division of Neuroradiology, University of Toronto, Toronto, Ontario, Canada; 4) Human Molecular Genetics , Christian de Duve Institute, University of Louvain Medical School; 5) Center for Vascular Anomalies &; 6) Department of Radiology, St Luc Hospital, Brussels, Belgium.

Vein of Galen malformations (VOGMs) are rare anomalies of intracranial circulation that constitute 30% of vascular malformations presenting in the pediatric age group. Most cases are sporadic and carry low recurrence risk.We report a case with VOGM associated with a novel mutation in the RASA1 gene. The proband was one of monozygotic twins born at 36-week gestation and diagnosed after delivery with VOGM.The pregnancy was complicated with a mild PIH. Fetal U/S confirmed a monochorionic-diamniotic twin pregnancy. The NT of the affected twin was 1.5 mm giving a risk of 1:4,109 for Down syndrome. The proband was born flat and pale and developed tachycardia with poor pulses. She had systolic cardiac murmur 3/6 and CHF.Brain MRI showed a large VOGM, right frontal lobe hypoplasia and cortical dysplasia. There was also immaturity of left frontal lobe. The baby had also nevus flammeus over the mid-forehead and nasal regions, bulbous nose, prominent tongue, intra-uterine growth retardation. Embolization of VOG was successfully performed and neurological follow-up showed no focal signs and a normal development at 9 months of age. Mutational analysis of the RASA1 gene revealed a 5 nucleotide deletion in exon 19, c.2532_2536delTTTAA, causing a frameshift and predicting a premature stop codon.The family history showed that the father had hydrocephalus secondary to Arnold-Chiari malformation.His sister and her two daughters also have facial-capillary malformation.RASA1 mutation was recently found to be associated with capillary and arteriovenous malformation.The finding of VOGM associated with RASA1 mutation add to the spectrum of vascular abnormalities associated with this gene mutation.

A case of generalizad hypertrichosis asocciated with cardiomegaly in Colombia. *J.C. Prieto[1,2], P.L. Paez[1].* 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Hospital la Victoria, Bogota, Colombia.

A case of a seven year old girl born in Bogotá (Colombia) of nonconsanguineos parents presents chronic pulmonary disease with moderated pulmonary hypertension and left ventricular hypertrophy associated to congenital generalized hypertrichosis. The patient was the product of the mother's thirth term 38-week pregnancy and cesarean delivery because ultrasonographic evidence of polyhydramnios. Birth weight and height was 4000 gr and 50 cm respectively. In neonatal period she had a cyanosis and tachipnea episode then she was admitted at Neonatal Intensive Care Unit where is documented a persistent arteriosus ductus (PAD) without another ultrasonographic finding. She has been hospitalized for multiples episodes of bronchopneumonia and for surgical correction of PAD. Normal psychomotor development. No familiar history. The positive clinical findings are: short stature, evident generalized hypertrichosis, mild bilateral palpebral ptosis, high nasal root, hypoplasic columella, anteverted narines, grade II/VI cardiac systolic murmur, bilateral fifth finger shorteness of hands. Congenital Suprarrenal hyperplasia is discarded. There are not Roentgenologic findings. Hypertrichosis associated with cardiomegaly and osteochondrodysplasia syndrome is characterized for generalized hypertrichosis, cardiomegaly in the vast majority of patients and osteochondrodysplasia more evident at ten years in some patients. Dominant vs recesive heritance mechanism has been described.

Cantu syndrome in a woman and her two daughters: Further confirmation of autosomal dominant inheritance and review of cardiac manifestations. *D.K. Grange[1], G. Singh[2].* 1) Div. Genetics and Genomic Medicine and; 2) Div. Cardiology, Dept. Pediatrics, St. Louis Children's Hospital, Washington University, St. Louis, MO.

Cantu syndrome, or hypertrichosis-osteodysplasia-cardiomyopathy syndrome, is a rare disorder of unknown etiology. Autosomal recessive inheritance was originally proposed (Cantu, 1982), but a father and his 3 affected children were reported by Lazalde (2000), making autosomal dominant inheritance likely. We report an affected mother and her two daughters, further confirming dominant inheritance. Patient 1 is a 38 year old woman with an enlarged heart since childhood. At age 20 she had a pericardial effusion and underwent pericardial stripping. Cardiac muscle biopsy was normal. She continues to have cardiomegaly and high output cardiac failure with elevated cardiac index on catheterization, but normal LV function. She is tall with macrocephaly, coarse facial features, excessive body hair, large tongue and prominent chin. X-rays show a thick calvarium, wide ribs, platyspondyly and broad metaphyses. Patient 2 is the 15 year old daughter. She has characteristic physical and skeletal findings of Cantu syndrome. She has cardiomegaly and increased pulmonary vascularity. Cardiac mass and chamber sizes are enlarged, but with normal systolic function and no pericardial effusion. Patient 3 is the 9 year old daughter. She also has similar physical features and bony abnormalities. She has marked cardiomegaly and had a pericardial effusion with exercise intolerance and orthopnea, requiring pericardiectomy. Cardiac cath showed enlarged cardiac chambers but normal LV function. 20 previous cases of Cantu have been reported; all had cardiomegaly, but only 2 had pericardial effusion. Cardiac biopsy was normal in one patient (Rosser, 1998) and showed mild disorganization of the muscle in another patient (Nevins, 1996). In our family, cardiac disease has been a prominent feature, with significant pericardial effusions. Ventricular function is normal in our patients, despite enlargement of all chambers and increased cardiac mass, as well as high cardiac output in the mother. Thus, the etiology of the cardiac manifestations in Cantu syndrome remains unclear and warrants further investigation.

Actual causes of congenital heart defects: a population-based study, Utah 1999-2003. *L.D. Botto, M. Feldkamp, J.C. Carey.* Pediatrics / Div Med Genetics, University of Utah, Salt Lake City, UT.

Heart defects are among the most common birth defects and major contributors to birth defect-associated infant deaths. Finding causes continues to challenge researchers. Although it is said that many cases are due to multifactorial inheritance, this is difficult to prove or disprove. Likewise, epidemiologic studies suggest many weak risk factors, but recognize few definite teratogens, such as retinoic acid or maternal diabetes. We evaluated a population-based cohort of births with major heart defects to identify causes, with a focus on genetic and familial conditions and teratogens. The study cohort included cases occurring among all pregnancy outcomes (livebirths, stillbirths, and pregnancy terminations) from 1999 through 2003 of women residing in Utah, and collected by the Utah Birth Defect Network. We included conotruncal, atrioventricular canal, and left- or right-sided obstructive defects; total anomalous pulmonary venous return; and complex conditions such as single ventricle and heterotaxias. We excluded atrial septal defects, ventricular septal defects, and patent ductus arteriosus. A pediatric cardiologist and clinical geneticists reviewed cases to assess phenotype and causes. We considered familial only instances with a documented affected first-degree relative. We identified 988 cases of heart defects in 239,454 births (rate, 4.1 per 1,000). Clinical review identified a chromosomal condition in 170 cases (17.2% of total), a genetic syndrome in 7 (0.7%), a recognized teratogen in 4 (0.4%) and other etiologies in 5 cases (0.5%). An additional 20 cases (2.0%) were familial using our definition. Thus a known etiology could be ascribed to 206 cases (20.8%). Of the 170 chromosomal cases, 97 (57%)were trisomies. Of the trisomies, 31 (32%) occurred among mother 35 years of age or older. Assuming that maternal age is in the causal pathway, we conclude that a) the main known actual causes of heart defects in this population are maternal age and teratogens; and b) that strict positive family history and known genetic conditions are uncommon causes. These findings underscore the need to aggressively seek causes of heart defects on a population basis.

Mutations in *CRELD1* are associated with cardiac atrioventricular septal defects in Down syndrome. *C. Maslen[1], D. Babcock[1], L. Bean[2], S. Sherman[2].* 1) Dept Molec/Med Genetics, L465, Oregon Health Sci Univ, Portland, OR; 2) Dept Human Genetics, Emory University School of Medicine, Atlanta, GA.

Complete atrioventricular septal defect (AVSD) is a common and severe form of congenital heart defect. Although sometimes seen as an isolated trait, AVSD is most often found in association with Down syndrome (DS). Trisomy 21 (T21) is not alone sufficient to cause AVSD as only ~25% of DS individuals are affected. However, T21 increases the susceptibility over 2000 fold compared with the general population. We hypothesize that the penetrance of genes associated with isolated AVSD will be increased in the context of T21. We previously identified *CRELD1*, also known as *AVSD2*, as the first known genetic risk factor for AVSD. There is incomplete penetrance, which is consistent with the fact that most cases of non-syndromic AVSD are sporadic. To test our hypothesis, individuals with a DS plus a complete AVSD were analyzed for sequence alterations in the coding region of *CRELD1*. Three different missense mutations were identified in 3 unrelated individuals from a total of 29 cases. All 3 non-synonymous changes are predicted to alter the structure or function of CRELD1. One of the mutations, an arginine to cysteine substitution (R329C), was previously reported in an individual with a sporadic isolated AVSD. R329 is in a calcium binding EGF domain, and the R329C substitution was shown to alter the protein structure as evidenced by a mobility shift on SDS-PAGE. The second mutation results in a cysteine to tryptophan substitution (C221W) in an EGF domain, which will disrupt protein folding. The third mutation, a glutamic acid to lysine substitution (E414K), introduces a change in charge. None of these mutations were identified in 400 race-relevant population control chromosomes, or in 50 chromosomes from individuals with DS and no heart defect. Thus, we have identified 3 mutations in 29 individuals with DS and AVSD (~10%), a higher percentage than that found among isolated AVSD cases (1/42, ~2%). This higher percentage is consistent with our hypothesis that T21 increases the penetrance of AVSD susceptibility genes. *CRELD1* is the first gene to be specifically associated with AVSD in DS.

The Natural History of Trisomy 12p. *R. Segel[1], I. Peter[2], L. Demmer[1], J. Cowan[1], J. Hoffman[1], D. Bianchi[1].* 1) Dept Pediatrics, Tufts Univ Sch Medicine, Boston, MA; 2) Institute for Clinical Research and Health Policy Studies, Tufts-New England Medical Center, Boston, MA.

Trisomy of the short arm of chromosome 12 is a rare chromosomal anomaly, with an estimated incidence of 1/50,000 births. It may present as a pure trisomy (complete or incomplete), as mosaic trisomy, or as a consequence of a parental translocation, thus involving other chromosomal abnormalities. Prior reports are limited to descriptions of the clinical syndrome at birth or early infancy. Little is known about the natural history or life expectancy. In this study we describe long-term outcome and the differences between patients with mosaic trosomy 12p compared to patients with full trisomy. This study is based on detailed questionnaires to families and physicians, photographs, and medical records. We present a series of 16 patients with trisomy 12p; 6 of them are older than 10 years. Most patients are born at term with normal or above normal birth weight. 7/16 patients were born with a major congenital anomaly, but no single anomaly was present more than once. A clear and consistent dysmorphic facial pattern was apparent in all of the patients. Most patients over 7 years old had a seizure disorder. All patients had developmental delay with speech affected more severely than motor skills. 6/16 patients were described as being very social and interactive. 6/16 had severe behavioral problems and 7/16 had significant sleep disturbances. Facial features of the 3 adult patients were different than the younger individuals. We also differentiated between patients with pure trisomy 12p, mosaic trisomy 12p, and trisomy 12p with other chromosomal abnormalities and showed that the oucome of patients with mosaic trisomy 12p is better than the outcome in the other groups. Patients with trisomy 12p should be followed closely for poor feeding and hypoglycemia in the neonatal period, and for the development of hearing loss, behavioral and sleep problems throughout childhood. This study provides the most comprehensive natural history of trisomy 12p to date, including outcome in 3 adolescents and 3 adults, and demonstrates the clinical variability in this syndrome.

Late Evening Settling & Early Morning Sleep Maintenance Differentiate the Sleep Patterns of Adolescents & Younger Children with Smith-Magenis Syndrome (SMS). *W.C. Duncan[1], R.S. Morse[2], D. Krasnewich[2], A.C.M. Smith[2].* 1) MAP, NIMH, NIH/HHS, Bethesda, MD; 2) OCD, NHGRI, NIH/HHS, Bethesda, MD.

Sleep disturbance is the major correlate of negative behavior in Smith-Magenis syndrome (SMS). Decreased total sleep begins in infancy and continues through adulthood. However, there have been no formal studies to document possible developmental changes in sleep. Sleep in SMS is often characterized by a phase-advanced profile (early sleep & waking onset). Anecdotal reports suggest that some individuals with SMS have a delayed sleep profile (late sleep & waking onset). In healthy controls, a delayed sleep pattern is often typical of teenagers. This study examines if this delayed sleep pattern is also characteristic of sleep in older children and teenagers with FISH confirmed SMS. We compare in individuals with SMS the nightly activity-rest patterns of subjects > 10 years (n=7) with subjects 10 years (n=15). Additionally, we compare activity-rest patterns of subjects with SMS with an age-matched sibling (SIB) control group (n=10). Activity-rest patterns were assessed by actigraphy, a non-invasive measurement of at-home behavior. Subjects were enrolled in the NIH IRB-approved SMS natural history study and continued on their existing drug regimen. Subjects wore an Actiwatch for 2-4 weeks. Data were analyzed using Actiware-Sleep software (Mini-Mitter Co, Inc.). Activity counts during the first three hours (Early Act) and last three hours (Late Act) were compared, adjusting for unequal variances. Results: Clock times of Sleep Onset ($p=0.17$) and Waking Onset ($p<0.03$) were earlier in younger than in older SMS and SIB groups. Early Act was similar in 10-y SIB and SMS. In contrast, Late Act was increased in 10-y SMS compared with 10-y SIB ($p=0.0034$), and compared with >10-y SMS ($p=0.03$). Early Act was increased in >10-y SMS compared with 10-y SMS ($p=0.04$) and >10-y SIB ($p=0.05$). Preliminary analysis indicated no effect of melatonin on levels of Early and Late Act in children 10-y with SMS. These results indicate treatments for sleep disturbance in SMS should target age-dependent differences in activity levels during early versus late night sleep period.

Partial trisomy 4q (4q25q31.1) from a familial chromosome insertion with a characteristic mild phenotype. *A. Iglesias[1], M.J. Macera[2], J. Breshin[2], A. Babu[2].* 1) Dept Pediat, Div Gen, Beth Israel Med Ctr, New York, NY; 2) Dept Med, Div Mol Med & Gen, Wyckoff Heights Med Ctr, Brooklyn, NY.

Prenatal diagnosis was done due to history of a familial chromosome rearrangement. The mother had two previous miscarriages, one with a confirmed unbalanced translocation. She is a carrier of a balanced insertion rearrangement between chromosomes 2 and 4; the long arm segment (4q25q31.1) of 4 is inserted in the short arm of 2 at 2p21. Her karyotype was 46,XX,ins(2;4)(p21;q25q31.1).ish der(2)(wcp4+). Amniotic fluid cells analysis in the last pregnancy revealed an unbalanced karyotype consisting of a derivative chromosome 2 from the mother; 46,XY,der(2)ins(2;4)(p21;q25q31.1)mat. The fetal karyotype had a partial trisomy for the long arm segment of 4; 4q25q31.1. The breakpoints designated in both maternal and fetal karyotypes were revised based on comparative genomic hybridization (CGH) performed postnatally using peripheral blood lymphocytes of the proband. After counseling, the couple opted to continue the pregnancy. The proband was born full term. Prenatal and postnatal growths were normal, although head size has been smaller. Motor and language delay were noted early. By 3 ½ years he still had a small head with a narrow forehead. Positive findings were hypertelorism, depressed nasal bridge, inverted v shape upper lip, high palate and vertically placed ears. An asymmetric intergluteal groove towards the left was noted. Hands were short with tapering fingers. Toes were short. Mild muscular hypotonia was noted. By 3 ½ development was appropriate for his age. In summary, we present a case of partial trisomy 4 as a result of a maternal balanced translocation with a distinctive mild phenotype. These findings are similar to previous reported cases confirming the nature of the disorder and suggesting that a trisomy of the distal part of 4q seems to be related with the abnormal development, while the proximal ones are more related with the presence of dysmorphic features. Future cases and the extended use of array-CGH will help to elucidate the genotype-phenotype correlations.

Familial Cat Eye Syndrome. *D. Waggoner, R. Anderson, S. Schwartz.* Department of Human Genetics, Univ of Chicago, Chicago, IL.

Cat Eye syndrome is a well described clinical condition associated most commonly with an isodicentric bisatellited marker chromosome from 22q. The clinical features can include coloboma, supracuricular ear pits or tags, total anomalous pulmonary venous return, and mild mental retardation. There is significant clinical variability including individuals with mild phenotype. The majority of cases are sporadic but some familial cases have been reported. We report a two generation family segregating a marker chromosome derived from chromosome 22 and show molecular data mapping the breakpoints of the marker. We also review the clinical phenotypes of the familial cases known to date. The proband for our family had total anomalous pulmonary venous return and bilateral preauricular ear pits. Her father was noted to have bilateral preauricular ear pits and lateral vision loss, with normal heart and normal intelligence. A paternal uncle had a unilateral ear pit with normal intelligence. The marker chromosome resulted from breakpoints at 22q11.21 and was found in 100% of the proband cells, was mosaic in the father present in only 45% of cells, and was not present in the paternal uncle. The findings in this family are important in that they illustrate: (1) a rare two generation family reported that emphasizes the variability of clinical features; (2) that familial cases can occur and impact genetic counseling; (3) that parents should be carefully examined for subtle features suggestive of Cat Eye; (4) that although other family members may have subtle features of the syndrome, the marker chromosome may not be present; (5) that although our proband and her fathers breakpoints were in LCR-22-2, there was considerable phenotypic differences between the two individuals and (6) that the mosaicism in the father is most likely due to mitotic loss and may contribute to the differences in phenotype.

Deletion 13q in an infant with IUGR and dysmorphism - a case report. *K. Yeboa[1], P. Koduru[2], L. Tambini[1], R. Perrone[2], S. Gupta[2].* 1) Medical Genetics, St. Luke's- Roosevelt Hosp. Ctr., NY; 2) Laboratory Medicine, North Shore Univ. Hosp., Manhasset, NY.

Chromosome deletion is generally deleterious due to monosomy for the lost genes. The 13q deletion syndrome is a distinct entity comprising of a number of variable manifestations. Investigations of the part of the lost genome associated with these manifestations have been instrumental in mapping loci for a number of disorders namely, retinoblastoma (RB-1), holoprosencephaly (ZICZ), Hirsch sprung disease (EDNRB) and neural tube defects to 13q33-q34. Here, we present an infant with dysmorphic facie born to a 35yrs old, G3P2, woman with type 11 diabetes. Prenatal history was remarkable for low MSAFP, severe IUGR and oligohydraminos. At 1.2 weeks after birth baby weighed 3.9lbs (10-25%); head was microdolichocephalic with HC:28cm (10%), L:44cm (10%)with narrow bifrontal diameter, small AF. Facial dysmorphism includes hyperteloric eyes, low set ears, depressed nasal bridge; neck was normal, chest symmetrical and abdomen soft. No malformation of cranium, brain, heart and kidneys was noticed. Genitalia was normal, however anus was placed anteriorly. Chromosome analysis showed an abnormal karyotype: 46,XX,del(13)(q31.2q32.3). FISH studies revealed deletion of the subtelomeric region on del(13q) chromosome. Hence karyotype: 46,XX,del(13)(p13q13.1::q32.3q34::q34). Parental chromosomes were normal. Deletion of 13q32 region is associated with major malformations, severe intellectual disability, growth retardation and distal limb abnormalities. Present case has comparatively milder phenotype as compared to the reported cases with deletion of 13q32 region. This may be due to the fact that deletion has not extended to the gene rich 13q32.3 region. Present case is remarkable for growth retardation. Growth hormone deficiency was present in two cases with monosony of 13q31-q32 region. These findings indicate that locus for GH deficiency might reside in this region. We recommend that 1. Chromosome analysis should be performed on all cases of prenatal as well as postnatal growth retardation, 2. All cases with deletion of 13q31-q32 region should be evaluated for growth hormone deficiency.

The Beckwith-Wiedemann Syndrome: genetic and epigenetic defects in a bipartite cluster of imprinted genes. *R. Della Casa[1], G. Sebastio[1], D. Melis[1], F. Majo[1], R. Tenconi[2], M. Silengo[3], M.M. Rinaldi[4], A. Sparago[5], F. Cerrato[5], A. Riccio[5], Italian BWS Study Group.* 1) Dept of pediatrics, Federico II University, Naples, Naples, Italy; 2) Dept of Medical Genetics, University of Padoa, Padoa; 3) Dept of Pediatrics, University of Turin, Torino; 4) Dept of Medical Genetics, Cardarelli Hospital, Naples; 5) Dept of Environmental Science, SUN, Caserta, Italy.

Alteration of the DNA methylation at the imprinting centres, either IC1 or IC2, and uniparental paternal disomy (UPD) for 11p15.5 alleles are the most common molecular abnormalities in Beckwith-Wiedemann syndrome (BWS). We have characterised the genetic alterations at IC1 and IC2 in a cohort of 56 Italian patients. We detected alteration in IC2 in most of the patients (43%); methylation defects at IC1 and UPD were found in 14% and 18% of the patients, respectively, whereas no mutation was detected in 25% of patients. The table shows the different prevalence of clinical features of BWS as found in the present cohort of patients.

Genotype	Overgrowth	Hepatomegaly	Nephromegaly	Wilms tumor	Omphalocele
IC1	62	50	88	25	0
IC2	50	48	17	0	33
UPD	20	60	40	10	0
No mutation	28	14	28	0	14

The results of this genotype/phenotype correlation suggest that the presence of IC1 alteration is frequently associated with nephromegaly and a higher risk of Wilms tumor. This indicates the need of an accurate surveillance of kidney involvement in BWS with IC1 defect.

Clinical, ultrasound and histopathological features of girls with ovarian cysts GNAS1 R201 mutated. *L. de Sanctis[1], L. Delmastro[1], L. Artesani[2], A. Linari[3], R. Lala[4], P. Matarazzo[4].* 1) Dept. of Pediatric Sciences, Univ. of Torino, Torino, Torino, Italy; 2) Radiological Service, Regina Margherita Childrens' Hospital; 3) Div. of Pathology, Regina Margherita Childrens' Hospital; 4) Div. of Pediatric Endocrinology,Regina Margherita Childrens' Hospital.

A gain-of-function mutation at codon 201 (R201) in the GNAS1 gene, encoding for Gs-alpha protein, has been described in DNA samples from ovarian cysts in girls with peripheral precocious puberty, isolated or included in the McCune Albright syndrome (MAS). We report the clinical/hormonal, genitopelvic US and ovarian hystological features of 6 patients with ovarian cysts. In all GNAS1 analysis in DNA samples from ovarian cist after cystectomy identified the R201 mutation. All 6 patients began with thelarche or menarche at 4-36 months of age. Cushing syndrome and liver dysfunction was also present in 1 patient, skin dysplasia in 2 others. Hormonal investigations showed peripheral precocious puberty, with low LH/FSH and high 17-beta-estradiol values. At US examination, uterus had adult-like morphology and thin stripes of endometrial echos in all patient, the ovaries were multifollicular with 1-3 monolateral anechogenic cysts, even reaching diameters of 50x42 mm. The macroscopic appearance of the cysts was consistent with the follicular type. Microscopic evaluation showed granulosa cells stratified upon a theca layer; signs of luteinization or presence of smaller cysts in the wall were occasionally recognizable. In a follow-up of 5-8 years, bone and skin dysplasia were disclosed in the patient with Cushing syndrome, and bone dysplasia in the 2 patients with skin dysplasia, thus depicting a classical MAS. Notwithstanding antiestrogen treatment, these 3 patients alternated periods of progression and regression of pubertal development and hyperestrogenism for the appearence of new cysts, even bilaterally. In a follow-up of 5 months-3 years in the 3 subjects with isolated precocious puberty no other MAS signs appeared and pubertal development and hyperestrogenism regressed after cystectomy; in 1 of them an estrogen-secreting cyst recurred monolaterally, responsible for a relapse of precocious puberty.

Autistic sibships: The role of female gender in determining outcome. *S.K. Martin, J.H. Miles, T.N. Takahashi.* Dept Child Health, Div Med Gen, Univ Missouri Hospital, Columbia, MO.

There is a growing body of evidence that autism (AD) in males and females is phenotypically dissimilar and under different genetic control (Lamb et al., Stone, et al.). We previously reported that females with essential autism have better outcomes, higher IQs and milder AD symptoms than unrelated males (Miles et al. 2004). This study further defines the role of gender and questions whether male-female (MF) sibships are genetically different from male-male (MM). Nine MF and MM sib pairs who met DSM-IV criteria for AD in at least 1 sib and AD or PDD in the other had complete genetics evaluations. MF sibs showed the most disparity. On the ADI-R, sisters had fewer AD symptoms than their brothers in 28 of 36 categories ($p=0.0001$). Sisters outperformed brothers in 13 out of 15 social categories ($p=0.000002$). There were no differences in the areas of communication or repetitive behaviors. Though not reaching significance, sisters had higher mean IQs (100.3 vs 86.5) and were less apt to be macrocephalic (11% vs 56%), factors usually linked to better outcomes. To examine differences between families with and without AD girls, we compared MM and MF boys. On the ADI-R, the MM & MF boys had similar symptom scores overall, though MM boys did better in 12 of the 15 social categories ($p=0.003$); there were no differences in communication or repetitive behavior. IQ scores, handedness, head size and history of regression were no different for boys from MM vs MF sibships. There were no differences in family histories of neuropsychiatric disorders for the MF and MM sibships. This study confirms our previous finding that girls with essential AD are less severely affected than boys. Comparing MM and MF boys revealed no major differences which does not support the model of different genetic control of autism in MM vs MF families. Remarkably, children, regardless of gender, selected both on the basis of essential AD and having an AD sib, had higher IQs, fewer AD symptoms and better outcomes than those from singleton families, indicating essential AD and being an AD sib are additive outcome factors which define a more homogeneous higher functioning autism subgroup.

LEVEL OF SPEECH: A VARIABLE IN PARENT REPORT OF MOOD RELATED MOVEMENT IN CHILDREN WITH AUTISTIC DISORDER. *R.K. Abramson[1], A.V. Hall[1], S.A. Ravan[1], H. Cope[2], J. Gilbert[2], M.L. Cuccaro[2], H.H. Wright[1], M. Pericak-Vance[2].* 1) Dept Neuropsychiatry, USC School of Medicine, Columbia, SC; 2) Duke University Center for Human Genetics, Durham, NC.

Repetitive behaviors and stereotypies in children with Autistic Disorder (AD) may be influenced by mood. There are few reports of level of speech on parent report of irritability, stereotypy and hyperactivity. **Objective**: To assess the relationship between level of speech, parent report of irritability, stereotypy and hyperactivity on the Aberrant Behavior Checklist (ABC), and Autism Diagnostic Interview-Revised (ADI-R) Factor 1 Repetitive Motor and Stereotyped Behavior (RMSB) (Cuccaro, 2003). **Methods**: Participants (n=81) were drawn from the Duke/USC molecular study of AD. Diagnoses were confirmed by the ADI-R and medical records. The ABC was completed for each individual. Using Discriminant Function Analysis with level of speech (question 19, ADI-R) as the grouping variable, the irritability, stereotypy, and hyperactivity subscale scores from the ABC were combined to create a new factor of mood related movement F-MRM. On this factor, the variables loaded in the following manner, Irritability = 0.697, Stereotypy = -0.270, and Hyperactivity = 0.58. **Results**: Discriminant scores for F-MRM for children with useful speech (n=61) were significantly higher (t=3.042, df=79, p=0.003) than for children with no useful speech (n=20). Pearson Correlation was negative(r= -0.237, p=0.033, n=81) for F-MRM and RMSB, and absent for F-MRM and ADI Factor 2 Insistence on Sameness. **Conclusions**: Useful speech may influence parent report of irritability, stereotypy and hyperactivity as captured by F-MRM. As F-MRM increases, RMSB decreases. Parent report contributes heavily to evaluation of AD and to phenotypic subgrouping for linkage studies. Overall level of speech may be an important variable in parent perception and report of mood related movement.

Abnormalities of voluntary eye movements in a patient with neurotrypsin defect. *S. Chokron[1], D. Milea[2], F. Molinari[3], A. Consoli[4], D. Cohen[4], A. Munnich[3], L. Colleaux[3], A. Philippe[3].* 1) Fondation Rothschild, Paris, France; 2) Service d'Ophtalmologie, Hôpital de le Pitié-Salpêtrière, Paris; 3) INSERM U393, Hôpital Necker-Enfants Malades, Paris; 4) Service de Pédopsychiatrie, Hôpital de la Pitié-Salpétrière, Paris.

Neurotrypsin mutation is a cause of autosomal recessive mental retardation. To date, three consanguineous families who are all originally from the same area of Eastern Algeria have been identified. We describe the case of a 16 year-old boy in order to define the phenotype associated with neurotrypsin defect. Until he was 18 months old, the first milestones of psychomotor development are normal (age of walking, first words). Clinical examination reveals impaired voluntary saccadic eye-movements in the horizontal and vertical direction whatever the nature of the stimulation (visual, auditory, somesthesic). Eye movements are always associated with compensatory head thrusts. The patient has difficulties to keep visual fixation towards a target. He shows also severe deficit in color discrimination and in face processing. On the other hand, the recognition of animals and objects is correct. Ophthalmological examination is unremarkable. Full scale IQ was 40 on the Wechsler Intelligence Scale for Children (WISC-III) with a verbal IQ score of 46 and a performance IQ score of 46. We analyze these clinical findings with the cerebral MRI results.

Can pulmonary hypertension in NF1 be secondary to a vasculopathy? *D. Stewart[1], L. Christiansen[2], W. Miller, Jr.[3], W. Nichols[4], M. Pauciulo[4], L. Messiaen[5], G. Tu[6], R. Pyeritz[3], D. Ross[7].* 1) NHGRI; 2) St Joseph's, Reading PA; 3) UPenn; 4) CCHMC; 5) UAB; 6) Lung Center of Nev; 7) UCLA.

Pulmonary hypertension (PH) in neurofibromatosis type 1 (NF1) may be due to pulmonary interstitial fibrosis, a rare complication of the disease. Primary pulmonary hypertension (PPH; not attributable to any known secondary cause) in NF1 has been reported but is poorly characterized. We studied 2 patients with PPH in NF1 with the mosaic pattern of lung attenuation on chest CT, a radiologic finding frequently observed in patients with PH due to vascular disease. We also report the first genetic testing of BMPR2 in individuals with PPH in NF1. BMPR2 is the causative gene of familial PPH. Patient 1. A 72 year-old female with NF1 presented with progressive dyspnea; she had signs of NF1 and cor pulmonale. Chest CT showed a mosaic pattern but no evidence of interstitial lung disease. Right heart catheterization confirmed PH. Evaluation for causes of secondary PH was unrevealing. Mutation testing of BMPR2 revealed a rare, non-conservative SNP in exon 12. Patient 2. A 56 year-old woman with NF1 presented with progressive dyspnea. Chest CT showed a mild mosaic pattern. Cardiac catheterization revealed elevated pulmonary pressures. Evaluation for causes of secondary PH was unremarkable. Her symptoms improved with epoprostenol. No mutations or polymorphisms were identified in BMPR2. Discussion. Pulmonary vasculopathy may underlie PPH in NF1. 1) Vasculopathy in NF 1 is a well-documented manifestation of the disorder described in many vascular beds. 2) Samuels et al (1999) described a patient with NF1 with PH secondary to diffuse intimal thickening from fibrous tissue; the changes were similar to the vaso-occlusive lesions found in the arteries of other NF1 patients. 3) The mosaic pattern observed in our 2 patients can be consistent with a vascular process. 4) The PPH in our 2 patients is not explained by mutations in BMPR2. Conclusion. 1) Vasculopathy of NF1 itself should be considered in a patient with NF1 and PPH. 2) The PPH of NF1 may be responsive to epoprostenol. 3) The role of rare non-conservative SNPs in BMPR2 in patients with NF1 is unclear and needs further exploration.

***SYMPHONIE* : A knowledge-base to systematically connect symptoms with gene-related diseases.** *M. Ohtsubo[1], S. Moriwaki[1], C.X. Wang[1,2], Y. Hotta[2], T. Horisawa[3], K. Daicho[3], K. Kawaguchi[3], N. Miura[4], N. Mori[5], K. Sato[6], N. Shimizu[7], T. Terao[8], S. Minoshima[1,7].* 1) Photon Med Res Ctr; 2) Dept Ophthalmol, Hamamatsu Univ Sch Med; 3) Chi Co., Ltd; 4) Dept Biochem; 5) Dept Psychiat Neurol; 6) Dept Anat Neurosci, Hamamatsu Univ Sch Med; 7) Dept Mol Biol, Keio Univ Sch Med; 8) President, Hamamatsu Univ Sch Med, Japan.

Symptoms appearing in human gene-related diseases should be invaluable natural phenotypes caused by pathogenic variation in DNA sequence for functional genomics. We have created the words 'symptome' and 'symptomics' by combining symptom with -ome/-omics. In the new paradigm 'Postgenome Symptomics', (a) disease-associated symptoms with genome variation data and various accompanying non-genetic information are widely collected for each of individual cases, (b) they are extensively analyzed and systematically classified/categorized together with reference information from animal models to organize a set of ontologies, and (c) knowledge-bases for various scopes are created with those ontologies as frameworks to integrate collected information. We are carrying out the postgenome symptomics and creating *SYMPHONIE* (SYMPtomics Hamamatsu Ontology for New Investigative Etiology) as a knowledge-base to connect symptoms with gene-related diseases. Various classes of symptom data including chief complaint, physical finding, results of laboratory examination, associating information such as onset age, anamnesis, family history as well as DNA sequence data and disease name if known are being collected for skin and eye diseases as a trial. Current version of *SYMPHONIE* has features such as (1) a diagnosis supporting function by which narrowing-down and search for gene-related diseases using symptom and patient's data; (2) a reference function to obtain the detailed information of each disease and significance for differential diagnosis from similar disorders. The mutation information of disease responsible genes can be seen *via* a hyperlink to *MutationView* which has been constructed at Keio University. *SYMPHONIE* should be useful for clinicians, basic researchers, students as well as pharmacogenomics industries. A prototype of *SYMPHONIE* will be demonstrated.

Congenital Cataracts, Subcortical Heterotopias, Vermis Hypoplasia , Learning Difficulties and Dysmorphism in a 13 year old Male. *P. Bitoun[1], B. Benzacken[2], E. Pipiras - Pereny[2], J. Gaudelus[3].* 1) Gen Medicine, CHU Paris-Nord, Hosp Jean Verdier, Bondy, Cedex, France; 2) Histo-Embryo-Cytogenetics and Assisted Reproduction Biology; 3) Pediatrics.

Authors present the case of a 13 year old male with a history of congenital cataracts ,facial dysmorphism,learning difficulites mostly with reading and writing cerebellar vermis hypoplasia and paraventricular heterotopias . This young man is followed in visual handicapped clinic since age 6. He was born to a 30 year old G1P1 mother and 29 year old non consanguineous healthy father after an uneventful term pregnancy with meconium fluid and normal apgars. His BW was 3380 grams, Height was 49,5cm , OFC was 34 cm. Bilateral Cataracts were removed by 4 months for lack of visual pursuit.Writing and graphic difficulties were noted at age 4. Evaluation showed midface hypoplasia,short upturned nose,thick lips,cupped ears, short 4th metacarpals,hyperlaxity and he was followed by a speech therapist.A diagnosis of reading and and writing dyspraxia was made. Sensory integration of hearing , visual and kinesthetic stimuli remains difficult. His best corrected distant visual acuity remains at 4/10. He acquired reading and writing but with ongoing difficulties. Fragile X,high resolution caryotype, telomeric screen and GSalpha protein assay were normal, G protein was 91%. Xrays showed pseudoepihysis of the metacarpals. GH ,cortisol,TSH, T3, T4 and PTH 1-84 assay were normal. MRI showed lateral ventricular dilatation; tiny areas of subcortical and paraventricular heterotopias in T2 and flair sequence,pineal gland cyst,vermis hypoplasia and a small pituitary gland. Discussion Periventricular heterotopias have been described by Oda et al (1993), Kamuro and Tnokuchi (1993) and Di Mario 1994 as a possibly X-linked condition but no cerebellar anomalies or cataracts have been reported. This condition appears unique with the association of cataracts and dysmorphism with heterotopias and vermis hypoplasia.

Angelman Syndrome: a resource to unfold autism genes. *M.T. Bonati[1], F. Monteverdi[1], S. Russo[2], F. Cogliati[2], P. Finelli[2, 3], D. Giardino[2], M. Elia[4], L. Larizza[3].* 1) Clinic of Medical Genetics, Istituto Auxologico Italiano, Milan, Italy; 2) Laboratory of Medical Genetics Istituto Auxologico Italiano, Milan; 3) Department of Biology and Genetics, University of Milan; 4) Neurology Serv., IRCCS Oasi Maria S.S., Troina (EN).

Autism (AD) is a neurodevelopment disorder with a complex genetic etiology. Involvement of 15q11-q13 chromosome region in AD has been indicated by linkage studies and duplications. Moreover, some features found in Agelman Syndrome (AS), such as severe mental retardation, absence of speech, abnormal EEG/epilepsy, inappropriate social behavior, overlap with those often seen in AD. We administered the ADOS protocol 13 AS patients including the known genetic subtypes, namely: deletion of maternally derived 15q11-q13 copy (n=6); paternal chromosome 15 uniparental disomy (UPD)(n=2), imprinting center (IC) defects (n=1) and UBE3A mutations (n=4). The parents were administered the ADI-R protocol. Five out of 6 deleted and one of the two UPD patients received the ADOS classification of autism. One deleted patient and three out of 4 AS with UBE3A mutation fitted the autism spectrum category. The remaining patients were out of the spectrum. There were no differences in autism diagnosis as a result of age. Excluding the IC defects, one may extrapolate that AS patients belonging to each class can receive a comorbid diagnosis of autism and that less severe autistic symptoms seem to privilege patients with UBE3A mutation than those with the deletion. A comparison of social and communication ADOS-items between the AS group and 10 selected idiopathic autism patients was undertaken. Deficits in both domains of the comorbid autism group mirrored those of the idiopathic autism patients, with a quantitative difference, as the following items scored higher/worse in the second group: frequency of vocalization to others, intonation abnormalities, unusual eye contact, social smile, integration of gaze and other behaviors during social overtures. Development of the study by testing a higher number of patients will provide highlights on the behavior overlap between AD and AS consistent with a role in AD etiology for UBE3A and neighboring genes.

Autism and Alcoholism: A quest for genetic linkage. *C.D. Sauer, T.N. Takahashi, J.H. Miles.* Dept Child Health, Div Med Gen, Univ Missouri Hospital, Columbia, MO.

Autism (AD) is a complex neuro-developmental disorder that has a heterogeneous genetic etiology and a wide array of behavioral and phenotypic traits. Our previous family studies demonstrated a significant genetic overlap between autism and alcoholism with 35% of AD children having a significant family history of alcoholism (Miles et al., 2003). Autism and alcoholism are both highly heritable and etiologically heterogeneous disorders and for both there is biochemical and clinical support for some shared genetic origins. Dysregulation of the dopamine and serotonin neurotransmitter systems occur in both autism and alcoholism. In addition, there is an overlap in drugs used to treat both disorders. In our families, significant family loading for alcoholism correlated with regressive onset autism (52.5% vs. 35.8%, p= 0.04) and decreased incidence of macrocephaly in the child with autism (14.7% vs. 40.6%, p=0.0006). This suggests that the overlap with alcoholism may hold for a subset of autism and that there may be genes common to both disorders. We reviewed published autism (8) and alcoholism (4) linkage and association studies to determine areas of possible genetic overlap. Regions were considered positive for overlap if the linkage peaks were no more than 10 cM apart. Four areas of overlap were identified on chromosomes 2q11, 4q21-23, 15q21 and 16p13. There are a number of evocative genes in these shared regions. Region 2p11.1-q12.2 contains gene BAFME2, associated with various forms of epilepsy. The mutually linked 15q21region contains a dyslexia susceptibility locus, DLX1 and region 16p13 contains the EIM gene for infantile myoclonic epilepsy. The significance of the gamma subunit of alcohol dehydrogenase gene at 4q21-23 is unclear since alcohol dehydrogenase has no apparent relation to autism. Genetic linkage and association studies of complex behavioral disorders have been hampered by poor replicability. We suggest that molecular study of an appropriately chosen subgroup of families selected on the basis of both autism and alcoholism may improve the detection of linkage for these complex neurologic disorders.

Clinical and morphological characterization of Lathosterolosis. *G. Andria[1], M. Rossi[1], I. Parisi[1], R. Tuzzi[1], A. Battagliese[1], A. Pepe[1], R. Vecchione[2], M. D'Armiento[2], M. Cervasio[2], L. Terracciano[2], G. Corso[3], P. Ferrari[4], F. Rivasi[5], G. Parenti[1].* 1) Dept of Pediatrics, Federico II University, Naples; 2) Dept of Pathology, Federico II University, Naples; 3) Dept of Clinical Biochemistry, University of Foggia; 4) Dept of Pediatrics, University of Modena; 5) Dept of Pathology, University of Modena, Italy.

Lathosterolosis (LS) is a rare defect of cholesterol biosynthesis (DCB), due to the deficiency of 3-beta-hydroxysteroid-delta-5-desaturase (SC5D). Only two patients have been reported in the literature, both with multiple congenital anomalies and liver involvement (cholestasis in both and massive mucolipidosis-like inclusions in one). Here we report on the characterization of a third case of LS, suggesting intrafamilial variability of LS and expanding the phenotypic spectrum of the disease. The patient was an aborted fetus, sibling of the first case described by us, presenting with four limbs hexadactyly, clubfeet and lumbosacral meningocele. The diagnosis of LS was made retrospectively by molecular analysis of the SC5D gene in DNA samples obtained from histological preparations from the fetus. The fetus carried the same two mutations as her living sister (R29Q; G211D). The fetal phenotype suggests a possible involvement of cholesterol biosynthesis derangement in neural tube closure. Liver histology by optic microscopy showed normal portal tracts, marked extramedullary hematopoiesis with atrophy of hepatocytic laminae and hemosiderinic pigment within periportal hepatocytes and Kupffer cells. These histological features have been previously reported as signs of pre-natal liver disease in other DCB. No foamy histiocytes were noted. We also looked for the presence of inclusions in skin fibroblasts from our living LS case. Fibroblasts were cultured in delipidated medium for 3-7 days and examined by electron microscopy. Lamellar inclusions, similar to those found in the other previously reported LS case, were noted, confirming that this is a feature of LS.

Robinow Syndrome without mesomelic shortening of limbs. *O.A.P. Artigalás, L.O. Dewes, M.B. Golbert, F. Hauser, M.T.V. Sanseverino, J.C.L. Leite.* Medical Genetics Service, Hosp Clin P Alegre, Porto Alegre, RS, Brazil.

This report describes a female newborn, born after a 41-week pregnancy. It was the couple's first child, without consanguinity or family history of malformations. The mother was 34 years old, with an uneventful pregnancy. The mother denied use of any medication, drug or alcohol during regnancy. The first ultrasonography was performed in the 11th week of pregnancy, and it showed an increased nuchal translucence (4,9 cm). The mother was referred for evaluation at our service, where some tests where performed: a normal fetal ecocardiography, an amniocentesis resulting in a 46,XX cariotype, negative tests for infecions, and a color ecodoppler showing a single umbilical artery and a protodiastolic incisure in both uterine arteries. The birth was by vaginal delivery, weight of 3845 grams, lenght of 50 cm and head circunference of 35cm. Apgar score was 9 at 1st minute. Full skeletal x-rays and cranial CT scan showed no abnormalities. The physical examination showed bilateral enlarged thumbs, bilateral bifid hallux, enlarged eyelid slits, macrostomia with gingival hypertrophy and ankiloglossia, auricular pits, bilateral duplicated earlobes, normal female genitalia, pre-sacral pit. These findings were considered consistent with the diagnosis of Robinow syndrome. The syndrome is characterized by a face that reminds of a "fetus", with proeminent forehead, hypertelorism, enlarged mouth, small nose with anteverted nostrils. There may be an important gingival hypertrophy. Other findings include micropenis,hydronephrosis or urinary tract infections, cleft lip an palate, bifid fingers. Congenital heart malformations have been described in some cases. About 80% of the cases present with mesomelic shortening of limbs. Families with autossomal recessive and dominant cases have been reported. The recessive families seem to have more severe anomalies of the vertebrae and mesomelic shortening of upper limbs. In the recessive families, there are homozigous mutation in the ROR2 gene, located in the 9q22 cromossome. The gene for the dominant type is not known yet. The patient we present is being evaluated for ROR2 and possible candidate genes for the dominant type.

Evaluation of Limb Phenotypes in Patients with Cornelia de Lange Syndrome. *M.A. Deardorff[1], L.G. Jackson[1, 2], D. Yaeger[1], I.D. Krantz[1].* 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Obstetrics and Gynecology, Drexel University School of Medicine, Philadelphia, PA.

The Cornelia de Lange syndrome (CdLS) is a multisystem developmental disorder with facial dysmorphia, hirsutism, cardiac defects, growth and cognitive retardation, gastrointestinal abnormalities and limb malformations primarily of the upper limbs are primarily affected that range from relatively normal small hands to oligodactyly and severe reductions of the entire forearm. Lower limbs are generally spared but may have syndactyly of toes 2 and 3.

Mutations in NIPBL, the human homolog of the Drosophila melanogaster Nipped-B gene, have been shown to cause CdLS. Currently, we are able to detect mutations in approximately 45% of CdLS probands. While frameshift, nonsense, splice site and missense mutations have all been identified, the majority of mutations are protein truncating and likely result in haploinsuffiency as a disease causing mechanism.

To characterize mutations in NIPBL and limb deformities in CdLS, we performed a retrospective analysis of records for 840 patients with CdLS. Both severity of reduction and laterality of defect were scored. Overall, 17% had severe reductions, 15% had moderate reductions and 67% had milder deformities. Mutation positive rates for these subsets were 74%, 57% and 28% respectively. Truncating mutations were seen in 93% of patients with severe reductions and 57% in both the moderate and milder classes. Of those with reductions, 44% were more severe on the right, 19% were more severe on the left and 37% were symmetric.

Our data suggests that patients with more severe limb reductions are more likely to have identifiable mutations compared with those with less affected limbs. This raises further questions about the sensitivity of limb development to the dosage of NIBPL. Furthermore, the finding that the right limb is more often affected suggests that NIPBL may interact or be influenced by mechanisms that determine left-right laterality.

A patient with acromesomelic dysplasia-type Maroteaux associated with abdominal pseudo aortic aneurysm. *H. Ohashi[1], Y. Ohashi[1], H. Mochizuki[1], N. Mitsui[1], M. Saitoh[2], M. Sakuragi[2], G. Nishimura[3].* 1) Saitama Children's Medical Ctr, Saitama, Japan; 2) Saitama Cardiovascular and Respiratory Center; 3) Tokyo Metoropolitan Kiyose Children's Hospital.

Acromesomelic dysplasia, type Maroteaux, (AMDM) is a rare autosomal recessive skeletal dysplasia characterized by severe dwarfism with shortening of the middle and distal segments of the extremities. Both missense and protein-truncating mutations in natriuretic peptide receptor 2 gene (NPR2) have recently been reported to cause AMDM (Cynthia et al, 2004). We report here a 28-year-old Japanese male with AMDM associated with abdominal pseudo aortic aneurysm. The patient was born to healthy but consanguineous parents (first cousin). His father is 155 cm (-2.75 SD) and mother 153 cm (-0.98 SD) in height, respectively. The patient was initially diagnosed in infancy as achondroplasia because of short limb dwarfism and relative macrocephaly. His mental development was normal. At age 27 years, he suffered from severe abdominal pain and was found to have abdominal pseudo aortic aneurysm, which was subsequently treated with a stent graft. When seen by us at age 28 years, his height was 118.5 cm (-9.3 SD), OFC 57.1 cm (+0.92 SD). His features noted were long face, hypertelorism, marked shortening of the middle and distal limbs, relatively large big toes, and redundant skin of fingers. X-ray study revealed marked shortening of long bones of forearms and hands, and mild platyspondyly. Based on these findings, we concluded that he has AMDM. Sequencing analysis of entire coding region of NPR2 gene showed that the patient has homozygous 1972C>T (L658F) mutation, and his parents are heterozygous carriers. To our knowledge, aneurysm found in our patient is a previously unreported complication in AMDM. We considered two following possibilities: 1) aneurysm is a coincidental occurrence in the patient, and 2) aneurysm is a rare but important complication of AMDM especially in adulthood.

Craniosynostosis-Marfan-like syndrome with normal intelligence and apparently increased risk of aortic dissection in 6 patients - from Furlong to Loeys-Dietz syndrome. *S.O. Lewin[1], J.M. Opitz[1], J.C. Palumbos[1], K.M. Dent[1], P. Lenglet[1], P. Bayrak-Toydemir[3], H. Pannu[2], A. Lafont[2], D.M. Milewicz[2], J.C. Carey[1].* 1) Div Medical Genetics, 2C412SOM, Univ Utah Medical Ctr, Salt Lake City, UT; 2) Univ Texas Medical Sch Dept Internal Medicine 6431 Fannin, MSB 4 202 Houston TX 77030; 3) ARUP Laboratories Dept of Pathology 500 Chipeta Way Salt Lake City UT 84108.

We present 6 patients to delineate further a craniosynostosis-Marfan-like condition suggestive of Shprintzen-Goldberg syndrome (SGS)with normal intelligence and an apparently higher risk for aortic dissection at a young age. The recent paper by Loeys et al (*Nature Genetics*, March 2005) describing mutations in TGF1 and 2 receptors in 10 families with findings that overlap but are not typical of Marfan syndrome or SGS has confirmed a clinical impression we have had for several years that some patients called SGS have a disorder we called Furlong syndrome (Furlong et al., 1987). Findings in our 6 patients (3 male) included: craniosynostosis, mild hypertelorism, marfanoid habitus, arachnodactyly, eye involvement (esotropia, orbital hypoplasia) no lens dislocation in all. Intelligence was normal in all. Three patients had fatal aortic dissection at 4.5, 12 and 16 years respectively. All had been followed on a Marfan protocol. The finding of mutations in TGFR1 and 2 in the patients of Loeys et al spurred us to look in our patients. Of the 3 patients who died, one has a confirmed mutation in TGFR2, one has no mutation identified in TGFR1 or 2 and the third was not studied. The remaining 3 patients are still being being tested. The pathogenesis of the craniosynostosis-Marfan-like disorders is still unclear, and the role of TGF receptor family and its interaction with fibrillins is being explored. There is an urgent need for clinicians to distinguish which patients may have an increased risk of aortic and other vascular rupture at a young age so they can be followed closely. Patients with atypical Marfan or SGS should have TGFR1&2 genes studied as part of their diagnostic workup.

The deletion 7q36.3 syndrome. *J. Pappas, E. Moran.* Human Genetics Program, New York Univ, Sch Medicine, New York, NY.

We present three unrelated cases with deletions in the chromosome band 7q36. Case 1 and 2 have terminal deletions that encompass the band 7q36.3 and case 3 has interstitial deletion 7(q36.1q36.3). The presentation of case 1 and 2 was similar to ten published cases with deletion 7q36.3 and included microcephaly, growth retardation with gastroesophageal reflux, mild to moderate mental retardation, hypertelorism, ptosis or blepharophimosis, midface hypoplasia, malar hypoplasia, absent incisors, midline cleft palate and broad tip of the nose. Case 3 presented with developmental delay without any dysmorphic features or malformations. The del(7)(q36.1q36.3) in case 3 was established with chromosome analysis of peripheral blood using G-banding. FISH using subtelomeric DNA probes (Vysis, Inc) was normal indicating that the deletion was not including the D7S427. The initial karyotypes of cases 1 and 2 were reported normal. Subtelomeric FISH revealed deletion of D7S427 in cases 1 and 2 and the deletions were subsequently characterized by G-banding to be del(7)(q36.2) in case 1 and 46,XY,der(7)t(7:8)(q36;q24.3) in case 2. The duplication 8q24.3 contributed minimally to the phenotype of case 2 (Pappas, J ACMG meeting 2004). Genes localized in 7q36.3 include SHH and HLXB9 that are respectively associated with holoprosencephaly spectrum and the Currarino syndrome. Horn, D et al (2004) suggested that patients with deletion of 7q36.3 present with minimal clinical expression of these syndromes. We suggest that case 1 and 2 and the ten published cases with similar clinical and cytogenetic findings have the deletion 7q36.3 syndrome. Four out of these twelve cases have hypoplasia of the corpus callosum that can be associated with haploinsufficiency of the SHH gene. Five out of these twelve cases have sacral abnormalities that can be associated with haploinsufficiency of the HLXB9 gene. Our cases provide further support that the deletion 7q36.3 syndrome is a distinct contiguous gene syndrome with specific dysmorphic features. We suggest that the critical area of the syndrome is 7q36.3 encompassing the SHH and HLXB9 genes and the marker D7S427.

WAGR caused by a novel unbalanced t(11;15)(p13;p12) demonstrating a 7 megabase deletion by fluorescent in situ hybridization. *P.A. Lennon[1], D.A. Scott[1], A. Eglash[2], D.S. Wargowski[3], A. Patel[1], S.W. Cheung[1].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Family Practice, University of Wisconsin, Mt. Horeb, WI; 3) Department of Pediatrics, University of Wisconsin-Madison School of Medicine, Madison, WI.

Aniridia usually occurs in isolation, but may also occur as part of the WAGR contiguous gene deletion syndrome, which includes Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation. Variability in WAGR phenotypes led to the molecular characterization of the breakpoints on 11p13 involved in the deletions associated with the WAGR syndrome. This helped to identify the gene positions of PAX6, which predisposes for aniridia, and of WT1, which predisposes for Wilms tumor. We present a female infant with aniridia, bilateral posterior capsular cataracts, nystagmus, left-sided glaucoma, mild unilateral hydronephrosis, and gross motor delay. Family history was negative of relatives with aniridia or similar eye abnormalities. Chromosome analysis revealed an unbalanced t(11;15)(p13;p12). Subsequent WAGR fluorescent in situ hybridization (FISH) probe panel analysis demonstrated deletion of all four clinical probes, verifying haploinsufficiency for both PAX6 and WT1. FISH-mapping of the breakpoints on chromosome 11 revealed a 7 Mb deletion within 11p1311p14. This combination of clinical and cytogenetic findings strongly suggests a diagnosis of WAGR. Genotype-phenotype comparisons between this patient and other reported patients with deletions and/or translocations involving the region between 11p1211p14 will be presented, including patients with WAGR and WAGR + obesity (WAGRO).

Fetal Hypoplastic Left Heart Sequence (HLHS) and Chromosomal Anomalies. *A. Many[1,2], M. Thompson[1], E.J.T. Winsor[1], S. Keating[1], E. Jaeggi[4], J. Smallhorn[4], D. Chitayat[3,5].* 1) Dept. of Pathology and Laboratory Medicine; 2) Dep. of Obstetrics & Gynecology; 3) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital,; 4) Div. of Cardiology; 5) Div. of Clinical and Metabolic Genetics,Dept. of Paed., The Hospital for Sick Children, Univerisity of Toronto, Toronto, Ontario, Canada.

Objective: To provide information on the incidence and type of chromosome abnormalities detected in cases detected prenatally with HLHS. Methods: Prenatally diagnosed cases with HLHS between 1995-2005 were evaluated. Most cases were detected by both detailed fetal ultrasound and echocardiography. Results: 63 pregnant women with fetal HLHS were identified and chromosome analysis was done in 47. The karyotype was abnormal in 11 (17%). In 3 cases, trisomy 13 was detected and other chromosomal abnormalities were also observed such as trisomy 18 (1 case), 46,XX, der(6)t(6;18)(p24;q22)mat (1 case), 47,XX,+21/46,XX (1), 47,XX,+21/46,XX (1), 45,X (1 case), 45,X/47,XXX (1 case), 47, XX i(12)(p10)/46,XX (1 case), 46,XY. ish del(X)(q26.2q26.2)(Z1C3-)mat (1 case) and 46,XX,del(22)(q11.2q11.2)(TUPLE 1-) (1 case). Conclusions: chromosome abnormalities are common in prenatally detected HLHS. All chromosomally abnormal cases had additional extra cardiac abnormalities and one of the cases had deletion at 22q11.2.

Subtelomeric Familial Rearrangement Between the Telomeres of 7p and 20q Resulting in Partial Trisomy 20qter/Partial Monosomy 7pter: Clinical Phenotype and Molecular Cytogenetic Analysis. *M. Al-Owain[1], M. Iqbal[2], N. Sakati[3], Z. Al-Hassnan[1], A. Teebi[4].* 1) Department of Medical Genetics, King Faisal Specialist Hospital and Reserarch Center, Saudi Arabia; 2) Department of Pathology, King Faisal Specialist Hospital and Reserarch Center, Saudi Arabia; 3) Department of Pediatrics, King Faisal Specialist Hospital and Reserarch Center, Saudi Arabia; 4) Division of Clinical and Metabolic Genetics, the Hospital for Sick Children, Toronto, Canada.

We report 5-½ year old Saudi girl with dysmorphic facial features, growth retardation, complex congenital heart disease, and anorectal anomalies. Her weight is 11.6 Kg (<<5%), height is 103 cm (5%), and OFC 43.75 (<<2%). She has peculiar facial features with small triangular face, prominent and posteriorly rotated ears, high nasal bridge, thin lips, and high-arched palate with palatine ridge; and small hands and feet. The cardiac malformation consists of double outlet right ventricle, large ventricular septal defect, mild subvalvular pulmonary stenosis, and malposition of great arteries. She had imperforate anus with rectovestibular fistula. Ultrasound of the kidneys was normal. Skeletal survey demonstrated anterior subluxation at S2-3 level, otherwise normal. MRI of the brain showed pachygyria and polymicrogyria with thin but well-formed corpus callosum. Formal developmental assessment at the age of 5 years revealed significantly immature social and linguistic delays; however her intelligence is entirely normal (IQ 94). Additionally, she has moderate attention deficit and hyperactivity disorder of the combined type, but there is no history of aggressive behavior. Chromosomal analysis revealed normal karyotype. Subtelomeric FISH analysis showed unbalanced translocation between the telomeres of 7p and 20q resulting in partial trisomy 20qter/partial monosomy 7pter. The mother is a balanced carrier of the same subtelomeric rearrangement. To our knowledge this is the first cryptic subtelomeric translocation that involves 7p and 20q.

Mild to moderate postnatal abnormalities in a child with del(6)(q25.1q25.2). *P. Koduru[1], S. Gupta[1], R. Perrone[1], J. Antonelli[2], P. Krietzer[2], J. Fox[2].* 1) Dept Laboratory Medicine, North Shore Univ Hosp, Manhasset, NY; 2) Department of Pediatrics, Schneider Childrens Hospital, New Hyde Park, NY.

Hemizygosity of the constitutional genome is one of the leading etiologic factors underlying congenital anomalies, post natal physical and/or developmental delay. Severity of abnormalities is correlated with the extent of deletions. These deletions may be frequent leading to a specific syndrome, or unique; in the latter type delineation of an associated syndrome is difficult. Here, we present a case of a 6.5 year-old patient with an interstitial deletion in distal 6q and mild to moderate postnatal abnormalities. The propositus is the 5lb 6 oz product of 36-week gestation delivered by NSVD to a 25 year-old G2P1 mother. Neonatal period was complicated by poor such and swallow requiring NG tube feeding for the first two years. She began walking at 2 years and started talking by about third year. Endocrinological evaluation was sought at 6 years because of short stature. At this time the patient weighed 15.7 kg, (<5%, 50% for 4 year-old), reached a height of 102 cm (about 10%), and had a HC of 49.5 cm (about 10%). Other physical findings were remarkable for a high broad forehead, a short neck, hypermobility of the elbows and digits, and extensive side burns. The patient had a 2/6 systolic murmur loudest at apex. Cardiac evaluation was significant for myxomatous thickening and prolapse of both the mitral and tricuspid valves. The patient was enrolled in a regular second grade class with supplemental speech therapy. Karyotype of PHA stimulated peripheral blood from the patient showed an interstitial deletion in the distal long of chromosome 6, 46,XX,del(6) (q25.1q25.2); parental chromosomal studies were normal. Several cases of interstitial deletion in the long arm of chromosome 6 are reported; the majority of them are mapped to the region between 6q14->q23. Deletions in the distal long arm are infrequent. There is considerable heterogeneity in clinical features of patients with deletions in the distal region. Nevertheless, all patients had mental retardation; other frequently noticed features included developmental delay, growth retardation, and hypotonia.

Defining the 3p14 microdeletion syndrome. *F. Mari[1], S. Gimelli[2], T. Pramparo[2], C. Pescucci[1], C. Speciale[1], M.A. Mencarelli[1], G. Hayek[3], M. Zappella[3], O. Zuffardi[2], A. Renieri[1].* 1) Molecular Genetics, Med Genet, University of Siena, Siena, Siena, Italy; 2) General Biology and Medical Genetics, University of Pavia, Italy; 3) Child Neuropsychiatry, Azienda Ospedaliera Senese, Italy.

We here report a 26 year-old male patient with mental retardation and dysmorphic features. Facies is characterized by high forehead, epicanthic folds attenuating with the age, broad nasal bridge, bulbous and broad nasal tip with hypoplastic alae nasi, slightly posteriorly angulated ears of normal length with thick helix and hypoplastic lobules. He has a normal head circumference. He also has very small hands and feet and pes planus, contractures of finger joints and camptodactyly of the 5 finger. He is able to walk even if on a broad base and language is absent. A brain MRI, performed at 14 years, showed hyperplasia of corpus callosum. During the examination he shows an aggressive and self-injuring behavior even if parents refer a quite behavior. Standard karyotype was normal. High resolution karyotype revealed the presence of an interstitial deletion: 46,XY,del(3)(p14.3;p14.1). Whole genome array-CGH analysis confirmed a deletion of about 8 Mb of the short arm of chromosome 3. Interstitial deletions of proximal 3p were reported in other 13 cases. All of them were identified by standard karyotype. Some of them are slightly larger deletions totally missing the band p14 and the others partially overlap extending toward the centromere. The one reported here is the smaller reported deletion. Some dysmorphic features like high forehead, epicanthic folds and dysmorphic ears seem to be consistent with a deletion of this region. A wider use of array-CGH may lead to the identification of additional microdeletions, further delineating a specific syndrome. We are therefore searching for other patients with overlapping deletions in order to further define a potential genotype-phenotype correlation.

Immunologic Abnormalities in Smith-Magenis syndrome (del 17p11.2). *W. Introne[1], A. Jurinka[1], D. Krasnewich[1], F. Candotti[2], A.C.M. Smith[1,3].* 1) OCD/NHGRI/NIH, Bethesda, MD; 2) MGBB/NHGRI/NIH, Bethesda, MD; 3) Georgetown Univ.Med. Ctr., Washington, DC.

Since its first description in 1982, the clinical phenotype of Smith-Magenis syndrome (SMS) has been well characterized, including minor anomalies, developmental delay/MR, behavioral characteristics, and sleep disturbance. In 1996, Greenberg et al. reported decreased serum immunoglobulin levels (IgM) in 3/13 (23%) SMS patients studied. Clinical history information commonly includes chronic otitis media often leading to recurrent ear tube placement, chronic sinusitis, and upper respiratory tract infections. To further evaluate this relationship, a systematic study of serum immunoglobulins IgA, IgG, and IgM was conducted to determine the frequency of immune function abnormalities. Immunoglobulin profiles obtained at the initial visit were examined in 49 individuals (30F/19M) with confirmed SMS diagnosis (del17p11.2). Mean age was 6.8 yr.(range 6 mo.-21 yr.). All individuals were enrolled on an IRB-approved SMS natural history study at NIH (protocol 01-HG-0109). Observed values were compared with published age normative data (Jolliff et al., 1982) and defined as Low (5%tile), Normal (5-95%tile) or High (95%tile). **Results**: Immunoglobulin abnormalities were observed in 24/49 (49%) of our SMS study group. In general, IgA levels clustered in the lower limits of normal, with 13/49 (26.5%) SMS subjects greater than 2 standard deviations below the mean (Low); one subject had a borderline high IgA level (95%tile). Similar findings were observed for IgG (9/49 Low) and IgM (10/48 Low). All three levels were low in one child; 11 children were Low for two of three immunoglobulins. Only 25/49 (51%) had normal IgA, IgM and IgG levels for age. The observed distribution was significantly different than expected (p=.0001). **Summary**: Low immunoglobulin levels were observed more frequently than previously reported in SMS and may contribute to the recurrent infections observed. Longitudinal assessment of immune function is needed to understand the significance of these findings.

CHD7 (CHARGE) mutation and successful T-cell infusion in a patient with choanal atresia, hypocalcemia, GU reflux, heart defect, and congenital T-cell failure. *E. Lisi[1,2], L. Hoefsloot[3], A. Baas[3], K. van der Donk[3], D. Loeb[1,4], G. Thomas[1,5], J. Winkelstein[1,6], A. Kline[7], J. Hoover-Fong[1,2].* 1) Johns Hopkins Univ, Baltimore, MD; 2) McKusick-Nathans Inst Genet Med, Baltimore, MD; 3) Dept Human Genet, Radboud Univ Nijmegen Med Centre, Nijmegen, The Netherlands; 4) Dept Onc & Ped, Sidney Kimmel Comp Cancer Center; 5) Kennedy Krieger Inst, Baltimore, MD; 6) Dept Immun & Ped; 7) Harvey Inst Hum Genet, GBMC, Baltimore, MD.

This is a 6 month old Caucasian male with unilateral choanal atresia, glottic web, tracheomalacia, perinatal hypocalcemia, grade 5 vesicoureteral reflux, aberrant left subclavian artery, severe T-cell deficiency, and cupped auricle. He had a tracheostomy and G-tube placement with Nissan fundoplication, and later allogenic peripheral blood mononuclear cell infusion at 3 months. Post-infusion course was complicated by graft versus host disease. However, engraftment was successful, as he tolerated a culture-positive pertussis infection and responded to immunizations. Hypocalcemia and T-cell deficiency are consistent with 22q11 deletion syndrome. Such extreme congenital T-cell failure is not common in CHARGE syndrome, though choanal atresia, GU reflux, and ear anomalies are associated (Coloboma, Heart defects, Atresia of choanae, Retarded growth/development, Genital abnormalities, and Ear anomalies/deafness). An aberrant left subclavian artery is atypical for both disorders. Due to poor T cell quality, initial peripheral blood karyotypes failed. FISH for 22q11 deletion syndrome on interphase nuclei was normal. Sequencing fibroblast DNA demonstrated a 6155-6157 CTC>AGA heterozygous mutation in exon 31 of CHD7 (numbering based on GenBank entry NM_01778). The CT>AG is a nonsense mutation, leading to premature termination (S2052X). The C>A is a silent mutation (R2053R). Parental sequence over these nucleotides was normal. This case illustrates a mutation in a newly identified gene for a disorder often on clinical geneticists differential with 22q11 deletion syndrome. Furthermore, this is an example of extreme congenital T-cell deficiency in CHARGE syndrome with the first reported successful treatment by unrelated donor T-cell infusion.

Optimal features predicting 22q11.2 deletion syndrome in adults with tetralogy of Fallot. *A.S. Bassett[1,2,3], A. Fung[2], G.D. Webb[3,4], M.A. Gatzoulis[3,5], E. Chow[1,2].* 1) Dept of Psychiatry, University of Toronto, Toronto, ON, Canada; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Division of Cardiology, Dept of Medicine, University Health Network, Toronto, Ontario, Canada; 4) Adult Congenital Heart Center, Univ of Pennsylvania, Philadelphia, USA; 5) Adult Congenital Heart Program, Royal Brompton Hospital, London, UK.

22q11.2 Deletion Syndrome (22qDS) continues to be under-recognized, particularly in adults. Determining an optimal set of features using standard methods could be helpful in clinical settings where it is infeasible to test for the deletion in all individuals, e.g., adults with tetralogy of Fallot (TOF). We are actively screening for features of 22qDS in patients with TOF followed at a congenital cardiac clinic for adults. We systematically assessed adults for the presence of features including: dysmorphic facies, voice abnormalities including hypernasality, learning difficulties or special education, birth defects and hypocalcemia. We detected a 22q11.2 deletion in 31 of 102 adults (49 M, 53 F; mean age = 32.8y, SD = 10.3y) who had FISH using standard clinical probes. We used area under the receiver operating curve (AUC) to determine which feature(s) were best for detection of 22qDS. Our analyses revealed no single feature was adequate as a good (AUC > 0.8) screening test. A combination of global dysmorphic features, learning difficulties and voice abnormalities yielded the highest AUC (0.83, 95 % CI 0.75-0.91). However, including just dysmorphic facies and learning difficulties yielded a similarly high AUC (0.82, 95% CI 0.76-0.89), suggesting these two clinical features may be adequate in selecting individuals at high risk for 22q11.2 deletions. Cardiologists following adults with conotruncal and other cardiac anomalies should actively assess for the presence of dysmorphic facies and learning difficulties in order to identify patients most likely to have 22qDS.

Identical twins with Klinefelter syndrome (47,XXY) and gender dysphoria. *C.A. Friedrich[1], S.H. Gleason[2], G.L. Barnett[1], C.W. Yu[1].* 1) Dept Prev Med, Medical Gen,; 2) Dept Psychiatry, Univ Mississippi Medical Ctr, Jackson, MS.

A man was evaluated for depression and gender dysphoria. He had been treating himself with estrogen and aldactone obtained without a prescription and wanted to pursue sex-change surgery. Due to his abnormal hormonal profile, blood chromosomes were studied and showed a 47,XXY karyotype. It was recommended he discuss with his identical twin the twins risk for having Klinefelter syndrome. Cytogenetic study on the brother was performed and he also has a 47,XXY karyotype. He is also interested in sex-change surgery. Both brothers also had low levels of free and total testosterone. Both brothers have had major academic problems, reported speech and articulation problems, and psychological problems that are known to occur often in patients with Klinefelter syndrome. Neither man is interested in pursuing a sperm count analysis at present to assess fertility. Both men declined recommended testosterone replacement therapy because it would interfere with sex-change surgery. Identical twins with Klinefelter syndrome have been reported rarely. Gender dysphoria is not known to be a feature of Klinefelter syndrome, and complicates the standard recommended treatment. The occurrence of gender dysphoria in identical twins may represent the expression of another gene or genes that both patients possess.

Multiple pterygium syndrome in first cousins. *M.T. Greally.* Dept Pediatrics, Saad Specialist Hosp, Al-Khobar, Saudi Arabia.

Multiple pterygium syndrome may be inherited as an autosomal dominant, recessive or X-linked recessive trait. The syndrome is characterized by webbing of the skin of the neck, joint contractures, and craniofacial, skeletal and other anomalies. In the autosomal dominant variant (OMIM # 178110) both severe and mild symptoms have been reported in the same family. The X-linked recessive form (OMIM # 312150) has been described in a small number of patients and is a lethal variant. At least two autosomal recessive variants have been described: Escobar syndrome (OMIM # 265000) and lethal multiple pterygium syndrome (OMIM # 253290). There is considerable overlap of clinical features between all variants of this syndrome although some abnormalities appear to be syndrome-specific. The affected individuals presented here are from three families of first cousins. The parents are second cousins: two brothers and one sister married to two sisters and one brother. The proband is a 6-year-old boy with clinical features of lethal multiple pterygium syndrome. An older sister, who died at one month of age, had joint contractures, lung hypoplasia and a severe cardiac defect. A younger brother had severe lung hypoplasia and joint contractures and died at 3 days of life. In one family of first cousins 14-year-old twin boys are affected. In the other family there are two affected boys. The proband has webbing of the neck, elbow, knee and axillae, downslanting palpebral fissures, ptosis, low-set ears, micrognathia, rocker-bottom feet, camptodactyly, low posterior hairline, hypoplastic genitalia and a crouched stance. He has kyphosis of the upper dorsal spine with fusion of vertebral bodies, increased interpedicular spaces, spina bifida in the sacral region and left-sided diaphragmatic eventration. All affected children have normal intelligence. The features of multiple pterygium syndrome in the proband combine those described in both Escobar syndrome and lethal multiple pterygium syndrome. This family is currently undergoing investigation for possible location of the gene responsible for this condition. It will be interesting to see if multiple pterygium syndrome shows locus heterogeneity or if the different types of this syndrome are all allelic variants.

Two familial cases of Parry-Romberg Syndrome--evidence of Mandelian inheritance and vascular involvement?

A. Tsai. Section of Clinical Gen & Metabolism, Childrens Hosp, Denver, CO.

Parry-Romberg syndrome is characterized as slowly progressive atrophy of the soft tissues of half the face, accompanied by epilepsy, trigeminal neuralgia, and changes in the eyes and hair. To date, no unifying etiology has been identified although many other clinical associations have been reported: localized scleroderma, brain space occupying lesion, infection and trauma. Schievink et al 1996 reported the assocation of intracranial aneurysms and Woolfenden et al., 1998 demonstrated reversible vessel caliber changes on cerebral angiography. Many affected individuals also manifest stroke, stroke-like(TIA) and migraine symptoms. Therefore, vascular component may play very important role in the pathogenesis of this condition. Most cases were sporadic and review of the literature did not support autosomal dominant inheritance (OMIM). I herein report two familial cases with this condition. Family one composed of one affected mother and 2 affected daughters. Mother was diagnosed at 28 years with Reynolds phenomenon and autoimmune diseases. One daughter was diagnosed at 13 with noticeable facial asymmetry. The other one was diagnosed in 20s with minimal facial asymmetry yet severe headache of vascular nature. Both daughters have very similar MRI findings: abnormal cerebral deep white matter with increased T2 signal. Family two composed of a father and daughter with facial asymmetry, malocclusion and misalignment of teeth. Father was 28 and the daughtor was 3 at diagnosis. My two familial cases suggest that Parry-Romberg Syndrome can present as autosomal dominant inheritance at least in a subset of individuals. The first family also suggests that the ascertainment of this diagnosis may not be correct. While most patients with this diagnosis have facial asymmetry; facial asymmetry may not be the only cardinal feature. The association with autoimmune Reynolds phenomenon which has a strong vascular component serves another evidence for vascular disturbance. I hypothesize the gene for Parry-Romberg syndrome may be inherited as an autosomal dominant trait as a predisposition with multifactorial modification as seen in many autoimmune diseases.

Cardiovascular Malformations in deLange Syndrome. *B. Strauss[1], A. Lin[2], B. Pober[1,3], V. Dalili-Shoaie[1], S. Malik[4], M. Curtis[5], V. Kimonis[1].* 1) Genetics, Boston Children's Hospital, Boston, MA; 2) Genetics & Teratology, MassGeneral Hospital for Children, Boston, MA; 3) Surgery, Children's Hospital, Boston, MA; 4) Cardiology, University of Arkansas Medical Sciences, Little Rock, AR; 5) Genetics, University of Arkansas Medical Sciences, Little Rock, AR.

Cornelia de Lange syndrome (CdLS) is characterized by distinct facial features, growth restriction, limb and GI abnormalities, and developmental problems. Mutations in the gene NIPBL have been identified recently in association with CdLS (Krantz et al., 2004). Large series have reported cardiovascular malformations (CVMs) in 13-25 percent. The largest genotype-phenotype analysis reported that septal defects were most common but did not analyze CVMs in detail. Upon literature review, we observed a variety of CVMs. We also studied patients from our catchment area as well as from the University of Arkansas. Our review focused on the pattern of CVMs in a total of 64 patients. The most common CVMs were atrial and ventricular septal defects (36/64 or 56 percent), followed by pulmonic valve stenosis (7 isolated, 4 with septal defects for 11/64 or 17 percent). Both exceeded the general population frequency of the Baltimore-Washington Infant Study (37.7 and 7.9 percent, respectively). No other CVM class was more common than in the general population: 1 single ventricle, 6 TOF, 2 atrioventricular canal defect, 6 left sided obstruction (2 classic HLHS, 1 variant, 1 mitral atresia, 1 COA, 1 aortic stenosis), 1 PDA, and 1 aorto-pulmonary window. Thus, septal defects and pulmonic stenosis appear to be over-represented in CdLS. However, both over and under-ascertainment were likely. Many septal defects closed spontaneously; others may have been missed because of no imaging or autopsy. Failure to include milder CdLS cases may limit inclusion of less serious CVMs. We are eager to collaborate to pursue genotype-phenotype studies of the NIPBL gene, using well-defined patients with uniform cardiology imaging. We conclude that diverse CVMs are associated with CdLS, though both septal defects and pulmonic stenosis appear to be more common. (A.L. supported by MA Center for Birth Defects Research and Prevention, Massachusetts DPH.).

A Congenital, Rhizomelic Skeletal Dysplasia Associated With Bilateral Imperforate Irises. *D.L. Skidmore[1], S. Unger[1,2], A. Superti-Furga[2], D. Rootman[3], A. Levin[3], J. Pierre- Louis[1,4], D. Chitayat[1,4].* 1) Division of Clinical Genetics & Metabolics, Hospital for Sick Children, Toronto, ON, Canada; 2) Center for Pediatrics and Dept. of Human Genetics, University of Freiburg, Germany; 3) Dept of Ophthalmology, Hospital for Sick Children, Toronto, Canada; 4) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada.

The combination of a lethal skeletal dysplasia and abnormality of the anterior chamber of the eye was reported once (Akaba et al., 1996), we report a case of osteochondrodysplasia with absent pupils seemly distinct from this case. Our patient was the product of her parents first pregnancy and her parents were non-consanguineous. Prenatally, short limbs were detected on an ultrasound at 34 weeks gestation (but not at 20 weeks gestation). At birth, she was noted to have rhizomelic limbs, severe platyspondyly, delayed maturity of the pubic bones and gracile ribs and long bones. Craniotabes was also present. There was occipitalization of the posterior arch of C1 with narrowing of the spinal column. The spinal cord itself was not impinged on, and the childs neurological examination and an MRI of the spinal cord and brain were unremarkable. The head was microcephalic with proportionate microphthalmia, with an abnormal anterior segment in which iris failed to perforate, causing absence of the pupils. The structures of the posterior segment of the eye appeared normal on ultrasound and MRI, as did the central nervous system. The child is now several months old and thriving and there has been no evidence of respiratory distress. Her skeletal features did not correspond to those of common dysplasia. This case represents a novel association of congenital rhizomelic skeletal dysplasia with an ophthamological anterior segment abnormality, namely an imperforate iris.

A Patient with Distinctive Eyebrows, Syndactyly of the Feet, Unilateral Hypoplastic Fifth Finger, and Pili Torti: A New Syndrome. *D. Gul.* Dept. of Medical Genetics, GATA Medical School, Ankara, Turkey.

There is a wide variation in the color, distribution and density of eyebrows. Some hereditary variations are of no known significance, but others are associated with other developmental defects, or are parts of a recognized syndrome. In this report an association of a distinctive eyebrow with other abnormalities in a male is presented. The proband was a 20-year-old male, referred to our hospital because of his facial appearance and foot syndactyly. He was born as second one of four children to healthy nonconsanguineous parents. He was morphologically normal during pregnancy and early childhood. Family history was negative. On admission, his height was 190 cm and weight was 82 kg. The mental status of the individual was normal. He had a mildly remarkable facial appearance: telecanthus, mildly narrow palpebral fissures, dysplastic and posteriorly rotated ears. His hair was curly and dark in general, and dense particularly in the occipital area. The eyebrows were interrupted and arched with late thinning, resembling that of Mr. Spock of the movie, Star Trek. His beard was not dense, but growing upward. Microscopic examination of the scalp hairs showed pili torti. Thumbs and little fingers were short, and on the left, there was a dysplastic nail and marked deficiency. Unilateral incomplete cutaneous syndactyly of the 4th and 5th fingers of the left hand was also noted. Right 5th finger had a single flexion line while left 5th finger was normal.Craniography showed impressiones digitatae. Cytogenetic study with high resolution banding revealed a normal 46,XY karyotype. The case presented here is differentiated from the condition named as tricho-odonto-onchyo dermal syndrome reported by Pinheiro et al. [1981], Kabuki syndrome, and fetal hydantoin syndrome, similar to those of cases reported by Berkenstadt et al. 1988, Gross-Kieselstein and Har-Even 1989. The small number of reported cases would suggest that the phenotypic spectrum of this group of disorders has not been fully defined. This case presented here represents a new distinct entity with bilateral eyebrow abnormality accompanied by multiple congenital abnormalities.

Spondylocostal Dysostosis with urogenital anomalies: Casamassina Morton Nance Syndrome. *J. Montoya, R. Garcia, I. Zarante, F. Suarez.* Inst de Genetica Humana, Univ Javeriana, Bogota Cundinamar, Colombia.

Newborn female, product of fourth pregnancy, 37 years old mother. Caesarean delivery due to placentary insufficiency, the prenatal ultrasound reported mesenteric cyst, and enhanced, nucal translucency. Karyotype by amniocentesis was a normal 46 XX. On medical examination the patient presented a single umbilical artery, mammary hypertelorism, diastasis of cranial sutures, low set ears and overfolding of the helix, short neck with redundant skin, and a right paraumbilical mobile mass of hard consistency. Rhizomelic shortening of upper limbs, asymmetric short thorax and urovaginal fistula. The Echocardiogram showed pulmonary hypertension and permeable oval foramen. Abdominal Ultrasound found hypoplastic kidneys with increased echogenicity, loss of corticomedular differentiation and in pelvic fossa was observed a tubular and serpiginous structure with echogenic content inside suggestive of intestinal liquid. Thorax X-rays, demonstrated asymmetrical costal arches with right hypoplastic ribs and thoracic hemivertebras. The exact aetiology of the abdominal mass was not definitely establish, the abdominal mass reduce by itself without any specific treatment. We believe that the association of a single umbilical artery, urogenital anomalies and spondylothoracic dysplasia suggested that this is a distinct entity of the Jarcho-Levin syndrome (OMIM: 27300) and the case could be a new patient with the Casamassina Morton Nance Syndrome (OMIM: 271520).

Characterization of a severe Smith-Lemli-Opitz Syndrome Mutation. *L.S. Correa-Cerro, F.D. Porter.* Heritable Disorders Branch, NICHHD/NIH, Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is a common autosomal recessive metabolic disorder in Caucasians. SLOS is due to a deficiency of 7-dehydrocholesterol reductase (DHCR7) activity that results in elevated 7-dehydrocholesterol levels and typically decreased cholesterol levels. The clinical spectrum ranges from mild to severe. Here we report a severely affected SLOS patient who died 12h after birth. Cranial facial features included an asymmetric calvarial vault, cleft palate and micrognathia. External genitalia were ambiguous. Pathological examination of the heart showed dysplastic mitral valve, patent foramen ovale, patent ductus arteriosus, aortic valvular stenosis, and hypoplastic left ventricle. Karyotype was 46,XY, and chromosome 22 deletions were excluded by FISH using the Tuple 1 probe. The patient was a compound heterozygote for DHCR7 mutations IVS8-1G>C and 957A>G (T319A). We analyzed the effect of the T319A mutation on protein stability and subcellular localization using a Flag epitope tag in COS cells. COS cells were transfected with either a mutant DHCR7 expression plasmid (Flag-DHCR7T319A) or an expression plasmid expressing DHCR7 (Flag-DHCR7). After 24h, RNA was extracted and analyzed for gene expression by relative quantitative PCR. Both the Flag-DHCR7 and the Flag-DHCR7T319A were expressed. Western blot analysis of cell lysates from COS cells transfected with a Flag-DHCR7T319A expression construct detected a slight band of the mutant protein under conditions where the control Flag-DHCR7 protein was very well detected. Immunostaining of cells established the endoplasmic reticulum localization of DHCR7 in COS cells transfected with Flag-DHCR7. In contrast, only background fluorescence was observed in COS cells transfected with Flag-DHCR7T319A. These data suggest that the T319A mutation destabilizes DHCR7 and in combination with a null allele, IVS8-1G>C, can result in a severe phenotype.

A Japanese Michelin tire baby syndrome patient complicated with Lowe syndrome. *M. Hara[1], T. Kondoh[1], S. Oka[2], A. Tanaka[1], O. Shimokawa[3], N. Harada[3], N. Miyake[4], N. Matsumoto[4], H. Moriuchi[1].* 1) Dept of Pediatr, Nagasaki Univ Hosp, Nagasaki, Japan; 2) Dept of Pediatr, Sasebo Kyosai Hosp, Sasebo, Japan; 3) Kyushu Med Sci Nagasaki Lab, Nagasaki, Japan; 4) Dept of Hum Genet, Nagasaki Univ Grad Sch of Biomed Sci, Nagasaki, Japan.

Congenital symmetrical circumferential skin crease is a cardinal manifestation of Michelin tire baby syndrome (MTBS), and associated with additional clinical features. On the other hand, Lowe syndrome, also called oculo-cerebro-renal syndrome of Lowe (OCRL), is an X-linked recessive disorder characterized with cataract, hypotonia, mental retardation, renal tubular dysfunction and rickets, and is caused by mutation of OCRL1 gene located on Xq26.1. We here report a MTBS patient complicated with Lowe syndrome. Patient, a 21-month-old boy, is the second child of nonconsanguineous healthy mother and father aged 34 and 39 years, respectively, when the boy was born. He was born at 39 weeks of gestation with weight and length of 2,804 g (-1.0 SD) and 48.0 cm (-0.9 SD), respectively. He had bilateral congenital cataracts, for which both eye lenses were removed surgically at 1 month of age. He was also noted to have hypotonia, developmental delay, bilateral undescended testes and multiple circumferential skin creases. Magnetic resonance imaging examination revealed severe thickened adipose tissue around extremities and shoulders. His growth has been deteriorated from 6 months of age, and his height and weight were 71.8 cm (-4.2 SD) and 7,475 g (-3.4 SD), respectively at 21 months of age. Thus, although he was diagnosed as MTBS, he was unique to have bilateral cataract and developmental delay. At 10 months of age, pan-aminoaciduria and renal tubular acidosis were detected; therefore, he was compatible with Lowe syndrome. His total DQ is around 30 at 21 months of age. Microarray-based comparative genomic hybridization analysis disclosed no abnormality using subtelomeric and other BAC/PAC clones including OCRL1 region of Xq26.1. This is the first case of MTBS complicated with Lowe syndrome and further examinations will be needed to clarify whether those two syndromes are etiologically related or occurred by chance.

Genetic heterogeneity of Shprintzen-Goldberg syndrome. *R. Kosaki[1], D. Takahashi[2], T. Udaka[2], M. Matsumoto[3], S. Ibe[4], T. Isobe[5], Y. Tanaka[6], K. Kosaki[2].* 1) Dept of Clin Genet & Mol Med, Natl Children's Med Ctr, Tokyo; 2) Dept of Pediatrics, Keio Univ Sch Med, Tokyo, Japan; 3) Dept of Orthoped Surgery, Keio Univ Sch Med, Tokyo, Japan; 4) Dept Orthoped Surgery, Ibaraki Prefectural Rehabilitation Ctr, Ibaraki, Japan; 5) Dept of Pediatrics, Ibaraki Children'fs Hospital, Ibaraki, Japan; 6) Dept of Pediatrics, Ichikawa General Hosp, Tokyo Dental College, Chiba, Japan.

Shprintzen-Goldberg syndrome (SGS MIM[182212]) is characterized by craniosynostosis and Marfanoid features. To date, two mutations in FBN1 have been reported among SGS patients: C1223Y and P1148A amino acid substitutions. The heterozygous C1223Y substitution occurred de novo and was located at one of the six highly conserved cysteine residues within the 47 repetitive EGF-like domains; this substitution was thus considered pathogenic. On the other hand, the P1148A substitution, which was initially regarded to be pathogenic, was later found to be a polymorphic variant. Hence, C1223Y is the only FBN1 mutation that has been unambiguously associated with the SGS phenotype to date. Recently, Loeys et al. reported six families with TGBFR2 and four families with TGFBR1 [MIM 190181] mutations who presented with a previously undescribed aortic aneurysm syndrome characterized by hypertelorism, bifid uvula and/or cleft palate, and generalized arterial tortuosity with ascending aortic aneurysm, collectively referred to as Loeys-Dietz aortic aneurysm syndrome. Similarity between LDAAS and SGS was discussed in their paper. We document two patients with classic SGS phenotype: one with a heterozygous TGFBR2 mutation (IVS5-2a>g) leading to a 10-amino acid insertion in the kinase domain, and the other with a heterozygous FBN1 mutation (C1221Y) leading to the disruption of a disulfide bond, as in the C1223Y mutation. In addition, the patient with the FBN1 C1221Y mutation was heterozygous for the T315M substitution of TGFBR2, a known functionally relevant polymorphism. We suggest that genetic heterogeneity is present in the pathogenesis of SGS and that TGFBR2 can act either as the causative gene or as a modifier gene in the pathogenesis of SGS.

X-LINKED RECESSIVE FUSION OF METACARPALS IV- V ASOCIATED WITH CARPAL SYNOSTOSIS.

J. Mantilla, L. Arnaud, P. Barros. División de Genética, Centro de Investigación Biomédica de Occidente, IMSS. Guadalajara, México.

INTRODUCTION Metacarpal synostosis is a rare malformation, clinically variable, and causally heterogeneous. It usually affects the 4th and the 5th metacarpal bones, and can be observed as an isolated anomaly on otherwise normal individuals, or associated with other malformation as the Waardenburg-anoftalmy syndrome. In its isolated form, only three families have been reported showing X-linked inheritance. We report a fourth family with five males affected in three generation, confirming the X-linked recessive pattern of this abnormality. In addition, fusion of carpal bones is segregating in this family, which has not been reported before. CLINICAL REPORT The propositus, a nine years old male, was born after 39 weeks of an uneventful pregnancy from healthy and unrelated young parents. By maternal side, there are other four affected males. At birth, height was 51 cm, weight 3050 gr and head circumference 35 cm. Normocephaly and normal facial features. Upper limbs showed bilateral hipoplasy and ulnar deviation of 4th and 5th fingers. X-ray reveled proximal fusion between IV and V metacarpals with brachyphalangia of the 5th finger; other four members of this family showed the same malformation. The propositus and other two individuals showed additionally carpal fusion (trapezius and trapezoid), with ulnar deviation and tenar hipoplasy. CONCLUSSION We report a family carrying an IV-V metacarpal synostosis, with an additional fusion of the carpal bones. This very interesting association of malformations has not been reported previously. Additionally, this large family confirms the recessive X-linked inheritance mode of this abnormality.

Phenotypic spectrum of CHARGE syndrome in antenatal and postnatal series with *CHD7* gene truncating mutations correlates with expression during human development. *D. Sanlaville[1], H.C. Etchevers[1], M. Clément-Ziza[1], B. Keren[1], S. Audollent[1], V. Abadie[2], D. Bonnet[2], F. Brunelle[2], G. Couly[2], P. Hubert[2], D. Jan[2], Y. Manach[2], D. Sidi[2], A. Munnich[1], M. Vekemans[1], J. Amiel[1], T. Attié-Bitach[1], S. Lyonnet[1].* 1) Dept Genetics and INSERM U393, Hopital Necker Enfants Malades, Paris, France; 2) Dept Pediatrics and Surgery, Hopital Necker Enfants Malades, Paris, France.

The acronym CHARGE, coined by Pagon refers to a non-random cluster of malformations first described by Hall including **C**oloboma, **H**eart malformation, choanal **A**tresia, **R**etardation of growth and / or development, **G**enital anomalies, and **E**ar anomalies, all features being inconstant and non specific. This Multiple Congenital Anomalies - Mental Retardation syndrome is frequent, and prognosis remains poor. Recently, *CHD7* gene mutations have been identified in CHARGE patients, however the function of *CHD7* during development remains unknown. We therefore studied a series of 10 antenatal cases ascertained on pathological examination and compared with 60 postnatal cases in whom the diagnosis was suspected, considering modified Pagon criteria. The findings of *CHD7* mutations in each of the fetuses allowed us to better delineate the full phenotypic spectrum of the developmental anomalies resulting from *CHD7* haploinsufficiency. Conversely, the percentage of mutations in postnatal series did not exceed 50 %. Interestingly, arhinencephaly and semi-circular canal agenesis were two very frequent features that do not belong to diagnostic criteria so far. Moreover, *in situ* hybridization analysis of the *CHD7* gene during early human development emphasized the role of *CHD7* in the development of central nervous system, internal ear, neural crest of pharyngeal arches, and more generally showed a good correlation between specific *CHD7* expression pattern and the developmental anomalies observed in CHARGE syndrome.

A Japanese patient with Klippel-Trenaunay-Weber syndrome complicated with renal arteriovenous abnormality. *A. Tanaka, T. Kondoh, Y. Nakashima, H. Moriuchi.* Dept of Pediatr, Nagasaki Univ Hosp, Nagasaki, Japan.

Klippel-Trenaunay-Weber (KTW) syndrome is characterized by large cutaneous hemangiomata with hypertrophy of the related bones and soft tissues. Previously, KTW syndrome patients with hematuria due to the rupture of hemangioma in intrapelvic region have been reported, but macrofistulous arteriovenous (AV) communications are very rare. In contrast, Parkes Weber (PW) syndrome is characterized by a cutaneous flush with underlying multiple micro-AV fistulas, in association with soft tissue and skeletal hypertrophy of the affected limb. Whether KTW syndrome and PW syndrome are in the same entity is unknown. We here report a KTW syndrome patient with renal AV abnormality. Patient, a 9-year-old girl, is the second child of nonconsanguineous healthy mother and father aged 33 and 35 years, respectively, when she was born. Hemihypertrophy of right leg was pointed out at birth. The circumference of the right femoral region was 2.0 cm larger than that of the left corresponding region. The length of the right leg was 2.0 cm longer than that of the left. Her right femoral bone was bigger than the left in bone X-P. Echogram of her abdomen and right femoral region showed enlargement of the right kidney and soft tissue hypertrophy of the right leg, respectively. Magnetic resonance imaging (MRI) of her right leg at 5 years of age revealed soft tissue hypertrophy with subcutaneous hamangioma and venous dilatation. Her karyotype was 46,XX. She was diagnosed as KTW syndrome and followed by orthopedists because of her leg hemihypertrophy. At 8 years of age, she developed macrohematuria. Abdominal echogram with color doppler studies, enhanced computed tomography and MRI examinations were indicative of AV malformation or fistula of her right kidney. Recently, RASA1 and VG5Q genes, both of which are located on 5q13.3, were reported to be causative of capillary or AV malformation seen in KTW syndrome or PW syndrome, respectively. Therefore, complication of AV malformation in KTW syndrome may have implications in the etiology and pathogenesis of the two syndromes. Further radiological and genetic studies are needed to clarify the pathogenesis of renal AV malformation in our case.

Pterygium colli, craniofacial dysmorphism, asymmetric chest deformity, short stature, microcephaly and global developmental delay: A new MCA/MR syndrome? *EvaM. Tomiak[1,2], GailE. Graham[1,2].* 1) Division of Medical Genetics, Children's Hospital of Eastern Ontario, Ottawa, Canada; 2) University of Ottawa.

Pterygium colli, which can be a consequence of prenatal lymphedema, can occur as an isolated finding. It can also be seen in Klippel-Feil sequence, in association with a variety of partial aneuploidies and aneusomies, and in several common and a few rare single gene disorders. Pterygium colli has been described as a component of several MCA/MR syndromes, where it is seen in combination with trigonecephaly and pectus excavatum (Haspelagh syndrome), microcephaly, hypotonia and growth failure (18p deletion), or characteristic facial features (mosaic trisomy 22; partial trisomy 3q). Pterygium colli and MR have also been reported in association with macrocephaly and hypoplastic inverted nipples (al-Gazali LI et al: Clin Dysm 1996; 5(4):321-7), and with edema, epilepsy and pachygyria of the frontal lobes (Fryns JP et al: J Med Gen 2000; 37:460-2).

We describe a 10 year old boy with pterygium colli, global developmental delay, microcephaly, short stature, asymmetry in chest musculature and nipple hypoplasia, who does not appear to fit any of these previously described conditions. He has an extremely long, narrow face with bitemporal narrowing, malar hypoplasia, and prominent anteverted ears. Additional features include valvular pulmonic stenosis, secundum ASD, hypotonia, delayed bone age and minor interdigital syndactyly. There is no history of seizures, developmental regression or behavior problems. Chromosomal, amino acid and urine organic acid analyses have all been normal, as have hand xrays and abdominal ultrasound.

The possibility of a previously unrecognized autosomal recessive condition is raised by the presence of parental consanguinity. Despite extensive literature searches and informal presentation at international dysmorphology meetings, we have not been able to find a unifying diagnosis. We propose that this constellation of features may represent a new distinctive syndrome and hope, by way of this communication, to identify similar individuals at other centres.

Initiation and preliminary analysis of National Cohen Syndrome Database. *L. Nye, J. Renner, H. Wang.* DDC Clinic for Special Needs Children, Middlefield, OH.

Cohen syndrome (CS) is a rare autosomal recessive disorder with about 100 cases reported. The disease is characterized by facial dysmorphism, microcephaly, hypotonia, developmental delay, myopia and retinal dystrophy, neutropenia, and truncal obesity. The mutation of COH1 gene on chromosome 8q22 is believed responsible for CS. However, we believe that CS remains underdiagnosed or misdiagnosed in many cases in the United States because of rarity of the disease, pleiotropic phenotype, unavailability of clinical testing, and lack of extensive study. As an effort to improve disease diagnosis and clinical management and to promote more effective CS research, we have recently initiated the National Cohen Syndrome Database (NCSD) through DDC Clinic for Special Needs Children in Middlefield, OH, where most Old Order Amish CS patients receive their medical care and service coordination. The questionnaire was distributed to the families of 58 patients registered in our National Cohen Syndrome Family Center; 26 are Amish or Amish-originated (Amish) and 32 non-Amish Caucasians (non-Amish). Thirty-seven completed questionnaires, 20 from Amish and 17 from non-Amish, have been entered in NCSD with 2 patients excluded, as they do not fit the CS phenotype. Average patient age is 21 years (range from 1.5 to 45), with 41% male and 59% female. Preliminary analysis of NCSD has shown that although typical CS features have been documented in almost all patients, a significant phenotype variation has been observed among ethnic groups, even among affected siblings in the same family. Some clinical features, although not reported as part of CS before, have been observed during routine primary care for our Amish patients, and confirmed in most non-Amish patients, such as an unusual cry soon after birth (63%), superior hearing capacity (53%), and anxiety (71%). Surprisingly, among the non-Amish patients, only one has DNA mutation confirmation, reflecting the lack of basic research on CS in the US. The ongoing expansion of NCSD, with the addition of more patients, clinical data, and genotype determination, will hopefully lay some ground work for further CS study in this country.

A new panel of microsatellite markers in the PAR1 identifies deletions downstream of *SHOX* in patients with Léri-Weill dischondrosteosis (LWD) and idiopathic short stature(ISS). *S. Benito-Sanz[1], N.S. Thomas[2], C. Huber[3], D. Gorbenko del Blanco[1], M. Aza-Carmona[1], J. Crolla[2], V. Maloney[2], J. Argente[1], A. Campos-Barros[1], V. Cormier-Daire[3], K.E. Heath[1].* 1) Dept. Endocrinology, Hospital Infantil Universitario Niño Jesús, Universidad Autónoma de Madrid, Madrid, Spain; 2) Wessex Regional Genetics Laboratory, Salisbury District Hospital, UK; 3) Dept. of Genetics and INSERM U393, Hospital Necker Enfants Malades, Paris, France.

Léri-Weill dyschondrosteosis (LWD) is an autosomal dominant skeletal dysplasia characterized by short stature and Madelung deformity. *SHOX* mutations have been associated with LWD, Langer mesomelic dysplasia (LMD) and idiopathic short stature (ISS). *SHOX* is located in the pseudoautosomal region 1 (PAR1) of the X and Y chromosome. Previous studies have identified that 60% of LWD patients have a *SHOX* mutation, the majority of which are deletions, whereas in the remaining 40% no genetic defect has been discovered.

We designed a new panel of microsatellites (n=18) in the PAR1 to screen for deletions in the 5' and 3' regions of *SHOX* in LWD/ISS patients in whom no *SHOX* mutation was detected by microsatellite analysis, dHPLC or DNA sequencing. New microsatellites were identified with the help of the Tandem Repeat Finder program (http://tandem.bu.edu/trf.html). We analyzed a cohort of 80 LWD, 18 ISS patients and 2 with Madelung deformity and normal height.

PAR1 deletions downstream of *SHOX* were identified in 12 LWD patients (15%), 1 ISS patient (5.6%) and a patient with normal height and Madelung deformity. The new panel of markers and SNPs within the region allowed us to finely map all 14 deletions to a region 30-530 kb 3' downstream of *SHOX*. Deletions were of variable size (80-500kb) and all shared a common deleted region of 29kb. The identification of PAR1 deletions not including *SHOX* in LWD/ISS patients suggests the presence of either: 1) a position effect affecting transcriptional control of *SHOX* or, 2) the involvement of a second locus in the pathogenesis of LWD and short stature. (sara_bsanz@yahoo.es).

The spectrum of cardiovascular anomalies in Costello syndrome includes arteriopathy. *A. Lin[1], L. Bird[2], J.G. Gillessen-Kaesbach[3], P. Grossfeld[2], R. Hamilton[4], D. Hicks[5], M. Innes[6], B. Kerr[7], U. Moog[8], M. Rebolledo[5], K. Vaux[2], D. Wieczorek[3], K. Gripp[9].* 1) Genetics and Teratology, MassGeneral Hosp, Boston, MA; 2) Univ California, San Diego, CA; 3) Institut Humangenetik, Universitatsklinikum Essen, Germany; 4) Hosp for Sick Children, Toronto, Canada; 5) Children's Hosp Orange County, CA; 6) Alberta Children's Hosp, Calgary, Canada; 7) CM and Manchester Children's Hospitals, England; 8) Univ Hosp Maastricht, Netherlands; 9) A.I. duPont Hosp for Children, Wilmington, DE.

Cardiovascular anomalies have been noted in 2/3 of Costello syndrome (CS) patients, of whom about 1/3 each have a cardiovascular malformation (CVM) (usually pulmonic stenosis, PS), cardiac hypertrophy (often hypertrophic cardiomyopathy, HCM), and/or rhythm abnormality (atrial tachycardia). One-fourth have more than one problem. We studied 61 pts and highlight 14 with arterial anomalies. Although a specific gene defect has not been identified in CS, a deficiency of elastin binding protein has been demonstrated. As an elastinopathy, arterial defects would be predicted. PATIENTS: We reviewed 28 new pts (17 enrolled in a natural history plus 11 from individual authors) and 33 well-documented literature cases. Of the total 61, 16 (26%) had a CVM (76% PS), 31 (51%) had HCM and 32 (52%) had a rhythm disturbance (75% atrial tachycardia). Arterial abnormalities were observed in a total of 14 pts including 4 pts with mild aortic root dilation; a boy who died from a stroke at 27 mos. attributed to cerebral vasculopathy; a 6 mos old girl with HCM who died with coronary artery fibromuscular dysplasia; 2 young girls with severe systemic hypertension (HTN), one of whom has pulmonary HTN; a teenage girl with HTN; 3 pts with coarctation; and 2 pts with supravalvar PS. CONCLUSIONS: In this series, HCM and atrial tachycardia were more common and CVMs slightly less common; reporting bias is suspected. We suggest that cardiovascular disease in CS includes arteriopathy with occlusion and dilation of both small and large vessels, a pattern resembling what is seen in Williams syndrome, the prototypic elastinopathy. Additional pts and further analysis are needed to delineate this initial observation.

Ehlers-Danlos Syndrome Type VIB with Characteristic Facies, Decreased Curvatures of the Spinal Column, and Joint Contractures in Two Unrelated Girls. *T. Kosho[1], J. Takahashi[2], H. Ohashi[3], G. Nishimura[4], H. Kato[2], Y. Fukushima[1].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Department of Orthopedics, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 3) Division of Medical Genetics, Saitama Children's Medical Center, Iwatsuki, Saitama, Japan; 4) Department of Radiology, Tokyo Metropolitan Kiyose Children's Hospital, Kiyose, Tokyo, Japan.

Ehlers-Danlos syndrome, kyphoscoliosis type (EDS VI) is an autosomal recessive disorder, characterized by fragile, hyperextensible, and bruisable skin; generalized joint laxity; hypotonia; kyphoscoliosis, and fragility of the globe. The disorder with EDS VI phenotype but normal activity of lysyl hydroxylase is termed EDS VIB, while EDS VIA is the form with deficiency with deficiency of the enzyme. We describe two unrelated girls, aged 11 and 14; with clinical manifestations of EDS type VIB, characteristic facies, skeletal abnormalities, and other features. They had Marfanoid habitus with pectus excavatum; fragile, hyperextensible, and readily bruisable skin with widened, atrophic scars; recurrent hematomas; generalized joint laxity; hypotonia; scoliosis; and mild delay of gross motor development. Lysyl hydroxylase deficiency was ruled out in Patient 1. Parental consanguinity was present in Patient 2. They both had in early childhood down-slanting palpebral fissures, drooping lower eyelids, short nose, small mouth, and long philtrum. Facial features that persisted included thick eyebrows, hypertelorism, strabismus, blue sclerae, low-set and slanted ears, hypoplastic columella, high arched palate, and thin upper lip. They had tubular stenosis of the phalanges, metacarpals, and metatarsals; decreased physiological curvatures of the spinal column with tall vertebrae; and joint contractures including talipes equinovarus and progressive talipes valgus. Their hearing of high-pitched sounds was impaired. They had constipation and recurrent cystitis with an enlarged bladder. In view of these findings, we propose that these two girls represent a clinically recognizable subgroup of EDS type VIB.

Identification of two novel frame-shift mutations of TOCF1 in Korean patients affected with Treacher-Collins syndrome. *G. Kim[1,2], J. Kim[2], H. Yoo[1,2].* 1) Med Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Genome Research Ctr, Asan Medical Ctr, Seoul. Korea.

Treacher Collins syndrome (TCS; OMIM 154500) is an autosomal dominant disorder of craniofacial development. Clinical characteristics of TCS include malar hypoplasia, micrognathia, downward slanting palpebral fissures, lower eyelid coloboma, malformed auricles, conductive deafness, and cleft palate. Recently, the TOCF1 gene (TOCF1) has been identified as the gene mutated in this craniofacial disease. TCOF1 encodes the nucleolar phosphoprotein treacle that interacts with the upstream binding factor (UBF) and regulates transcription of the ribosomal DNA gene. Using PCR-direct sequencing of the exonic regions of TOCF1, we found two novel mutations, D1379GfsX14 and D1379RfsX14, from two unrelated Korean patients with TCS, both causing a frame-shift mutation at Asp 1379. The D1379GfsX14 and D1379RfsX14 mutations were caused by c.4134_4135insG and c.4134_4135insA, respectively. Both mutations are presumably expected to disturb the regulatory function of TOCF1, deleting the carboxyl-terminal region. Our findings further confirm that functional haploinsufficiency of TOCF1 is responsible for the phenotypic features of TCS. The newly identified mutations will be useful for further understanding of the essential roles of TOCF1 in craniofacial development.

Rhizomelic shortness of upper limbs, abnormal facial appearance and Congenital Heart defect. *F. Suarez[1,2], L. Martinez[2].* 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Hospital Universitario Clinica San Rafael, Bogota, Colombia.

6 months female, normal term delivery. No medication or alcohol during pregnancy. Healthy unrelated parents. Mother of 16 years old. Birth weight 1,8 kg, Body length: 45 cm. OFC: 34 cm. The clinical examination at birth showed sloping forehead, upturned nose, down-turned corners of the mouth and simple ears. Rhizomelic shortness only of upper limbs, normal hands, fingers and nails. Pectum carinatum umbilical hernia and hipoplasia of the clitoris. The Echocardiogram showed Patent foramen ovale, ventricular septal defect, overriding aorta, and right and left ventricular dilatation. vertebral column and lower limbs were normal. The patient developed heart failure and died. Some of these manifestations overlap with those of Robinow syndrome, but we believe that is a new syndrome with particular abnormalities in face, heart defect and exclusive rhizomelic shortening of upper.

Microcephalic Osteodysplastic Primordial Dwarfism type I/III in a Mennonite patient: prenatal ultrasound features and further support for an autosomal recessive mode of inheritance. *J.L. Lauzon, F.P. Bernier.* Dept Medical Genetics, University of Calgary, Calgary, AB, Canada.

We present a young girl with Microcephalic Osteodysplastic Primordial Dwarfism (MOPD) type I/III who was born to a consanguineous Mennonite couple. The pregnancy was complicated by severe IUGR and microcephaly detected on prenatal ultrasound at 19 weeks gestation. Other physical features described on prenatal ultrasound included micrognathia, a sloping forehead with a bulbous broad nose and nuchal thickening. Fetal MRI showed a large interhemispheric cyst and agenesis of the corpus callosum. Post-natal physical examination confirmed the prenatal ultrasounds findings and in addition, noted the presence of small palpebral fissures, absence of scalp hair as well as lack of eyebrows and eyelashes, a prominent nasal root and broad nose were noted. She also had contractures of the elbows and shoulders, brachydactyly with tapered fingers, and thick hands and feet. MRI of the brain post-natally showed an interventricular cyst and lissencephaly. The long bones were short and slightly bowed with mild splaying of the metaphyses. Bilateral hip dislocation and horizontal acetabular roofs were also seen on the skeletal survey. Although the patient has been gaining some weight, the prognosis remains guarded due to her severe microcephaly and extensive CNS involvement. This case highlights the possibility for prenatal diagnosis of MOPD I/III and in hindsight MOPD could have been suspected based on the information available prenatally. MOPD is felt to be an autosomal recessive condition based on previous reports of affected children of consanguineous parents. Thus far, no responsible genes have been identified however the occurrence of this condition in a consanguineous Mennonite not only provides further evidence of an autosomal recessive etiology, the identification of further cases in this population may provide an opportunity to identify the responsible gene by using an autozygosity mapping approach.

Characterization of two cases of partial trisomy 21 due to t(3;21) and t(14;21) translocations. *Y. Kondo[1,2], S. Mizuno[3], K. Yamada[2], Y. Yamada[2], C. Hayakawa[4], T. Ishii[5], N. Wakamatsu[2].* 1) Department of Pediatrics, Nagoya University Graduate School of Medicine, Nagoya, Aichi, Japan; 2) Department of Genetics, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Aichi, Japan; 3) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan; 4) Residental Facilities for Children with Mental and Physical Disabilities, Aichi Human Service Center, Kasugai, Aichi, Japan; 5) Department of Pediatric Psychiatry, Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan.

Down syndrome (DS), the most common birth defect associated with mental retardation, delayed development, characteristic facies and congenital heart disease is caused by mostly trisomy of chromosome 21. Although the critical region underlying this syndrome has been refined to a 1.6-Mb region (DS critical region: DSCR) on chromosome 21q22, the underlying molecular mechanism remains unknown. Here, we present two cases of partial trisomy 21 with clinical features distinct from DS. These patients presented with moderate mental retardation and short stature, but the typical facial appearance of DS was not observed. Each patient had a similarly sized extra chromosome 21 by cytogenetic analysis. We performed FISH analysis to examine whether deletions of DSCR might be associated with unusual clinical features in these cases. The results showed that each extra chromosome 21 contained a distal part of chromosome 3p or 14q at the telomeric region of chromosome 21q. The translocation breakpoint of 21q for each patient was located on the centromeric side of DSCR and the sizes of partial trisomy 21 are ~34.5Mb (21pter-q22.1) and ~33.0Mb (21pter-q22.1) respectively. Taken together, these two patients with partial trisomy 21 lack all of DSCR on chromosome 21q22, and their distinct clinical features are likely caused by the genes located at 21pter- q22.1 and the distal part of chromosome 3p (~9.0 Mb) or 14q (~13.3 Mb).

Mutation study of fibroblast growth factor receptor 2 (FGFR2) gene in Korean kindred with craniosynostosis syndrome. *H.J Kim, S.Y Jeong, J.A Yang, S.J Park.* Dept Medical Genetics, Ajou Univ Col Medicine, Suwon, Korea.

Craniosynostosis is a group of diseases that is generally defined as a premature fusion of one or more cranial sutures. More than 150 syndromes associated with craniosynostosis have been delineated and causative mutations of single genes have been identified in ¡20% of cases. The major genes involved in craniosynostosis encode the transcription factor TWIST and three fibroblast growth factor receptors (FGFRs), FGFR1, FGFR2, and FGFR3. FGFRs are signal-transduction molecules that serve as high affinity receptors for at least 22 fibroblast growth factors (FGFs). FGFRs share a similar sequence structure, characterized by three extracellular immunoglobulin-like domains (IgI, IgII, and IgIII), a single-pass transmembrane segment, and a split tyrosine kinase (TK1/TK2) domain. Mutations in FGFR2, located at 10q26, cause a variety of craniosynostosis syndromes including Crouzon, Pfeiffer, Apert, and Jackson-Weiss syndromes, etc. Molecular basis for the phenotypic variations of FGFR2 gene mutation is not clear. The great majority (94%) of pathogenic FGFR2 mutations are missense in exon IIIa/IIIc, and all confer gain of function to the mutated protein. Few mutations in other regions of FGFR2 including a kinase (TK1/TK2) domain have been reported. In this study, we carried out mutation study of the FGFR2 gene in two Korean kindred with craniosynostosis syndrome. As the results, two point mutations were identified. Missense mutation, C342S, was detected in the exon IIIc of the mutation hotspot region of FGFR2 of 7 years old sporadic case with Crouzon syndrome. The C342S mutation is highly recurrent in Crouzon, Pfeiffer, and Jackson-Weiss syndromes. Another mutation, K641R, was identified in 7 years old familial case with Pfeiffer syndrome and his mother. The K641R mutation in TK2 domain is very rare and only two cases (familial and sporadic) with Pfeiffer syndrome have been reported. These results indicate the allelic heterogeneity of FGFR2 mutations in Korean kindred. With a review of the previously reported cases, clinical variations of patients with FGFR2 mutations were discussed.

A simple multiplex protocol suitable for screening for *MECP2* mutations in girls with mental retardation. *C.M.B. Carvalho[1], W. Camargo[2], S.D.J. Pena[1].* 1) Biochemistry, UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Psiquiatra Infantil do Centro Geral de Pediatria, FHEMIG, Belo Horizonte, Minas Gerais, Brazil.

Mutations in the *METHYL-CpG-BINDING PROTEIN 2* (*MECP2*) gene are associated with a pleomorphic clinical picture. Although the most common presentation is Rett syndrome (RTT), *MECP2* mutations have also been found in patients presenting with autism, Angelman syndrome (AS) or less specific forms of developmental delay. This suggests that perhaps all girls with mental retardation should be screened for *MECP2* mutations. However, implementation of such systematic screening using DNA sequencing, with or without previous mutation-detecting techniques, would be extremely time-consuming and expensive. Thus, there is a need for more simple and inexpensive techniques suitable for clinical laboratories, even at the sacrifice of sensitivity. We thus developed a simple PCR-based multiplex minisequencing protocol capable of detecting the most common *MECP2* mutations. This system theoretically allows the detection of the major point mutations and insertion/deletions, especially in exon 4, in approximately 64% of Rett syndrome patients. In most cases the mutation can be diagnosed without need for sequencing. Using this assay we detected mutations in two out of five patients clinically diagnosed as having RTT (a novel *MECP2* frameshift deletion 863_881del and a missense mutation R133C). We also screened twelve patients who had tested negative for Angelman syndrome and found one with a nonsense mutation - 808 CT or R270X. Two of these Angelman patients had a silent, probably polymorphic, mutation 1233 CT. The simplicity and low cost of this methodology qualifies it a potential screening technique for use in girls with developmental delay.

Bannayan-Riley-Ruvalcaba Syndrome: An unusual presentation with painful vascular malformations in the extremities and Y16 X PTEN nonsense mutation. *R. Klatt, A.S. Teebi.* Div Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada.

Bannayan-Riley-Ruvalcaba syndrome or Ruvalcaba-Myhre syndrome is a phenotypic spectrum characterized by macrocephaly, hamartomatous polyps of the gastrointestinal tract, mucocutaneous lesions, and increased risk of developing neoplasm. Variable developmental delay is common and hemangiomas are found in about 10% of the cases. As with Cowden syndrome, this disorder is often caused by mutations in the PTEN gene. We report on a 12 year old girl who presented at the age of 6 years with a limp and about 2 years later had an MRI which showed probable vascular malformation involving her left foot. Around the same time she developed pain and swelling in her left forearm and in the palm of her right hand which on MRI also demonstrated similar findings. A similar lesion was later seen on the left 4th finger. Dermatology assessment was suggestive of blue rubber bleb nevus syndrome. A wedge biopsy of the lesion in her arm demonstrated a vascular malformation. Her manifestations otherwise included macrocephaly with upswept hairline, antimongoloid eye slant, dental malocclusion, leg length discrepancy, and normal intelligence. Family history showed that the father has macrocephaly. No one else in the family had vascular malformations. Two maternal first cousins were born with neural tube defects. Two distant female relatives had had breast cancer in their fifties and sixties. PTEN gene mutation analysis identified a nonsense mutation, TAT to TAA, at codon 16 in exon 1. Because PTEN mutations are known to predispose to cancer, the information has a great impact on the patient and her family. The case presented here demonstrates the importance of studying PTEN mutations in patients with vascular malformations associated with macrocephaly.

Clinical and cytogenic characterization of a patient with monosomy 1p36 and trisomy 22q13. *R. Saadeh[1], G. Thomas[2], N. Aranyakasemsuk[2], T. Wang[1].* 1) Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD; 2) Genetics Lab, Kennedy Krieger Institute, Baltimore, MD.

Deletion of chromosome 1p36, a well-recognized contiguous gene deletion syndrome, is the most commonly observed terminal deletion in humans with a frequency of 1 in 5000 in the general population. Although most (72%) monosomy 1p36 were found to be due to true terminal deletions, 17% were complex and associated with derivative chromosome 1 (Heilstedt et al., AJHG, 72:1200). Clinical phenotypes for most of these complex alterations of 1p36 have not been well characterized. We report a case of a one-year old male with monosomy of 1p36 and trisomy 22q13.3. This child has a history of IUGR, global developmental delay, hypotonia, and infantile spasms. He has plagiocephaly, microcephaly, large anterior fontanelle, posteriorly rotated and low set asymmetric ears, neurosensorial hearing loss, exotropia, a high arched palate, oropharyngeal dysphagia, Ebstein anomaly, cerebral subependymal cysts, and dysgenesis of the corpus collosum. A high-resolution karyotype study revealed 46,XY and a banding pattern suggestive of terminal deletion of 1p36 and possible rearrangement involving 22q. A fluorescent in situ hybridization (FISH) panel for telomeres confirmed that this child was monosomic for 1p36 (probes: CDC2L1, CEB108/T7) and trisomic for 22q13.3 (probe: D22S1726). Studies on his parents showed that his father carried a balanced translocation of 46XY, t(1;22) (p36.3;q13.3) while his mother had a normal karyotype. To our knowledge this is the first reported case of a patient with monosomy 1p36 and distal 22q trisomy, which emphasizes the need for sub-telomere FISH study in all individuals with monosomy 1p36 to identify de novo or inherited chromosomal rearrangements.

Nail Patella Syndrome: Expansion of the phenotype and first evidence for an association between *LMX1B* mutation position and nephropathy. *E.M.H.F. Bongers[1], F.T. Huysmans[2], G.F. Borm[3], A.M.F. van Remortele[1], J. Schoots[1], L. Hoefsloot[1], R.J.C. Admiraal[4], A. van Kampen[5], H. van Bokhoven[1], E. Levtchenko[6], N.V.A.M. Knoers[1].* 1) Dept of Human Genetics, Radboud University Medical Centre Nijmegen, Nijmegen, Netherlands; 2) Dept of Internal Medicine, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Dept of Epidemiology and Biostatistics, Radboud University Nijmegen, Nijmegen, The Netherlands; 4) Dept of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) Dept of Orthopaedic Surgery, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 6) Dept of Paediatric Nephrology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Nail Patella Syndrome (NPS) is characterized by developmental defects of dorsal limb structures, nephropathy, and glaucoma and caused by heterozygous mutations in the LIM homeodomain transcription factor *LMX1B*. In order to identify possible genotype-phenotype correlations, we performed *LMX1B* mutation analysis and in-depth investigations of limb, renal, ocular, and audiological findings in 106 subjects from 32 NPS families. We detected normal tension glaucoma and sensorineural hearing impairment as new symptoms associated with NPS. Quantitative urinanalysis revealed proteinuria in 21% of individuals. A significant association was identified between the presence of renal involvement in an NPS patient and a positive family history of nephropathy. Sequencing of *LMX1B* revealed 18 different mutations, including 6 novel variants, in 28 families. Individuals with an *LMX1B* mutation located in the homeodomain showed significantly more frequent proteinuria compared to individuals carrying mutations in the LIM-A and LIM-B domains. No clear genotype-phenotype association was apparent for extrarenal manifestations. This is the first study indicating that family history of nephropathy and mutation location might be important in precipitating the individual risk for developing NPS renal disease. We suggest that the NPS phenotype is broader than previously described and that normal tension glaucoma and sensorineural hearing impairment are part of the syndrome.

Affective states and anxiety among Fragile X premutation carriers. *J. Hunter, E. Allen, A. Abramowitz, M. Rusin, R. Letz, M. Leslie, L. Scott, G. Novak, S. Sherman.* Emory University, Atlanta, GA.

FMR1 contains a CGG repeat sequence in its 5 UTR which results in Fragile X Syndrome (FXS) when it exceeds 200 repeats. Alleles with long unmethylated repeats in the range of ~59-199, termed premutation alleles, have recently been associated with premature ovarian failure in females and a tremor/ataxia syndrome in older males. Both conditions are unrelated to the FXS phenotype. Previous studies have produced conflicting reports of depression and anxiety among premutation females. To further examine these behaviors, we investigated associated measures of depression and anxiety taken from our battery of neuropsychological tests obtained from 82 males and 280 females age 18-50 with varying repeat alleles. The Positive Affect Negative Affect Scales (PANAS) provides measures for positive affect (PA) and negative affect (NA) and the Social Phobia and Anxiety Inventory (SPAI) provides measures for social phobia (SP) and agoraphobia (AP). For preliminary analysis, the subjects were grouped into non- and premutation carriers (< 59 repeats and > 58 repeats) and the mean test scores for the two classes were compared after adjusting for age, gender, race, income, IQ, and education. Subsequently, linear regression was performed using repeat size as a continuous predictor variable. For NA, there was no difference between groups, the adjusted mean for premutation carriers being 2.99 and for noncarriers 2.92. However, repeat size was a significant predictor of NA in the linear regression model accounting for 1.2% of the variance ($p=0.04$). For PA, the adjusted mean for premutation carriers (35.53) was significantly lower than that for noncarriers (36.58) ($p=0.05$). For SP, the mean for premutation carriers (7.54) was significantly higher than the mean for noncarriers (7.31) ($p=0.05$). Similarly, for AP, the mean for premutation carriers (3.71) was significantly higher than the mean for noncarriers (3.55) ($p=0.05$). Repeat size as a continuous variable was not significant in the linear regression model for any of these three measures. Results are consistent with previous reports of increased emotional morbidity associated with premutation carriers.

CONGENITAL NYSTAGMUS X LINKED: REPORT OF A COLOMBIAN FAMILY. *R. Garcia[1], JC. Prieto[1,2].*
1) Pontificia Universidad Javeria, Bogota D.C., Cundinamarca, Colombia; 2) Hospital La Victoria. Bogota D.C., Cundinamarca, Colombia.

Patient of twenty two years old, male, from Bogotá (Colombia), assessed for medical genetics in Hospital La Victoria (Bogotá, Colombia). Remitted to medical genetics for neurology with diagnosis of congenital nystagmus. Patient with congenital horizontal nystagmus, initial assessment and management for ophthalmology since two years old until seven years old, with glasses until fourteen years old when suspended voluntarily. He refers remote sight difficulty, adequate near sight, no progression of symptoms. Antecedents of atopical dermatitis, no parental consanguinity, and thirteen male relatives by maternal line with similar disease. On medical examination we found wide nasal bridge, permanent pendular horizontal nystagmus, alternating endotropia, the rest of medical examination was normal. Ophthalmologic assessment reports not corrected, visual sharpness in right eye was 20/400 and in left eye 20/200, color vision was normal, symmetrical horizontal nystagmus, head torsion with sight fixation, increased amplitude with fixation, decrease with convergence and extreme sight, evaluation of anterior segment demonstrate bilateral mild atrophy of iris; bilateral ocular fundus was normal. We made diagnosis of congenital nystagmus X linked. Finally we present a colombian family with fourteen affected men with congenital nystagmus and a clear model of recessive X linked inheritance.

Anal malformations in a two-generation family with split feet and TP63 mutation. *K. Jedele[1], D. Morash[2], J. Kasser[2], M. Puder[2], K. Marchand[3], V. Kimonis[2,3], D. Levine[3].* 1) Gundersen Lutheran Medical Center, LaCrosse, WI; 2) Children's Hospital, Boston, MA; 3) Beth Israel Deaconess Medical Center, Boston, MA.

Split and/split foot malformation type 4 (SHFM4) and Ectrodactyly-ectodermal dysplasia (EEC) are two in a spectrum of disorders characterized by varying degrees of ectrodactyly, facial clefting and ectodermal dysplasia caused by heterozygous TP63 mutations.

We describe a family referred after prenatal ultrasound showed bilateral foot clefting in a female fetus. The father had similar clefting of both feet, and low anal atresia repaired at two days of life. On examination, he had the clefting of the feet, unilateral 3/4 toe syndactyly, mildly thin and dysplastic nails, but no skin, hair or palatal abnormalities. Postnatal examination of the daughter confirmed the split feet and revealed anterior displacement of the anus without other malformations. Sequencing of exons 5, 6, 7, 8, 13 and 14 of TP63 (GeneDx, Gaithersburg, MD) demonstrated a heterozygous point mutation, K193E, in both father and daughter. This mutation has only been reported once, in a two-generation family with SHFM without other complications. The similar findings in these two families supports the genotype-phenotype correlation seen in Tp63-related disorders.

A literature review found six cases of anal atresia and one of rectal atresia associated with EEC. This report is the first with anal atresia and SHFM, and the first multigenerational anal involvement in TP63-related disorders. In addition, the daughter is the first person reported with anterior displacement, rather than anal atresia. Our new cases indicate that anal malformations may be more common than previously thought in TP63-related disorders, especially as anterior anal displacement may be more easily overlooked than anal atresia. We suggest that evaluation for anal malformations be done on all patients with TP63-related disorders. Finally, these nine cases indicate a role for TP63 in anorectal development.

Diagnostic Testing of MeCP2 Gene-The Malaysian Experience. *R. Ariffin[1], Y.S. Choy[2], W.T. Keng[2], L.H. Ngu[2], N. Noor[1].* 1) Genetic Unit,Dept of Pathology, General Hospital,Kuala Lumpur, Malaysia; 2) Paediatric Department,General Hospital,Kuala Lumpur,Malaysia.

Rett Syndrome (RTT) is an X-linked neurodevelopment disorder affecting 1/10000-15000 girls. Rett Syndrome causing gene was identified as MECP2 on chromosome Xq28; missense, frame shift and nonsense mutations have been found in the methyl-binding and transcriptional repression domains of the gene in both familial and de novo cases. The phenotype overlaps significantly with that of other disorder such as autism, nonsyndromic mental retardation and idiophatic cerebral palsy. There are rare reports of males born into Rett families who suffered from severe neonatal encelophalophaty and died in early infancy.

The objective of this research is to determine the common mutation pattern in the Retts syndrome cases among Malaysian children. We hope also to identify any novel mutation/ polymorphism among our population.

We extracted DNA from 30 patients suspected to have Rett Syndrome based on clinical features. Then we ran PCR according to optimized protocol. PCR product was run on 1% agarose gel. We proceeded to analyze the ultimate MECP2 gene by focusing on coding region exon 1, 2 and 3. We ran a series of temperature titration on PCR product amplified using primers flanking MECP2 exonic region. on WAVE DHPLC (Denaturing High Performance Liquid Chromatography) against a known wild type sample in 10 cases due to limited resources. Four were identified to carry possible mutation trace of which one is confirmed showing a 16bp deletion on the overlapping region of exon 3d and 3e together with one SNP on exon 2b. The remaining 3 is to be confirmed based on sequencing result.

Biochemical defects suggestive of mitochondrial dysfunction in Rett Syndrome. *G. Bibat[1,2], L. Kratz[1,2], R. Kelley[1,2], L. Farage[3], A. Horska[3], P. Barker[3], J. Pevsner[1,2], S. Naidu[1,2].* 1) Kennedy Krieger Institute Baltimore, MD; 2) Johns Hopkins School of Medicine Baltimore, MD; 3) Department of Radiology Johns Hopkins Hospital.

Objective: To search for evidence of mitochondrial dysfunction in Rett Syndrome (RTT). Methods: We studied 34 female patients with RTT (ages 1-14 years) with known mutations in the MeCP2 gene. Urinary organic acids (UOA) were quantified by gas chromatography/mass spectrometry. Blood lactate (19/34) and MR Spectroscopy (MRS) (24/34) were also obtained. Results: 11/34 patients had increased levels of UOA in patterns characteristic of mitochondrial disease. These abnormalities were not characteristic of a specific type of mitochondrial dysfunction but were general markers for either primary or secondarily (e.g. redox abnormality) disturbed mitochondrial substrate transport. Blood lactate levels were normal in all subjects including 6/11 patients with abnormal UOA. However, sampling was random and not optimized for detecting milder degrees of diet-sensitive lactic acidosis. MRS showed no elevation of brain lactate in any of the 11 patients studied including 8 with UOA abnormalities. Three patients with increased UOA levels at 3 years of age had normal results at ages 7,13, and 14 years respectively, at which time their blood lactate and MRS results were also normal. UOA abnormalities did not correlate with anticonvulsant use. In this cohort, patients with proximal mutations within the methyl-CPG binding domain (MBD) of the MeCP2 gene were more likely to have UOA abnormalities than those with more distal mutations. Conclusion: We demonstrate mitochondrial dysfunction in RTT as shown by abnormal UOA. However, the basis for these abnormalities remains unknown in view of the normal blood and brain lactate levels. The occurrence of similar mutations in patients with and without urine organic acid abnormalities could reflect the effects of skewed x-inactivation. In patients with the RTT phenotype, the presence of UOA abnormalities should not direct diagnostic testing for a primary mitochondrial disorder to the exclusion of a search for mutations in MeCP2 gene.

Clinical variability in newborn infants with Beckwith-Wiedemann syndrome. *H. Kawame[1], K. Shimizu[2], T. Nakamura[2].* 1) Div Medical Genetics, Nagano Children's Hosp, Nagano, Japan; 2) Div Neonataology, Nagano Children's Hosp, Nagano, Japan.

Beckwith-Wiedemann syndrome (BWS) is a multi-system disorder characterized by macrosomia (gigantism), macroglossia, and abdominal defects (omphalecele) as major classical features. The etiology of BWS is genetically heterogeneous. Although the molecular genetic testing has been available, the diagnosis of BWS is made primarily on clinical findings. Characteristic features of BWS seem to be evident at birth, but in the clinical setting the definite diagnosis is often difficult in the newborn period. To evaluate the phonotypic spectrum and diagnosis of BWS in the newborn period, we reviewed the findings in 7 patients suspected to having BWS who are ascertain through Genetic Clinics at Nagano Children'fs Hospital from April 2004. The diagnosis was considered based on the criteria described by Shuman & Weksberg.

Average week of gestation at delivery was 36 weeks, and 5 patients were delivered at earlier than 37 weeks. At birth, only 2 patients had birth weight and length above 90th centile, and one had birth weight below 10th centile. Only one patient presented classical triad, i.e. macrosomia, omphalocele, and macroglossia at birth. Four developed macroglossia with age when those had no protruding tongue at birth. One patient with congenital heart defect and not-typical face at birth developed remarkable growth acceleration and macroglossia, and was finally diagnosed as BWS with 11p duplication by chromosomal analysis. Other features included congenital heart defect (2), polydactyly (1), cleft palate (1), inguinal hernia (1), hypothyroidism, and hepatoblastoma (1: at 2-month-old) (1). In summary, classical features are not always appreciated in the newborn infants with BWS. The diagnosis of BWS should be considered for newborn infants with any of associated features of BWS, and the criteria proposed by Shuman & Weksberg is useful for identification of the possible diagnosis of BWS.

Central nervous system malformations in Townes-Brocks syndrome: a case report. *B. McInnes[1], F. Bernier[1], J. Kohlhase[2].* 1) Dept of Medical Genetics, Alberta Children's Hosp, Calgary, AB, Canada; 2) Institute for Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany.

Townes-Brocks syndrome is a pleiotropic multiple congenital anomaly syndrome which has cardinal features of limb, anal and ear malformations. Our patient presented at birth with anterior ear tags, imperforate anus, Grade 2 hypospadias, broad thumbs and 3-4 cutaneous syndactyly of the left foot as well as a hypoplastic 2nd toe. ABR studies done at 4 months of age were completely normal. He was the product of a pregnancy complicated by hyperemesis and pregnancy induced hypertension. A diagnosis of Townes-Brocks syndrome was considered during the neonatal period. Further family history revealed the patient's father underwent minor surgery at birth for a rectal membrane. Audiological evaluation on the father showed a mild to moderate sensorineural hearing loss for the mid to high frequencies in the left ear with normal hearing in the right. The father's parents and siblings are healthy with no congenital anomalies or chronic health conditions. The patient subsequently developed partial complex seizures and migraine headaches for which he is not being treated. MRI revealed a mild Arnold-Chiari malformation type I with no focal abnormalities and increased size of the lateral ventricles. Serial MRI studies showed minimal tonsillar herniation (6mm) at the level of the foramen magnum which has remained stable. CSF cine study showed some restricted flow at the level of the foramen magnum posteriorly and this has also remained unchanged. *SALL1* mutation analysis revealed a frameshift mutation (1815-1816insAA) in both the patient and his father that is previously undescribed but is predicted to introduce a premature stop codon. Other frameshift mutations have been found in the *SALL1* gene and thus, this new mutation is presumed to be pathogenic. Currently, our patient is being monitored for neurological complications of Chiari I. Our case, along with one other TBS patient with CNS malformations, supports the conclusion that these anomalies are a rare finding and further demonstrate the variability in the phenotype and anatomical systems affected by mutations in *SALL1*.

Healthcare utilization of Down Syndrome infants in Alberta, Canada. *F.P. Bernier[1], M. Ghaffari[2], W. Chang[4], W. Agamah[2], F. Wang[3], L. Svenson[3], T. Chowdhury[2].* 1) Dept Medical Genetics, University of Calgary, AB, Canada; 2) Alberta Health and Wellness Funding and Costing, Edmonton, AB, Canada; 3) Alberta Health and Wellness Health Surveillance Branch, Edmonton, AB, Canada; 4) Dept of Medicine, University of Alberta, Edmonton, AB, Canada.

A pilot study was undertaken in a Canadian Province with a universal health care system to examine the feasibility of using existing population health datasets to derive data on healthcare utilization, co-morbidities and health care expenditure for a cohort of patients with Down syndrome (DS). A cohort of DS infants was obtained from Alberta Congenital Anomalies Surveillance System (ACASS) for 2000-2002. This cohort was linked with four Province of Alberta administrative data sets: hospital inpatient care, ambulatory care, physician claims, as well as the health care insurance registry. All of our 82 DS patients were successfully linked to the inpatient and physician claims dataset whereas linkage to the ambulatory care dataset could not be obtained in 5 patients, likely because of no contact with this part of the health care system. The DS newborns median length of stay (LOS) was 8.5 days, with a quarter staying < 5 days and another quarter staying > 22 days. The LOS was shorter for those from metropolitan regions (5.5 vs. 16 days, p=0.052). Rehospitalization was common is this cohort: 14.1% were re-hospitalized in 30 days, 24.7 % in 90 days, and 34% in 180 days. The most important risk factors for re-hospitalization were cardiac disorders and the gender of the newborns: odds-ratios (90% CIs) were 14.9 (3.7-60.0) for those with vs. without a cardiac disorder; and 0.27 (0.1-0.8) for female vs. male newborns. Further analyses of co-morbidities as well as health care expenditure estimates are also available. Our pilot project demonstrates the feasibility of using comprehensive datasets for assessing the health care utilization of patients with genetic syndromes in order to better understand the natural history, co-morbidities as well as the resources required in order to plan appropriate resource allocation.

Subtelomere FISH in 79 patients with mental retardation and dysmorphic features detects 9 rearrangements. *A. Battaglia[1,2], A. Novelli[3], C. Ceccarini[3], JC. Carey[2].* 1) Inst Child Neurology & Psych, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Division of Medical Genetics, Dept. of Pediatrics, University of Utah, Salt Lake City, UT, USA; 3) IRCCS-CSS Mendel Institute, Rome, Italy.

Unexplained developmental delay/mental retardation (DD/MR) represents a continuing challenge in clinical diagnosis because in 40% of moderate/severe MR and 70% of mild MR the etiology remains unknown. 5.8% of patients with normal 400-500 band karyotype have subtle subtelomeric rearrangements [Biesecker, 2002]. The yield of new cases identified may increase by preselection based on the degree of MR, physical features and family history [Knight et al,1999; de Vries et al,2001; Riegel et al,2001; Rio et al, 2002]. We performed subtelomere FISH analysis in a cohort of 79 individuals (2 families) with MR, dysmorphic features and a normal karyotype, observed over a 24 month period. Nine subtle unbalanced rearrangements were identified in 13 patients. The findings included three cryptic unbalanced familial translocations; two unbalanced de novo translocations; three de novo deletions; and one de novo duplication. The most common abnormality involved chromosome 1p (3/9). Complex rearrangements were present in 9/13 patients, partial monosomy in 3/13, and partial duplication in 1/13. The time from first normal karyotype to positive subtelomeric FISH result ranged from 3 to 18 years. Six out of 13 cases occurred de novo. The subtelomeric FISH results were useful for adjusting the recurrence risk, giving a better informed patient prognosis, and helping to focus medical screening and monitoring. The results satisfied families in search of a diagnosis, and impacted family planning. The patients with subtelomeric rearrangements showed family history of MR (6/13), prenatal onset growth retardation (11/13), postnatal poor growth (9/13) or overgrowth (2/13), two or more facial dysmorphic features (13/13), one or more nonfacial dysmorphic features and/or congenital abnormalities (13/13). Our findings show a high diagnostic yield (11.4%) of subtelomeric FISH analysis when performed in well selected patients.

Prader-Willi-Like phenotype: investigation of 1p36 deletion in 41 patients with delayed psychomotor development, hypotonia, obesity and/or hyperphagia, learning disabilities and behavioral problems. *C.S. D'ANGELO[1], J.A. DA PAZ[2], C.A. KIM[3], D.R. BERTOLA[3], C.I.E. DE CASTRO[1], M.C. VARELA[1], C.P. KOIFFMANN[1].*
1) Human Genome Study Center, Department of Genetics and Evolutive Biology, Institute of Biosciences, University of São Paulo; 2) Child Neurology Service, Department of Neurology, Hospital das Clínicas, University of São Paulo School of Medicine; 3) Clinical Genetics Unit, Childs Institute, Hospital das Clínicas, University of São Paulo School of Medicine, São Paulo,SP,Brazil.

Monosomy 1p36 is one of the most commonly observed mental retardation syndromes in humans that results in a clinically recognizable phenotype including delayed psychomotor development and/or mental retardation (MR), hypotonia, epilepsy, hearing loss, growth delay and/or obesity, microcephaly, brachycephaly, deep-set eyes, flat nasal bridge and pointed chin. Besides, a Prader-Willi syndrome-like phenotype has been described in patients with 1p36 monosomy. Herein, forty-one patients presenting neonatal hypotonia, developmental delay, obesity and/or hyperphagia, behavioral problems and learning disabilities who tested negative for PWS were investigated by FISH and/or microsatellite markers to disclose 1p36 deletions. Twenty-six of the forty-one patients were analyzed with a 1p-specific subtelomeric probe, and one terminal deletion was identified {46,XX.ish del(1)(p36)([TelVysion1p]-)}. Thirty of the 40 patients were investigated by microsatellite markers, and no interstitial 1p36 deletion was found. Our patient presenting the 1p36 deletion did not have the striking features of this monosomy, but her clinical and behavioral features were quite similar to those observed in patients with Prader-Willi syndrome (PWS), except for the presence of normal sucking at birth. Our patients phenotype could be due to the extent of the deletion, (2.5 Mb), smaller than usually seen in monosomy 1p36 patients. Therefore, chromosome 1p36.33 deletion should be investigated in patients with hypotonia, developmental delay, obesity and/or hyperphagia, behavioral problems and learning difficulties who test negative for PWS. Supported by FAPESP, CEPID/FAPESP, CAPES, CNPq.

Pachygyria and chromosome 22q11 deletion: Cause or coincidence? Report of an additional case. *G. Viot[1], A. Lebbar[1], F. Lewin[2], C. Adamsbaum[3], MC. Nassogne[4], A. Raas-Rothschild[5].* 1) Dept Genetics, Hosp Cochin, Paris, France; 2) Maternity, Hosp Saint Vincent de Paul, Paris, France; 3) Dept Radiology, Hosp Saint Vincent de Paul, Paris, France; 4) Dept Neurogenetics, Hosp Saint-Luc, Bruxelles, Belgique; 5) Dept Human Genetics, Hadassah Hebrew University Medical Center, Jerusalem, Israël.

Pachygyria with 22q11 deletion has been reported (Am J Med Genet : 2003;117(1):80-2; Am J Med Genet : 2004;131(3):322-4) and the question of weather it is a cause or a coincidence raised. Recently, we have the opportunity to diagnose a boy with pachygyria and chromosome 22q11 deletion. At the age of 7 years, this boy showed severe motor and developmental delay (walk and expressive language skills were absent), generalized tonic-clonic seizures, microcephalia (-2,8 SD), behavioral disorders. Clinical examination revealed cupped ears, puffy eyelids, long slender fingers. Neither cardiopathy nor hypocalcemia were present. Brain MRI demonstrated an opercular and frontal pachygyria. No mutation of DoubleCortine gene, no deletion of 17p13.3 region were found whereas a 22q11.2 deletion was detected by FISH analysis using the TUPLE-1 probe. Several central nervous system anomalies have been reported with 22q11 deletion. This observation is an additional case in favour of a relationship between this deletion and pachygyria. cardiopathy or hypocalcemia.

Rothmund-Thomson Syndrome - Analysis of Genomic Instability in two patients. *S. Tinschert[1], B. Algermissen[2], H. Tönnies[3], H.-P. Berlien[2], H. Neitzel[3].* 1) Institut für Klinische Genetik, Medizinische Fakultät Carl Gustav Carus, TU Dresden, Germany; 2) Elisabeth Klinik Berlin, Abteilung Lasermedizin, Berlin, Germany; 3) Institut für Humangenetik, Charité Universitätsmedizin Berlin, Germany.

Rothmund-Thomson syndrome (RTS) (OMIM 268400) is a rare autosomal recessive disorder characterized by photosensitive poikiloderma, small stature, skeletal abnormalities, and juvenile cataracts. It is associated with genomic instability and increased risk for mesenchymal cancers. Mutations in the RECQL4 gene (8q24.3), encoding a protein of the family of helicases, were identified in a subset of RTS patients. Cytogenetic studies identified a somatic mosaicism of either trisomy 8 or isochromosome 8q in a few patients. We analyzed two patients with RTS and their phenotypically normal parents using several cytogenetic techniques including sister chromatid exchange analysis. The two patients showed evidence of increased spontaneous and induced chromosomal breakage. Furthermore, lymphocyte and fibroblast karyoptyping revealed clonal numerical and structural chromosomal abnormalities in particular of chromosomes 8, 7, 9, and 22. A RECQL4 gene mutation was identified in only one of the patients indicating genetic heterogeneity. Teleangiectasias were treated with a flashlamp pumped dye laser (Photognost, BAASEL, wavelength 585nm, pulse 200s, 5,0-6,2 J/cm2) and resulted in complete lesional response. Interestingly, cytogenetic studies of fibroblasts from affected skin after laser therapy showed fewer aberrations than before.

Unilateral cleft lip and palate with hypotonia and developmental delay with duplication of NIPBL region by microarray analysis. *A.S. Teebi, R. Klatt.* Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

The majority of cleft lip and palate cases are non-syndromic and follow a multifactorial pattern of inheritance. The association of clefting with other even subtle dysmorphic features with or without developmental delay suggests a syndromic association. A subtle chromosomal anomaly might be the underlying cause. We report here a male child assessed first at the age of 1 year as a part of multidisciplinary team assessment and then in follow-up at 2.5 years of age. On initial physical exam the patient was found to have unilateral cleft lip and palate, unilateral left mild epicanthic folds, prominent ears with flashy ear lobule, flat occiput, hypotonia, and mild developmental delay. Routine chromosomal analysis, high resolution chromosomal analysis, SKY and FISH for microdeletion 22q 11 were all normal. The follow-up visit showed height, weight, and OFC to be within normal limits. At this time hypotonia became less prominent and developmental delay became more evident. An ultrasound of the abdomen was normal and FMR-1 testing was negative. Microarray CGH analysis with the SignatureChip^{TM}, which contains 831 clones for 230 genetic loci on 41 chromosome arms, detected an abnormality in the DNA of the specimen. The abnormality is characterized by a gain of a single copy of the three BACs containing the NIPBL region on 5p13. FISH analysis using BAC clones from this region confirmed the duplication. Loss of function mutations in the NIPBL gene result in Cornelia de Lange syndrome (OMIM X608867, 122470). To our knowledge, this is the first description of an individual with a duplication of the NIPBL locus. Microarray analysis of the DNA from both parents was normal which suggests a de novo event in the child. This case demonstrates the importance of searching for subtle chromosomal abnormalities in investigating cases of cleft lip and palate with developmental delay as well as in cases with subtle dysmorphic features and developmental delay. This case also illustrates the usefulness of array CGH in these investigations.

Molecular characterization and identification of a *de novo* marker chromosome in a child with mild developmental delay. *H.O. Shah[1,3], A. Igleasias[2], B. Miller[1], J.H. Lin[1,3], A. Karnik[1], J. Sherman[1,3], M.J. Macera[4].* 1) Nassau University Medical Center, East Meadow, NY; 2) Div. of Genet., Dept. of Pediat., Beth Israel Medical Center, New York, NY; 3) State University of Stony Brook. Stony Brook, NY; 4) Div. of Mol. Med. & Genet., Dept. of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

The proband at 31/2 years, was referred to genetic services due to a history of mild developmental delays. The family history was unremarkable and his mother denied any use of known teratogenic agents during pregnancy. He was a 6 lb. 10 oz. product of an uncomplicated full term pregnancy and was delivered vaginally without reported complications. Upon examination, his weight was 35.4 lb (25th centile), height was102 cm (75th centile) and his head was 48 cm (<5th centile). He had microcephaly with narrow forehead; mild epicanthal folds; hyoplastic alae nari; bulbous tip and soft ears and mildly decreased muscular tone. Cytogenetic analysis of peripheral blood revealed a 47,XY,+mar karyotype. The marker chromosome was small and unidentifiable with GTG banding. Both parents had normal karyotypes. Comparative genomic analysis (CGH) of DNA from the probands peripheral blood identified additional material on chromosome 8 bands q11.21 to q11.22. Centromeres are suppressed in CGH so FISH analysis with 8(D8Z2) (Vysis) probe was used to verify that the centromere had a chromosome 8 origin. A small detectable signal separate from the D8Z2 signal, was observed with whole painting probe for chromosome 8 (wcp8, Vysis), confirming the presence of 8q11.2. A ring configuration would be the most stable configuration with these breakpoints, so the karyotype was revised to 47,XY,+mar.ish r(8)(p11.1q11.2)(DZ82+,wcp8+). To our knowledge, this is the first reported case in the literature of an additional r(8) with these breakpoints. The use of CGH coupled with FISH now provides a method for the identification of such minute marker chromosomes. Identification and classification will lead to a better understanding of the clinical manifestations caused by these markers, thus providing improved treatment for those affected individuals.

Ring chromosome syndrome: report of 12 cases. *B. Vasconcelos[1], L.M.J. Albano[1], C.I.E. Castro[2], D.R. Bertola[1], I.C. Sbruzzi[1], C. Koiffmann[2], C.A Kim[1].* 1) Genetics Unit, Instituto da Criança, São Paulo, Brazil; 2) Bioscience Institute - São Paulo University, São Paulo, Brazil.

Ring chromosomes result from terminal breaks and a subsequent fusion of both arms of the same chromosome or a telomere dysfunction. The clinical features depend on the size of the material lost. Ring syndrome (Cotè et al., 1981) is characterized by growth delay, no major malformations, minor anomalies and mental retardation, independently of the chromosome involved. We decided to study 12 ring chromosome cases in order to delineate their phenotype. Five of the cases were mosaic (42%), 3 of them confirmed by FISH technique. The patients age ranged from 2mo-18y, involving the following chromosomes: 2 (1); 4 (1); 5 (1); 10 (1); 13 (1); 18 (2); 22 (2); X (1); and two rings were not identified. The clinical features were: short stature - 11/12 (92%); developmental delay/mental retardation - 10/11 (91%); craniofacial dysmorphysms - 10/12 (83%), specially dysplastic ears - 8/12 (67%); speech delay - 9/11 (82%); microcephaly - 6/12 (50%); skeletal abnormalities - 4/12 (33%); strabismus and genitourinary anomalies 3/12 (25%); and central nervous system anomalies - 2/12 (17%). Our findings were in accordance with that of the literature. Cutis girata, present in one 22 ring chromosome case, confirmed by FISH, has already been previously reported, suggesting that this finding could be specially associated with 22 ring chromosome. The high frequency of dysplastic ears in our sample (67%) may indicate that this sign is the most important minor anomaly in ring syndrome. Major malformations such as central nervous system and genitourinary anomalies were also detected in our cohort.

PRESENTATION OF TWO COUPLES WITH BALANCED RECIPROCAL TRANSLOCATION AND RECURRENT ABORTION THAT INVOLVE TO THE CHROMOSOME 4. *G. Noceda-Rivera, G. Razo-Aguilera, R. Baez-Reyes.* Deparment of Genetics, National Institute of Perinatology. Mexico,City.

The incidence of a chromosomal arrangement is of 1 in 500 individuals of the general population,is so most of the carrier of balanced reciprocal translocation, they are normal in their phenotype, detected during citogenetic studies due to problems in the reproduction, such as recurrent abortion, previous descendence with birth defects or sterility. We present two cases that we saw in the Clinic of Genetics of the Reproduction and Prenatal Diagnosis. CASE 1: Female patient of 29 years old, 31 years old her couple, not consanguineous, G-IV P-I A-II, the karyotypes with result of the patient: 46,XX t(4;6)(p10;p10) and her husband: 46,XY, the family study was completed. CASE 2: Female patient of 36 years old, 33 years old her couple, not consanguineous, G-IV C-II P-I A-III, she went to the consultation of prenatal diagnosis with 16 weeks gestational age by maternal age and recurrent gestacional loss, the karyotypes resulted for the patient: 46,XX and her husband: 46,XY t(4;9)(p14;q22), we offered amniocentesis being reported karyotype 46,XX, the family was completed.The correlation of the break points with the genes involved in both cases was made. Is necessary an appropiate genetic advice for translocations carriers, that imply to determine the risk based on the carrier member, involved chromosomes, the segregation form and the family genetic history, that which allows to calculate the reproductive risk with more certainly.

Short stature in patients with 47 XXY- an unusual coexistence of another genetic syndrome. *L. Ngu[1], Y. Choy[1], W. Keng[1], A. Ruziana[2], M. Aminah[2].* 1) Genetic Unit, Pediatric Inst, Kuala Lumpur Hosp, Kuala Lumpur, Malaysia; 2) Cytogenetic laboratory, Kuala Lumpur Hospital.

Klinefelter syndrome, or 47 XXY is the commonest sex chromosome disorder affecting 1 in 750 to 1000 males. They are usually not suspected in children as the classical features of the syndrome usually manifest in mid or late adolescence. They may be diagnosed if karyotyping is done for children with learning difficulties, language disorders or attention deficits. Most of the individuals with 47 XXY are normal in height in the first 5 years of life and height velocity increased after 5. They have tall stature by adolescence. Therefore, it would be most surprising to know the result of karyotyping done for the evaluation of a child with short stature.

We report here 2 patients identified to have 47 XXY and another syndrome. One of them was diagnosed having Noonan syndrome as he had short stature, webbing of the neck, sparse hair, hypertelorism, epicanthal folds, down-slanting palpebral fissures, flat nasal bridge, low set ears and small chin. He also had a small patent ductus arteriosus and ventricular septal defects which closed spontaneously. His bone age was delayed and his height was falling off percentiles chart. There was a deficient response in growth hormone stimulation test.

The other patient was referred for a suspicion of skeletal dysplasia because of short stature and mesomelic shortening. He had Robinow syndrome with hypertelorism and prominent eyes, flat and short nasal bridge, upturned nares, broad thumbs and big toes and bilateral cryotchidism. Skeletal survey revealed hemivertebra at T8. Growth hormone stimulation test showed a normal response. Both the patients had 47 XXY in 100% of their blood and skin cells tested. Deletion in the SHOX gene was ruled out by FISH. Since 47 XXY is a relatively common condition, the coexistence of another genetic syndrome is the most plausible explanation for short stature in these individuals. There were 2 previous reports on 47 XXY associated with Noonan syndrome and Russell syndrome.

Severe hypotonia and SMA in an infant with an unbalanced chromosomal complement. *S. Ben Shachar, L. Potocki, S.R Lalani.* Department of Molecular and Human Genetics, Baylor College of Medicine, Texas Children's Hospital, Houston.

Unbalanced chromosomal translocations occur with a frequency of 1:2500 and are often characterized by dysmorphic features and multiple congenital anomalies. Hypotonia can also be a feature in these patients, yet is also seen in several single gene disorders. We present a patient with multiple congentital anomalies, dysmorphic craniofacial features, severe hypotonia, and absent deep tendon reflexes, who presented at age 4 months with respiratory distress requiring mechanical ventilation. Imaging studies including brain MRI and head CT scan revealed lambdoid, coronal and sagittal craniosynostosis without definite brain parenchymal abnormalities. G-banded chromosome analysis revealed an abnormal male complement: 46,XY,der(3)(3;7)(p25;q36). Chromosomal microarray analysis confirmed this cytogenetic abnormality and also revealed trisomy of the Sonic Hedgehog (SHH) locus. In reviewing of the medical literature, we found that the features in our patient were unique as compared to other patients with chromosomal aberrations of these regions. Furthermore, although chromosome analysis and CMA revealed an unbalanced translocation, the severity of the hypotonia prompted further clinical investigation. Muscle biopsy and molecular analysis of this patient confirmed an additional diagnosis of spinal muscular atrophy type I (SMA). Chromosome analysis and DNA analysis of the parents are pending. This case presentation exemplifies the need for continued diagnostic testing in patients with unusually severe presentations. Molecular testing in this family allowed for more accurate counseling regarding prognosis in this patient and recurrence risk for future pregnancies, thus enabling informed decision making.

Is it Alagille or William syndrome? The importance of microarray studies in difficult cases. *P. Shah[1], P. Murphy[1], D.L. Skidmore[2], S. Scherer[2], W. Halliday[3], D. Chitayat[2,4].* 1) Dept Pediatrics, Mount Sinai Hosp, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Pathology and Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 4) Prenatal Diag & Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada.

Both Williams syndrome and Alagille syndrome are difficult to diagnose at birth, as the characteristic facial dysmorphisms may not be present.The main findings of Alagille syndrome in the newborn include dysplastic pulmonary valves, vertebral abnormalities, conjugated hyperbilirubinemia. We report a newborn with findings suggestive of Alagille syndrome that was found to have Williams syndrome. He was born by C-section for severe IUGR at 31 weeks. Amniocentesis revealed a normal male karyotype. In keeping with Alagille Syndrome, the baby developed direct hyperbilirubinemia on day 2 of life with elevated liver enzymes. Echocardiogram revealed proximal left pulmonary artery narrowing and a small VSD. X rays revealed butterfly vertebrae. In addition, in the first week of life, there was an unexplained period of diffuse hyperpigmentation in a Caucasian child, which waned after several days. The baby had an acute deterioration on day18 and died. Autopsy revealed renal and pulmonary abnormalities, and microcephaly with partial agenesis of corpus callosum. Bile ducts were identified, making Alagille syndrome less likely. Concordantly, microarray comparative genomic hybridization (CDG) demonstrated the absence of a microdeletion at the Alagille locus, and instead demonstrated a microdeletion at 7q11.23. FISH confirmed the unexpected diagnosis of Williams syndrome. This case further demonstrated the importance of microarray CDG in the neonatal period in assisting in the diagnosis of conditions for whom that characteristic dysmorphisms may not be apparent in the first months of life. In this case, the diagnosis of Williams syndrome enabled the provision of accurate counseling which otherwise would have not been possible. In light of the atypical features for Williams Syndrome, attempts are underway to further delineate the size of the deletion.

No causative genomic aberrations by BAC microarray CGH in forty patients with Kabuki make-up syndrome.

N. Miyake[1,2,3], O. Shimokawa[1,3,4], N. Harada[3,4], K. Yoshiura[1,3], N. Niikawa[1,3], N. Matsumoto[3,5]. 1) Departments of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) Departments of Pediatrics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 3) CREST, Japan Science and Technology Agency, Kawaguchi, Japan; 4) Kyushu Medical Science Nagasaki Laboratory, Nagasaki, Japan; 5) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Kabuki make-up syndrome (KMS) is a congenital anomaly disorder characterized by specific facial features, mild to moderate mental retardation, postnatal growth delay, skeletal abnormalities, and unusual dermatoglyphic patterns. The multisystem involvement of the KMS phenotype suggests that KMS is caused by a microdeletion or microduplication involving several genes. Microarray using 2,173 BAC clones covering the whole human genome has been constructed. All clone spotted were confirmed to show a unique signal at the predicted chromosomal location by in-house FISH analysis. A total of 40 KMS patients were analyzed by BAC microarray CGH (BM-CGH). In two KMS patients, visible cytogenetic chromosomal abnormalities could be precisely detected by BM-CGH. In addition, microdeletions at 39 clones and duplications at 145 clones in 40 KMS cases were identified by BM-CGH and were confirmed by FISH, but most of them were not considered to be responsible for the pathogenesis of KMS because the same copy changes were observed in normal control individuals. One deletion at 2p11.2 and one duplication at Xp22.3 found in KMS may be related to the phenotype as they were not observed in normal controls, although this remains inconclusive. The constructed microarray was proved to be reliable for the detection of known chromosomal rearrangements in KMS patients, but no uniform rearrangement in KMS could be detected. Thus KMS is unlikely to be a microdeletion/duplication syndrome.

Involvement of chromosome 7q31 region in the Russell- Silver syndrome. *V. Adir[1], S. Shalev[2], Y. Hujeirat[2], A. Shalata[1], Z.U. Borochowitz[1].* 1) The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Technion-Rappaport Faculty of Medicine, Haifa, Israel; 2) Department of Genetics, HaEmek Medical Center, Afula, Israel.

Russell- Silver syndrome (RSS) is a clinically and genetically heterogeneous developmental disorder involving growth retardation and a characteristic small triangular face. Chromosome 7 has been strongly implicated in RSS cases. Several cases involving reciprocal translocation, matUPD(7), and segmental deletions have been reported. However the specific region responsible for the disorder is unclear and the mechanism which causes this condition remains unknown. Here we report on a young male suspected of possessing RSS. Pre and post natal growth retardation was identified. Clinical examination revealed sparse hair, small-triangular facial features, high-wide forehead, low rotated ears, hypoplasia of the mid-phalanges of fingers as well as clinodactyly of the fifth finger. Molecular testing of polymorphic markers along chromosome 7 revealed an absence of paternal contribution alleles at D7S1817 and IVS17BTA. Our results suggest a de novo interstitial deletion of chromosome 7 at band q31 of about 12Mb. A second, less likely scenario, would entail a segmental matUPD(7) at that region. The proximal breakpoint is located at 7q31.1 between the polymorphic makers D7S692 and D7S1817 and the distal breakpoint which is located at 7q31.3 between marker D7S487 and the CFTR gene. Screening the suspected deleted region for candidate genes reveals few genes which could be clearly indicated as playing an important role in cell growth and development. A previous report on duplication of this region in a patient with mild facial dysmorphism and a moderate mental retardation together with UPD(7) in RSS suggests dosage sensitive mechanism of this region in growth and developmental processes. We suggest that this region should be taken into consideration as being responsible for the clinical features of this patient and possibly for the RSS phenotype.

A 2.5 Mb deletion in the 19p13.2 region detected by CGH-array in a boy with mental retardation, behavioural troubles and short stature. *A. Jacquette[1], R. Gesny[1], M. Rio[1], O. Raoul[1], M. Vekemans[1], A. Munnich[1], N.P. Carter[2], V. Cormier-Daire[1], L. Colleaux[1].* 1) Department of medical genetics and Inserm U 393, Necker Hospital, Paris, France; 2) Wellcome Trust Sanger Institute, Hinxton, U.K.

CGH-array is a new tool to describe small rearrangements of chromosome that have never been reported before. Here, we report the case of a 12-year-old boy with a 19p13.2 deletion revealed by CGH-array. He was first seen at the age of 2 for behavioural troubles with hyperactivity, self injury and heteroaggressivity . He had a pre and post natal growth retardation (weight and height on -5 SD), a psychomotor delay (walk at 30 months of age, a few words at 12 years of age), some facial dysmorphic features with hypertelorism, prominent forehead, short philtrum, large mouth and low-set ears with thick lobes and hypospadias. In addition, MRI showed a complete absence of corpus callosum. The first screening (including metabolic and chromosomal investigations) was normal. Based on the behavioural troubles, the dysmorphic features and the severe mental retardation, he had benefited from a CGH-array analysis (3 523 clones, provided from the Wellcome Trust Sanger Institute) and this investigation led to the identification of a 2.5Mb deletion in the 19p13.2 region. Microsatellites analysis confirmed the absence of paternal contribution. To our knowledge, this is the first case report of a so small deletion in 19p13.2 region in association with a severe mental retardation with behavioural troubles, short stature and dysmorphic features.

Molecular Diagnosis in fetuses with Holoprosencephaly : microdeletions have major occurrence. *C. Bendavid[1,2], C. Dubourg[1,2], I. Gicquel[1], P. Saugier-Veber[3], M.R. Durou[2], L. Pasquier[4], S. Jaillard[5], B.R. Haddad[6], C. Henry[5], T. Frebourg[3], S. Odent[4], V. David[1,2].* 1) Faculte de Medecine, Rennes1, UMR 6061 CNRS, Rennes, France; 2) Laboratoire de Genetique Moleculaire, CHU Pontchaillou, Rennes, France; 3) Laboratoire de Genetique, INSERM U614, CHU Rouen, France; 4) Genetique Medicale, CHU Hopital Sud, Rennes, France; 5) Laboratoire de Cytogenetique, CHU Pontchaillou, Rennes, France; 6) Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC, USA.

Holoprosencephaly (HPE), the most common structural malformation of the forebrain in humans, can be early detected in fetuses during pregnancy by prenatal ultrasound. But, among these HPE fetuses with normal karyotypes, only 14% have point mutations in known HPE genes (SHH, ZIC2, SIX3 and TGIF). As shown previously, life-born infants with HPE have 22 % point mutations but also 4% large rearrangements detectable by FISH and real time quantitative PCR (qPCR) in HPE genes. Consequently, we hypothesized that microdeletions should also be involved in HPE fetuses that usually have more severe phenotypes or associated malformations. We screened DNA from 73 HPE fetuses that had normal karyotypes and no mutations in four HPE genes (SHH, ZIC2, SIX3 and TGIF) for the presence of microdeletions. Real time quantitative PCR assays were employed for rapid determination of HPE genes copy numbers and identified microdeletions were confirmed by FISH or Quantitative Multiplex PCR of Short Fluorescent Fragments analysis (QMPSF). Seven microdeletions in a total of 73 samples were detected : 2 in SHH, 2 in SIX3, 2 in ZIC2 and 1 in the TGIF gene. Thus, we identified microdeletions in 9.5% of prenatal HPE samples compared in 4% in postnatal HPE samples. These data suggest that microdeletions are a common cause for prenatal HPE. Their detection can be best achieved by the QMPSF testing method that proved to be the most efficient for testing several genes in a single assay.

Y-chromosome microdeletions in patients with 45,X/46,XY gonadal dysgenesis. *F. Alvarez Nava, H. Puerta, M. Soto, A. Rojas-Atencio, L. Pineda.* Unidad de Genetica Medica, Univ del Zulia, Maracaibo Zulia, Venezuela.

Introduction: Among the disorders with numerical abnormalities of the Y-chromosome is 45,X/46,XY mosaicism. Its clinical manifestations include varying degree of impairment of testicular development. The commonest structural abnormalities of Y-chromosome are microdeletions of the long arm (Yq) in one or more of the three AZF (Azoospermic Factor) regions, AZFa, b or c. Deletions involving one of these three AZF loci result in the loss of multiples genes normally expressed in testicular embryonic development and adult testicular tissue and so they are associated with spermatogenic failure. Objective: Since deletions of AZFc region has been related to 45,X/46,XY mosaicism we studied whether microdeletions of AZF loci could affect the clinical and gonadal phenotype in patients with 45,X/46,XY karyotype. Materials and methods: We screened for Y-chromosome microdeletions on DNA isolated from both peripheral blood lymphocytes (PBL) and gonads of 11 Venezuelan patients with 45,X/46,XY mosaicism. Y-microdeletions analyses were performed using a multiplex polymerase chain reaction (PCR)-based technique with 20 sequences-tagged-sites (STSs). Results: Three patients had Y-microdeletions on PBL-DNA and five patients had Y-microdeletions on gonadal-DNA. Although more and larger Y-microdeletions were found on DNA-gonadal than DNA-PBL among our patients, there is not a correlation between Y-microdeletions and severity of phenotype. Conclusions: These data are compatible with a sequence-model in which the primary alteration in 45,X/46,XY mosaicism is a molecular defect in Y-chromosome specific DNA-sequences that result in the mitotic loss of Y-chromosome. Therefore, the global Y-chromosome instability is detected at DNA-level as partial and interstitial Y-chromosome microdeletions, and at cytogenetic-level as a 45,X/46,XY mosaicism.

MLPA is a highly effective diagnostic method in 22q11.2 microdeletion syndrome. *L. Fernández[1], P. Lapunzina[1], D. Arjona[2], D. Elorza[3], L. García-Guereta[4], I. López Pajares[1], M.L. De Torres[1], M.A. Mori[1], M. Palomares[1], M. Burgueros[4], J. Pérez[3], A. Delicado[1].* 1) Department of Medical Genetics, Hospital Universitario La Paz, Madrid, Spain; 2) Sequencing Unit, Hospital Universitario La Paz, Madrid, Spain; 3) Department of Neonatology, Hospital Universitario La Paz, Madrid, Spain; 4) Department of Pediatric Cardiology, Hospital Universitario La Paz, Madrid, Spain.

22q11.2 deletion syndrome is widely diagnosed by commercial fluorescence in situ hybridization (FISH), the chromosomal breakpoints and size of the deletions mostly determined either by polymorphic STR markers segregation tests or by specific hybridizations. Multiplex Ligation-dependent Probe Amplification (MLPA) can be a useful resource to detect haploinsufficiency in 22q11.2 and other chromosomal regions associated with DiGeorge/velocardiofacial syndrome in a single assay. We have compared the results of the three techniques on a group of 30 patients affected with 22q11.2 deletion syndrome and previously diagnosed by FISH. MLPA was successful in diagnosing all the patients, and in regard of the deletion size, the MLPA results were concordant with the STRs for all the patients and they resolved 7 cases that were uncertain by STRs due to uninformative results, lack of parental data or problems in markers amplifications. Other copy number variations can also be detected in patients with apparently no typical deletions. This supports the usefulness of the MLPA as a diagnostic tool for 22q11.2 microdeletion syndrome, as a rapid, easy, feasible and high-throughput method.

Natural history of trisomy 18 fetus diagnosed in the third trimester. *K. Kurosawa, Y. Igarashi, T. Yamamoto, K. Sameshima, T. Setoyama, M. Takei, T. Hirabuki, M. Yamanaka, Y. Kuroki.* Kanagawa Children's Med Ctr, Yokohama, Japan.

Trisomy 18 is the second most common autosomal trisomy in liveborn infants, and occurs at a frequency of 1 per 3,000 - 5,000 live births. Conbined with the ultrasonographic examination, multiple marker screening test involving the maternal serum AFP, uE3, and hCG in second trimester was reported to identify about 60% of trisomy 18 with a 0.4% false positive rate. The life expectancy of trisomy 18 after live born reveals the high infant motality rate . About 90% children with trisomy 18 die before their first birthday. Recently the natural history of trisomy 18 of live born was investigated and reviewed extensively. However, there is still a lack of precise data about their natural history in the cases diagnosed prenatally in third-trimester. To delineate the natural history of 18 trisomy fetus prenally diagnosed in the third trimester, we reviewed the 50 cases diagnosed after 27 weeks of gestation in our institute between 1994 and 2003. As the control subjects, we compared the life expectancy, complications, and sex ratio with those of transferred from other hospitals after live-born. 57% of the cases were live births, and 43% were stillbirths. Prenatally diagnosed cases reached to live-born showed no difference in the prognosis and life expectancy to the control group. The sex ratio was about 1 at that time of prenatally diagnosed, but rapidly declined at term. These information was valuable for counseling to families with the prenatally diagnosed cases and will provide insight into the sex ratio of the disorder.

A duplication of distal Xp associated with hypogonadism, hypoplastic external genitalia, mental retardation and congenital abnormalities. *L. TELVI[1], M. MINZ[1], C. BELLESME[2], J.M. DUPONT[3], P. BOUGNERES[2].* 1) Cytogenetics Laboratory, Hospital St Vincent de Paul,; 2) Endocrinology Department, Hospital St Vincent de Paul; 3) Cytogenetics Laboratory, Hospital Cochin, Paris, France.

An unusual case of a boy presented with a partial duplication of distal Xp sequences is described. The proband, an 7 year old boy, showed mental retardation, dysmorphic features, hypogonadism, hypoplastic external genitalia, short stature and hypotrophy. His karyotype was 46,Y,dup(X)(p21.2-22.3). The proband's mother showed the same karyotype. We used a panel of probes located in the short arm of the X chromosome for the identification of chromosomal anomaly. In 1996 we published a case with an inv dup(Xp) and similar phenotype. However, this kind of cases are rares. Their study is usefull for specially prenatal genetic counceling. We compared this two cases and the other cases published in the litterature.

A possible locus for Fryns syndrome at 1q41q42. *B. Pober[1,2], C. Prada[4], F. Blaise[3], T. Boyd[3], R. Jennings[1], L. Wilkins Haug[5], J.P. Fryns[6], C. Lee[5], S. Kantarci[2], D. Casavant[2], P.K. Donahoe[2], V. Kimonis[4].* 1) Dept Surgery, Childrens Hosp, Boston, MA; 2) MassGeneral Hospital for Children, Boston, MA; 3) Dept Pathology, Childrens Hospital, Boston, MA; 4) Division Genetics and Metabolism, Childrens Hospital, Boston, MA; 5) Dept Pathology or Obstetrics, Brigham Womans Hospital, Boston, MA; 6) Center for Human Genetics, University Hospital of Leuven, Leuven, Belgium.

Fryns syndrome, the most common syndrome associated with congenital diaphragmatic hernia (CDH), is presumed to be autosomal recessive based on reports of affected siblings and parental consanguinity. The phenotype is broad but cardinal features include: distinctive facial dysmorphology, CDH, pulmonary hypoplasia, distal digital/nail hypoplasia, and one or more characteristic major malformations. We report a 1q41q42 microdeletion detected by CGH in a case clinically diagnosed with Fryns syndrome.

A female infant, twin B, was born at 37 weeks. Placenta was dichorionic diamniotic; amniocentesis was 46,XX from both sacs. Twin B experienced respiratory distress, was difficult to intubate, and died at 1 hour. An autopsy demonstrated: coarse dysmorphic facies, enlarged fontanelles, cleft palate, distal phalangeal and nail hypoplasia, large left CDH, mild right diaphragm eventration, pulmonary hypoplasia, possible laryngeal stenosis, and a VSD. Karyotype on fetal skin was normal. Twin A is healthy and nondysmorphic at 3 months of age.

Application of array-based Comparative Genomic Hybridization using the Spectral Chip 2600 demonstrated deletion of 3 clones mapping to 1q32.3-1q42.2. Deletion involving 1q41q42 was independently confirmed by FISH and by use of the SignatureChip which showed deletion of 9 clones. Cytogenetic abnormalities in or near this chromosome band have been previously reported in CDH patients. Our finding suggests that deletion or mutation of a gene in this locus can lead to CDH, and possibly Fryns syndrome. This finding also indicates that Fryns syndrome may be etiologically heterogeneous since all cases appear not to follow an autosomal recessive pattern of inheritance.

Pursuing the identification of DURS1 gene. *H. Baris[1,3], W-M. Chan[1], C. Andrews[1,3], J. Ranells[4], T. Pal[5,6], E.C. Engle[1,2,3].* 1) Dept of Medicine (Genomics), Children's Hosp, Boston, Boston, MA; 2) Dept of Neurology, Children's Hospital Boston, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Department of Pediatrics University of South Florida; 5) H. Lee Moffitt Cancer Center and Research Institute, Tampa, Florida; 6) The University of South Florida, College of Medicine, Department of Interdisciplinary Oncology and Pediatrics, Tampa, Florida.

Duane syndrome (DS) is a genetically heterogeneous strabismus disorder with horizontal gaze restriction and globe retraction. There are 3 identified DS loci. DURS1 was cytogenetically mapped to 8q13; DURS1 patients have sporadic DS accompanied by other clinical findings. In 2002, Pizzuti et al. demonstrated disruption of CPA6 in a DS patient carrying a de novo reciprocal balanced translocation t(6;8)(q26;q13); 18 sporadic DS patients did not harbor mutations in the CPA6 gene. To further investigate the role of CPA6 in sporadic DS, we have screened 106 sporadic Duane syndrome patients by denaturing high-performance liquid chromatography. We find no coding mutations in CPA6. Next, we identified a boy with DS, high-frequency hearing loss, velopharyngeal incompetence, decreased upper body strength, fine motor in coordination, learning disabilities, and attention deficit disorder. FISH for velocardiofacial syndrome on 22q11 was normal and chromosomal analysis revealed 47,XY,inv(8)(p11.1q13.1)+mar[5]; 46,XY,inv(8)(p11.1q13.1)[1]. Parental chromosome analyses are not available. M-FISH and FISH with chromosome 8 centromeric probe confirm that the marker chromosome contains chromosome 8 material. We performed further FISH analyses and demonstrate 1) the mosaic marker chromosome contains duplication of the centromeric breakpoint region of 8q, encoding at least two known genes; 2) the telomeric breakpoint is on band 8q13.2 flanked by BAC clones RP11-50A22 and RP11-779P1 and containing VEST1. VEST1 is expressed in the inner ear, and is of unknown function. Although we cannot exclude the potential role of the mosaic marker chromosome in the pathogenesis of our patient's disorder, VEST1 is a DS candidate gene.

Array-CGH for the identification of autism susceptibility loci. *M.R. Mansouri[1], A-C. Thuresson[2], C. Betancur[3], M. Leboyer[3], C. Gillberg[4], C. Langford[5], N. Dahl[1].* 1) Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Clinical Genetics, Uppsala University Children's Hospital, Uppsala, Sweden; 3) INSERM U513, Faculty of Medicine, University of Paris XII, Créteil, France; 4) Dept of Child and Adolescent Psychiatry, Göteborg Universitet, Göteborg, Sweden; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, United Kingdom.

Autism is characterised by impairment in reciprocal social interaction and communication and restricted and stereotyped behaviour with developmental abnormalities which appear in the first three years of life. The prevalence for autism is around 0.5% of the general population. There is strong evidence supporting genetic components behind idiopathic autism. Recent studies have indicated constitutional large-scale copy number alterations in patients with mental retardation using microarray based comparative genome hybridization (array-CGH). We hypothesise that genomewide array-CGH will allow for the identification of gene regions and genes involved in normal cognitive development by studying patients with autism. Using 1 Mb array-CGH, we have initiated screening of three cohorts of patients including 60 sib-pairs with autism, 50 singleton cases with autism only and 100 patients with autism and associated features such as dysmorphism sampled in France and Sweden. The results of these ongoing studies will be presented and discussed.

Novel findings in 46,XY females with partial gonadal dysgenesis using a targeted CGH based clinical microarray.

J. Li[1], S. Cheung[1], D. Lamb[1], K. McElveavey[2], C. Bishop[1]. 1) Dept of Molecular and Human Genetics and OB/GYN, Baylor College of Medicine, Houston, TX, USA; 2) Dept of Developmental Biology, Institut Pasteur, Paris, France.

In man, male sex is determined by the dominant action of the primary testis determining gene, Sry, located on the Y chromosome. Deletions or mutations of Sry are known to lead to XY sex-reversal. However, a significant number of cases of XY female sex reversal do not involve the Y and are associated with autosomal chromosomal rearrangements. These include deletion of terminal 9p, distal 10q, 11p, 17q and duplications of 1p and Xp. For the most part these patients have not been systematically studied and the critical deletion intervals were poorly defined. We have previously reported a chromosomal microarray analysis (CMA) for quickly and efficiently identifying chromosomal rearrangements. We have applied this targeted chromosomal microarray for CGH based analysis of clinically relevant chromosomal disorders and subtelomeric regions to two XY female patients with gonadal dysgenesis. Case 1: previously described with a complex rearrangement with two clonal populations i.e. 46,XY,t(9;14)(p24;q11) and 46,XY,t(9:14)(p24;q11),+r(14) (Genomics 42:271,1997). A deletion was detected at the molecular level from 9p24 to 9pter. CMA indicated the patient harbored deletions of 4 clones spanning 2.2 Mb of genomic DNA corresponding to the 9p24.3 region. Case 2: previously described with an apparently normal 46,XY chromosome complement using high resolution karyotype analysis. A deletion of distal 9p24 was detected by molecular analysis of microsatellites (Am J Hum Gent 63:901, 1998). The CMA revealed a loss of 2 clones encompassing a 1 Mb region on the distal short arm of 9p24.3. In addition, CMA indicated a gain of 2 clones encompassing approximately 0.5 Mb region on the distal short arm of 7p22 that was previously undetected. The major advantages of this selected human genome array include: interrogation of clinically relevant genomic regions, the ability to test for a wide range of duplication and deletion syndromes in a single analysis.

Phenotype of cryptic subtelomeric 4q deletions in 4 patients of different age. *M. Edwards[1,2], K. Fagan[3], G. Peters[4], A. Hackett[1,2].* 1) Hunter Genetics, HNE Health Service, Waratah, NSW, Australia; 2) University of Newcastle, Australia; 3) Cytogenetics, Hunter Area Pathology Service, Newcastle; 4) Cytogenetics, Children's Hospital at Westmead, Australia.

Four female patients with moderate to severe intellectual disability were found to have 4q subtelomeric deletions on screening by FISH, after normal routine blood karyotyping. Three had a similar phenotype.

Clinical Feature	Patient DM	MR	CL	KL
Dolichocephaly	+	+	+	-
Craniosynostosis	-	+	+	-
Sagittal ridge	+	+	+	-
Ptosis	+	+	+	-
Long narrow face	+	+	+	-
Gothic palate	+	+	+	-
Tall/thin build	+	+	+	-
Macrocephaly	+	+	+	+

DM had a de novo 4q deletion. CL and her niece MR had an unbalanced reciprocal t(4;15). Some features of DM, MR and CL are seen in Shprintzen-Goldberg syndrome, although none had arachnodactyly. Patient KL aged 39 had short stature, seizures, coarse face, cataracts, glaucoma, brachydactyly. Detailed FISH deletion mapping will be presented.

TEN YEARS OF EXPERIENCE OF THE CLINIC OF GENETICS OF THE REPRODUCTION IN THE NATIONAL INSTITUTE OF PERINATOLOGY. *R. Baez-Reyes, G. Noceda-Rivera, DG. Mayen-Molina.* National Institute of Perinatology.

The fertility is the capacity to reproduce that have the human beings and the genetic factors play a fundamental paper. Of the 10 to 15% of the couples have some problem of the procreation. In the National Institute of Perinatology, the Clinic of Genetics of the Reproduction was formed as such from 1995 and to date it fulfills the requirements for the population's integral attention, being channeled the patients of the Clinic of Pregestational Risk or the Clinic of Biology of the Reproduction. To date a total of 9900 consultations, being in order of frecuency the factors for those couples have gone: recurrent abortion: 6069 (61.3%), previous descendence with birth defects: 1818 (18.36%), maternal age: 1308 (13.2%), sterility: 357 (3.6%). We have been carried out a total of 3900 karyotypes, being normals: 3708 (95.07%) and abnormals: 192 (4.92%). The form of boarding of the couple is shown, being simultaneous where the study plan is schematized, to the patients we dissipate the doubts and explain the procedures and diagnostic possibilities. According to the result we channeled to the suitable service, giving an integral attention. Should the need arise we also sent for their handling to other instances and we give to they the write material. Of this way their valuation is completed, being of extraordinary interest for the doctor in the systematic of diagnostic orientation.

Twinning and assisted reproductive technologies in patients with Beckwith wiedemann syndrome. Data from the Spanish Overgrowth Syndrome Registry. *P. Lapunzina[1,2], L. Magano[2], A. Delicado[2], M.L. de Torres[1], M.A. Mori[1], F. Cabañas[3], L. Fernández[1], M. Palomares[1], I. Incera[2], P. Arias[2], I. López Pajares[1], R. Gracia[4].* 1) Dept Medical Genetics, Hospital Universitario La Paz, Madrid, Spain; 2) Dept Molecular Genetics, Hospital Universitario La Paz, Madrid, Spain; 3) Dept Neonatology, Hospital Universitario La Paz, Madrid, Spain; 4) Dept Pediatric Endocrinology, Hospital Universitario La Paz, Madrid, Spain.

Publications over the past years have seeded concern about the possibility of an increased incidence of rare genomic imprinting diseases in children born of assisted reproductive technologies (ART). Thus, increasing attention has recently focused on potential epigenetic disturbances resulting from embryo culture, somatic cell nuclear cloning and ART. On the other hand, monozygotic twinning occurs more frequently among Beckwith Wiedemann syndrome (BWS) patients than it does in the general population, and many of these twins are discordant for BWS. Three different studies pointed to an association between ART and the development of BWS. Seven patietns with BWS from USA, 6 from France, 7 from UK and 4 from other European countries have been born after ART so far. The Spanish Overgrowth Syndrome Registry has been established in 2003 aimed to record patients with overgrowth syndromes (OGS). It is located at the Hospital Universitario La Paz, in Madrid, Spain. All patients with an OGS (and in some cases their relatives) are included in a specific database. Nowadays, more than 30 Hospitals have been contributing to the Registry, and about 300 patients have been recorded. In addition, clinical photographs are requested. Written permission for both clinical photographs and biological samples are obtained. About 47 patients with complete data and diagnosis of BWS, 5 showed either twinning or had been born after ART. The table shows the main characteristics of these patients.

# Patient	Pregnancy	Twinning	The other twin	Molec. studies
1	Without ART	Double	No affected	11p UPD
2	ICSI	Double	No affected	ND
3	ICSI	Double	No affected	ND
4	ICSI	Double	No affected	Alt. Imprinting
5	ICSI	Single	-	Pending

Our data also confirmed previous reports in large series of patients with BWS. In these series an increase of twinning and children born after ART have been observed. These data also pointed out that epigenetic mechanisms are probably related to both the techniques of ART and the biological process of twinning.

Chimerism in a phenotypic male with 46,XY/46XX and lack of spermatogenesis. *D. Wand, C. Gläser, C. Höfers, I. Hansmann.* Institut für Humangenetik und Medizinische Biologie, MLU Halle-Wittenberg, Halle (Saale), Germany.

Chimerism is being used to describe an organism with cells from two or more zygotes or their derivatives. True chimerism appears to be extremely rare being detected mainly by somatic effects of coexisting XX/XY cells. The few cases reported are hermaphrodites or of female phenotype. We report about an extremely rare case of a 35 year-old male with azoospermia and chimerism. He was referred with his female partner for genetic counselling preceding infertility treatment. He was born after an uneventful pregnancy to nonconsanguinous parents. He has one older clinically normal brother. At an age of 6 years penile hypospadia was corrected in addition to herniotomy, right. At the age of 14 years he was hospitalised due to mammary hyperplasia, orchiectomia left and orchidopexia right. Examination at an age of 24 years revealed hypergonadotropic hypogonadism and lack of any spermatogenesis. Testosteron substitution was initiated. Karyotyping of cultured lymphocytes revealed 46,XY and 46,XX in 66 % and 34 %, respectively of cells analysed. FISH with X and Y chromosome specific probes confirmed the results (68 % with XY and 32% with XX signals). For further investigation genotyping was performed by PCR for SRY and 40 microsatellite markers spread over 10 different chromosomes. Probands DNA from peripheral blood is positive for SRY and demonstrates heterozygosity for 2 alleles at all X chomosomal loci tested. Altogether 8 of the 35 autosomal loci tested revealed 3 alleles. At the remaining loci only 1 allele or 2 alleles were detected. The data observed are compatible with chimerism derived from 2 cell lines each containing an identical haploid genome from one parent and a different haploid genome from the other parent. A similar constitution has been reported for a 46,XX/46,XY hermaphrodite. Results from genotyping were consistent with a double paternal and single maternal genetic contribution (Giltay J et al. 1998). The most likely mechanism suggested i.e. a parthenogenetically dividing haploid ovum and fertilization of both resulting haploid and genetically identícal blastomeres by 2 sperm may hold true also to explain the genetic constitution of our case.

Autosomal Dominant Coffin-Siris Syndrome With Premature Thelarche. *M. Flynn[1], J.M. Milunsky[1,2,3].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Coffin-Siris syndrome is a well-known MCA/MR syndrome [OMIM 135900]. Diagnostic criteria have evolved to include growth restriction, MR, absence of the terminal phalanges of the fifth finger, hypoplasia or absence of the fifth fingernails and toenails, hirsutism, and characteristic coarse facial features. Although typically AR, AD inheritance has also rarely been reported. We describe a mother and her two daughters who meet the clinical diagnostic criteria for Coffin-Siris syndrome. Both sisters had FTT, hypotonia, and dev delay. Multiple minor dysmorphic features consistent with Coffin-Siris syndrome were noted for both sibs. Sib 1 had a VSD, delayed bone age, premature thelarche, foreshortened halluces, hypoplastic fifth toenails, bilateral fifth finger clinodactyly, and rocker-bottom feet. She did not have adrenarche. RUS, ophthalmology exam, head MRI, HR chromosomes, subtelomeric FISH, and FISH 22 analyses were all normal. Sib 2 had PPS. She had right severe hearing loss and left mild conductive hearing loss. She had Tanner I genitalia and no thelarche. She had hypoplastic fifth toenails and shortened fifth toes bilaterally. RUS demonstrated an extra left renal pelvis with no evidence of hydronephrosis. Foot Xrays for Sib 1 noted absent distal phalanges of the fifth toes and hypoplastic middle phalanges of the fifth toes. Xrays for Sib 2 noted that the distal phalanges of the fifth toes had not yet ossified. Hand Xrays for Sib 1 noted hypoplastic distal phalanges of the fifth digits with absent epiphyses. The mother of these two sibs required special assistance in school. Her facial features and Xray findings are similar to her daughters. Hence, AD inheritance is the likely mode of inheritance in this family. Premature thelarche has previously been reported once in Coffin-Siris syndrome (Brunetti-Pierri et al., 2003). One of our patients is the second reported individual with premature thelarche, providing further evidence that it may be a clinical feature of the syndrome.

EGR2 mutations: a natural history study of 10 patients and functional analysis of neuropathy associated alleles.

W. Wiszniewski[1], K. Szigeti[1], P. Mancias[2], G.M. Saifi[1], G. Miller[3], L. Keppen[4], D. Daentl[5], J.R. Lupski[1]. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Neurology, University of Texas, Health Science Center, Houston, TX; 3) Department of Neurology, Baylor College of Medicine, Houston, TX; 4) Department of Pediatrics and Adolescent Medicine, University of South Dakota School of Medicine, Sioux Falls, SD; 5) Shriners Hospitals for Children Northern California, Sacramento, CA.

We ascertained 10 patients with EGR2 mutations and examined the natural history of the disease by regarding progression and respiratory compromise [mean follow-up 17.5+/-10]. Three patients were from an AD, 3 from AR family and in 4 patients the sporadic neuropathy was associated with de novo mutations. Even the same mutations caused different phenotypes; e.g. heterozygous R359W caused CMT1, DSN and CHN in three different families. Respiratory compromise in the form of documented restrictive pulmonary disease was present in 3/7 (43 %) unrelated patients, in one case resulting in respiratory failure and death at 6 years. Cranial nerve findings were present in 60 % and involved the facial nerve, cranial nerve III, IX and XII. The progression of the disease was rapid, moderate or mild, depending upon the mutation. Interestingly, the toxic gain of function mutations resulted in moderate to severe progression, whereas the homozygous loss of function mutation in the AR family had minimal, if any, progression of the neuropathy. In vitro functional studies were performed, including transcription activity assays and localization studies utilizing constructs generated by in vitro mutagenesis. We did not find a correlation between mutations and outcome, thus it is extremely difficult to prognosticate patients with EGR2 mutations. However our study confirmed that respiratory compromise and cranial nerve dysfunction are commonly associated with EGR2 mutations and can be useful clinical findings in guiding molecular diagnostic.

The confirmation of the diagnosis of CHARGE syndrome with the first Finnish adult patient. *S.J. Kivirikko, S. Ala-Mello.* Deparment of Clinical Genetics, Helsinki Univ. Centr. Hospital, Helsinki, Finland.

The acronym CHARGE refers to an association first described in 1979. With an estimated birth incidence of 1:12.000, this condition is a rather common cause of multiple congenital anomalies. The combination and the severity of the malformations can be very variable. The major anomalies include coloboma, heart malformation, choanal atresia, growth and/or mental retardation, genital anomalies, ear anomalies and/or deafness. Our patient was a 39-years-old woman without a specific diagnosis having several health problems. We report her natural history with photographs. Bilateral sensorineural hearing loss was detected at the age of 3 years. She has bilateral chorioideal coloboma, but the visual loss is not remarkable. She has renal agenesis on the right side, but no cardiac malformation. The right malformed ear has been operated in childhood, after which she has been able use the hearing aid. The most patients with CHARGE diagnosis have mutations involving CHD7 gene (chromodomain helicase DNA-binding protein-7) (Vissers et al Nature Genetic 36:955-957, 2004). After that it is more appropriate to speak about CHARGE syndrome than association. The confirmation of the clinical diagnosis of our patient was perfomed by detecting a pathogenic mutation 5982GA (W1994X) heterozygously in exon 30.

Osteopathia Striata with Cranial Sclerosis: A clinical report of two Asian Indians. *S. Reddy.* Health Diagnostic Lab, Southfield, MI.

This clinical report describes two cases of Osteopathia Striata with Cranial Sclerosis (OS-CS) in two Asian Indians from Southern part of Indian subcontinent. A 25-year old man was referred for management of osteopathia striata with cranial sclerosis. The patient had multiple congenital abnormalities including cleft lip, hypertelorism, flat nasal bridge and prominent occipital bony protrusion. Radiographic evaluation revealed cranial sclerosis, longitudinal striations in the metaphyses of femur and tibia. Serum calcium, phosphorus and alkaline phosphatase were normal.Bilateral mixed hearing loss was present. The second patient was 31-year old woman presented with multiple congenital abnormalities such as cleft lip, cleft palate, hypertelorism and club feet. There was bilateral decreased hearing. She complained chronic lower extremity pain but there were no fractures. She had severe intellectual impairment.This syndrome is familial and is believed to be transmitted as an autosomal dominant trait but some authors suggested X-linked inheritance. Longitudinal striations of osteosclerosis in the long bones, disfigurement in the cranial and facial bones due to osteosclerosis were discussed.

A new recessive connective tissue disorder with fleshy swelling of lips, lid and cheeks, macrocephaly, hyperextensible skin and severe scoliosis. *A. Verloes[1], A. Benmansour[2], G. Mortier[3], G.E. Pierard[4], M. Le Merrer[5].* 1) Clinical Genetics Unit and INSERM U676, Hosp Robert Debre, Paris, France; 2) Pediatrician, Oran, Algeria; 3) Dpt of Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Dpt of Dermatopathology, University Hospital Sart Tilman, Liege, Belgium; 5) Dpt of Genetics and INSERM U393, Hopital Necker Enfants Malades, Paris, France.

We report on three sibs born to first cousins Algerian parents, affected by the same progressive MCA syndrome. The hallmarks of this syndome are: 1) macrocephaly (+ 2 to + 3 SD), 2) progressive, fleshy swelling of the lip, cheeks and upper eyelids, 3) retrognathia, gothic palate and crowded teeth, 4) very sparse eyebrowses and mildly sparse, normally growing hair, 5) protruding, simple ears, 6) hyperextensible, non loose skin with easy bruisability, 7) severe, progressive scoliosis and 8) severe hyperlaxity of ankle joints and lesser hyperlaxity of small joints. Mental development was normal (1/3) or slightly delayed. One child had seizures. There was no bone dysplasia nor dysostosis, no bone fragility, no blue sclerae, no papyraceous scars, no valvular anomalies, no arachnodactyly. Skin biopsy showed alterations compatible with Ehlers-Danlos syndrome. This family appears to show a unique syndrome with Ehlers-Danlos-like dermatological features, facial dysmorphism, progressive swelling of the soft tissues of the face, and severe scoliosis, recessively inherited. To our best knowledge, this constellation of findings has not been previously reported.

GENETIC AUTOPSY NORMATIVE DATA. *R. Lebel, J. Archie, J. Collins.* Greenwood Genetic Ctr, Greenwood, SC.

While the medical genetics community has long advocated the importance of autopsy to clarify the etiology of adverse pregnancy outcome, only a small number of geneticists participate directly in obtaining and interpreting prenatal growth data in the autopsy suite. Literature on the interpretation of weights and measurements is somewhat scattered and disparate; some reports organize data by gestational age, while others categorize by another weight or measurement. Worldwide literature on normative data (taken, insofar as can be determined, from non-dysmorphic individuals) was reviewed. Meta-analysis undertaken on crown-heel and crown-rump lengths; circumferences of the head, chest, and abdomen; hand and foot lengths; inner canthal, outer canthal, and inter-nipple distances; and weights of body, brain, thymus, heart, lungs, spleen, liver, kidneys, and adrenals. Despite the diversity of the populations studied, there is impressive concordance, such that meaningful and clinically useful regression curves could be generated in most cases. In other cases existing published regressions were used. The regression curves were incorporated into a computer program, aiding the interpretation of these anthropometric features by calculating percentiles and proportions of the expected mean, applicable to stillborn or neonatally deceased individuals. The program is currently used in a statewide fetal and neonatal autopsy service, adding greater precision to reports of findings. This improves the probability of accurate syndromic diagnoses, with greater consequent overall success in the autopsy effort. Thus it promotes the three major goals for such a service: (1) assisting in the familys grief resolution, (2) appreciating the etiology and therefore also the recurrence risk, and (3) adding to the body of knowledge of the epidemiology of genetic disease and pregnancy loss.

Staged separation of craniopagus conjoined twins (CCT): Medical and neurodevelopmental status one year after separation. *R. Marion, J. Goodrich, D. Staffenberg.* Dept Pediatrics, Neurosurgery and Plastic Surgery, Childrens' Hosp at Montefiore, Bronx, NY.

Occurring in 1 in 10 million livebirths, craniopagus conjoined twinning is a rare, devastating anomaly. Literature review reveals that attempts to separate CCTs using a single surgical procedure have resulted in one or both twins either dying or suffering permanent neurologic damage. We describe a set of CCTs in whom separation was accomplished using a staged surgical approach and present an update on their condition 1 year after separation.

Born in the Philippines via c section in 4/02, the twins arrived at our center at 17 mos of age. MRI and MRA revealed that although scalp, skull, dura and cerebral venous return were shared, brains appeared to be separate. Multiple medical problems, including FTT, DD, severe hypertension in one twin, etc. were also noted; therapy to improve these was begun. Rather than attempt separation in a single surgical session, we chose to perform multiple smaller operations; during each, bridging vessels were divided in hopes that the twin in whom no venous return from CNS existed would generate such vessels from collaterals.

Over 10 months, 4 procedures were performed. The twins tolerated each procedure well and received PT, OT and ST between surgeries. Repeat MRA showed that a second plexus of veins had developed. Final separation was accomplished in early August 2004.

Nearly one year after separation, the boys are healthy, with height, weight and HC all in normal range. Medical problems have included hypertension in one twin (resolved after separation), OSA (treated with T & A), and serous OM (treated with M & T). Though they continue to exhibit speech delay, they are walking, riding tricycles, and showing no evidence of permanent neurologic deficit.

We describe the first case of intact survival of both members of a pair of CCT. The status of these twins one year after separation strongly suggests that staged separation is the optimum management for such twins.

A de novo missense mutation in a critical homodomain of the POU3F4 gene caused X-linked male congenital profound sensorineural hearing impairment in a large Chinese family. *Q.J. Wang[1,2,4], Q.Z. Li[1,4], S.Q. Rao[3,4], Y.L. Zhao[1], H. Yuan[1], W.Y. Yang[1], D.Y. Han[1], Y. Shen[2].* 1) Department of Otolaryngology/ Head and Neck Surgery, Chinese PLA General Hospital, Beijing 100853, China; 2) Chinese National Human Genome Center, Beijing 100176, China; 3) Departments of Cardiovascular Medicine and Molecular Cardiology, the Cleveland Clinic Foundation, OH 44195, USA; 4) These authors contributed equally to this work.

It is known that about 5% of male congenital profound hearing impairment are inherited in X-linked inheritance, but its underlying molecular determinant remains to be identified. A large five-generation Chinese family with multiple familial cases of gender-specific congenital profound hearing impairment was identified and clinically evaluated. Model-based genetic linkage analyses were performed with the use of microsatellite polymorphisms to determine the locus for the sex-linked trait. Positional cloning and mutation analyses were performed with the family and unrelated population-based controls to establish molecular evidence that caused the specific X-linked inheritance pattern in the large Chinese family. Clinical investigations of the pedigree demonstrated the striking feature of the extremely high penetrance in the male members, but no penetrance in the female members. Linkage analyses mapped the disease to the chromosomal region Xq13.1-Xq23 (maximum X-linkage lod score, 3.27). Mutation screening of the candidate genes in the linkage region by direct sequencing revealed a de novo missense substitution (925T-->C) in POU3F4 gene, which leads to a substitution (Ser309Pro) of a serine for a proline residue at amino acid position 309. To further exclude the possibility that this mutation is a polymorphism, we conducted direct sequencing on 240 unrelated control subjects. None of the control subjects had the de novo mutation. In conclusion, multiple analysis approaches demonstrated that these disorders were caused by a founder mutation in POU3F4 gene. Our findings provided novel molecular evidence to implicate the pleiotropic role of POU3F4 gene in the development of hearing loss in humans.

Cornelia de Lange syndrome or Goldberg-Shprintzen syndrome? From the clinical phenotype to the mutational analysis of NIPBL and KIAA1279 genes through the natural history. *M.L. Giovannucci Uzielli, M. Ottaviani, M. Levi, S. Toccafondi, L. Di Medio, S. Stagi, L. Carosi, S. Guarducci, U. Ricci, E. Lapi, L. Giunti.* Paediatrics Genetics Unit, University of FLorence, Florence, Florence, Italy.

In three of four children of consanguineous Italian parents, on the basis of the clinical phenotype only, we firstly posed a diagnostic hypothesis of Cornelia de Lange syndrome: especially significant where the microcephaly and the mental retardation in the three children, and the facial characteristics more expressed in the propositus, a 10 year old boy. The partially meaningful clinical patterns of the two sisters, and the presence of other discordant clinical aspects, kept nevertheless us hesitant on the definitive diagnosis. The natural history, observed in the propositus and in one of the two sisters, during more than ten years, offered us new useful diagnostic data: in particular, recurrent episodes of bowel pathology due to severe and progressive Hirshsprung disease, recently brought us to consider the diagnosis of Goldberg-Shprintzen syndrome, a rare AR disorder, characterized by microcephaly, mental retardation, Hirshsprung disease, and a peculiar face, in part superimposable in CdLS and GOSHS. We hope that the ongoing mutational analyses of NIPBL and KIAA1279 genes, may clarify the molecular basis of the clinical phenotype, to reach a final diagnosis of the disorder recurrent in this consanguineous family.

Bladder exstrophy associated with congenital macrothrombocytopenia of Fechtner type - evidence for a common genetic cause? *B. Utsch[1], S. Karle[1], V. Schuster[2], H. Lenk[2], U. Jacobs[1], A. Kujat[3], H. Reutter[4], W. Rascher[1], J. Dötsch[1], J. Martignetti[5], M. Ludwig[6], R.B. Tröbs[7].* 1) Dept. of Pediatrics, University Erlangen/Nuremberg, Erlangen, Germany; 2) Dept. of Pediatrics, University of Leipzig, Leipzig, Germany; 3) Dept. of Human Genetics, University of Leipzig, Leipzig, Germany; 4) Dept. of Human Genetics, University of Bonn, Bonn, Germany; 5) Dept. of Human Genetics, Mount Sinai School of Medicine, New York, NY, USA; 6) Dept. of Clinical Biochemistry, University of Bonn, Bonn, Germany; 7) Dept. of Pediatric Surgery, University of Leipzig, Leipzig, Germany.

Bladder exstrophy is a rare urogenital malformation. Hitherto, no underlying gene defects are known but this group of malformations seems to be genetically heterogeneous. We report on a case of exstrophic bladder associated with congenital macrocytic thrombocytopenia. The parents are not consanguineous and family history was unremarkable. Laboratory results were normal except for macrothrombocytopenia of 10,000/l and platelet volume of 13.9 fl. An amniocentesis showed a normal karyogram. Hematological examinations revealed an unremarkable granulocytopoiesis and erythropoiesis. Since no leukocyte inclusions were found Epstein syndrome was suggested for which mutations in *MYH9* on chromosome 22 are known, and which are inherited in an autosomal-dominant manner. The locus for Opitz II syndrome for which urogenital malformations are reported is located next to the *MYH9* gene on 22q11.2 (distance ~12.2 Mb according to www.genome.ucsc.edu) but both loci did not show linkage to each other. FISH analyses with probes *TUPLE1* und *N25* detected no gross alteration. Direct sequencing of the *MYH9* gene yielded a heterozygous de-novo missense mutation (C287T) in the index patient resulting in an amino acid exchange S96L. The mechanism for the association described remains unclear since the reported mutation in *MYH9* was already described previously without a similar urogenital phenotype. Nevertheless, it can be due to unknown mechanism in the surrounding region or a co-inheritance of a neighboring mutated gene. Additional potential symptoms of Epstein syndrome could be still inapparent in our patient.

Maternal Uniparental Disomy for the whole chromosome 15 in a newborn with classic Prader Willi syndrome phenotype, associated to a large interstitial deletion of chromosome 15q encompassing the entire Fibrillin-1 gene sequence. Molecular studies, and 3-years clinical follow-up. *M. Levi, M. Ottaviani, S. Toccafondi, L. Di Medio, S. Stagi, L. Carosi, S. Guarducci, I. Sani, U. Ricci, E. Lapi, L. Giunti, M.L. Giovannucci Uzielli.* Dept Paediatrics, Genetics Unit, University of Florence, Florence, Italy.

In a newborn male, with classic PWS clinical phenotype, we identified a UPDmat15: by using a battery of DNA polymorphic markers, to well define the mat(15)UPD, we identified an unexpected interstitial submicroscopic deletion 15q21 of one of the two maternal chromosomes 15, encompassing the entire Fibrillin-1 gene. MLPA-based analysis confirmed the complete absence of FBN1 gene. Maternal Uniparental Disomy (UPD) accounts for approximately 25% of PWS patients. A parent of origin specific methylation imprint has been demonstrated for the chromosome 15q11-13 region using methylation sensitive restriction enzymes, in all cases of PWS, characterized by deletion, UPD or imprinting mutation. Marfan syndrome is an Autosomal Dominant multi-system connective tissue disorder, due to mutations in the Fibrillin-1 (FBN1) gene. More than 200 different mutations were reported in the 235 kb, 65 exon-containing gene, on 15q21. Only few multi-exon FBN-1 deletions were discovered. We report the first case of entire deletion of FBN-1 gene: we found no other cases described in the literature, but we heard of a subject with complete heterozygous deletion of FBN-1 gene and clinical Marfan phenotype. Our patient is now 3-years old: his staturo-ponderal development is between the 25 and the 50 centile. The clinical phenotype is striking suggestive of PWS, no clinical patterns of Marfan syndrome are until now present. It could be interesting to consider how features of PWS might make Marfan features less obvious, and viceversa. No significant ultrastructural variation of the skin and subcutaneous tissue. No cardiovascular, ocular or orthopaedic anomalies. This unique case of complete heterozygous deletion of FBN1 gene may expand the knowledge of mutational mechanisms and genotype/phenotype correlation of fibrillinopathies.

Associated malformations in children with limb reduction defects. *B. Dott, Y. Alembik, M.P. Roth, C. Stoll.* Medical Genetics,Faculte de Medecine,Strasbourg,France.

Infants with limb reduction defects(LRD)often have other associated congenital defects.The purpose of this investigation was to assess the prevalence and the types of associated malformations in a defined population.The prevalence and types of associated malformations in infants with LRD were collected in all livebirths,stillbirths and terminations of pregnancy between 1979 and 2002 in 320,810 consecutive births in the area covered by our population based registry of congenital anomalies.Of the 246 LRD infants born during this period,58.1% had associated malformations.Associated malformations were more frequent in infants who had upper limb reduction defect(63.2%) than in infants with lower limb reduction defects(48.4%).Malformations in the cardiac system and in the central nervous system were the most common other malformations,15.2% and 10.6% of the associated anomalies,respectively,followed by anomalies in the genital system(10.1%),in the renal system(6.8%),and in the digestive system(6.3%).There were 16(6.5%)cases with chromosomal abnormalities,including 8 trisomies 18,and 2 22 q 11 deletion, and 56(22.8%) nonchromosomal dysmorphic syndromes.There were no predominant dysmorphic syndromes,but VA(C)TER(L) association.However numerous dysmorphic syndromes were registered including,among them,the following : EEC,OFD,Klippel-Trenaunay-Weber,OAVS,CHARGE,Townes Brocks,Moebius,Du Pan, SLO,hypoglossia-hypodactyly,amniotic band,De Lange,Rubinstein-Taybi, Fanconi,TAR,Roberts,Holt-Oram,and fetal diethylstilbestrol.Seventy one(28.8 %)of the cases were multiply,non syndromic,non chromosomal malformed infants.Prenatal diagnosis was performed in 48.8 % of dysmorphic syndromes with LRD,whereas prenatal ultrasonographic detection was only 23.9 % in cases with isolated LRD.The overall prevalence of associated malformations,which was more than one in twoinfants,emphasizes the need for a thorough investigation of infants with LRD.A routine screening for other malformations especially cardiac,central nervous system,urogenital system,facial clefts,and digestive system may need to be considered in infants and in fetuses with LRD.

Multiple congenital anomalies in a surviving donor twin of an acardiac twin pregnancy; further support for a vascular etiology of oculo-auriculo-vertebral spectrum. *R. Smith[1], S. Ellingwood[1], D. Dressel[2], R. Chard[3], J. Wax[3], M. Pinette[3].* 1) Div Genetics, Dept. of Pediatrics; 2) Dept. of Pathology; 3) Div. of MFM, Dept. of OB/Gyn, Maine Medical Center, Portland, ME.

We report a 4 mo. old male, former donor twin of an acardic twin pregnancy, whose various anomalies fit the oculo-auriculo-vertebral (OAV) spectrum. He was the product of a 32 6/7 wk pregnancy born to a 20 y.o. G2P0 mother. Chromosomes were 46, XY and 22q11.2 FISH deletion studies were normal. The pregnancy was followed conservatively for TRAP sequence diagnosed at 16 wks gestation. The infant was born by elective c-section prior to signs of heart failure. His birth weight was 1.66 kg. Congenital anomalies noted at birth included; ileal atresia, right sided microtia with atretic external auditory canal, right sided hemifacial microsomia, cutis aplasia on the scalp, abnormal cervical and thoracic vertebrae with several fused ribs on the right, small muscular VSD and bicuspid aortic valve, hypoplasia of the distal phalanx of the right thumb, and left renal pelviectasis. His acardiac twin had a classic appearance with no true head, but developed trunk and limbs, with multiple internal and external anomalies. The placenta was monochorionic, monoamnionic with a single cord stalk which bifurcated 1.5 cm above its insertion. Each cord had two vessels. A complex true knot was present 2.0 cm. above the bifurcation.

The etiology of OAV spectrum is felt to be heterogeneous with support for both environmental and genetic influences. Abnormal vascular flow has experimentally been shown to cause hemifacial microsomia, and has been suggested to be a factor in the OAV spectrum. We postulate that abnormal blood flow existed in this pregnancy as demonstrated by the discordant acardiac twin which has a known vascular pathogenesis, by placental morphology, and by the additional finding of ileal atresia and cutis aplasia in this infant. This case argues for a placental anastamosis mediated vascular pathogenesis as the cause of the multiple anomalies seen in this case and supports the hypothesis of a vascular etiology in OAV spectrum.

Changes in the prevalence of at birth congenital malformations in Belarus in view of the Chernobyl accident. *G.I. Lazjuk, O.I. Zatsepin, R.D. Khmel, I.L. Babicheva.* National Research Institute of Hereditary and Congenital Diseases, Minsk, Belarus.

In Belarus, since 1979 on the bases of Institute of Hereditary and Congenital Diseases a republican registry of congenital malformations (CM) has been functioning. Data over 40 thousand fetuses and newborns with congenital malformations was recorded by the beginning of the year 2005 in the republican registry of CM. A Long-term research conducted in the field of possible teratogenic and genetic consequences of the Chernobyl accident gives possibility to draw the following conclusions: I.Since the middle of eighties a steady increase of CM prevalence is observed in Belarus, found similar in contaminated and control areas. II.From 1987 to 1989, a significant access of the prevalence at birth of mandatory registered (MR) CM was observed in the regions, ascribed to the strict radiological control area (SRCA) with 137Cs soil contamination exceeding 15 Ci/km2, as compared to the control. Relative risk (RR) for MRCM was found RR1987-1989 = 1.57 with 95% confidence interval being = 1.29;1.89 III.No direct teratogenic effect of the impact of Chernobyl NPP fallouts on fetus was registered. CM of central nervous system might be the only one possible exception. An increased prevalence of at birth of anencephaly (0.8‰) was observed in the regions of SRCA in 1987, significantly acceding the control values (0.2‰) (RR1987 = 4.49; 95%CI = [1.12; 17.95]). Moreover, more than twofold increase of the percentage of head circumference deficiency was registered among the newborns (n=912), born in the second half of 1986 and first half of 1987 whose intrauterine development took place in the mostly contaminated areas of Gomel region, as compared to the control group (n=1121). IV.Maximal monthly cluster of Downs syndrome (31 cases registered vs. 14 expected) with the highest increase observed in Gomel region; as well as an increased CM prevalence with high contribution of de novo mutations (multiple CM, reduction defects of limbs and polydactyly), registered in SRCA within the first 3 years after the accident, might be an indicator of indirect teratogenic effect due to gametic mutations.

Maternal MTHFR genotype contributes to the risk of non-syndromic cleft lip and palate. *N.H. Elcioglu[1], A.S. Yusufagiç[1], O. Celebiler[2], M.U. Erdim[2], R. Bircan[3], C. Erzik[3].* 1) Department of Pediatric Genetics, Marmara University Medical School, Istanbul, Turkey; 2) Department of Plastic Surgery, Marmara University Medical School, Istanbul, Turkey; 3) Department of Medical Biology, Marmara University Medical School, Istanbul, Turkey.

The pathogenesis of orofacial cleft lip with or without cleft palate (CL/P) is complex with the interaction of various genetic and environmental factors. Recently MTHFR functional polymorphisms were found to increase the risk of this common malformation, although this finding is still debated. In order to determine whether MTHFR variants are risk factors for nonsyndromic CL/P in Turkish population we carried out a case- parents triad study. 56 non-syndromic CL/P patients, their parents were genotyped for the 677C>T (p.Ala222Val) and 1298A>C (p.Glu429Ala) polymorphism in the MTHFR gene. Genotype and allel frequencies were compared with 2 control groups from the same population used in previous studies. Additionally the transmission of variant alleles from parent to the affected child were analyzed with the transmission disequilibrium test (TDT) in 46 trios. As a result TDT analysis showed no significant distortion in both allele transmission. There was also no difference for MTHFR 677C>T mutation frequencies between CL/P cases and their fathers compared to both control groups. But the association studies revealed significant differences in allele frequencies between mothers of CL/P patients and the controls. Mother carrying 677C>T homozygote genotype had 3 fold higher risk for having a CL/P child when compared to controls (**OR: 3.14, p: 0.03). The 'combined heterozygosity' (677C>T /1298A>C) genotype which was observed in % 28 of the mothers, remained insignificantly compared to the controls (OR: 2.27, p:0.07). This work supports the hypothesis that a lower MTHFR enzyme activity in pregnant women, commonly related to the homozygote MTHFR 677C>T polymorphism, could be responsible for a higher risk of having CL/P affected offspring. Therefore these mothers should treated with higher dose of Folic acid during the periconceptional period, rather than the recommended low dosage for the general population prevention.

NSD1 polymorphic DNA markers for microdeletion screening in patients with Sotos syndrome. *I.. Kondo[1,3], H. Yamagata[1], Y. Tabara[1], T. Miki[2], F. Yamaguchi[3], K. Kuwajima[3].* 1) Dept Medical Genetics, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Geriatric Genetics, Ehime Univ Sch Medicine, Ehime, Japan; 3) Dept Pediatr. Ibaraki Prefectural Handicapped Children's Center, Ibaraki, Japan.

Sotos syndrome (SoS: OMIM 1175509 is an overgrowth syndrome associated with multiple congenital anomalis and developmental delay. Diagnostic characteristics are specific facial features (prominent forehead, receding hairline, hypertelorism, downward slanting palpebral fissures, small nose and prominent jaw) in addition to large head circumference and advanced bone age. Patients with SoS had either a common microdeletions including NSD1 gene or point mutations in NSD1 gene. The microdeletions were identified in majority SoS patients in Japna, but point mutations were common in non-Japanese patients with SoS. However, a half of patients with clinical features of SoS had not any mutations in NSD1 gene, even after mutation screening by direct sequencig and FISH analysis. We have developed an easy screening method for microdeletions in NSD1 gene using PCR approach. Two polymorphic DNA markers in introns 3 and 17 in NSD1 gene were identified and only 12 in 257 individuals were homozygous for the intron 3 polymorphic marker in a Japanese population, suggesting that a heterozygosity for this marker was 95.3% in Japanese population. In addition, five polymorphic DNA markers in exons 5 and 23 of NSD1 gene were highly heterogeneous, but these markers were in complete linkage disequilibrium in Japanese population. Using these DNA markers in NSD1 gene, three patients with SoS were homozygous for the polymorphic marker in intron 3 of NSD1 gene and microdeletion was confirmed based on parental genotypes, and two patients with SoS who were heterozygous for these marker had missense mutations in NSD1 gene after DNA direct sequencing in NSD1 gene.

Genetic counselling for early initiation of renoprotection in familial juvenile hyperuricemic nephropathy. *C. JACQUOT[1], D.P. GERMAIN[2].* 1) Nephrology, Hopital Europeen G. Pompidou, Paris, France; 2) Genetics, Hopital Europeen G. Pompidou, Paris, France.

Background : Familial juvenile hyperuricemic nephropathy (FJHN, OMIM 162000) is an autosomal-dominant disorder characterized by decreased urate excretion and the development of progressive interstitial nephritis leading to chronic renal failure. A locus for FJHN has been identified on chromosome 16p12 close to the MCKD2 locus, which is responsible for one type of medullary cystic kidney disease (MCKD2). UMOD, the gene encoding the uromodulin protein (also known as Tamm-Horsfall protein), maps within the FJHN/MCKD2 critical region and mutations in UMOD have recently been reported in families with FJHN/MCKD2, which are allelic disorders.

Case report : We describe a new family in which a 51-year-old male with hyperuricemia and renal insufficiency (serum creatinine 385 mol/L) was diagnosed with FJHN. His 21-year-old clinically asymptomatic son was found, through pedigree analysis, to have hyperuricemia and increased serum creatinine (148 mol/L), while his two daughters, with yet normal uricemia and serum creatinine levels, are awaiting molecular diagnosis. Renoprotection with allopurinol and angiotensin converting enzyme inhibitors was started in the probands asymptomatic son, in an attempt to avoid gout episodes and prevent progression of kidney failure. Interestingly, the probands parents are both healthy at 75, raising the hypothesis of a de novo mutation in the proband. They are currently being investigated for the presence or absence of the mutation in the UMOD gene.

Discussion : Thirty-one mutations associated with MCKD2 and FJHN in 205 patients have been described in the UMOD gene, with a cluster in exons 4 and 5. FJHN might be more frequent than previously thought. Sequencing of exons 4 and 5 of the UMOD gene is an easy way to confirm the diagnosis. Genetic counselling is key for the early onset of renoprotection in affected individuals in order to prevent hyperuricemia and progression of kidney insufficiency.

VLA-4 gene polymorphisms in Italian patients with Multiple Sclerosis. *V. Andreoli, F. Condino, M. Liguori, I. Manna, A. La Russa, R. Cittadella.* Institute of Neurological Sciences,National Research Council, Pianolago di Mangone, Cosenza, Italy.

Multiple sclerosis (MS) is the most common human demyelinating disease of the central nervous system (CNS), caused by an interplay of environmental and genetic factors. Very late antigen 4 (VLA-4) is a member of the integrin family and it is considered to be a key adhesion molecule in immune responses. On the basis of its role, it is expected that VLA-4 inhibitors would have anti-inflammatory activity because blocking of this integrin has the potential to inhibit the process that play important roles in inflammation. Recently 4 integrin antagonisms are currently being evalutated as therapeutic agents in chronic inflammatory diseases, like MS. We hypothesized that, because the T-cell activation drives a conformational change that alters the VLA-4 molecule from a low-affinity to high-affinity state with its ligands, the polymorphic 4-subunit of VLA-4 gene may represent a good target for association studies in MS and could be involved as candidate for drug resistance to the disease. To address these findings, this study focused on two genetic polymorphisms of the 4 -subunit: a single point mutation at position 3061 producing an arginine (CGG) to glutamine (CAG) transversion at amino acid position 844, and a C to A transversion at position 269 in the promoter region of exon 1. However, we do not have in literature objective data on the frequency of this variants in MS. We investigated the association of two single nucleotide polymorphisms at position 269 in the promoter region of exon 1 and 3061 in the exon 24 of the VLA-4 gene, through a case-control study involving 280 Italian patients from southern Italy with definite MS, and 255 age and sex-matched healthy controls from the same geographical area. Our results showed no significant differences in the allele and genotype distribution of the VLA-4 polymorphisms between MS patients and controls suggesting that, despite a biological plausibility, this VLA-4 gene polymorphisms are not significantly associated with MS in Italian patients.

Association of Variants in the CD244 Gene with Type 2 Diabetes in Pima Indians. *Y. Guo[1], V. Ossowski[1], J. Wolford[2], R.L. Hanson[1], S. Kobes[1], C. Bogardus[1], M. Prochazka[1].* 1) NIDDK/PECRB, NIH, Phoenix, AZ; 2) TGen,Phoenix,AZ.

A prior genome-wide linkage scan in Pima Indians indicated a type 2 diabetes mellitus (T2DM, onset age under 45 years) susceptibility locus on chromosome 1q21-q23. To narrow the location of the putative underlying mutation, we are analyzing single nucleotide polymorphisms (SNPs) across this region in over 1000 Pima Indians from the original linkage study. So far, linkage disequilibrium mapping showed several distinct areas associated with T2DM. One such region spans the CD244 gene which codes for a transmembrane receptor expressed in the immune system. Because abnormalities of the immune system have been recently implicated in the pathogenesis of T2DM, we investigated CD244 as a candidate gene. Sequencing of the 9 exons, exon-intron boundaries, 5' and 3' un-translated regions, and 1.6 kb of the 5' putative promoter of CD244 in 24 diabetic and 23 non-diabetic Pima Indians identified 9 variants, with a minor allele frequency between 0.08 and 0.20. The 3'UTR SNP rs485618 (G/A substitution) was associated with diabetes onset-age under 45 years (P=0.006, OR=3.19, 95%CI=1.40-7.28, additive model; P=0.008, OR=3.28, 95%CI=1.37-7.84 dominant model) after adjusting for sex, nuclear family membership and Pima heritage. The risk allele A had a frequency of 0.08. In a subgroup of 250 non-diabetic full-heritage Pimas who have undergone detailed metabolic testing including measurements of body composition, oral glucose tolerance, and hyperinsulinemic-euglycemic clamp, the risk allele A was marginally associated with lower glucose disposal rates (P=0.06, dominant model) after adjusting for age, sex, family membership, percentage of body fat. Although we did not detect any obvious functional variants (e.g. in the coding sequences, splice sites), the observed associations may reflect an effect of a variant on the expression of CD244, or could be markers for a nearby causative mutation. A CD244-/- knockout mouse was recently developed by a separate group, and we plan to investigate these mice for a potential effect of CD244 deficiency on the regulation of glucose metabolism.

High prevalence of brachymesophalangia-V in an endogamous population from eastern Nepal. *K.D. Williams[1], J. Blangero[2], D.L. Duren[1], C.R. Cottom[1], S. Lawrence[1], T. Dyer[2], B. Jha[3], J. Subedi[4], S. Williams-Blangero[2], B. Towne[1].*
1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Tribhuvan University Institute of Medicine, Kathmandu, Nepal; 4) Miami University, Oxford, OH.

Brachymesophalangia-V is a skeletal anomaly characterized by a short and broad middle phalanx in the fifth digit. It occurs frequently in individuals with certain genetic disorders (e.g., Down Syndrome), but is also observed in otherwise normal individuals. Brachymesophalangia-V appears to be an autosomal dominant trait, and studies suggest that it may be caused by mutations in the GDF5 gene on chromosome 20q. Population prevalence rates are generally very low (< 1%), but we have recently discovered an unusually high frequency of brachymesophalangia-V among children participating in the Jiri Growth Study, a genetic epidemiological study of child health conducted in the endogamous Jirel ethnic group of eastern Nepal. The Jirel population numbers approximately 5000, most of who are in one very large extended pedigree. A hand-wrist x-ray is taken annually of each child in the Jiri Growth Study to assess their skeletal development. X-rays of 1,310 Jirel children (645 boys; 665 girls) were examined for presence or absence of brachymesophalangia-V; 75 cases were observed in boys (11.6%) and 62 cases were observed in girls (9.3%), for a combined prevalence rate of 10.5%. As an initial step toward elucidating the genetic architecture of brachymesophalangia-V in the Jirel population, we used a variance components-based method for pedigree data (SOLAR; Almasy and Blangero, 1998) to estimate its heritability. The additive genetic heritability of brachymesophalangia-V is significant ($h^2 = 0.32$, $p = 0.004$). Future work will include collecting phenotypic data from older relatives of Jirel children who have brachymesophalangia-V to confirm its mode of inheritance, conducting linkage analyses to identify chromosomal regions harboring genes responsible for brachymesophalangia-V, and examining variations in candidate genes such as GDF5. Supported by NIH grants HD40377, AI37091, AI44406, and MH59490.

Analysis of a cohort and case/control study for congenital malformations in 20.000 births of 8 Colombian hospitals. *N. Garcia, F. Gil, F. Suarez, I. Zarante.* Intituto de Genetica Humana, Pontificia Universidad Javeria, Bogota D.C., Distrito Capita, Colombia.

Objective: To determine the frequency of congenital malformations in 8 Colombian hospitals from June of 2001 to December of 2003 and to describe any association with prenatal risk factors. Method: A study with operating modality was carried out, case-control nested to a cohort during the period of the 1º of June of 2001 to the 31th of December of the 2003. All intrahospitalary births were considered; alive of any weight and stillborn over 500 g occurred in the room of labours of each hospital participating in ECLAMC-VIDEMCO project (Latin-American collaborative study of congenital malformations - Colombian study of congenital malformations) . For each malformed patient a form case was filled out and that of the respective control excepting the malformed stillborn which do not have control. Results: The total number of births was 20 485, 20 236 they were live birth and 249 stillborn. The proportion of congenital anomalies was of 3.50% (719). The 3.5% of the livebirth presented malformations in the group of stillborn they presented them in 13%. The associated factors that were found significantly to the presence of malformations were: consumption of alcohol (OR: 2.1 (1.28.3.5) 95% CI, antecedent of abortion (OR: 1.27 (1.02-1.58) 95% CI (1.28.3.5) and the vaginosis, OR: 1.46. (1.20-1.90) 95% CI. Conclusion: This initial approximation provides data on type and frequency of congenital malformations and prenatal risk factors in Colombia.

Multiple voluntary articular subluxations in a boy with congenital onychodysplasia of the index fingers (Iso-Kikuchi syndrome): Two independent mendelian events? *L.O. Barajas-Barajas[1,2], C. García-García[1], J.R. Corona-Rivera[2].* 1) Servicio de Génética, Dirección de Rehabilitación, Sistema DIF Jalisco, Guadalajara, Jalisco, México; 2) Instituto de Genética Humana Dr. Enrique Corona Rivera, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Benign joint hypermobility can be observed in about 9% of normal population and is a cardinal feature in more severe disorders, including Ehlers-Danlos syndrome, osteogenesis imperfecta and Marfan syndrome. Voluntary or habitual subluxation has been described for the hip and shoulder articulations. We present a boy with multiple voluntary articular subluxations who also showed congenital onychodysplasia of the index fingers (COIF), also named Iso-Kikuchi syndrome. The propositus, was born from a 21-year-old G1 healthy mother after a term pregnancy. Birth weight was 2850 g, birth length was 50 cm, and Apgar scores were 9 and 10 at 1 and 5 minutes, respectively. Psychomotor development was normal. Examination at 3 years of age showed normal weight, length and OFC, dolichocephaly, small facies, epicanthal folds, down-slanting palpebral fissures, small chin, abnormal ears, narrow shoulders, genu recurvatum, skin syndactyly between second to third toe fingers, flat feet, and hyperelastic skin. He presented voluntary subluxations at the shoulder, elbow, hip, and fifth metacarpophalangeal articulations. Both index fingernails showed polyonychia (split rudimental). The remaining fingernails and toenails were normal. Skin biopsy reported increased elastic fibers. A 23-year-old father was referred with scapular hypermobility. Our patient fulfills the criteria for diagnosis of COIF. However, to the best our knowledge, observed articular findings has not been previously described in patients with COIF. It remains unclear if multiple voluntary articular subluxations in this case are related to COIF or are fortuitous probably mendelian associations.

13 years follow up of patient with Schwartz-Jampel Syndrome. *M. Padilla R, L. Figuera V, C. Garcia G.* Genetics Division, CIBO, IMSS, Guadalajara, Jalisco, Mexico.

The 23 years old proposita was the product of the second uncomplicated pregnancy; from non-consanguineous and health parents (father and mother of 44 and 41 years respectively). She has been followed by our department since age of 4 years to date with diagnosis of Schwartz-Jampel syndrome (SJS). Normal mental development and no positive familiar history. The symptoms started at age of 2 years with severe retrognathia, bilateral eye blepharofimosis and at age of three she initiated facial deformation. To attract attention the off bone affectation, because it was publish who syndrome atypical form. The characteristics facials and abnormality dental be characteristics syndrome, but not abnormality bone. Exploration Normocephalic, normal implantation of hair line, large forehead, to level facies, lower implantation and posterior rotation ear, blepharophimosis, contracture of the facial muscles, thorax asymmetric with right to predominate, short and clinodactyly of 5th fingers. To exploration Intraoral to observe tooth bad position, retention tooth (2nd and 3rd lower molars), vestibularitation incisive, posterior cross bite, increase over bite, gingivitis, mouth respiration, microstomie, temporomandibular joint stiffness, microretrognathie. Electromyography showed miotony, metabolic screen show to positive mucopolisacaridosis and positive tiosulphate. Patient received application botulinic toxin, to leave it for application painful. SJS, (OMIM 255800) is a rare autosomal recessive disorder characterized by the presence of myotonia with a mask-like face and skeletal dysplasia with growth retardation. Although rare, SJS has been divided into two types defined by the age at manifestation of the symptoms. The clinical variability observed in SJS could reflect heterogeneity in the molecular basis of this condition. Linkage of SJS to human chromosome 1p34-p36.1 has been shown in families of different ethnic origins, suggesting that SJS results from mutations at a single locus, witch transcribe the protein heparan proteoglicain sulphate 2 (perlacan) (hspg2). However, all the families used for the published studies presented with the condition during infancy or early childhood.

Molecular analysis of NIPBL gene in 40 Italian patients affected by Cornelia de Lange syndrome with wide phenotypic spectrum. *A. Selicorni[1], S. Russo[3], M. Bottigelli[1], D. Milani[1], A. Bentivegna[2], C. Cavalleri[3], C. Gervasini[2], G. Scarano[6], L. Memo[4], P. Castronovo[2], M. Masciadri[3], M.T. Di Vizia[7], C. Sforzini[8], E. Tarantino[5], L. Larizza[2].* 1) Pediatrics, University of Milan, Milan, Milani, Italy; 2) Medical genetics, Milan; 3) Ist Auxologico Italiano, Milano; 4) Genetica Clinica Treviso; 5) Genetica Clinica Pisa; 6) Genetica Medica Benevento; 7) Istituto Gaslini Genova; 8) Ospedale Valduce Como.

Cornelia de Lange syndrome (CdLS) is a MCA/MR disease characterized by pre/post natal growth retardation, facial dysmorphisms, mental retardation, hirsutism, small hands and feet or limb reduction defects. Occasional major malformations and specific medical complications are described too. Recently heterozygous mutations were reported in the previously uncharacterised gene, NIPBL, mapping in 5p13.1 and encoding a delangin protein. Mutation rate detected within CdLS patients ranges from 20 to 47%. DHPLC and direct sequencing of the 46 coding exons of NIPBL were carried on in a cohort of 40 patients with a medical diagnosis of CdLS and a wide variability in the expession of the phenotype. Every patient has been characterized as regard growth, psychomotor development, limb morphology, presence of major malformations and medical complications. Mutations were found in 15/40 patients, with a percentage of 37,5%.We found 14 sequence alterations, including 8 truncating, one in-frame deletion, 4 splice site and one missense, identified in 15 patients. Out of the 8 truncating mutations, two are stop codon, R797X and R2470X, the latter of novel description, while the remaining are never reported frameshift alterations, (459_460delC,2371_2372delC,2738_2743insTCACC, 2914_2915delA,7876_7877insA) with the exception of 2479_2481delAG described in two patients and recorded twice in our cohort. Correlating the genotype results to the phenotype we have found a relevant incidence of limb malformations in the mutated subjects (6 on 10 of the analized patients) while no clear correlation was demonstrated with severity of mental and growth retardation. We thank Fondazione Mariani and Associazione Italiana Sindrome di Cornelia de Lange for the collaboration and the support.

Five novel mutations in the FGD1 gene in Aarskog-Scott syndrome. *T. Kaname[1], K. Yanagi[1], Y. Chinen[2], N. Okamoto[3], K. Kurosawa[4], M. Tsukahara[5], M. Yamada[6], T. Kondoh[7], K. Naritomi[1].* 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) Dept Pediatrics, Univ Ryukyus, Nishihara, Japan; 3) Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 4) Clinical Research Institute, Kanagawa Children's Medical Center (KCMC), Yokohama, Japan; 5) Faculty of Health Science, Yamaguchi University School of Medicine, Ube, Japan; 6) Rihabilitation Center for Disabled Children, Kumamoto, Japan; 7) Department of Pediatrics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan.

Faciogenital dysplasia 1 (FGD1) gene was identified as a responsible gene for Aarskog-Scott syndrome (AAS). The FGD1 mutations are found in approximately 20% of AAS patients and no genotype/phenotype correlation has been found. We found five novel mutations of the FGD1 gene in 9 Japanese patients with AAS. Of 9 patients, 4 patients are familial AAS (two families) and 5 patients are sporadic, and two sporadic patients do not have mutations in the FGD1 gene. There are two missense mutations in exon 6 and exon 11, one nonsense mutation in exon 15, and two point mutations at splice junction (exon 6 and exon 14). The mutations are different in each patient except in the same family. All mutations are suspected to reduce the FGD1 function. By comparison of clinical feature in AAS patients between with and without FGD1 mutation, it was suggested that a joint hyperextension, which includes hypertension of the proximal interphalangeal joints and flexion of the distal interphalangeal joints would be one of the typical feature of AAS with FGD1 mutation.

Neuroblastoma in a patient with Noonan syndrome: Possible genotype/phenotype correlations in *PTPN11*. *A. Kwan, C.J. Twist, M. Manning.* Dept Pediatrics, Stanford Univ Med Sch, Stanford, CA.

Noonan syndrome (NS) is a multiple congenital anomaly syndrome characterized by short stature, webbed neck, dysmorphic facial features, pectus abnormalities, congenital heart defects, cryptorchidism, coagulation defects, and developmental delay. An increased association between NS and certain malignancies, such as juvenile myelomonocytic leukemia (JMML) and neuroblastoma, has been reported. Mutations in *PTPN11*, the gene encoding the protein tyrosine phosphatase Shp-2, have been identified in ~50% of NS patients. Genotype/phenotype correlations show that specific germline mutations in *PTPN11* are associated with the development of JMML in NS. Somatic *PTPN11* mutations have also been reported in isolated neuroblastoma. We report a patient with NS and a *PTPN11* mutation who also has neuroblastoma and discuss the importance of developing further genotype/phenotype correlations.Our patient is a 2 year 3 month old female referred for dysmorphic features, infantile scoliosis and developmental delay. Physical exam revealed a broad forehead, hypertelorism, downslanting palpebral fissures, epicanthal folds, low-set, posteriorly rotated ears, widely-spaced, inverted nipples, a low posterior hairline and marked scoliosis. Spinal MRI identified bilateral thoracic paraspinal and periaortic masses and a separate tumor of the left adrenal gland, consistent with stage 4 disease. Biopsy of the primary tumor confirmed the diagnosis of neuroblastoma without *MYCN* gene amplification. Constitutional chromosome analysis at the >550 band level and subtelomeric probes were normal. *PTPN11* mutation analysis revealed a G to T transversion in exon 3, resulting in a tyrosine to aspartate substitution at amino acid 62. Four patients have been described with NS and neuroblastoma. One had a *PTPN11* mutation in exon 13 and another had a tyrosine to cysteine substitution in the same residue affected in our patient. We report the third patient with NS and neuroblastoma who has a *PTPN11* mutation. This association suggests that further genotype/phenotype correlations are necessary and may aid in screening and management for NS patients who might be at risk for developing neuroblastoma.

Morphologic characteristics in hemizygous Fabry disease patients. *M. Ries[1], D.F. Moore[2], C. Robinson[1], C. Tifft[3], K. Rosenbaum[3], R.O. Brady[1], R. Schiffmann[1], D. Krasnewich[4].* 1) Developmental and Metabolic Neurology Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 2) Section of Neurology, Department of Internal Medicine, University of Manitoba, Canada; 3) Division of Genetics, Metabolism, and Center for Prenatal Evaluation, Children's National Medical Center, Washington, DC; 4) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Objectives: 1) To characterize morphometric characteristics in hemizygous patients with Fabry disease (FD). 2) To evaluate internal consistency of the proposed Fabry dysmorphology scale and the inter-rater-variability.

Design: Cross-sectional dysmorphology assessment by a panel of three independent clinical geneticists.

Participants: N=38, mean age 3810.8 years (range: 10-60).

Results: We identified periorbital fullness, prominent lobules of the ears, bushy eyebrows, recessed forehead, acute nasal angle, broad fingertips, generous nose/bulbous nasal tip, prominent supraorbital ridges, shallow midface, full lips, prominent nasal bridge, broad alar base, short fingers, prominent superficial vessels of hands and feet, coarse features, posteriorly rotated ears, and 5th digit brachydactyly. Crohnbachs alpha was 0.68. After principal component analysis (PCA) the initial 25-feature set was statistically reduced to the number of independent features supported by the data set. The statistical dimensionality of the data set determined by PCA suggested a core of 10 features. Lights kappa for n-observer inter-rater-variability was 0.38 while Cohens kappa allowing pair-wise rater comparison varied between 0.20 - 0.53.

Conclusions: Patients with FD have common characteristic morphological features of the face, trunk, and extremities. Some of these features are subtle as documented by the inter-rater-variability. Awareness of these features may facilitate the diagnosis of patients with FD and identification of affected family members.

Quantitative changes in the dermatoglyphic phenotype of Nail Patella Syndrome (NPS). *C.A. Brandon[1], N.M. Scott[2], K. Neiswanger[1], S.M. Weinberg[1], K.M. Bardi[1], B.S. Maher[1], A.L. Towers[3], M.L. Marazita[1].* 1) Ctr for Craniofacial and Dental Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Michigan, Ann Arbor, MI; 3) Div Geriatric Med, Univ Pittsburgh, Pittsburgh, PA.

NPS is a rare genetic developmental disorder (22/1,000,000) caused by mutations in the LMX1B gene on 9q34, which is responsible for dorsoventral patterning and limb development. Multiple hand and nail anomalies are seen in individuals with NPS, including nail dysplasia with a gradient of severity across the hand, an increase in arch patterns and an increase in extralimital triradii. Dermatoglyphic data was ascertained from 29 unrelated NPS cases, from unaffected family members (UFM, n=7), and controls from the literature (n=720). Total (TRC) and absolute ridge counts (ARC), stratified by hand, digit, and pattern type, were tabulated and compared between cases, controls and UFM. Overall, cases had lower ridge counts compared to both controls and UFM. Cases also had lower per digit mean TRC for all digits, with digits III and IV the most significantly different (p0.05). To evaluate individual pattern size differences, we also calculated the mean ARC of each fingerprint pattern type, regardless of digit location. A decrease in the size of ulnar loops (p=0.009) and a moderate increase in the size of whorls (p=0.067) was observed in cases. There is not clear evidence that the gradient of severity of the nail dysplasia is reflected in the dermatoglyphic phenotype. This is the first study of the quantitative dermatoglyphic phenotype in NPS. These results indicate that the mutations in the LMX1B gene and its affect on distal limb development result in quantitative changes of the dermatoglyphic phenotype of NPS. Supported by NIH grants R01-DE016148, P50-DE016215.

Congenital Bilateral Perisylvian Syndrome (CBPS): familial recurrence, clinical and psycholinguistic aspects correlated with MRI. *I.L. Brandão-Almeida[1], M. M. Guerreiro[2], S. R. V. Hage[3], C. Guimarães[2], M. A. Montenegro[2], F. Cendes[2], I. Lopes-Cendes[1].* 1) Dept Medical Genetics, Campinas State University, Campinas, Brazil; 2) Dept Neurology, Campinas State University, Campinas, Brazil; 3) Dept Speech Pathology, University of São Paulo, Bauru, Brazil.

Congenital bilateral perisylvian syndrome (CBPS) is a malformation of cortical development most frequently caused by perisylvian polymicrogyria (PMG), with an increased number and smaller cortical folds than normal brain. We aimed to correlate the clinical and neuroradiologic data with the psycholinguistic aspects in a large group of patients with CBPS. Thirty two patients (twenty two males and 10 females) with mean age of 17.4 years (range, 5-65 years) were studied. Fourteen were isolated patients and 18, belonging to 5 unrelated kindreds, had familial recurrence of the disease. MRI scanning, neuropsychological tests and language evaluation was obtained in all patients. Their cognitive level was assessed using one of the Wechsler intelligence scales. Language testing was performed according to semi structured protocol that evaluated vocabulary, free conversation, and repetition. **Results:** Twenty-eight patients had polymicrogyric appearance of perisylvian cortex, characterizing the syndrome named PMG. One had unilateral PMG and only 3 patients had normal perisylvian region (one of whom had bilateral parietal posterior PMG and two had bilateral frontal PMG). Significant prenatal events, were reported in 14 patients. All patients had similar neurologic dysfunction, mainly primarily pseudobulbar paresis. Hemiparesis was present in only 3 patients. Seven of our patients had epilepsy. Specific language impairment was found in 13 patients and psychological assessment showed that global cognitive deficit was not present in most of them, although they usually have lower verbal IQ when compared to their performance IQ. None of our patients had facial dysmorphic features.**Conclusions:** Severity of clinical manifestations in CBPS is correlated with extent of cortical involvement. Epilepsy is not a common feature in patients with CBPS. Most of our patients have speech delay or language difficulties,including dyslexia.

Maternal Plasma Folate and Cleft Lip and Palate in Philippines. *M. Tolar[1], A. Al-Jabeiti[2], T. Pawar[2], M. Tolarova[2].* 1) Pediatrics, PCRC Core Laboratory, Univ California, Children,s Hospital, San Francisco, CA; 2) Orthodontics, Craniofacial Genetics, University of the Pacific A. A. Dugoni School of Dentistry, San Francisco, CA.

The etiology of nonsyndromic orofacial clefts (OFCs) is multifactorial, involving genetic and environmental factors. A low folate intake and disturbances of the folate metabolic pathway have been shown to play a critical role in the etiology of dysraphic anomalies such as neural tube defects, orofacial clefts, and conotruncal heart defects. Our pilot study was focused on the comparison of plasma folate levels (PFLs) between two groups of women in Cebu City, Philippines - those who had a child affected with cleft lip and palate, and those who had a healthy child. Our sample consisted of 57 mothers of patients affected with OFC and 57 mothers of unaffected children. The Immulite 1000 analyzer (Diagnostic Products Corporation, CA) was used for quantitative measurements of PFLs in plasma. The normal range of folate concentration in human plasma is 3-17 g/L. The mean PFL for mothers of cases was 3.44 g/L (SD=1.6), while the mean PFL for control mothers was 4.04 g/L (SD=1.43). The difference was statistically highly significant (t-test; p= 0.0001). There was a tendency for higher frequencies of case mothers in the low PFL groups and for higher frequencies of control mothers in the high PFL groups. Chi square test for trend confirmed a dose dependent effect (2 = 5.1389; p=0.0234). The highest risk for having a child with a cleft was found for mothers with PFL lower than 2.68 g/L. A support of Rotaplast International, Inc., for sample collection and a support of UOP A. A. Dugoni School of Dentistry for acquisition and analysis of data are acknowledged.

Ovarian dysfunction among premutation carriers of the *FMR1* gene. *S.L. Sherman, A.K. Sullivan, E.G. Allen, K. Harkreader, J. Brown, C. Small, M. Marcus.* Emory Univ, Atlanta, GA.

Premature ovarian failure (POF), defined as cessation of menses before the age of 40, occurs in 1% of women in the general population. Women who carry the *FMR1* premutation allele have a significantly increased risk for POF: about 13% have POF and the penetrance depends, in part, on the CGG repeat size. Our goal is to determine the reproductive profile of women who carry the premutation to identify clues about the cause of their ovarian dysfunction. For our current study sample of 466 non-carriers and 339 premutation carriers, we have obtained *FMR1* repeat size and transcript level, X-inactivation status, reproductive history using a structured interview and, in a subset of women, serum FSH levels. Traits consistent with a diminished oocyte reserve would include increased dizygotic twinning rate, increased spontaneous abortion, and decreased fertility. Among premutation carriers, we found a non-significant increase in dizygotic twinning and no evidence for increased miscarriages or clinically significant decreased fertility. We also examined menstrual cycle characteristics. There was no significant difference in age at menarche among groups. We found that carriers showed a significantly shorter cycle length ($p<0.001$), and, for those not on HRT, a significantly shorter bleed length compared to non-carrier women ($p=0.013$). However, premutation carriers did not have a greater variability in cycle length, a trait that is associated with infertility. We have also examined the effect of smoking, a known endocrine disruptor, on age at menopause. By survival analysis, we found a significant difference in the age at menopause for women who have ever smoked compared to women who have never smoked for both premutation carriers ($p=0.004$) and for non-carriers ($p<0.001$); the interaction between smoking status and premutation status was not significant. We hypothesize that these symptoms are due to increased follicular atresia as a result of the accumulating toxic effect of expanded *FMR1* transcripts.

Novel mutation in the gamma-D crystallin gene (CRYGD) associated with polymorphic congenital cataract. *O.V. Plotnikova[1], A.P. Grigorenko[1], E.K. Ginter[3], E.I. Rogaev[1,2].* 1) Mental Health Research Center, RAMS, Moscow, Russian Federation; 2) Brudnick Neuropsychiatric Research Institute, UMASS Medical School, Worcester, MA,USA; 3) Research Center of Medical Genetics, Institute of Clinical Genetics, RAMS, Moscow, Russian Federation.

Aims: Previously we described a new form of cataract termed polymorphic congenital cataract (PCC) and mapped the locus for PCC to the gamma-crystallin gene (CRYG) cluster on human chromosome 2q33-35 in large unique large pedigree from genetic isolate of Turkmen origin in Middle Asia (Rogaev E.I. et al., Human Molecular Genetics, 1996). The cataract is characterized by irregular opacity with variable location between the fetal; nucleus of lens and the equator. The color of opacity also varies from shining crystal-like to snow-white. The genetic isolate and PCC pedigree is characterized by complex ethnic origin, high endogamy and a high coefficient of inbreeding (>3%). The frequency of the PCC gene in this population is 2.47%. We searched for the gene and mutation causing the PCC. Methods: In a survey of the population, at least 34 affected sibships with PCC were identified. Large pedigree with 105 individuals with PCC was reconstructed. 100 members from Turkmen pedigree were used for genotyping analysis. Coding regions of the CRYGA, CRYGB, CRYGC and CRYGD genes were amplified by PCR using genomic DNA from affected and non-affected individuals in this pedigree. The PCR products were sequenced and analyzed for heterozygous or homozygous variations. Results: Novel mutation was identified in gamma-D crystallin gene (CRYGD) that segregate with PCC in this pedigree. The mutation resulted in amino acid substitution of the encoded gamma-D crystallin protein. All affected individuals were found to be heterozygous for this missense- mutation confirming autosomal-dominant inheritance of the PCC. Three common single nucleotide polymorphisms in CRYGB and CRYGD were also detected. Conclusion: This is the first report of a mutation in the CRYGD protein resulting in autosomal dominant polymorphic congenital cataract, which is characterized by wide variations in phenotype of non-nuclear lens opacities.

539 Cases of Gastroschisis: Increased risk of aneuploidy among fetuses of older mothers. *D. Durand[1], A. Cronister[2], R. Stoessel[3], D. Abad[1].* 1) Genzyme Genetics, Miami, FL; 2) Genzyme Genetics, Phoenix, AZ; 3) University Perinatal Associates, Palm Beach Gardens, FL.

Purpose: To determine the chromosome abnormality rate, gender differences and maternal age characteristics of amniocentesis samples submitted with the indication of gastroschisis. Methods: The Genzyme Genetics Laboratory database was queried from 2000 - 2005 to identify all amniotic fluid samples submitted with a referral indication of gastroschisis. Information on cytogenetic results, fetal gender and maternal age was documented and statistically analyzed. Results: 543 amniotic fluid samples with a referral indication of gastroschisis were identified. Cytogenetic analysis was not possible on 4. Of the remaining 539 the mean maternal age was 22.81 years among chromosomally normal fetuses and 33.08 among chromosomally abnormal fetuses. This difference was statistically significant ($p<0.0001$). Among the chromosomally normal group, there were 274 males and 255 females (a male to female ratio of 1.08:1). Ten chromosome abnormalities were identified, seven of which were male. Nine were trisomes and one was 45,X/46,XX karyotype. The overall aneuploidy rate was 1.86%. There was no statistically significant difference between the aneuploidy rates of male fetuses (2.49%) compared to female fetuses (1.16%) ($p=0.3437$). Discussion: Our data confirms the previously reported 1-2% aneuploidy rate associated with gastroschisis. The male to female ratio of 1.08:1 is also consistent with previous reports. Of interest, all but two of the trisomy cases were male and the mean maternal age in the aneuploidy cases was significantly elevated compared to maternal age among fetuses with normal karyotypes. Conclusions: We present data on 539 fetuses with gastroschisis. To our knowledge, this represents the largest series of prenatally diagnosed gastroschisis cases reported. This is also the first report of mosaic Turner syndrome associated with gastroschisis. Based on this data, it appears the risk of aneuploidy in fetuses with gastroschisis is increased in fetuses of older mothers.

Extreme phenotypic variability and a new mutation in HLXB9 in a Currarino syndrome kindred. *R. Wang[1], J.R. Jones[2], S. Chen[3], R.C. Rogers[2], M.J. Friez[2], C.E. Schwartz[2], J.M. Graham[1].* 1) Dept. Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Greenwood Genetics Ctr, Greenwood, SC; 3) Dept. Pediatric Surgery, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Currarino syndrome (MIM #176450) is an autosomal dominant disorder of hereditary sacral dysgenesis. Partial sacral agenesis, presacral mass, and anal malformations comprise the classic triad, but gastrointestinal, genitourinary, and neurologic anomalies are common. The syndrome is caused by mutations of the hox gene HLXB9 located on 7q36. It has three exons, encoding a 403 amino-acid protein with a homeodomain spanning residues 243 to 302. To date, 25 different mutations have been identified: all 9 missense mutations lie within the homeodomain; the rest are nonsense, frameshift, splice site mutations or whole-gene deletions. No genotype/phenotype correlations exist, and there is marked inter and intrafamilial variability. We present a family with a newly discovered mutation in HLXB9. The proband is a female without anal or sacral malformation presenting with perianal sepsis. Imaging revealed an inflammatory presacral mass, normal sacrum, spinal cord, and urogenital structures. Biopsy showed fibrous and neuronal elements. Her father has episodic constipation, but examination was unremarkable without malformation or hypertonia. Imaging showed normal sacrum without presacral mass or meningocele. His sister has bicornuate uterus, presacral teratoma, recurrent urinary tract infections, and perianal sepsis. Her daughter had neonatal bowel obstruction and anal stenosis requiring sequential dilatation, bicornuate uterus, and chronic constipation that has improved with age. Her daughter has the Currarino triad and required a diverting colostomy due to severe neonatal bowel obstruction. She recently developed recurrent urinary tract infections and hydronephrosis was found. Mutation analysis revealed that these patients had a previously unreported nonsense mutation, E283X, absent in tested asymptomatic first-degree relatives. This family provides additional information on the degree of intrafamilial variability associated with HLXB9 mutations, with phenotypes ranging from asymptomatic to severely affected.

Redefining the Clinical Phenotype in Angelman Syndrome Using Microarray-Based Comparative Genomic Hybridization Testing in Children with Known Deletions. *S.U. Peters[1], T. Sahoo[2], A.L. Beaudet[2], J. German[2], L.M. Bird[3], R. Barbieri-Welge[3], T.J. Bichell[3], C.A. Bacino[2].* 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Dept Mol & Human Genetics, Baylor Col Medicine, Houston, TX; 3) Dept Pediatrics, San Diego Children's Hosp., San Diego, CA.

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe mental retardation, ataxia, and a happy disposition. Although there are four different molecular types of Angelman Syndrome, deletions of the 15q11-q13 region account for approximately 70% of the Angelman Syndrome patients. These deletions are usually detected by fluorescent in situ hybridization (FISH) studies. The deletions can also be sub-classified based on their size into Class I and Class II with the former class being the larger of the two. We have studied 30 children with Angelman Syndrome with known deletions using a microarray-based comparative genomic hybridization (CGH) assay and analyzed their phenotypic severity, especially expression of the autism phenotype, in order to establish clinical correlations. Based on the analyses of 22 children thus far, those with larger, Class I deletions have a more severe phenotype than children with smaller, Class II deletions. Specifically, children with Class I deletions were significantly more likely to meet criteria for autism ($p=.01$), and had lower cognitive scores ($p<.05$) as compared to children with Class II deletions. Trends were noted with Class I children receiving lower scores for expressive language ($p=.06$) and receptive language scores ($p=.07$). Although no differences in seizure severity were noted between the two groups, children with Class I deletions required more medications to control their seizures in comparison to the Class II group ($p = .046$). There are four known genes (NIPA 1, NIPA 2, CYFIP1, & GCP5) that are deleted in class I but not class II deletions, thus raising the possibility of a role for these genes in autism as well as the development of expressive language skills in particular. In light of these genotype/phenotype correlations, implications of our findings for re-defining the clinical and behavioral phenotype in Angelman syndrome will be discussed.

A Structure-Function Study of MID1 Mutations Associated with a Mild Opitz Phenotype. *L. Mnayer[1], S. Khuri[1], H. Merheby[1], G. Meroni[2], L. Elsas[1].* 1) The Dr. John T. Macdonald Foundation Center for Medical Genetics, University of Miami, FL; 2) Telethon Institute, Naples, Italy.

The X-linked form of Opitz syndrome (OS) affects midline structures and produces a characteristic, but heterogeneous phenotype that includes mental retardation, hypertelorism, broad nasal bridge, widows peak, cleft lip/cleft palate, congenital heart disease, laryngotracheal defects, and hypospadias. The MID1 gene is implicated in OS, and maps to Xp22 encoding a 667 amino acid protein that contains a ring finger motif, two B-box zinc fingers, a coiled coil, a fibronectin type III (FNIII) domain, and a B30.2 domain. OS is seen as a severe disorder; however, here we describe a case of an intelligent male who has a milder phenotype. He presents with hypertelorism, broad nasal bridge and widows peak, hypospadias, pectus excavatum, and a surgically corrected tracheo-esophageal fistula, but without mental retardation, cleft lip/palate or heart disease. We identified a novel mutation (P441L) which we localized to the FNIII domain of MID1. Unlike almost all other reports of MID1 missense mutations associated with OS, P441L presents with a milder phenotype. While OS phenotypes have been attributed to mutations in the C-terminal part of MID1, little is currently known about the structure function relationships of MID1 mutations, and how they affect phenotype. A literature review suggests that missense mutations within the FNIII domain of MID1 are associated with a milder presentation of OS than missense mutations elsewhere in MID1. All truncating mutations (frameshift, indels) lead to severe OS. We used homology modeling of the MID1 FNIII domain to investigate possible structure-function changes by missense mutations. Preliminary results suggest that these mutations cause disruption of protein-protein interactions, either within MID1 or between MID1 and other proteins. We correlate the findings to the resulting milder phenotype and absence of CNS involvement, which is most likely due to differences in MID1 expression during embryonic development. It may be that the FNIII domain is important for midline differentiation after neural tube and palatal structures are completed.

Musculoskeletal findings in the older patient with Cornelia de Lange Syndrome. *A.D. Kline[1], C.P. Pichard[2], I. Krantz[3], P.D. Sponseller[2].* 1) Harvey Inst Human Gen, Greater Baltimore Medical Ctr, Baltimore, MD; 2) Dept Orthopedics, Johns Hopkins Univ School Medicine, Baltimore, MD; 3) Div Human Gen, The Children's Hosp Philadelphia, Philadelphia, PA.

Individuals with Cornelia de Lange syndrome (CdLS) exhibit a variety of musculoskeletal anomalies, ranging in severity from minor hand findings to severe reduction defects with single digits. Although specific anomalies have been described, management and treatment guidelines have not been evaluated, nor have aging and limb involvement been studied or correlated with intelligence and severity. Through an ongoing clinical study to assess aging, orthopaedic involvement has been evaluated in 36 adolescents and older patients with CdLS to date, with 44% over 18 years of age. 33% have absent forearm(s); higher than previously noted. 77% were ambulatory without assistance. More severe findings were seen in individuals with a lower range of intelligence, similar to previous reports. Several anomalies not previously recorded were seen in our patients. Bunions were found in 72%, and leg length discrepancy in 31%; both could be a function of aging. Delayed skeletal maturity was noted in 10%. Orthopedic procedures were performed on 36% of the patients, more on the lower than upper extremity, and more procedures were done in children with lower birth weights and higher intelligence. Findings indicative of possible premature aging in CdLS include degenerative joint disease, osteopenia and fractures in the late teens or early 20's. Further investigation into etiology for these is ongoing. 33% of our patients have undergone mutation analysis of the NIPBL gene, and comparisons of detectable molecular changes with musculoskeletal findings and severity of involvement will be made.

Gene polymorphisms or haplotypes in the Endothelial cell protein C receptor as potential risk factor for Idiopathic recurrent pregnancy loss: a population-based case-control study. *D. Bercovich[1,2], D. Levi[1], G. Sarig[3], C. Schochat[1], G. Tenenbaum[3], B. Brenner[3].* 1) Human Molec Genetics & Pharm, MIGAL-Galilee Technology Ctr, Kiryat-Shmona, Israel; 2) Tel Hai Academic College; 3) Hemostasis Unit, Rambam Medical Center, Haifa, Israel.

Idiopathic recurrent pregnancy loss (RPL) is associated with maternal thrombophilia but still 30-50% of RPL cannot be explained and might be associated with new or unknown thrombophilia. Moreover, the potential role of maternal thrombophilia in neonatal thrombosis is not established. The endothelial cell protein C receptor (EPCR) functions as an important regulator of the protein C anticoagulant pathway by binding protein C and enhancing activation by the thrombin-thrombomodulin complex. A soluble form of EPCR circulates in plasma and inhibits APC anticoagulant activity, thus, functions as procoagulant component. In order to find new thrombophilic risk factors for RPL, we studied the EPCR gene polymorphisms and soluble EPCR (sEPCR) levels in women with RPL compared to healthy controls. Analysis of three DNA alterations (SNP) in the EPCR gene; 1651 C>G in the 5' UTR, 6936 A>G Ser219Gly and 7014 C>G in exon 4, were evaluated in 215 women with RPL and 232 women without pregnancy complications. Differences in allelic frequencies were found between women with RPL and controls in SNP 1651 C/G (C 0.36, G 0.64 and C 0.23, G 0.77, respectively, OR=0.54, P=0.0016) and SNP 7014 C/G (C 0.23, G 0.77 and C 0.33, G 0.67, respectively, OR=1.5, P=0.0086). haplotype C;A;G (SNPs: 1653, 6936 & 7014 respectively) were significant more frequent in the RPL group (OR=1.83, P=0.023) and haplotype G;A;C were significant more frequent in the control group (OR=0.49, P=0.028). Genotype 6936AG was found to be associated with high levels of sEPCR; mean levels of sEPCR in women with genotype 6936AA was 120Â37 ng/ml compared to 250Â73 ng/ml in genotype 6936AG, P=0.001. Genotype 6936AG frequency (14%) as well as sEPCR levels did not differ between women with RPL and controls (153Â70 ng/ml and 135Â61 ng/ml, respectively). In conclusion: these results suggest that SNPs 1651 C/G and 7014 C/G in the EPCR gene might be associated with RPL.

Molecular genetics of Warburg Micro Syndrome (microphthalmia, cataract, microcephaly and microgenitalia).

I.A. Aligianis[1,2], C.A. Johnson[1], D. Chen[3], D. Hampshire[4], K. Hoffman[5], N.V. Morgan[1], P. Gissen[1], J.R. Ainsworth[6], J. Morton[2], T.G. Barrett[1], D. Pilz[7], N. Stoodley[7], L. Tee[1], J. Bond[4], L.W. Harris[8], R. Trembath[8], S. Mundlos[5], D. Tannahill[3], C.G. Woods[9], E.R. Maher[1,2]. 1) Medical and Molecular Genetics, University of Birmingham, Birmingham, West Midlands, United Kingdom; 2) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Birmingham,UK; 3) Embryo Gene Expression Patterns, The Wellcome Trust Sanger Institute, Cambridge, UK; 4) Molecular Medicine Unit, St. James' University Hospital, Leeds, UK; 5) Max Planck Institute for Molecular Genetics, Berlin, Germany; 6) Birmingham Midlands Eye Hospital and Birmingham Childrens Hospital, Birmingham, UK; 7) Clinical Genetics Department Cardiff and Neuroradiology Department, Frenchay Hospital , Bristol, UK; 8) Division of Medical Genetics, Departments of Medicine and Genetics, University of Leicester, Leicester, UK Neuroradiology Department, Frenchay Hospital , Bristol, UK; 9) Department of Medical Genetics, Cambridge Institute for Medical Research, Cambridge,UK.

Warburg Micro syndrome is a severe autosomal recessive disorder characterised by developmental abnormalities of the eye and central nervous system and microgenitalia. We previously undertook a 10cM genome -wide linkage scan in eight consanguineous families to map the first Micro locus (WARBM1) to 2q21.3. Homozygous inactivating mutations in RAB3GTPase activating protein (RAB3GAP) were then found in 12 of 18 Micro syndrome families. In mouse we found significant expression of Rab3GAP in the developing eye and brain. Mutation analysis has now been performed in a further 10 families. This has not only confirmed that Micro syndrome is a heterogenous disorder but extended the phenotype associated with dysregulation of the Rab3 pathway. Further clinical investigations to delineate the endocrine and neuroradiological features of the condition have been undertaken. RAB3GAP has a critical role in regulating the function of the four Rab3 family members that are implicated in neurotransmitter and hormone release by calcium mediated exocytosis. The Micro syndrome phenotype demonstates that RAB3GAP is essential for the normal development of the brain , eye and genitalia. We hypothesise that the underlying pathogenesis of Micro syndrome is a failure of exocytic release of ocular and neurodevelopmental trophic factors.

Detection and mapping of chromosome aberrations in congenital diaphragmatic hernia patients using array CGH. *A. Slavotinek[1], A. Moshtefi[1], R. Davis[2], E. Leeth[3], R. Keller[1], K. Nobuhara[4].* 1) Dept Pediatrics, U585P, Univ California, San Francisco, San Francisco, CA; 2) Comprehensive Cancer Center, UCSF, CA; 3) Evanston Northwestern Healthcare, Evanston, IL; 4) Dept Pediatric Surgery, UCSF, CA.

Congenital diaphragmatic hernia (CDH) is a common birth defect with a high mortality and morbidity. We are currently performing array CGH on DNA from probands with syndromic and non-syndromic CDH to detect and map chromosome aberrations. We have used the HumArray 3.1 BAC array with an average resolution of 1.4 Mb to study 30 patients, 10 with syndromic CDH, 15 with non-syndromic CDH and 5 with CDH and previously known cytogenetic aberrations. In four of these patients, we have mapped 15q26.2 deletions that overlap with the critical 5 Mb region for CDH delineated by Klaassens et al. (2005). These patients all have features consistent with 22 reported patients who had 15q24-15qter deletions, allowing characterization of a recognizable gene deletion syndrome comprising CDH, intrauterine growth retardation, pulmonary hypoplasia, cardiac defects, a single umbilical artery and talipes/rockerbottom feet. In 2 patients with known cytogenetic deletions, we have mapped an 8 Mb deletion of 4p16 and a 4-10 Mb deletion of 1q41-1q42.2. Monosomy for these chromosome regions has previously been reported with CDH, but the critical regions had not been molecularly defined. We conclude that array CGH is vital to exclude submicroscopic chromosome rearrangements in patients with CDH and additional anomalies. Klaassens et al., AJHG 2005;76epub.

Genetic and life-course determinants of bacterial infections: a birth cohort study over 30 years. *M.-R. Järvelin[1], P. Elliott[1], M. Levin[3], A.-L. Hartikainen[4], U. Sovio[1], J. Key[1], S. Cheng[5], J.A. Summerfield[2].* 1) Department of Epidemiology and Public Health, Imperial College, London, UK; 2) Division of Medicine, Imperial College, London, UK; 3) Division of Pediatrics, Obstetrics and Gynaecology, Imperial College, London, UK; 4) Department of Public Health and General Practice, Oulu, Finland; 5) Department of Human Genetics, Roche Molecular Systems, Alameda, CA, USA.

Objective. To test the hypothesis that polymorphisms in the MBL and TNF genes contribute to the risk of bacterial infections. **Methods.** A nested case control study in The Northern Finland Birth Cohort of 12,058 live births followed-up to age 31. Data on life-course and admissions to hospital with severe/recurrent bacterial infection and with non-infectious diseases (classified by ICD 8-10) based on records from neonatal period, questionnaires at ages 1, 14 and 31 years and national cause-of-death and hospital discharge registers up to age 31. 327 cases (157 severe) were matched with 651 controls by sex, maternal education and parity. **Results.** MBL haplotypes were not associated with infection risk. The rare TNF (-308 A/A) genotype associated with a two to three fold risk of bacterial infection compared to G/G genotype; unadjusted OR 2.9 (95% CI 1.04-8.3), 3.01 (1.1-8.5) adjusted for birth weight and 2.2 (0.7-6.5) further adjusted for early life factors. Many non-infectious diseases (respiratory diseases, congenital malformations) were associated independently with risk of infection, and adjustment for these diseases generally attenuated the genotype-phenotype association. TNF (-308 A/A) genotype was associated with higher risk for blood and skin diseases. Low birth weight and low maternal body mass index were independently associated with risk of bacterial infection (lowest decile vs. the rest, OR 2.1 (1.3-3.6) and OR 1.7 (1.08-2.76), respectively). Farmer background reduced the risk of infections (farmers vs. highest 3 classes, OR 0.6 (0.4-0.9)). **Conclusions.** Lifecourse exposures and genetic polymorphisms are important determinants of bacterial infections. This study illustrates the complexity of genetic analyses of multifactorial disorders.

Autosomal dominant Peters anomaly in a large family without causative mutations in PAX6 and CYP1B1 genes.

Y. ALANAY[1], N. BERKER[2], U. ELGIN[2], B. VOLKAN-SALANCI[1], N.A. AKARSU[3], E. TUNCBILEK[1], M. ALIKASIFOGLU[1]. 1) Dept of Pediatrics, Clinical Genetics Unit,Hacettepe University , Ankara, Turkey; 2) Ulucanlar Eye Research Hospital, Ankara, Turkey; 3) Gene Mapping Laboratory, Department of Pediatrics,Hacettepe University, Ankara, Turkey.

Peters anomaly (MIM 604229) includes central corneal opacity and iridocorneal adhesions due to defects in the posterior corneal stroma, Descemets membrane and corneal endothelium. It occurs as an isolated abnormality or in association with various ocular defects and congenital anomalies. Familial type is usually autosomal recessive however, dominant inheritance is rarely reported. A few cases have been associated with mutations in PAX6, RIEG, PITX3 and CYP1B1. Here we report the phenotypic presentation in a multiplex family that fits in the Peters anomaly spectrum. The complete pedigree consists of a total of 44 members(16 affected)in an autosomal dominant inheritance pattern. The six examined affected members demonstrate bilateral microcornea, corneal opacity, iridocorneal adhesions, nystagmus and strabismus without glaucoma or cataract. PAX6 gene mutations were previously excluded based on sequencing analysis of the coding region of the gene. In this study, we analyzed the coding region (exon 2 and 3) of CYP1B1, the major known cause of primary congenital glaucoma. No causative mutation except two reported SNP changes (V432L and a silent chance D449D) has been identified. Compound heterozygosity in codon 432 (V432L/R) is suggested to be associated Peters anomaly (Molecular Vision 2005; 11: 66-70). Published data on CYP1B1 polymorphisms show that the frequency of leucine allele in healthy Turkish control population is 71%, therefore the observed heterozygous V432L change in this study is not consistent with a causative relationship. In conclusion, the lack of cataract and glaucoma in Peters anomaly, with presence of microcornea, nystagmus and strabismus suggests a clinical phenotype in between autosomal dominantly inherited cataract-microcornea syndrome (MIM 116150) and Peters anomaly itself which has variable patterns of inheritance. PAX6 and CYP1B1 genes are less likely to be responsible for this phenotype.

MORM syndrome (mental retardation, truncal obesity, retinal dystrophy, and micropenis), a new autosomal recessive disorder, links to 9q34. *D.J. Hampshire[1], K. Springell[1], M. Ayub[2], E. Roberts[1], H. Jafri[3], Y. Rashid[3], J. Bond[1], J.H. Riley[4], C.G. Woods[5].* 1) Molecular Medicine Unit, University of Leeds, St James's University Hospital, Leeds LS9 7TF, UK; 2) Department of Psychiatry of Learning Disabilities, St Luke's Hospital, Middlesbrough TS4 3AF, UK; 3) Department of Obstetrics and Gynaecology, Lady Wellington Hospital, Lahore, Pakistan; 4) Discovery and Pipeline Genetics, GSK, New Frontiers Science Park North, Harlow CM19 3AW, UK; 5) Department of Medical Genetics, CIMR, University of Cambridge, Addenbrooke's Hospital, Cambridge CB2 2BP, UK.

A consanguineous pedigree is described where fourteen individuals are affected with a novel autosomal recessive disorder which causes static moderate mental retardation, truncal obesity, a congenital non-progressive retinal dystrophy and micropenis in males. We have named this condition MORM syndrome. This disorder shows similarities to Bardet-Biedl syndrome and Cohen syndrome; however linkage to the known Bardet-Biedl (BBS1-8) and Cohen syndrome loci was excluded. Autozygosity mapping identified a single homozygous region shared by all affecteds on chromosome 9q34.3, with a maximum LOD score of 5.64. We believe this to be the first example of the identification of a sub-telomeric recessive locus by autozygosity mapping.

The Pompe Registry: demographics, methods of diagnosis and preliminary genotype-phenotype correlation. *K. Sims.* Molecular Neurogenetics, Massachusetts General Hosp, Boston, MA.

Pompe disease is a rare, lysosomal disorder secondary to deficiency of alpha-glucosidase and glycogen storage in skeletal and cardiac muscle with variable disease progression. The Infantile-onset form presents in first months of life with hypotonia, generalized muscle weakness and cardiomyopathy followed by death from cardiorespiratory failure often by 1 year. A Late-onset form shows little cardiac involvement, and slower progression of muscle weakness. Eventual loss of ambulation and respiratory insufficiency causes early mortality. To better understand the natural course of this disease, a global Pompe Registry has been initiated.

Results: *Demographics:* Currently, 70 patients are enrolled in the Registry. 31 (44%) female, 39 (56%) male, 50 (71%) Caucasian, 2 (3%) Black, 2 (3%) Asian. Average age is 30.1 years with 40 (57%) patients > 20 years, 10 (14%)10-20 years, 20 (29%) 1-10 years and none < 1 year. 13 (19%) patients were diagnosed as Infantile-onset, mean age 7.4 months (0.9-18.4 months). 48 (69%) were diagnosed as Late-onset, mean age 31.8 years (1.3-64.0 years). *Diagnostic Data:*34 (49%)were diagnosed by DNA analysis and 48 (69%) by enzyme assay [29% lymphocyte, 26% fibroblast,15% leukocyte]. 44% of patients were tested using more than one diagnostic method. Muscle biopsies were performed on 34%. *Genotype Data:* Mutation analysis in 30 patients identified 11 unique mutations. Two occurred more than once: IVS1-13T>G (19/30, 63%) and IVS1-13T>C (2/30, 7%). Those with IVS1-13T>G were primarily Late-onset [84%] mean age 44.0 years (9.6-72.2 years).

Conclusions: Mutiple methods were used for diagnosis. DNA testing identified mutations in 20/30 [67%]. Data suggests a milder, Late-onset phenotype associated with common IVS1-13T>G mutation. Future Registry analysis may identify other correlates to clinical disease severity.

The Pompe Registry is a physician managed, Genzyme sponsored tool, designed to collect longitudinal patient data to improve understanding of this rare disease and enhance patient care..

An epidemiologic evaluation of patients with multiple vertebral segmentation defects. *S.J. Drescher[1], M.H. Reed[1,2,3], A.E. Chudley[1,3], J.A. Evans[1,3].* 1) Department of Biochemistry and Medical Genetics; 2) Department of Radiology; 3) Department of Pediatrics and Child Health; Faculty of Medicine, University of Manitoba, Winnipeg, Canada.

Introduction: Skeletal dysplasias involving segmentation defects of the spine and ribs have been described under many names including spondylocostal or spondylothoracic dysostosis, costovertebral dysplasia and Jarcho-Levin syndrome. These multiple vertebral segmentation defects (MVSDs) are clinically and radiographically heterogeneous, making genetic counselling for prognosis and recurrence risk difficult.

Methods: One aim of our study is to perform an epidemiologic evaluation of local cases with MVSDs, which will be useful for determining the nature and severity of these malformations. Using a scoring system for clinical and radiological information, we intend to perform cluster analyses to define groups of individuals with similar features. Our study population is being ascertained through review of literature and local cases obtained from the Genetics and Metabolism Program at our centre.

Results: Preliminary review of 84 local cases shows a 3:4 ratio of affected males to females. Most cases were livebirths, although several were detected prenatally and the pregnancies terminated. The finding of a number of cases with maternal diabetes will be followed as an etiologic factor. Although the association between maternal diabetes and caudal regression syndrome is well recognized, upper vertebral anomalies have been less well delineated in this group. Radiographically, defects were found at all levels of the spine, with thoracic anomalies being the most common. Cardiac, renal and limb malformations were those most commonly seen in assocation with MVSDs. Survival of liveborn cases varied from 15 minutes to more than 30 years.

Conclusions: These preliminary findings illustrate the heterogeneity of this population and the potential for identifying groups of individuals with similar features.

Novel mutations in the TWIST Box anti-osteogenic domain of *TWIST1* associated with single-suture craniosynostosis. *M.L. Seto[1], J. Chang[1], M. Hu[1], A.V. Hing[1], K. Kapp-Simon[2], P.K. Patel[2], M.L. Cunningham[1].* 1) Pediatrics, Division of Genetics and Developmental Medicine, University of Washington, Seattle, WA; 2) Surgery, Northwestern University Feinberg School of Medicine, Chicago, IL.

Craniosynostosis, the premature fusion of one or more cranial sutures, is a significant developmental disorder affecting 1 in 2500 live births. Single-suture fusion is the most prevalent form of craniosynostosis, with sagittal synostosis occurring in 1/5000 live births. We are conducting a multi-site, matched control, five-year longitudinal study of the neurobehavioral correlates of 250 infants with single-suture craniosynostosis. One focus of this study is screening each affected infant for mutations in candidate regions of genes known to cause craniosynostosis: *TWIST1*, *FGFR1*, *FGFR2*, and *FGFR3*.

Of 159 affected infants screened to date, we have found two mutations within the recently characterized TWIST Box, a functional domain of *TWIST1*. In humans, no TWIST Box mutations have been cited prior to this report. Our first patient has a nt.G556C mutation (which is expected to cause an Ala186Thr change) and unicoronal synostosis, facial asymmetry, and mild aortic valvular stenosis. Our second patient has a nt.C563T mutation (which is expected to cause a Ser188Leu change) and isolated (non-syndromic) sagittal synostosis.

While Saethre-Chotzen Syndrome is associated with *TWIST1* mutations, the association of isolated sagittal or non-syndromic craniosynostosis with a *TWIST1* mutation is a novel finding in humans. The Charlie Chaplin mouse, with a missense mutation in the same conserved residue as our second patient, also displays sagittal synostosis. The TWIST Box has recently been shown to interact with and directly inhibit *RUNX2* - a gene necessary and sufficient for osteoblast differentiation. Thus, we believe the TWIST Box mutations in our patients are causative of their single-suture craniosynostosis. Future studies will further elucidate whether our cases truly represent a genotype-phenotype correlation between TWIST Box mutations and non-syndromic, single-suture craniosynostosis.

Analysis of *SLC35A3* in Patients with Congenital Vertebral Malformations. *N. Ghebranious[1], L. Ivacic[1], E. McPherson[1], FS. Jacobsen[1], T. Faciszewski[1], JK. Burmester[2], RD. Blank[3], CL. Raggio[4], I. Glurich[2], K. Meddaugh[1], V. Kumar[1], PF. Giampietro[1].* 1) Marshfield Clinic, Marshfield, WI; 2) Marshfield Clinic Research Foundation, Marshfield, WI; 3) University of Wisconsin and GRECC Service, William S. Middleton Veterans Hospital, Madison, WI; 4) Hospital for Special Surgery, New York, NY.

Due to the sporadic nature of congenital vertebral malformations, traditional linkage methods to identify genes associated with the disease are not possible and therefore, a candidate gene approach is more appropriate. More recently, cattle with a specific point mutation in the Solute carrier family 35 (UDP-N-acetylglucosamine transporter), *SLC35A3* gene have recently been shown to have complex vertebral malformation syndrome (CVM). This autosomal recessive condition is lethal in cattle and is associated with congenital vertebral malformations and a variety of other birth defects that parallel various human congenital malformation syndromes including VACTERL, Klippel-Feil and Goldenhar syndromes. Because of the close phylogenetic relationship between humans and cattle, we hypothesized that mutations in *SLC35A3* may be associated with vertebral malformations in humans. To determine whether *SLC35A3* plays a role in human vertebral malformations, we sequenced the entire coding region and splice junctions of the *SLC35A3* gene in a cohort of 27 patients with a wide array of vertebral malformations from the Marshfield Clinic and Hospital for Special Surgery patient population. No significant mutations were found in the *SLC35A3* gene in any of the patients in the cohort. Several possibilities may account for the absence of mutations in these patients: a) the *SLC35A3* gene is not associated with human vertebral malformation as it is in bovine; b) the gene may be redundant in humans and mutations in other gene family members may be associated with congenital vertebral maformations; c) the disease is highly heterogeneous with multiple genes associated with the disease and thus a larger sample size is needed; and/or d) albeit less likely, but mutations could be clustered in the non-coding region of the gene that was not covered in this analysis.

Meier-Gorlin syndrome (MGS): Report of two cases. *T. Ben-Omran[1,3], F. Al-Murshedi[1], R. Babul-Hirji[1], D. Wherrett[2], D. Chitayat[1,3].* 1) Clinical/Metabolic Genetic, Hosp Sick Children, Toronto, ON, CanadaÁâ; 2) Division of Endocrinology, Department of Pediatrics, The Hospital for Sick Children,; 3) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

The Meier-Gorlin syndrome is a rare autosomal recessive disorder, characterized by severe growth retardation, bilateral microtia, micrognathia, and aplasia or hypoplasia of the patellae. Additional clinical findings include early closure of cranial sutures, microcephaly, low-set and simple ears; small mouth, full lips, cleft or highly arched palate; genitourinary tract anomalies, and various skeletal anomalies. Approximately 23 cases have been reported thus far. We report two unrelated patients with Meier-Gorlin syndrome. Patient 1: An 18-year-old boy was born at term to healthy, nonconsanguineous Caucasian parents. Antenatal ultrasound at seven months gestation revealed intrauterine growth retardation. Birth weight was 1999g (<3%) and length 44 cm (<3%). He was noted to have ambiguous genitalia and dysmorphic features, including bilateral microtia, epicanthic folds, hypertelorism, broad nasal bridge, and micrognathia and developed sensorineural hearing loss due to Mondini malformation, and has mild optic nerve hypoplasia. The karyotype was 46,XY. A skeletal survey, at 14 years of age, showed rudimentary right patella, abnormal fusion of the lunate and pisiform bilaterally, and mild cervical and thoracic scoliosis. Patient 2: This female patient is the first child born at term to healthy, non-consanguineous parents of African/Spanish ancestry. Antenatal ultrasound at five months gestation revealed IUGR. Birth weight was 2kg, length 43cm and OFC 32.5cm (all <3%). She had bilateral microtia, hypertelorism, and VSD and PDA on echocardiography with mild mitral incompetence. Skeletal survey showed absent patella. MGS is an AR condition with variability of ethnic origin. Our patients add to the panethnicity of this condition and expand the clinical manifestations to include ambiguous genitalia and Mondini malformation. Further studies are being done to delineate the gene associated with this condition.

Spectrum of Mitochondrial DNA Mutations in 18 Russian/Siberian Families with Lebers Hereditary Optic Neuropathy (LHON). *R.I. Sukernik[1], N.V. Volodko[1], M.A. Lvova[1], E.B. Starikovskaya[1], O.A. Derbeneva[1, 2], V. Procaccio[2], M.D. Brown[3], D.C. Wallace[2].* 1) Institute of Cytology and Genetics, SBRAS, 10, Lavrent'ev Ave, Novosibirsk, Russian Federation, 630090; 2) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, 2014 Hewitt Hall, Irvine, CA 92697-3940; 3) Division of Basic Medical Sciences, Mercer University School of Medicine, Macon, GA.

Subacute onset in young adults, bilateral, optic atrophy is the primary clinical sign of LHON, which is caused by missence mutations in the mtDNA genes encoding complex I subunits of the respiratory chain. We summarize results of the molecular genetic study of 18 genealogically unrelated families manifesting maternally transmitted visual failure consistent with LHON. The procedure entailed standard RFLP tests and mtDNA complete sequence analysis. Of 18 LHON families, 14 (78%) harbored common LHON mutations (G11778A, G3460A, and T14484C). The mutation G11778A identified in 8 of 9 Caucasian families, was preferentially associated with haplogroup TJ, and more specifically J1, J2 or T2. On the contrary, the mutation G3460A was confined to 3 indigenous families, Tuvan, Evenki, and Altaian, with their mtDNA types belonging to east-Eurasian lineages C3, D5 and D8, respectively. Heteroplasmy was detected in patients and their maternal relatives in two families, and in one of those (large Tuvan family) we were able to trace the origin of a de novo mutation. The mutation T14484C revealed in two extended pedigrees was associated with either haplogroup J1 or M9. In addition to these three primary mutations, a number of unique mutations (G3635A, C4640C, T10663C and A14619G) has been identified. The mutation A14619G (ND6/F19L) is a novel candidate mutation that has not been found in haplotype-matched or non-haplogroup (U4) control mtDNAs. The G14279A (ND6/S132L) is another novel mtDNA mutation revealed within the same geographic area (Zhadanov et al. 2005). Overall, it implies that this part of Siberia is conspicuous for variety of rare deleterious mtDNA mutations (G3635A, C4640C, G14279A, and A14619G) contributing to LHON expression.

Re-evaluation of Individuals with FXS After 10 Years (1995-2004) of Molecular Diagnostic Experience in a Tertiary Turkish Center. *E. Tuncbilek[1], Y. Alanay[1], D. Aktas[1], K. Boduroglu[1], E. Utine[1], B. Volkan-Salancı[1], M. Alikasifoglu[1], Hacettepe FXS Study Group[2].* 1) Clinical Genetics, Hacettepe University , Ankara, Turkey; 2) Faculty of Medicine, Hacettepe University, Ankara, Turkey.

Fragile X syndrome (FXS) is the most common inherited cause of mental retardation. Molecular diagnosis is available since 1991. At Hacettepe, 1600 DNA samples were tested and 107 families (126 FM individuals) have been identified in the past 10 years . Among these 106 were male probands with mental retardation. Only one family was identified due to premature ovarian failure (POF). Hacettepe University FXS Study Group was established in 2004. This study was constructed to overview the phenotypic features of our whole group reviewing their medical records. The reviewed records enabled us to see the evolution of age at diagnosis. The mean age at diagnosis has decreased from 8.08 yrs between 1995 and 1999, to 6.92 yrs between 2000 and 2004, and to 5.7 yrs in 2004. Prenatal diagnosis was available for 15 families (14%). Following this review 24/106 families were recruited for follow-up visits by the FXS Study Group. The physical and behavioral features were re-evaluated. Family history suggesting POF(58.7%) and FXTAS(4.5%) were questioned. Mean age at diagnosis was 5.73. Mean IQ was 49.720.4(range 25-90). Mean diagnostic score was 15.73. EEG abnormality was detected in 37.5% without previous seizure. Pervasive disorders were present in 31.8%, while oppositional defiant disorder and ADHD were diagnosed in 27.3%, and 22.7%, respectively. Nearly 50% of the patients had a cardiac abnormality, most common being MVP or mitral insufficiency (13.6%). Routine ENT examination revealed opaque ear drum in 23.8% with minimal conductive hearing loss. All were seen by a speech therapist. Strabismus was present in 1/23 patients. The results of this study are in correlation with previous reports on clinical problems in FXS. We emphasize the importance of multidisciplinary approach for the clinical problems in FXS. The high rate of family history for POF supports data suggesting routine screening for FMR1 premutation in idiopathic POF and indicates that consciousness should be increased among gynecologists.

Testing for subtelomeric abnormalities reveals a candidate region for Rubinstein Taybi syndrome. *E. Baldwin[1], J.A. Martinez[2], E. Crombez[2], S. Brodie[2], V. Vandergon[3], M. Fox[2].* 1) Children's Hospital Los Angeles, Los Angeles, CA; 2) University of California Los Angeles, Los Angeles, CA; 3) California State University Northridge, Northridge, CA.

A retrospective chart review at the University of California, Los Angeles (UCLA) identified the features and clinical presentations of individuals identified as carriers of a subtelomeric abnormality. Medical records for patients seen in the UCLA Genetics Clinic from January 2003 through December 2004 were reviewed. Of the 178 patients meeting criteria, 62 were tested by the UCLA Cytogenetics Laboratory for subtelomeric abnormalities using fluorescence *in situ* hybridization. Abnormalities were identified in seven (11.3%) of these individuals and included abnormalities of the 1p, 5q, 6q, 10q, 15q, and Xp subtelomeric regions. The patient identified with a cryptic 15q subtelomeric deletion had been previously given a clinical diagnosis of Rubinstein Taybi Syndrome (RTS) and lacked an identifiable mutation in the *CREBBP* gene. The patients phenotype included multiple cardiac anomalies, growth deficiency with a weight and height less than the third percentile, broad fingers and toes, and malar hypoplasia, consistent with a diagnosis of RTS. Candidate genes within the 15q subtelomeric region that could contribute to the phenotype in this patient include *NR2F2* and *MEF2A*. Both genes are involved in cardiac development, and *MEF2A* has been shown to interact with the gene for RTS. Considering that approximately 35% of individuals with clinical diagnoses of RTS will have a mutation in the *CREBBP* gene, the authors propose the subtelomeric region of 15q as a candidate region for a possible second gene contributing the RTS phenotype.

Screening for subtelomeric aberrations in children with mental retardation from Navarra. *M. Artigas-López, A. Alonso, A. Pérez-Juana, A. Bengoa, A. Valiente, M.A. Ramos.* Genetics, Hospital Virgen del Camino, Pamplona, Navarra, Spain.

Subtelomeric chromosome rearrangements are an important cause of idiopathic mental retardation (MR). The study was based on patients from Navarra, included in the Regional Registry of Birth Defects (RACEHNA). From the preliminary results in 60 children with unexplained MR and a normal G-banded karyotype, using a set of 41 subtelomeric fluorescent DNA probes, 6 subtelomeric aberrations (10%) were found. Except for one family all parents tested negative. Case 1: 46,XX,del(1)(pter). A 18-year-old dysmorphic female with patent ductus arteriosus, growth failure, microcephaly, severe MR. Case 2: 46,XX,del(17)(pter). A 5-year-old girl with moderate MR and mild facial dysmorphic features. Terminal deletion 17p has a distinct phenotype with lissencephaly as the main feature, however few cases with MR and mild features and phenotypically normal subjects have also been reported. Case 3: 46,XY,del(10)(pter). A 5-year-old boy with short stature, bicuspid aortic valve, pyeloureteral duplicity, pectus excavatum, moderate MR and very mild dysmorphism. Parents were not available. However, his younger sister with mild delay and similar facial features had the same FISH result, suggesting the inheritance of the aberration. Case 4: 46,XY,dup(1)(qter)/del(2)(qter). A 14-year-old youngster, with hypotonia and severe micrognathia at birth, at present moderate MR, with a marfanoid body habitus. Case 5: 46, XY, del(2)(qter). A 3-year-old boy with esophageal atresia and tetrallogy of Fallot, MR, trigonocephaly, small deep set eyes and dysplastic ears. Case 6: 46,XY,del(1)(qter). A 4-year-old boy with ocular coloboma, hypogenitalism, short stature, oligogyric microcephaly, severe MR and dysmorphia. As reported in previous studies, our preliminary results indicate that subtelomeric aberrations are a leading cause of MR. Given the wide variation observed in the positive cases and the diversity of the chromosomal rearrangements identified, more studies are needed in order to characterize the distinct phenotypes and be able to diagnose them with the specific probe for the chromosome involved.

Disruption of the *IL1RAPL1* gene associated with a pericentromeric inversion of the X chromosome causes MR and developmental delay. *S.S. Bhat[1], S. Ladd[1], F. Grass[2], B.R. DuPont[1], C.E. Schwartz[1], R.E. Stevenson[1], A.K. Srivastava[1].* 1) Greenwood Genetic Center, Greenwood, SC; 2) Department of Pediatrics, Carolina Medical Center, Charlotte, NC.

Characterization of X chromosomal rearrangements has proved to be a powerful tool in the identification of the X-linked mental retardation (XLMR) genes. We identified a 3 ¼-year-old male with MR and significant developmental delay. He also has a history of hand flapping and poor communication. Cytogenetic analysis revealed a pericentromeric inversion of the X chromosome: 46, Y, inv(X)(p22.1q13). The mother, who also has a history of learning difficulties and was in special class as a child, carried the same inversion on one X chromosome. Fluorescent in situ hybridization (FISH), using a panel of genomic clones, allowed the identification of a BAC clone from the Xp22.1 region spanning both the Xp22.1 and Xq13 breakpoints. The Xq13 breakpoint was narrowed to approximately 50 kb telomeric to the 3 end of *ACRC* gene. RT-PCR analyses detected no loss of expression of genes, *RPS4X*, *OGT*, *ACRC*, *CXCR3* and *KIAA2001*, present in the Xq13 breakpoint interval. Further analysis showed that the *IL1RAPL1* gene was disrupted by the Xp22.1 breakpoint and therefore its inactivation may be related to the mental retardation observed in the male patient. Defects of the *IL1RAPL1* gene have previously been shown to cause nonsyndromic XLMR. X-inactivation studies showed a random pattern of X-inactivation in the mother. It is likely that the learning disability in the patients mother is due to a partial loss of expression of the *IL1RAPL1* gene, which is disrupted by the inversion.

A new method for *ATRX* gene mutation analysis using mismatch-specific endonuclease (Surveyor^{TM} nuclease). *T. Wada[1], Y. Fukushima[1], S. Saitoh[2].* 1) Dept. Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Japan; 2) Dept. Pediatrics, Hokkaido University Graduate School of Medicine, Sapporo, Japan.

X-linked -thalassemia/ mental retardation syndrome (ATR-X, OMIM#301040) is a syndromic form of XLMR (S-XLMR), and characterized by severe mental retardation in males, dysmorphic facies, hemoglobin H inclusions, genital abnormalities, skeletal abnormalities and characteristic posture and/or behavior. ATR-X is caused by a mutation in the *ATRX* gene, which is also involved in other S-XLMRs and also in NS-XLMR in males. Approximately 10% of named X-linked MR syndromes are candidates for allelism based on phenotypic findings. Recently we have suggested that *ATRX* gene mutations can cause MR in females, unless the mutated allele is properly inactivated.
To analyze the full range of disease-causing mutations for genetic counseling, and to establish the phenotype-genotype correlations, we established a new *ATRX* gene mutaton screening method using mismatch-specific endonuclease (Surveyor^{TM}). Genomic DNA samples from 12 patients with ATR-X from 12 families were used for experiments. We designed PCR primers for all 36 exons and flanking introns. The length of PCR products ranged from 300 to 600 base-pairs. The PCR products from a patient and a control were mixed, and denatured and hybridized to form hetero- and homoduplexes. The mixture was digested by mismatch-specific endonuclease (Surveyor^{TM}). The digested products were analyzed by a DHPLC (WAVE system).
We confirmed that all 11 known mutations of our patients were detected by this method, some of which had been difficult to be detected by the DHPLC method only. And we found other two novel mutations outside the ADD and the helicase domains, where most mutations of the ATR-X patients resided. This system does not need to set temperature conditions depending on mutation's site, and could be a superior method to the DHPLC method. We have started screening *ATRX* mutations for MR patients with or without ATR-X phenotype.

A new cohort of MECP2 mutation screening in unexplained mental retardation: the occurrence of regression could be an indicator for routine molecular diagnosis. *A. Donzel, C. Thauvin-Robinet, V. Cusin, F. Mugneret, F. Huet, JR. Teyssier, L. Faivre.* Departement de Genetique, CHU de Dijon, France.

Besides to typical or atypical Rett, mutations in the MECP2 gene have been occasionally associated with severe encephalopathy, Angelman-like features, Prader-Willi-like features or unexplained X-linked mental retardation (MR). A few retrospective studies were designed to answer the question of whether or not an MECP2 mutation screening is indicated in boys with unexplained MR, and their compiled results showed a low frequency (1%) of MECP2 mutation in such cohorts. Here we performed MECP2 mutation screening by direct sequencing in a cohort of 146 well-characterized cases with MR (46 females, 100 males). The cohort included 2 groups depending if MR was isolated (92/146, group 1) or associated with other neurological features (54/146, group 2), including seizures, ataxia, microcephaly, autistic features and strabismus. None of the patients had stereotypes, regression nor irregular breathing. All patients had normal karyotype, Fragile-X study, MRI, plasmatic amino-acid and urinary organic-acid chromatographies. Two known pathogenic MECP2 mutations were found in two girls from group 2 (2/54, 4%), but none were found in group 1 with isolated non-specific MR (0/146, 0%). The R255X was found in a 3-year-old girl with psychomotor retardation and strabismus only, and the 1152-1192del41 mutation was found in another 2-year-old girl with psychomotor retardation, strabismus and ataxia at time of inclusion. Two years follow-up of both girls revealed some emerging features in favor of Rett-like phenotype, including loss of hand use, irregular breathing and manual stereotypes in case 1 and loss of speech in case 2. None of them had microcephaly or seizures. Ten non pathogenic sequence variants were also identified. We conclude that MECP2 mutations do not represent a major cause of non-specific MR and that MECP2 mutation screening could be useful in earlier diagnosis and genetic counseling in girls with ataxia or partial regression of motor or language skills with negative etiological investigations, even in the absence of progressive microcephaly and seizures.

A study on the distribution of Hepatitis B virus genotypes in local isolates of HBV in Malaysia using PCR-RFLP analysis. *J.B. Chook[1], S.F Yap[1], J.A. Tan[2].* 1) Dept Pathology, University Malaya, Malaysia; 2) Dept Molecular Medicine, University Malaya.

More than 350 million individuals worldwide are persistently infected with Hepatitis B virus (HBV) and more than two billion people have serological evidence of past infection. Individuals chronically infected with HBV can either be asymptomatic or demonstrate severe pathological consequences like liver failure, cirrhosis and hepatocellular carcinoma.

Current genomic typing of HBV confirms the distribution of HBV into eight genotypes, A - H. Genotypes A, B, C and D have been suggested as the predominant genotypes in Malaysia in common with other Asian countries. The molecular protocols for HBV genotyping include commercial hybridization assays, multiplex-PCR, PCR-restriction fragment length polymorphism (RFLP) and immunoassays that uses monoclonal antibodies against the *pre-S2* epitope. Genotyping of HBV in this study was carried out by PCR-RFLP with *Ava 2* and *Sau 3AI* for the *pre-S* region, and *Tas I* and *Hinf I* for the S-region. Samples with atypical restriction patterns were further analyzed using genotype-specific primer-PCR (GSP-PCR). The study population consisted of 115 randomly selected chronic hepatitis B patients positive for HBV DNA by the dot-blot hybridization assay.

The results obtained showed a frequency distribution of: genotype B - 53%, genotype C - 40%, genotype D - 1.7%, genotype A - 0.9% and indeterminants - 4.3%. Single genotype infection was observed in 95% (110/115) of the study population. Simultaneous infections by different subtypes of HBV were observed in 40% (46/115) of the individuals with the most frequent subtype combination being B1/B5 at 70% (32/46). Genotyping of the *Pre-S* region by PCR-RFLP indicated the presence of deletions in HBV genotypes A, B and C.

In conclusion, the PCR-RFLP assay established provides a rapid protocol as it only requires a single amplification reaction set-up. In addition, the PCR-RFLP assay allows the identification of HBV subtypes and detection of deletion mutants.

Mitochondrial mutations of Lebers hereditary optic neuropathy: a risk factor for multiple sclerosis? *R. Cittadella, I. Manna, A. La Russa, M. Liguori, V. Andreoli.* Institute of Neurological Sciences,National Resarch Council,Piano Lago of Mangone, Cosenza, Italy.

The occurrence of optic neuropathy in patients with MS-like disorders who carry one of the pathogenically significant mutations of Lebers hereditary optic neuropathy (LHON), a maternally transmitted disease characterized by acute or subacute, painless, bilateral loss of central vision due to optic nerve atrophy, as well as preferential maternal transmission of MS in affected parent-child pairs sopport the hypothesis that mitochondrial genes may implicate the etiology of MS. To evaluate the link between MS and LHON primary point mutations, we investigated a cohort of non related Italian clinically definite MS patients with optic nerve atrophy, as well as a cohort of patients without involvement of the optic nerve as controls. Each subject recruited to the study was fully informed and gave his/her consent. We searched for the presence of LHON mitochondrial mutations at nucleotide positions (np) 11,778, 3,460, 14,484 and 15,257 by mutation-specific polymerase chain reaction and restriction fragment length polymorphism. Our results suggest that there is no association between Italian patients with MS and mtDNA point mutations at np 11,778, 3,460, 14,484 and 15,257. Meanwhile, the results of several studies suggest a multifactorial etiology for MS, including multiple genetic factors of moderate effect rather than a very few genes of major biologic importance. However, the hypothesis that mitochondrial genes may implicate susceptibility to MS cannot be excluded.

Functional prove and further clinical evidence of the pathogenic relevance of TBX1 missense mutations. *A. Rauch[1], C. Zweier[1], H. Sticht[2], C. Campbell[3].* 1) Institute of Human Genetics, Friedrich-Alexander Univ, Erlangen, Germany; 2) Department of Bioinformatics of the Institute of Biochemistry, Friedrich-Alexander Univ, Erlangen, Germany; 3) Department of Biochemistry, University at Buffalo, NY.

Deletion 22q11.2 syndrome is the most frequent known microdeletion syndrome. It is associated with a highly variable phenotype including DiGeorge- and Shprintzen syndromes. From studies in several mouse models, haploinsufficiency of the T-box transcription factor TBX1, which is located within the common deletion interval, was suggested to cause the phenotype. Nevertheless, to date only 3 patients from Japan were described to have point mutations of TBX1 in association with five of the major phenotypes of 22q11.2 deletion. We report the first Caucasian patient with a TBX1 missense mutation within the T-box, associated with the typical facial gestalt, short stature and developmental delay. While all features are known to be associated with the 22q11.2 deletion syndrome, short stature and developmental delay were not previously reported in individuals with TBX1 mutations. The mutation in our patient was inherited from his father, who also showed short stature and facial anomalies. To prove the functional relevance of this mutation we tested our novel and the three published mutations in a transcriptional reporter assay. While the published truncating mutation showed remarkable reduction of TBX1 transcriptional activity, the published and our novel missense mutation showed significantly increased activity. The latter finding is in accordance with data from mouse models, showing the same phenotypic spectrum in both, TBX1 under- and overexpression. We therefore provide the first functional evidence for the pathogenic relevance of TBX1 missense mutations.

A locus for a new recessive form of limb-girdle muscular dystrophy with quadriceps atrophy. *J. Jarry[1], M.F. Rioux[1], Y. Robitaille[2], V. Khoury[3], I. Thiffault[1], M. Tétreault[1], L. Loisel[1], J.P. Bouchard[4], B. Brais[1].* 1) Laboratoire de neurogénétique, Centre de Recherche du Centre Hospitalier de l'Université de Montréal, Québec Canada; 2) Hôpital Ste-Justine, Montréal, Québec, Canada; 3) Département de radiologie, Hôpital Notre-Dame, Montréal, Québec, Canada; 4) CHA-Hôpital Enfant-Jésus, Université Laval, Québec, Canada.

Limb-girdle muscular dystrophies (LGMD) are characterized by a weakness and wasting of the proximal limb muscles, with typical sparing of the facial muscles. So far, seven autosomal dominant forms (AD-LGMD) and ten autosomal recessive forms (AR-LGMD) have been characterized. We have identified a cohort of 14 patients belonging to eight French-Canadian families displaying a distinct autosomal recessive form of limb-girdle muscular dystrophy with biceps and quadriceps atrophy and myalgia. This new form of LGMD displays extreme intra- and interfamilial variability. Clinical examination, magnetic resonance imaging, electromyograms, and muscle biopsies were performed to confirm the LGMD phenotype and to differentiate it from previously-described forms of the disease. A genome-wide scan was done with affected and unaffected individuals from two informative families and linkage was found to a less-than-3.3-cM locus not known to be linked to an LGMD (multipoint LOD score 4.56). We propose to name this new form LGMD2K.

Identification of a Novel Lamin A/C Mutation in a Chinese Family Affected with Prominent Atrioventricular Block and Autosomal Dominant Dilated Cardiomyopathy. *Q. Wang[1,2], L. Gui[2,3], X. Zhang[2], M. Liu[2], W. Li[2,3], L. Yan[4], R. Jin[3], Q. Wang[2,3], T. Ke[2], X. Wang[2], Zh. Tang[2], J. Yang[2,3], X. Wu[2,3].* 1) Ctr Molecular Genetics, ND40, Cleveland Clinic Foundation, Cleveland, OH; 2) Huazhong University of Science and Technology Center for Human Genome Research, Wuhan, Hubei 430074, China; 3) Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei 430022, China; 4) Electrocardiogram Lab, Jinshan Hospital, Jinshan, Shandong, 256000, China.

Abstract Dilated cardiomyopathy (DCM) is a disorder characterized by cardiac dilation and reduced systolic function. About 20% to 25% of DCM cases are familial, and the LMNA gene encoding the nuclear envelope protein lamin A/C is the most common gene identified for familial DCM. In this study, we characterized a large Chinese family with atrioventricular block (AVB) as the most prominent feature. Some patients in the family also have later onset DCM. No skeletal muscle dysfunction or joint contractures were detected in any member of the family. Genomewide linkage analysis mapped the AVB gene in the family to a marker at chromosome 1q21.2, where the LMNA gene is located. Direct DNA sequence analysis revealed a heterozygous G to A transition at nucleotide 244 in exon 1 of LMNA (GenBank accession number, 4000), resulting in a novel E82K mutation. The E82K mutation co-segregated with all affected individuals in the family, and is not present in 200 normal controls. Mutation E82K is located in the coil 1B rod domain of lamins A/C, which is a highly conserved unique heptad repeat domain specific to nuclear lamins . Conduction system disease in the family began in the third decades, and DCM developed in the fourth and fifth decades and is accompanied by advanced AV block. Echocardiography showed that atrial dilatation occurred earlier than ventricular dilatation in the patients. Ejection fractions (EF) didnt decrease even in the patients with the third degree AVB and AF. Our results identify the first, novel LMNA mutation in the Chinese population, and suggest that defects in lamin A/C plays an important role in families with AVB as the prominent clinical feature.

Myotilin mutations are associated with a significant number of Myofibrillar myopathy cases. *A. Shatunov[1], M. Olive[2], D. Hilton-Jones[3], I. Ferrer[2], M.C. Dalakas[1], L.G. Goldfarb[1].* 1) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, USA; 2) IDIBELL-Hospital de Bellvitge, Institut de Neurolpatologia, Barselona, Spain; 3) Department of Clinical Neurology, Radcliffe Infirmary, Oxford, United Kingdom.

Mutations in the Myotilin (MYOT, TTID) gene have been associated with variable syndromes including Limb girdle muscular dystrophy type 1A (LGMD1A) and a subgroup of Myofibrillar myopathy (MFM). We tested for MYOT mutations patients diagnosed as MFM, Desmin-related myopathy or Desminopathy, characterized clinically by lower limb muscle weakness slowly spreading to involve truncal, neck-flexor, facial, bulbar and respiratory muscles; skeletal myopathy was often combined with cardiomyopathy manifested by conduction blocks and arrhythmias. Sections of the affected skeletal and cardiac muscles showed abnormal fiber areas containing amorphous desmin-immunopositive deposits. Of a multinational MFM cohort consisting of 122 affected families or sporadic patients, eleven (9%) were identified as carrying MYOT mutations. Of these, Ser55Phe, Ser60Cys and Ser60Phe mutations were previously described, and Lys36Glu and Gln74Lys were novel. To compare, 24 of these families (20%) show the presence of mutations in desmin and none was found to carry mutations in alphaB-crystallin. The MYOT mutation-associated cases presented at the age of 42 to 77 years with lower limb muscle weakness and associated signs of cardiomyopathy, respiratory failure and peripheral neuropathy. Myopathological features of patients with MYOT mutations differed from desminopathy in several aspects: they exhibited (a) more abundant plaque-like irregular polymorphous inclusions strongly immunoreactive to myotilin, in addition to desmin; (b) multiple and prominent rimmed and centrally or subsarcolemmally located non-rimmed vacuoles; and (c) at the ultrastructural level, streaming Z-lines and focal dissolution of myofibrils at the absence of granulofilamentous material typically observed in phenotypes associated with desmin mutations. The frequency of Myotilinopathy in Spain was much higher than in other populations reaching 60% of cases diagnosed as MFM.

The clinical impact of emerging Dystrophin gene mutation detection techniques. *M.F. Buckley[1], P.J. Taylor[1], R. Pedersen[2], G.L. Mullan[1], S.L. Maroulis[1], B. Prosper Gutiérrez[1], F. de la Puente Alonso[1], H. Johnston[3], D. Mowat[1].* 1) Molecular & Cytogenetics Unit, Prince of Wales Hosp, Sydney, Australia; 2) Department of Medical Genetics, Sydney Children's Hosp, Randwick, Australia; 3) Department of Neurology, Sydney Children's Hosp, Randwick, Australia.

Mutation detection for the DMD gene is complicated by the fact that it is a large gene consisting of 79 exons spread over 2.2 MBp of gDNA. Most mutations involve copy number changes of one or more exons. Here we report the evolution, over the past twenty years, of a clinical diagnostic testing program for Duchenne and Becker muscular dystrophy. We examine both the changes in the observed mutation spectrum and the clinical impact of the improved capacity to detect exon deletions and duplications in a cohort of 512 Australian families referred to our laboratory. The three techniques considered are multiplex exon PCR, semi-quantitative PCR and MLPA. 40 percent of B/DMD families had a deletion mutation detected in an affected male individual by a multiplex PCR approach involving the analysis of 25 exons. Semi-quantitative PCR of 19 exons detected a further 4 percent deletion mutations in females who were either manifesting carriers of DMD or relatives of an affected male for which no DNA was available for testing. Thus, had DNA been available on an affected male individual for each family, the overall detection rate by exon multiplex PCR would have been 44 percent. MLPA of all 79 exons on patients in which a deletion was not detected by other methods increased the overall mutation detection rate for deletions to 50 percent. In 7 per cent of D/BMD families a duplication involving one or more exons was detected by semi-quantitative PCR of 19 exons with a further 4 percent being detected by MLPA. Overall, 11 percent of families were found to have exon duplications. In summary MLPA increased the combined detection rate of exon deletion and duplication mutations from 50 to 62 percent. In addition to this, MLPA inadvertently detected seven point mutations that lay under the probe binding sites.

Relationship between SCN1A mutations and SMEI. *S. Carrideo[1], E. Mannarino[2], G. Tortorella[2], G. Incorpora[3], A. Polizzi[3], F. Annesi[1], A. Labate[1,4], E.V. De Marco[1], F.E. Rocca[1], I.C Cirò Candiano[1], D. Civitelli[1], P. Spadafora[1], P. Tarantino[1], A. Gambardella[1,4], G. Annesi[1].* 1) Intitute of Neurological Sciences, National Research Council, Piano Lago - Mangone (CS), Italy; 2) Department of Paediatrics, University of Messina, Italy; 3) Department of Paediatrics, University of Catania, Italy; 4) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Mutations in the SCN1A gene are the major causes of GEFS+, which shows a marked phenotypic heterogeneity within families and most commonly manifests as febrile seizures (FS), or FS plus. It still remains uncertain if severe myoclonic epilepsy in infancy (SMEI) represents the end of the spectrum within the GEFS+ phenotype, or it should be considered a distinct entity, that is often related to de novo frameshift and nonsense mutations. Here we report three novel SCN1A mutations in three different patients. Two patients had SMEI phenotype with early infantile febrile seizures,absences, cognitive impairment, ataxia and drug resistance. The third patient had a milder epilepsy phenotype and normal neurological development. He had early prolonged FS, afebrile motor seizures and absences, which disappeared with antiepileptic therapy. The 26 exons of SCN1A gene were individually amplified using primers based on intronic sequences. The PCR products were then sequenced and analyzed with an automatic sequencer. We identified three novel SCN1A mutations. In the first of the two SMEI patients we found a missense mutation, T1289I. His mother and brother carried the same mutation, but they never had any seizure. The second SMEI patient carried a de novo frameshift mutation, 3840insT, that lead to a premature stop codon in the exon 19. The third patient with a milder phenotype carried a de novo single nucleotide substitution in the invariant AG splice acceptor site of intron 24. The results of our study illustrate that de novo SCN1A mutations do not always mean SMEI and vice versa. In this way, our study reinforce the belief that SMEI probably results from the cumulative effects or interactions of a few or several genes, of which the reported GEFS+ gene is only one player.

A novel exon skipping mutation of the NSD1 gene presents heterogeneous phenotypes of Sotos syndrome in a Japanese family. *S. Tei, S. Tsuneishi, M. Matsuo.* Pediatrics, Kobe University, Kobe, hyogo, Japan.

Sotos syndrome (SoS) is characterized by pre- and post-natal overgrowth, advanced bone age, distinctive craniofacial features (macrocephaly, frontal bossing with high hairline, high palate, prominent jaw), and variable degrees of mental retardation and is caused by mutations of the NSD1 gene located in 5q35. Microdeletions encompassing of this gene are identified in more than half of the Japanese cases. SoS with microdeletions shows often severer phenotypes than those carrying point mutations. Only 5 familial cases of SoS have been reported with confirmation of gene analysis. Here we report a Japanese family with SoS showing heterogeneous phenotypes and a novel mutation of the NSD1 gene in every affected member. We found the initial case (first son) from unconsanguineous parents who had typical phenotypes of SoS and died of Reye syndrome. Two consecutive children also met the criteria of SoS. Genetical analysis confirmed the first Japanese familial cases (mother and 3 children) carrying the same splice donor site mutation (IVS13+1G>A), which results in the in-frame skipping of exon 13. However, each case shows variable phenotypes and severity. Male individuals (two sons) showed symptoms related with central nervous system (CNS) including seizures, severer mental delay, feeding difficulty in infancy and periventricular subependymal cysts. Female individuals (daughter and mother) showed milder mental delay, and the daughter carried congenital heart defect (pulmonary stenosis). There may exist some difference dependent on gender in NSD1 splicing and/or epigenetic pathogenesis especially in CNS.

PTPN11 mutations in Noonan Syndrome: Mutation detection and phenotypic variability. *M. Hegde, J. Wiszniewska, A. Cirigliano, P. Ward, C. Eng, B. Roa.* Medical Genetics Laboratories, Baylor Col Medicine, Houston, TX.

Noonan syndrome (NS) is an autosomal dominant disorder characterized by a spectrum of symptoms and physical features.Affected individuals present with short stature,dysmorphic features,pulmonary valve stenosis and hypertrophic cardiomyopathy.NS is genetically heterogeneous,with mutations in the PTPN11 gene accounting for ~50% of both familial and sporadic cases.During the two- year period ending June 2005,280 individuals were referred to our laboratory for PTPN11 gene sequencing.In 113 individuals (40%)PTPN11 missense mutations were identified.We present data on two families with a striking variation in phenotypic expression for two allelic missense variants that affect PTPN11 amino acid residue Q510. The Q510 residue occurs in the phosphotyrosine phosphatase (PTP) domain of the PTPN11 protein and is evolutionary conserved. Allelic missense mutations Q510E and Q510P have been reported in a case of Noonan syndrome and in LEOPARD families, respectively.Notably, in one reported LEOPARD family, the Q510P mutation was found in an affected child and also in the mother,who did not present with clinical features except for lentigines.We studied a 3-yr old patient with clinical findings suggestive of Noonan syndrome,and identified the (1529A>C) Q510P heterozygous missense allele. Subsequent analysis of family members identified the Q510P in the patients mother and one sibling who both have similar findings as the proband;in addition, Q510P was also found in another sibling who is reported to be unaffected.A second family demonstrates clinical heterogeneity of the Q510R missense variant,which has not been previously reported.In this family, sequence analysis identified the (1529A>G) Q510R missense variant in a 41 yr old woman diagnosed with NS. Subsequent analysis identified the Q510R in one affected child, but not in a second child who is also reported to be affected.Allelic amino acid substitutions involving Q510 highlight the allelic and clinical heterogeneity of PTPN11 gene mutations associated with a spectrum of clinical presentations between NS and LEOPARD syndromes.These data highlight difficulties in genotype:phenotype correlations involving the PTPN11gene.

SPG7 analysis in spastic paraplegia: rare causative mutations but frequent variations. *N. Elleuch[1], C. Depienne[1], A. Benomar[2], AM. Ouvrard Hernandez[3], X. Ferrer[4], B. Fontaine[5], D. Grid[6], C.ME. Tallaksen[1], R. Zemmouri[7], G. Stevanin[1], A. Durr[1], A. Brice[1].* 1) INSERM U679 et Département de Génétique Cytogénétique et Embryologie, Hôpital de la Pitié-Salpêtrière, Paris, France; 2) Laboratory of Neurogenetics and the Department of Neurology, Hôpital des Spécialités, Rabat, Morocco; 3) Department of Neurology. Centre Hospitalier Universitaire, Grenoble, France; 4) Department of Neurology. Centre Hospitalier Universitaire, Bordeaux, France; 5) INSERM U546, Hôpital de la Pitié-Salpêtrière, Paris, France; 6) Généthon III, Evry, France; 7) Department of Neurology, Centre Hospitalier Universitaire Mustapha Bacha, Place du 1er Mai, 16000, Alger, Algeria.

Mutations in the SPG7 gene, which encodes paraplegin, are responsible for an autosomal recessive (AR) form of pure or complex hereditary spastic paraplegia (HSP). The aim of our study was to evaluate the involvement of the SPG7 gene in a large population of HSP families compatible with AR transmission. We analysed 136 probands with pure or complex HSP for mutations in the SPG7 using DHPLC and/or direct sequencing. We identified 49 variants including 8 mutations, 29 polymorphisms and 12 changes without known effect. In two families, originating from Morocco and Mauritania, we confirmed the deleterious nature of the compound heterozygous mutations. Both had complex HSP with cerebellar impairment. The ages at onset were similar, ranging from 27 to 32 years, and progression of the disease was rapid in both families. We also detected 19 families with only one mutation that was not found in a large control population. The mutations were highly deleterious in 4 of these families (3%), suggesting that they were probably causative. No mutation on the other allele was detected by direct sequencing of all exons or RT-PCR experiments. Our results therefore indicate that SPG7 mutations are rare and account for approximately 5% of HSP families compatible with AR inheritance. Cerebellar signs, or cerebellar atrophy on brain imaging, were the most frequent additional features in patients with SPG7 HSP. Finally, rare nucleotid variants in SPG7 are very frequent, complicating routine diagnosis.

The natural history of arrhythmogenic right ventricular cardiomyopathy (ARVC) in a homogeneous Newfoundland population. *T. Young[1], P. Parfrey,[2], S. Connors,[3], L. Thierfelder,[4], A. Bassett,[5], K. Hodgkinson[1,2].* 1) Discipline of Genetics, Memorial University, St John's, NF, Canada; 2) Patient Research Centre,Memorial University, St John's, NF, Canada; 3) Division of Cardiology, Memorial University, St John's, NF, Canada; 4) Max-Delbruk Centre, Berlin, Germany; 5) Clinical Genetics Research Program, CAMH, Toronto, ON, Canada.

Background: The natural history of ARVC in an etiologically homogeneous group is unknown. **Objectives**: To assess the natural history of autosomal dominant ARVC in a founder population linked to a 2cM DNA haplotype at 3p25 (ARVD5. **Methods**: We studied 426 subjects from well ascertained sibships (where the disease status of 50% of the sibship is known) from 16 ARVC families born at 50% a priori pedigree risk. Disease status was defined as high-risk (HR), low-risk (LR) or unknown based on serious cardiac events before 50 years, DNA haplotype testing and pedigree position. Subjects were ascertained both retrospectively (from the pedigree) and prospectively (from a screening clinic). We compared both male and female HR and LR subjects on age at presyncope (PS), syncope (S), palpitations (P), chest pain (CP), heart failure (CHF), hospitalization for cardiac events (H) and death. For the death analysis we used subjects from sibships where 100% of siblings disease status was known, and where HR status was based on DNA haplotype or pedigree position. **Results**: Time to event was significantly younger for HR (n=79) than LR (n=53) males for PS, P, CHF, H and death (p values 0.008 to 0.0001). The majority (75%) of male deaths were sudden. Significant differences were restricted to S and P (p=0.02) for HR (n=74) and LR (n=48) females. CHF, H and death occurred at significantly younger ages for HR males than HR females (p= 0.0001). **Conclusions**: Sudden cardiac death occurs frequently in males with heart failure a later manifestation in survivors. Chest pain appears not to be associated with disease. Palpitations may be useful diagnostic clues for both sexes.

Patients Learning About the Natural Evolution of Tuberous Sclerosis (PLANETS) Study. I: Description of the cohort and results for kidney angiomyolipomas. *B.E. Gould Rothberg, M.B. Bracken, E.B. Claus.* Department of Epidemiology and Public Health,Yale University, New Haven, CT.

Tuberous Sclerosis Complex (TSC) is an autosomal dominant genetic disorder caused by mutation in either the tuberin (TSC2) or hamartin (TSC1) genes. Although TSC is nearly 100% penetrant, its highly variable expressivity has hampered TSC natural history evaluations. To date, population-based epidemiologic studies performed have been underpowered. Here we describe the Patients Learning About the Natural Evolution of Tuberous Sclerosis (PLANETS) Study, our effort to assemble a large TSC patient cohort. We created a 268-item questionnaire addressing the major and minor TSC clinical manifestations, TSC genetics, patient demographics and general medical history. During Fall 2004, 7598 questionnaires were mailed to TS Alliance constituents recorded as TSC patients or their parents/grandparents/caregivers. Through February 2005, 938 surveys were completed and returned; 198 (21.1%) were self-completed with the remaining 740 (78.9%) by proxy. The mean age for the entire population is 21.6 15.9 years and 508 (54.2%) of the respondents are female. By gender, the mean age for females is 23.4 16.5 years and, for males, 19.4 14.9 years ($p<0.001$). 839 (90.1%) self-identified as White non-Hispanic with the remaining 99 listing another race. We selected kidney angiomyolipomas (AMLs) as the prototype TSC-related symptom to pilot our analysis. Of the 836 patients who underwent kidney imaging, 376 (45.0%) reported having kidney AMLs, estimating the prevalence of AMLs between 42% and 48%. Multivariable logistic regression reveals a 1.68-fold (95% CI=1.24-2.24) increased prevalence of AMLs in females versus males. We defined the cumulative incidence of kidney AMLs for subjects born since 1990 and report the median age at initial AML diagnosis as between 8-12 years. 112 (32%) of participants with AMLs reported either an AML hemorrhage or an AML-reducing procedure. These data establish PLANETS as the largest cohort of TSC patients ever assembled where extensive phenotypic annotation is available and will allow for the description of Tuberous Sclerosis Complex natural history.

Low concentrations of 25-hydroxy-vitamin D in sera of people with neurofibromatosis 1. *V. Mautner[1], M. Lammert[1], R. Friedrich[1], L. Kluwe[1], P. Lim[1], J.M. Friedman[2].* 1) Dept Neurology, Allgemeines Krank Ochsenzoll, Hamburg, Germany; 2) Dept Medical Genetics, University of British Columbia, Vancouver, Canada.

Osseous involvement is one of the cardinal features of neurofibromatosis 1 (NF1). The most characteristic bony manifestations are considered to be focal dysplastic lesions, but short stature is often seen and recent studies show that decreased bone mineral density frequently occurs in people with NF1. This is an important cause of morbidity, mortality and poor quality of life in individuals with NF1, yet the pathophysiology is not understood. Acquisition and/or synthesis and metabolism of vitamin D is one possible mechanism that influences bone mineralization. The purpose of this study is to determine if serum levels of 25-hydroxy vitamin D (25-OHD) in people with NF1 differ significantly from levels in controls.

We compared 25-OHD levels in sera of 53 individuals with NF1 to 58 controls. People with evidence of chronic liver disease, epilepsy, chronic GI disease, vitamin D supplementation, or unusual UV light exposure were excluded from the analysis. The mean value for 25-OHD in NF1 patients was 15.7 ug/l (sd=7.5) compared to 35.5 (sd=17.1) for controls ($p<<.001$). Gender ratios were similar in the groups: 33/53 NF1 patients and 38/58 controls were female. Mean ages of patients (39.3, sd=9.6) and controls (36.0, sd=8.8) were comparable, as was the time of year in which the sera were collected, the majority being collected in the winter months. Serum calcium levels on an unselected subset of the NF1 patients are similar between NF1 and control groups: NF1 mean level is 2.39mmol/L (n=18) and control mean is 2.38 mmol/L (n=58).

Further analysis will investigate other possible aspects of bone metabolism in NF1 patients and the influence of vitamin D on bone metabolism and calcium homeostasis. Vitamin D plays a key role in bone mineralization and low levels may provide an explanation for the osteopenia seen in NF1 and might offer the promise of a simple and inexpensive preventative strategy.

Defining phenotypic subgroups in autism using the Aberrant Behavior Checklist-C. *J.S. Brinkley[1], S. Donnelly[1], H. Cope[1], C. Wolpert[1], S. Brinkley[1], R. Carney[1], H. Wright[2], A. Hall[2], R. Abramson[2], J. Gilbert[1], M. Pericak-Vance[1], M. Cuccaro[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Dept of Neuropsychiatry, USC-SOM, Columbia, SC.

Efforts to identify susceptibility genes in autism have been hampered by genetic heterogeneity. Given the wide clinical variation in autism, a common strategy to address heterogeneity is use of clinically derived subgroups. These subgroups are then analyzed to determine whether the shared clinical features reflect underlying genetic mechanisms. In a novel approach to subgroup development, we employed the Aberrant Behavior Checklist-Community (ABC-C), a 58-item rating scale of behavior problems in individuals with developmental disorders. Using dimension reduction methods in our autism sample (N=276, M=9.4 years, sd=4.9) we identified two problem behavior factors from the ABC-C/ These factors are based on severity of self-injurious behavior (SIB) and intensity of verbally disruptive behavior (VSD) and created subgroups for each factor. These factors are not correlated (r=.23) and subgroups based on these factors differed significantly on multiple clinical indicators. Comparison of multiplex and singleton probands on the SIB and VSD mean factor scores revealed no differences on the VSD factor (p=0.80) but the multiplex group had significantly higher mean SIB scores (t=1.98, p=0.048). Intra-family correlations in 73 multiplex families yielded low concordance (SIB ICC= .15; VSD ICC = .06). Stratified analyses were conducted for regions of interest on chromosomes 15 and 17. Two-point linkage analysis (FASTLINK) yielded a 2-point Max HLOD of 1.69 for a HCV8865209 under the recessive model for the stratified SIB+ group. No other positive linkage results were found for SIB and VSD in stratified analyses. Similarly, no allelic or genotype association was detected using the pedigree disequilibrium test (PDT) and GenoPDT for multiple SNPs on chromosomes 15 and 17. In conclusion, both SIB and VSD appear to index distinct clinical groups within our autism dataset. Preliminary findings suggest that these phenotypic subgroups are not the result of underlying genetic mechanisms.

Autism in African American (AA) families: Phenotypic findings. *M. Cuccaro[1], S. Donnelly[1], H. Cope[1], C. Wolpert[1], R. Carney[1], R. Abramson[2], A. Hall[2], H. Wright[2], J. Gilbert[1], M. Pericak-Vance[1].* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Dpt of Neuropsychiatry, USC-SOM, Columbia, SC.

Genetic studies of autism, a common complex disease, encourage participants from all racial groups, but AA participants are underrepresented. Despite evidence that phenotypic and genetic differences exist in AA individuals in complex diseases such as Alzheimer disease and schizophrenia, there has been limited study of phenotypic variation in autism. Finally, study of AA families with autism fulfills a national scientific priority to involve minority populations in health related research. This study represents the first effort to systematically compare AA individuals with autism on standard phenotypic measures. Participants (AA N= 41/CA N=254) were ascertained through an autism genetics study. The clinical protocol included the ADI-R, Vineland Adaptive Behavior Scales (VABS), and Aberrant Behavior Checklist (ABC). The groups were compared on ADI-R items (initial words, phrase speech, motor coordination and age of onset), VABS Adaptive Composite Score and ABC scales. AA participants had delayed acquisition of first words (2=13.32, df=2, p<0.001) and phrase speech (2=10.33, df=2, p <0.006) and borderline significantly lower VABS composite scores (t=1.92, df=227, p=0.057). The groups did not differ on motor coordination, age of onset, or ABC scales. Our findings reveal phenotypic differences in AA autism families. Specifically, clinical-phenotypic differences indicative of a more severe phenotype were found in the AA participants. While we cannot rule out an ascertainment bias, the groups only differed on select measures. We conclude that efforts to track genetic variations in autism consider increased recruiting of different ethnic groups. Such can efforts can help identify potential phenotypic differences which may index unique genetic variation that confers risk to autism. Preliminary investigation of GABAergic candidates in AA families by our group (Collins et al, this meeting) suggests that phenotypic differences may not reflect underlying genetic susceptibility. However, there may be other loci that modify the susceptibility phenotype.

Behavioral phenotype of Cornelia de Lange syndrome: Relationship to physical phenotype, age and parenting stress. *C. Landy[1], B. Clark[2], A. Kline[3], M. Grados[4].* 1) University of Maryland, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD; 3) Greater Baltimore Medical Center, Baltimore, MD; 4) Johns Hopkins School of Medicine, Baltimore, MD.

Background: Cornelia de Lange syndrome (CdLS) is a generally sporadic multiple malformation syndrome involving characteristic facial features, growth retardation and mental retardation, for which the causal gene NIPB-L (5p13.1, 608667) has been recently identified. Behaviors associated with CDLS include self-injurious behavior (SIB), hyperactivity, aggression and stereotyped movements. The purpose of the present study was to characterize maladaptive behaviors in relation to physical features and examine the longitudinal manifestation of maladaptive behaviors in CdLS. The ultimate goal of this research is to define a behavioral phenotype of CdLS. Methods: Data was obtained from the parents of 28 affected children, ages 5-17 years, through mailed surveys and telephone interviews. The Aberrant Behavior Checklist (ABC) measured aggression, SIB, irritability, hyperactivity, and stereotypy. The Scoring System for Severity in Cornelia de Lange Syndrome determined severity of the physical manifestations of the disorder, and the Parental Stress Index (PSI) measured stress levels in the parents. Results: The mean age was 11 3.74 years, 39% male and 61% female. A significant positive relationship was seen between minor facial/physical features and hyperactivity ($t=2.54$, $p<.05$) and stereotypy ($t=2.27$, $p<.05$). Among physical features, the association was most notable for 2-3 toe syndactyly ($p < 0.01$). SIB was significantly higher in participants > 12 years ($t=2.20$, $p<.05$). Hyperactivity and stereotypies were not age-related. Parents of children with more severe behaviors showed marginally greater role restriction ($0.05 < p < 0.10$). Conclusions: Hyperactivity and stereotypy in children with CdLS appear to be associated with physical features of the disorder while SIB manifests at older ages. The severity of behaviors in CDLS may determine parental role restriction.

A fourth case further delineates the phenotype of a rare karyotype abnormality: 46,XX/47,XX,+r(X). *K. Jenny[1], I. Gadi[2], JJD. Morrissette[3], B. Powell[4], KW. Gripp[1].* 1) AI duPont Hosp for Children, Wilmington, DE; 2) Labcorp, Research Triangle Park, NC; 3) St Christopher's Hosp for Children, Phila, PA; 4) Children's Hosp Central, Madera, CA.

Introduction: Small supernumerary marker chromosomes (sSMC) occur in ~3/10,000 live births. The risk for an abnormal phenotype is 10-15%. About 60% of sSMCs are derivative chromosome 15; Pallister-Killian and Cat-Eye syndromes are due to extra derivative chromosomes 12 and 22, respectively. The sSMCs are classified as satellites or nonsatellited and often occur as mosaic. Ring chromosomes account for ~10% of sSMC. Supernumerary r(X) are rare, particularly without a 45,X cell line. Tumer (1998) reported two females and Powell (1999) reported one, each mosaic for a cell line with a small supernumerary r(X). Phenotypes were similar with jaundice, poor feeding, hypotonia, seizures, developmental delay, obesity, minor dysmorphia including flat face, low nasal bridge, small mouth and clinodactyly. The pt reported by Powell has since died from pneumonia and seizures. **Case Report:** A female presented at 12 months with hypotonia, developmental delay, brachycephaly, and asymmetric white matter volume loss on brain MRI. Pregnancy was notable for reduced fetal activity. Neonatal course included torticollis, gastroesophageal reflux, and jaundice treated for several weeks. Developmental delay became obvious at 7 months with poor head control and inability to sit independently. Chromosomes revealed a marker ring chromosome in 100% of lymphocytes. FISH studies showed the ring to be a derivative X chromosome, lacking the XIST gene. Buccal smear confirmed the marker to be present in 40% of cells; 46,XX/47,XX,+r(X). **Discussion:** 3 females with supernumerary r(X) lacking XIST are reported in the literature. We report a fourth case of 46,XX/47,XX,+r(X). All had developmental delay, hypotonia, obesity and minor dysmorphia. The XIST gene is necessary for the initiation of cis-acting X inactivation, suggesting that the genes present on the r(X) are active, resulting in a functional X disomy for these genes. The phenotype shared amongst the four pts likely results from functional genes present on the r(X).

The association of DAT1 gene Core Promoter polymorphism -67 T/A with ADHD. *A. Irani Shemirani[1,2], N. Moghimi[2], M. Keikhaee[2], E. Shirazi[3], M. Tehranidoost[4], S. Ehssani[2], H. najmabadi[2], M. Ohadi[2].* 1) Islamic Azad university,science and research branch,poonak, Tehran, Iran; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Evin, Tehran, Iran; 3) Iran university of Medical Science, Tehran, Iran; 4) Department of Psychiatry, Rozbeh Hospital, Tehran University of Medical Sciences, Tehran, Iran.

Association between attention deficit hyperactivity disorder (ADHD) and the 10-repeat allele of a polymorphism (a 40 bp variable number of tandem repeats) in the dopamine transporter gene (DAT1) has been widely documented. In this study, we examined whether either allele of the DAT1 core promoter -67 polymorphism is associated with ADHD in a case/control study. The allele and genotype frequencies of the polymorphism were studied in 100 patients and 163 controls, which were matched on the basis of sex, age and ethnicity. The genotype frequencies in the patients group were as follows: AA=15.5%; AT=71.8%; TT=12.6% vs. the genotype frequencies in the control group: AA=49%; AT=41.8%; TT=9.2% [2=31.11, df = 2, OR = 2.15 (95% CI=1.34-3.47, p 0.0001]. The T-allele of the -67A/T polymorphism revealed a ~1.6-fold excess in the patients group comparing with the controls (2=18.45, df = 1, p 0.001). For the first time, these findings provide tentative evidence of the contribution of the DAT1 gene core promoter polymorphism to the etiopathophysiology of ADHD at least in the Iranian population that we have studied. Replication studies of independent samples and family-based association studies are necessary to further evaluate the significance of our findings.

The optineurin gene and apolipoprotein E gene polymorphism in Japanese patients with normal tension glaucoma and primary open-angle glaucoma. *F. Mabuchi[1], S. Tang[2], Y. Toda[1], D. Ando[2], M. Yamakita[2], J. Wang[2], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1].* 1) Dept Ophthalmology, Univ Yamanashi, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Yamanashi, Japan.

Objective: To assess whether genetic polymorphisms of the optineurin (OPTN) gene and the apolipoprotein E (APOE) gene are associated with normal tension glaucoma (NTG) and primary open-angle glaucoma (POAG) in the Japanese population. Methods: Genomic DNA was examined in 144 patients with NTG, 166 patients with POAG, and 179 control subjects. PCR-SSCP and subsequent sequence analysis were performed for genotyping the OPTN gene, and the APOE allele frequency (2, 3, and 4 alleles) were studied by PCR-RFLP. A logistic regression model was used to simultaneously study the effect of multiple variables when comparing these patients with control subjects. Results: Adjusted for age, gender, and intraocular pressure, an appropriate twofold increased risk of NTG was found with the A alleles in c.412GA (P 0.05, odds ratio [OR] 2.17, 95% confidence interval [CI] 1.09 to 4.31) and c.603TA (P 0.05, OR 2.17, 95% CI 1.03 to 4.56) polymorphisms in the OPTN gene. An appropriate fourfold reduction in NTG risk (P 0.05, OR 0.27, 95% CI 0.09 to 0.77) was found with the APOE 2 allele. No statistically significant gene interaction was found between the OPTN and APOE gene polymorphisms for NTG and POAG. Conclusion: The OPTN and APOE gene polymorphisms were associated with NTG in the Japanese population. Further studies in the other ethnic populations should be performed to elucidate the relationship between these genes and glaucoma, and the interaction between these genes.

Peer relationships in Neurofibromatosis 1. *J. Reiter-Purtill[1], E.K. Schorry[1], R.J. Hopkin[1], K. Vannatta[1], A. Lovell[1], C. Gerhardt[1], B. Moore[2], R.B. Noll[3].* 1) Cincinnati Children's Hospital Medical Center; 2) Univ. of Texas, MD Anderson; 3) Univ. of Pittsburgh.

Limited data are available regarding the social function of children with NF1 from the perspective of peers. We examined peer relationships of school-aged children with NF1, using peer and teacher report, to better define potential social difficulties and to investigate the impact of disease severity. Fifty-nine children with NF1 and 59 age- and gender-matched classmates participated. Data collected in the classroom included a measure of social behavior, and 2 measures of social acceptance. Each child with NF was also ranked by a clinical geneticist using scales of Medical Severity, Cosmetic Severity, and Neurologic Severity for NF1 complications. Children with NF1 were described by peers as less popular, more withdrawn, and as having less leadership qualities compared to controls. They were also less likely to be chosen as a "best friend" and to have reciprocated friendships. Peers described them as less attractive and less athletically and academically skilled than controls. Despite being ranked by peers as less physically attractive, 91% were ranked by clinicians as having "minimal or mild" cosmetic effects of NF1. Teachers perceived children with NF1 as less popular and more withdrawn. Subsequent mediational analyses suggested that peer perceptions of appearance, academic competence, and athletic ability explained the pathway between NF1 and poor peer functioning.

Previous peer studies conducted in children with other chronic diseases without primary CNS involvement have indicated few peer problems. In contrast, the social problems for children with NF1 are similar to our findings for children surviving brain tumors. Poor peer relationships in NF1 may be related to a direct effect of the NF1 gene on neurologic functioning, indicating a need for interventions to assist children with social skills.

Aspiration and airway obstruction in CHARGE syndrome. *R.J. Hopkin, D.R. White, B.K. Giambra, C.L. Daines, M.J. Rutter.* Cincinnati Children's Hosp Medical Ctr, Cincinnati, OH.

CHARGE syndrome is a complex condition caused by mutations in the CHD7 gene. It is characterized by combinations of malformations including Colobomas, Heart malformations, choanal Atresia, Retardation, Genital anomalies, and Ear abnormalities including deafness. CHARGE syndrome is often associated with cranial nerve palsies and global neurologic deficits. Respiratory distress and aspiration have been reported as common complications. In fact, aspiration may be the leading cause of death in CHARGE syndrome. Nevertheless, little has been published on the nature of the airway disease associated with CHARGE. We report a study of 30 patients with CHARGE evaluated at a single center. 27 had formal airway assessment using microlaryngoscopy, bronchoscopy, FEES, and or video swallow. RESULTS: 20 patients required tracheostomy. 20 had airway obstruction excluding choanal atresia, 9 at multiple levels. Obstruction was due to pharyngomalacia including glossoptosis, laryngomalacia, subglottic stenosis, and tracheomalacia. 18 patients had clear evidence of chronic aspiration or bronchiectasis. An additional 6 had abnormal swallow that placed them at very high risk for aspiration. Only 2 patients had normal swallowing. 25 patients had gastrostomy tubes placed for feeding problems. Risk of aspiration appeared to be independent of anatomic malformations, but was often neurologic in etiology. CONCLUSION: These data indicate that airway abnormalities other than choanal atresia leading to obstruction are very common in CHARGE syndrome. Further, we found that aspiration is among the leading complications of this condition. The aspiration is often due to neurologic rather than structural abnormalities and therefore unlikely to be amenable to reconstructive surgery. These findings have important implications as protocols are developed for evaluation and management to improve the out come of CHARGE syndrome. We recommend formal airway and swallow evaluation as a routine part of the management for every child diagnosed with CHARGE syndrome regardless of presenting malformations even without signs of respiratory distress.

Congenital Malformations associated with misoprostol exposition during pregnancy in Colombia: case series. *C. Lopez, R. Garcia, F. Suarez, C. Villegas, I. Zarante.* Instiuto de Genetica Humana, Pontiifcia Universidad Javeriana, Bogota D.C., Colombia.

Misoprostol is a prostaglandin E1 analogue with abortive properties of limited efficacy, multiple descriptions of congenital defects associated with infants exposed to misoprostol in utero are reported. We presented 5 cases of newborns with congenital malformations, in which the mothers consumed and used intravaginal misoprostol application in order to interrup the pregnancy. The most frequent defects associated with Misoprostol in this series are equinovarus clubfoot, VII pair cranial nerve affection, and terminal transverse limb defects. We report a new case of bladder exstrophy with imperforate anus and one case of sirenomelia. This cases increase the evidence between congenital malformations and misoprostol as a teratogenic agent.

Decreased glutathione and antioxidant enzyme activities in cellular models of Machado-Joseph disease. *C.L Kuo[1], Y.C. Yu[2], M. Hsieh[2,5], C.S. Liu[1,3,4].* 1) Vascular & Genomic Res, Changhua Christian Hosp, Changhua, Taiwan; 2) Department of Biology, Tunghai University, Taichung, Taiwan; 3) Department of Neurology, Chung Shan Medical University and Chung Shan Medical University Hospital, Taichung, Taiwan; 4) Department of Neurology, Changhua Christian Hospital, Changhua, Taiwan; 5) Life Science Research Center, Tunghai University, Taichung, Taiwan.

Machado-Joseph disease(MJD) is an autosomal dominant spinocerebellar degeneration characterized by cerebellar ataxia and pyramidal signs associated in varying degrees with a dystonic-rigid extrapyramidal syndrome or peripheral amyotrophy as major neurologic signs. Unstable CAG trinucleotide repeat expansion in MJD gene has been identified as the pathologic mutation of MJD. The nature of the toxic insult of the mutant proteins will cause aggregation in the nucleus and cytoplasma and eventually lead to cell apoptosis. It is known that oxidative stress, induced by reactive oxygen species (ROS) or free radicals, plays an important role in pathogenesis of neurodegenerative disorders. Nonenzymatic and enzymatic components in the antioxidative system play critical role(s) to against oxidative stresses in the mammalian central nervous system. In addition, both SK-N-SH-MJD78 and COS-7-MJD78 -GFP cell lines have the lower levels of catalase, glutathione reductase and superoxide dismutase when compared to the wild-type cell lines under normal growth condition. Furthermore, the expression of glutathione reductase decreased in COS-7-MJD78-GFP mutant cells compared to that of COS-7-MJD26-GFP normal cells. It is known that when cells are under oxidative stress, the mitochondrial DNA is prone to damage. Our results further demonstrated that mitochondrial DNA copy number of mutant cells is reduced when compared to that of the parental cells. Our results indicated that mutant ataxin-3 might influence the activity of enzymatic components to remove O2- and H2O2 efficiently, and promote mitochondrial DNA mutation or deletion, which leads to dysfunction of mitochondria. Therefore, we suggested that the cell damage caused by greater oxidative stress in SCA3 mutant cells plays an important role, at least in part, in the cell apoptotic pathway.

Triallelic FMR1 gene in a girl with developmental delay and hyperkinetic behaviour. *J. Kapalanga[1,2,3], D.C. Riedell[3,4], A. Gandy[2,3], D. Wong[2,3].* 1) PEI Health Research Inst/SMC, Summerside, PE, Canada; 2) Pediatrics, Summerside Medical Center, Summerside, PEI, Canada;; 3) Faculty of Medicine, Dalhousie University, Halifax, NS, Canada; 4) Department of Pathology, Laboratory Medicine and Molecular Diagnostics, IWK Health Center, Halifax, Canada.

CGG trinucleotide repeat expansion in the 5end of the FMR1 gene is associated with fragile X syndrome, fragile X-associated tremor/ataxia syndrome, and FMR1-related premature ovarian failure. Finding of more than two copies of normal-sized CGG repeats in association with a clinical syndrome has not been reported previously. Here we report a case with 3 distinct FMR1 alleles. The patient was a 5-year girl with developmental delay, hyponasal speech, hyperkinetic behaviour and short attention span. There is a history of developmental delay in several maternal male cousins. The patients weight and height were both above the 95th percentile and her head circumference was between the 90th to 95th percentile. Audiology evaluation was normal. Biochemical testing was negative. MRI was unremarkable. Her cytogenetic analysis was unrevealing. Fragile-X testing by PCR revealed normal sized FMR1 alleles. However, she carried 3 copies of the CCG repeat in the FMR1 gene, and had 3 distinct FMR1 alleles rather than the expected 2 alleles. Her allele sizes were 10, 24 and 30 CCG repeats. The mother was homozygous for a 30 trinucleotide repeat allele. Southern analysis showed normal banding patterns. However, careful examination of the Southern blot suggested that there were 2 copies of methylated alleles rather than 1 copy. These combined results indicate that, although she does not have a detectable expansion in her FMR1 genes, she does appear to have 3 copies of this genetic region. A possible explanation could be that she has a cryptic duplication within the Xq28 region, including at a minimum a portion of the FMR1 gene. So although she does not have an expansion in her FMR1 genes, it is not possible to rule out the possibility that changes in one of her FMR1 genes (or an adjacent region) might be the basis for her clinical symptoms. Other molecular testing strategies will be initiated to further analyze this mutation.

Anophthalmia/Microphthalmia Registry: Registry clinical data support extended work-up of individuals with anophthalmia/microphthalmia. *A. Schneider[1], D. Moguillansky[2], T. Bardakjian[1].* 1) Dept of Genetics, Albert Einstein Medical Ctr, Philadelphia, PA; 2) Dept of Pediatrics, Albert Einstein Medical Ctr, Philadelphia, PA.

The Anophthalmia/Microphthalmia (A/M) Registry at Albert Einstein Medical Center (AEMC) in Philadelphia was established in 1994. Microphthalmia is a rare birth defect which is on the spectrum of eye anomalies with coloboma at the milder end and anophthalmia at the most severe end. Collectively the eye defect is referred to as MAC (microphthalmia, anophthalmia, coloboma) with an incidence of about 2/10,000 births. MAC is both clinically and genetically heterogeneous. There are well-described syndromes associated with MAC. However, gene screening is broadening the phenotypic spectrum of these conditions and at times merging previously distinct entities. The data collected thus far regarding the incidence of associated birth defects in the A/M Clinical Registry can be used to establish basic studies that should be performed on all individuals with MAC, whether or not a syndromal diagnosis is made. The data will also facilitate identification of new syndromes. Analysis of 200 cases in the A/M Registry revealed 104 males and 96 females. Overall the incidence of congenital heart disease in the Registry population was 11% compared to the general population incidence of less than 1%. Other striking findings included a high incidence of hearing loss, 4.5% compared to the population incidence of 0.3-0.4%, autism in 3.5% individuals compared to 0.2-0.6% in the general population and developmental delay in 34%. An in-depth analysis of this population will be presented. Our findings underscore the importance of a Clinical Genetics evaluation for every child with MAC and the necessity of a comprehensive work-up since not all findings are obvious. This should include a renal ultrasound, echocardiogram, hearing evaluation and developmental monitoring. The extended evaluation may help direct the gene screening to a specific gene or make a syndromal diagnosis which will provide the family with a prognosis and an accurate recurrence risk.

A novel mutation in the GUCY2D gene responsible for an early-onset severe RP different from the usual GUCY2D-LCA phenotype. *S. Hanein[1], I. Perrault[1], S. Gerber[1], J.L. Dufier[2], A. Munnich[1], J. Kaplan[1], J.M. Rozet[1].* 1) Dept Genetics,INSERM U393, Hopital des Enfants Malades, Paris, France; 2) Ophthalmology, Hopital Necker, Paris , France.

The purpose of the present study was to understand the recurrence of Leber congenital amaurosis (LCA) in a child born to two patients affected with different retinal disorders: a typical GUCY2D-LCA phenotype for the mother and an early-onset severe retinitis pigmentosa (RP) for the father. The 18 coding exons of GUCY2D were screened for mutations by Denaturing High Pressure Liquid Chromatography (DHPLC) and direct sequencing using specific primers in the three affected individuals of this family. The screening of the GUCY2D gene revealed that the mother was compound heterozygous for two mutations: c.3043+4A>T and c.2943delG while the father carried a homozygous 4bp insertion in exon 19 (c.3236insACCA) leading to a 28 amino acids elongation of the protein. The affected infant was compound heterozygous for the paternal insertion and the maternal c.3043+4A>T mutation. Patients carrying mutations in the retinal guanylate cyclase (GUCY2D) gene were reported to be constantly affected with a particular form of Leber congenital amaurosis (LCA) defined as a "congenital stationary cone-rod dystrophy with high hypermetropia, panretinal degeneration and highly reduced visual acuity". We report here, the occurrence of an early-onset severe RP, different from LCA, resulting from homozygosity for a 4 bp insertion in GUCY2D. Interestingly, this mutation is excepted to result in a 28 amino acid elongation of the protein contrary to all GUCY2D mutations accounting for LCA which are expected to be null alleles. This report gives support to the existence of exceptional GUCY2D mutations accounting for a milder and different phenotype compared to the typical GUCY2D congenital stationary cone-rod dystrophy.

Mapping of a Novel X-Linked Mental Retardation Syndrome to Xp11-Xp22. *Y. Wang, J.E. Martinez, F. Tan, C. Tuck-Muller, W. Wertelecki, T.-J. Chen.* Medical Genetics, Univeristy of South Alabama, Mobile, AL.

X-linked mental retardation is the most common and highly heterogeneous genetic condition including over 120 syndromic and nonsyndromic disorders. We reported mental retardation in a family with six affected males and two obligate carrier females in three generations. The first generation female carrier produced, from four different partners, four affected sons and a normal daughter. Her daughter went on to have two affected sons and two normal female offspring, all from different fathers, strongly indicating an X-linked pattern of inheritance. The affected males have moderate mental retardation, early global developmental delay, microcephaly and craniofacial dysmorphism, short stature, ptosis, muscle atrophy, joint contractures, pigmentary abnormalities and hypogonadism. Cytogenetic studies of the male patients were negative, and Fragile X syndrome was ruled out by DNA analysis of FMR1 gene. Thus, clinical manifestations in this family presented a previously unreported, X-linked mental retardation syndrome. Forty-eight fluorescent dye-labeled STR markers were used to determine the haplotypes of the family members. These markers covered entire X-chromosome with approximately 5cM resolution. Linkage analysis by the two point parametric method indicated the markers in the region of Xp11-Xp22 co-segregated with this disease phenotype. The maximal LOD score was obtained between markers DXS987 and DXS1068, a region containing the ARX and RSK2 genes. This region also overlaps with several other XLMR loci, such as MRX43, MRX54, and MRX59. Moreover, all patients in the second generation inherited the same X chromosome from the carrier of the first generation, and the female carrier in the second generation transmitted the X chromosome to all patients in the third generation, suggesting a strong segregation bias or meiotic drive. Further fine mapping and candidate gene screening is on going.

Fragile X tremor/ataxia syndrome in female premutation carriers. *S. Russo[1], F. Cogliati[1], A. Gessi[1], S. Goldwurm[4], G. Neri[2], G. Scarano[3], R. Cilia[4], A.P. Verri[5], G. Pezzoli[4], L. Larizza[1,6].* 1) Ist.Auxologico Italiano,Milano, Italy; 2) Ist.Genetica Medica,Università Cattolica,Roma,Italy; 3) Osp.G.Rummo,Benevento,Italy; 4) CentroParkinson,I.C.P.,Milano,Italy; 5) Ist.Neurologico Casimiro Mondino, Pavia,Italy; 6) Genetica Medica,Università di Milano,Italy.

Fragile X tremor/ataxia syndrome,FXTAS,is a neurodegenerative syndrome arising,after the fifth decade,among 30% of male carriers of FMR1 gene premutation.FXTAS is defined by a)progressive intentional tremor and/or ataxia,associated with peripheral neuropathy,mild parkinsonism,autonomic dysfunction,cognitive deficits including loss of memory and executive functions,b)symmetric hyperintensities on T2 weighted MR images of the middle cerebellar peduncles and c)intranuclear inclusions in neurons and astrocytes throughout the brain in postmortem samples from adult male PM carriers.Among FMR1 PM female carriers FXTAS is rarer,being reported so far only 7 women with FXTAS,all displaying a milder clinical presentation than the FRAXTAS males,a finding discussed in the context of X inactivation.We report on 3 PM female carriers with a diagnosis of probable FX/TAS,identified within a sample of 72 FRAXA families.They were representative of a heterogenous clinical spectrum including:a)ataxia,MR anomalies and occasional tremor started at 55 y in a 115 CGG PM carrier,b)rest tremor,motor impairment at left hand, gait impairment started at 50 y with a few cerebellar traits and MR evidencing a mild cortical cerebellar atrophy in a carrier of 96 CGG and c)mild head tremor and intentional tremor of the left hand started at 61 y old in a 79 CGG carrier,whose detailed neurological evaluation is under study.The Activation Ratio to evaluate random X inactivation was assessed and found consistent with a skewed inactivation in all index cases.Examination of the healthy premutated sister of the first affected female evidenced random X inactivation versus a complete skewed inactivation in the patient.Our molecular and clinical data support the hypothesis of the protective role for random X inactivation in FRAXA premutated FX/TAS females and suggest a female carrier neurological phenotype distinct from the classification built on PM FRAXTAS males.

Integrated Web-based Informatics for Array CGH. *C. Shaw, J. Fisk, A. Young, N. Whitehouse, S. Cheung, A. Patel, C. Chinault, P. Stankiewicz, J. Lupski, A. Beaudet.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Microarray CGH (a-CGH) is a powerful technique for determining variation in DNA copy number within clinical samples. The technique requires extensive sample tracking to ensure quality, and the data obtained are both massive in quantity and complex in content. We have developed a web based software to track, store, and analyze a-CGH results. As the collection of patients grows, the database also grows and becomes an ever more useful tool for clinical decisions. The database also serves as a resource to understand variation in copy number. The software and database are particularly useful to discriminate benign polymorphisms from clinically relevant alterations.

Our system provides a myriad of views to the array data. The first view is a single patient report which provides a comprehensive and orderly presentation of the experimental outcome for a single case. The patient report shows the raw, normalized, and integrated data on all clones as well as quality information on the DNA sample. This display provides variance information and the test-statistic to determine outcomes for individual clones and regions.

The system also provides dynamic queries for individual clones and genomic regions whereby all data available within the database - across all a-CGH results -- can be considered against the values observed in any particular case. These reports provide a powerful tool for distinguishing benign variation from those implicated in disease.

Our system is web based and therefore highly distributed. We utilize sophisticated backend analysis performed in the R open source statistical computing environment, and we use the MySQL database engine. As our patient database and array platform expand we believe this software will continue to be important. More generally, the web-based information system provides a model for translational research whereby molecular data from new methods are directly relevant to clinical practice.

Chromosome 15q abnormalities in autism: Phenotypic studies and molecular genetic analyses in 15q11-q13 and 15q23. *M. Smith, P.L. Flodman, M.E. Bocian, K. Osann, C. Mohdahl, B. Moore, P.A. Filipek, M.A. Spence.* Dept Pediatrics, Univ California, Irvine, Irvine, CA.

We report results of clinical, psychological and molecular genetic studies on five patients with autism who have abnormalities of chromosome 15q.Testing including autism evaluation (ADOS, ADI or CARS), IQ testing (Stanford Binet, Mullen or WISC) and language assessment. The Vineland Adaptive behavior test was carried out. FISH studies and microsatellite polymorphism analyses revealed that four patients have duplications of proximal 15q. One patient has a maternally derived interstitial duplication of SNURF-SNRPN and UBE3A loci; the GABA receptor loci are not duplicated. His phenotype differs from that in two other patients who have maternally derived 15q inverted duplications that extend from the centromere to BP4 and include the GABA receptor loci. The phenotypic differences suggest that verbal and social skills are negatively impacted by increased dosage of SNURF-SNRPN and UBE3A, while extra-copies of the GABA receptor gene cluster significantly impact performance IQ and adaptive behavior. We describe a patient with mild autism who has a paternally derived duplication of the PWS-AS gene region. It is not clear why only a subset of patients with paternally derived duplications of this region manifest symptoms. It is possible that one factor is the co-occurrence of mutations in the imprint control region. Studies on a fifth autism patient revealed SIN3A hemizygosity. SIN3A, histone deacetylases and MECP2 function as transcription co-repressors. The MECP2 complex to binds to methylated DNA in the SNURF-SNRPN region, and impacts imprinting and expression of UBE3A. MECP2 is deficient in Rett syndrome. Taken together results in these patients reveal a possible common pathway in the pathogenesis of some forms of autism e.g. altered expression of imprinted genes on 15q. Occurrence, in a patient with autism, of a deletion in 15q22-q23 that extends from 70, 000 to 73,600KB is of further interest in light of recent linkage studies that revealed that in female-male and male-female autistic sib-pairs maximal evidence was found with markers that map between 60,000 and 72,000 KB.

Genomwide comparison of human and mouse Common Fragile Sites and molecular characterization of five mouse Common Fragile Sites that are syntenic to human Common Fragile Sites. *E. Schrock[1, 2], K. Stout-Weider[1, 2], A. Matthaei[1, 2], K. Hermann[3], T. Heiden[1, 2], A. Helmrich[1, 2].* 1) Institute of Clinical Genetics, University of Technology, Dresden, Germany; 2) Institute of Medical Genetics, Charité Universitätsmedizin Berlin, Germany; 3) Signature Diagnostics, Potsdam, Germany.

Common fragile sites (CFSs) are expressed as chromosome gaps in cells of different species including human and mouse as a result of the inhibition of DNA-replication. They may serve as hot spots for DNA-breakage in processes such as tumorigenesis and chromosome evolution. This study presents a comprehensive analysis using conventional and molecular cytogenetic mapping of CFS frequencies in two mouse strains, BALB/c and C57BL/6, and in human probands. We show that CFS expression levels in chromosome bands are conserved between the two mouse strains and between syntenic mouse and human DNA segments. Furthermore, five additional mouse CFSs were found to be homologous to human CFSs on the molecular cytogenetic level (Fra2D-FRA2G, Fra4C2-FRA9E, Fra6A3.1-FRA7G, Fra6B1-FRA7H and Fra12C1-FRA7K) increasing the number of syntenic CFSs to eight. Focussing on human chromosome 7 we compared frequencies of malignancy and non-malignancy associated chromosome rearrangements to the expression pattern of CFSs. Using array-CGH-analysis and multicolor-FISH-mapping we located two amplification breakpoints of the breast cancer cell line SKBR3 within the CFSs FRA7G and FRA7H. Additionally, in contrast to previous reports, DNA helix flexibility is not increased in all so far molecularly defined 13 human and eight mouse CFSs compared to large non-fragile control regions.

CHK1 regulates fragile site stability. *S.G. Durkin, T.W. Glover.* Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

Common fragile sites are site specific gaps and breaks seen on metaphase chromosomes when DNA synthesis is partially inhibited. These conserved regions are often rearranged in cancer cells, and may serve as signatures of replication stress during early stages of tumorigenesis. We have previously shown that the ATR pathway is central in maintaining chromosomal integrity at these regions, most likely by responding to stalled or delayed replication forks. Here we have characterized the roles of the CHK1 and CHK2 kinases, targets of ATR which are phosphorylated and activated in the DNA damage checkpoint. Using RNAi, we depleted cellular CHK1 and CHK2 pools and examined the effects on total chromosomal stability and on the expression of the two most common fragile sites, FRA3B and FRA16D. In addition, we examined the effects of the low concentrations of aphidicolin (APH) used to induce fragile site breakage, but not inhibit replication entirely, on the post-translational modifications of both CHK1 and CHK2 and found ATM-independent phosphorylation of both proteins following treatment with low dose APH. We observed two phenotypes in cells depleted for CHK1 that were not observed in cells depleted for CHK2. Approximately 10-40% of these cells displayed discrete numbers of gaps and breaks, largely at specific common fragile sites, and ~60-90% of cells displayed extensive chromosome breaks and fragmentation exceeding scoreable levels. To determine if this chromosomal fragmentation was a result of apoptosis, CHK1 depleted cells were analyzed by annexin V staining for phosphatidylserine residues exposed on the outer cytoplasmic cell membrane, an early apoptotic event, and by treating CHK1 depleted cells with the apoptosis inhibitor zVAD analyzing chromosome breakage by both TUNEL staining and metaphase chromosome analysis. These analyses showed that the chromosome fragmentation resulting from CHK1 deficiency was not a result of apoptosis, but rather appeared to result from a requirement for CHK1 during normal replication. Our results demonstrate CHK1 is essential in regulating the integrity of fragile site regions, likely a result of its G2/M checkpoint function, and further delineate the importance for CHK1 in regulating S phase events.

Aplasia Cutis Congenita in an infant with de novo t(1;20)(p34.1;q13.1). *S. Gupta[1], L. Mehta[2], A. Shanmugham[2], A. Thomas[1], P. Koduru[1].* 1) Laboratory Medicine, North Shore University Hospital, Manhasset, NY; 2) Medical Genetics, Schneider's Childern's Hospital at NSUH, NY.

Aplasia cutis congenita (ACC) is a rare disorder characterized by localized absence of all skin layers. The defect may also involve deeper tissues such as muscle and bone, extending to the dura matter when the scalp is involved. The defect may be isolated or may occur in association with malformation syndromes such as Adams-Oliver syndrome or chromosome abnormalities and with other mechanisms such as twinning, trauma, specific teratogens or intrauterine infections. Chromosomal abnormalities have been rarely reported in association with ACC. We present a newborn with a de novo t(1;20) and cutis aplasia of the scalp. Amniocentesis was performed on a 34 year old, G5P2 woman at 15.6 weeks of gestation for reasons of maternal age and history of spontaneous abortions. The mother took Synthroid and Paxil during the pregnancy. Chromosome analysis of cultured amniocytes revealed a balanced translocation (1;20)(p34.1;q13.1). Both parents had normal karyotypes. Fetal echocardiogram and comprehensive sonogram were normal. The baby was born full term and noted to have a single rounded area of cutis aplasia (1 cm x 1 cm), without a bony defect, on the central occipital region. No other dysmorphic features or birth defects were present. Blood chromosomes confirmed the balanced translocation. Khan et al (1995) reported ACC in association with an unbalanced karyotype, monosomic for 12q and trisomic for 1q; another patient with de novo del(15)(q15.2q21.2) had pronounced scalp defects, dysmorphic features and mental retardation (Koivisto et al 1999). Structural rearrangements of chromosomes, including apparently balanced translocations, may result in subtle loss or gain of genomic material or influence gene function due to position effect and may indicate candidate regions of the genome to explore. In cases where there is an absence of another etiology for ACC, chromosome analysis should be performed. In our patient, further molecular studies are indicated to rule out submicroscopic deletions in the presence of a balanced translocation.

MOLECULAR CHARACTERIZATION OF AN INVERTED DUPLICATION OF CHROMOSOME X WITH TERMINAL Xp DELETION. *C. DUPONT[1], A. LEBBAR[1], C. TEINTURIER[2], F. BAVEREL[1], G. VIOT[3], D. LETESSIER[1], P. AUBOURG[2], J.M. DUPONT[1].* 1) Service dHistologie Embryologie Cytogénétique, Hôpital Cochin, Paris; 2) Service de Neurologie et endocrinologie Pédiatrique, Hôpital Saint- Vincent de Paul, Paris; 3) Génétique Médicale, Maternité Port Royal, Hôpital Cochin, Paris.

We report on a 6-year-old boy [GL] referred for karyotyping and searching for SHOX microdélétion. The most significant clinical findings in this boy were small stature, Madelung deformity, facial dysmorphy, developmental milestones moderately delayed and deficits in attention and memory abilities. Classical cytogenetic analysis had not shown any rearrangement. Fluorescence in situ hybridization (FISH) investigations using cosmidic probe M34F5 covering SHOX gene (Xp22.33) showed a microdélétion of this region. Given that GL phenotype includes clinical findings not classical in Leri-Weill syndrome, we tested subtelomeric Xp probe (CTC-839D20, Xp22.33) and found it deleted too. Interestingly, characterization of deletion proximal border using commercial probes localized in Xp22.3 (STS and KAL1), showed a partial duplication of Xp associated to the deletion. Then with BACs help, we finally diagnosed an inverted duplication Xp22.31-Xp22.32 (13,7 Mb) included STS, VCX-A and KAL1 genes associated to a terminal Xp deletion Xp22.33-Xpter (3,6 Mb) included SHOX and ARSE genes. Inverted duplications with a terminal deletion are complex chromosome rearrangements well defined on 8p and some other chromosomes (2q, 3p, 4p, 9p, 11p). But only one case has been described on chromosome X (Milunsky et al 1999). Interchromosomal or interchromatid mispairing leading to nonallelic homologous recombination appeared to originate this rearrangement. Short arm of chromosome X is a rich-genes region that we can discuss the phenotype of this child. Indeed, he has a mixed phenotype create by the loss of Xp subtelomeric region (attention and memory deficit), of SHOX gene (Leri-Weill syndrom) and ARSE gene (Chrondrodysplasia Punctata) and create by a chromosome X partial functional disomy including some important genes in human pathology (STS, VCX-A and KAL1).

FISH analysis to differentiate Type I and Type II deletions in Prader-Willi and Angelman syndrome patients.
A.E. Wiktor, E.C. Thorland, H.C. Flynn, D.L. Van Dyke. Dept Lab Med & Path, Mayo Clinic, Rochester, MN.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are two distinct syndromes that can result from deletion of 15q11.2-q12, uniparental disomy, or imprinting defects. Deletions of the 15q11.2-q12 region are recurrent and mediated by non-allelic homologous recombination events at low-copy repeats (LCRs) in this region. Type 1 deletions are larger deletions spanning breakpoint BP1 and the more distal BP3 breakpoint, and the smaller (by about 500kb) Type II deletions span BP2 and BP3. Depending on the extent of the deletion, behavioral differences have been described in both PW and AS patients. In both PWS and AS, Type I patients have a more severe phenotype including more severely delayed development and autistic features. Distinguishing between Type I and Type II deletions is useful in counseling PWS or AS patients, but current methods are research-based molecular assays. We have developed a home brew probe from DNA clones located between BP1 and BP2. Using fluorescent in situ hybridization (FISH) techniques, these probes can be used to distinguish between Type I and Type II deletions. Testing was performed on a series of 35 patients exhibiting a FISH deletion of SNRPN or D15S10. Six of 19 (32%) PWS and four of ten (40%) AS cases exhibited a BP1 deletion, as did 4 of 6 (67%) patients referred with an unspecified diagnosis. Ten patients with a supernumerary dic(15) also were tested; in seven cases, the probe was present on both arms of the dic(15), in two cases the probe was absent from both arms of the dup(15), and one case exhibited the BP1-BP2 probe without SNRPN on both arms of the dic(15). In each of these cases, the normal 15 homolog had a normal FISH pattern. To further investigate the possibility of BP1 deletions in patients with autistic-like features or attention deficit disorder, twenty patients were tested but none showed a BP1 deletion. We believe the use of this probe as a reflex test in samples with a deletion of SNRPN or D15S10 provides a sensitive technique to identify BP1 deletions in patients with PWS or AS.

T Lymphocytes from Older Individuals with Down Syndrome and Dementia Exhibit Telomere Shortening. *E.C. Jenkins[1], M.T. Velinov[1], L. Ye[1], H. Gu[1], E.C. Jenkins Jr.[1], D. Pang[1], D.A. Devenny[1], W.B. Zigman[1], N. Schupf[1, 2], W.P. Silverman[1].* 1) New York State Institute for Basic Research in Developmental Disabilities, Staten Island; 2) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York.

We have previously reported preliminary findings that telomeres, chromosome ends consisting of highly conserved TTAGGG repeats, were shorter in metaphase and interphase preparations from short-term whole blood cultures of women (49-59)with Down Syndrome and dementia (n=6) compared to age-matched women with DS without dementia (p=.028)(ASHG, 2004). Using quantitative telomere protein nucleic acid FISH analysis, we have now confirmed and extended our observations in eleven adults with DS (10 females and one male, a total of 22 individuals, 49-63 years), who were age- and sex-matched to adults with DS and no dementia. Subjects were ascertained through the NYS Developmental Disability Service System and followed at 18 month intervals for 3 cycles of data collection. Subjects were classified as demented if they developed progressive memory loss, disorientation, functional decline over a period of at least one year, and had a clinical diagnosis of AD. Cells in metaphase and interphase from demented versus non-demented subjects consistently exhibited increased telomere shortening as a function of reduced light intensity in cells from demented subjects. Our first study of a male with trisomy 21 and dementia suggests that our findings are not limited to females. Our first study of a female with trisomy 21 and a dementia status of questionable (indicating substantial uncertainty regarding dementia status, with some indications of mild functional and cognitive declines) compared to a female with trisomy 21 who was classified as non-demented, exhibited increased telomere shortening in T lymphocytes from the individual with a dementia status of questionable, thus strengthening our hypothesis that telomere shortening is a candidate as a biomarker of dementia status. This work was supported in part by NYS OMRDD, Alzh. Assoc. grants IIRG-99-1598,IIRG-96-077; by NIH grants PO1 HD35897, RO1 HD37425, RO1 AG014673, and RO1 AG14771.

Incidence of Microduplication 22q11.2 in Patients Referred for FISH Testing for Velo-Cardio-Facial and DiGeorge Syndromes. *P.D. Cotter[1,2], H. Nguyen[1], G. Tung[1], K.A. Rauen[2,3].* 1) Department of Pathology, Childen's Hospital Oakland, Oakland, CA; 2) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA; 3) Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA.

Microduplication of 22q11.2 has recently emerged as a new chromosomal syndrome. Previous reports ascertained microduplication 22q11.2 patients among referrals for FISH testing for velo-cardio-facial and DiGeorge syndromes (VCF/DGS). In one large series, 2% of patients had the microduplication. To further evaluate the incidence of the 22q11.2 microduplication, we prospectively screened all VCF/DGS patient referrals over a two year period from April 2003 through May 2005. In total, 372 patients were referred for FISH testing with VCF/DGS as part of the clinical differential diagnosis. FISH analysis was performed using either the TUPLE1/ARSA probe set or the D22S75/n85a3 probe set according to the manufacturers instructions. Twenty metaphases were scored for the microdeletion by FISH in each patient. In addition, 50 interphase nuclei were scored to look for the additional signal associated with the 22q11.2 microduplication. In a control sample, both the TUPLE1 and D22S75 probes readily identified the microduplication at interphase, but somewhat less reliably at metaphase. We identified 30 patients (8%) with 22q11.2 deletions by FISH on metaphase chromosomes from the 372 patients referred. No patients were identified with the 22q11.2 microduplication by interphase FISH. Our data suggest that in an unselected population of patients referred for VCF/DGS testing the incidence of the microduplication might be lower than previously reported. Although the incidence of microduplication 22q11.2 might be low in the VCF/DGS population undergoing FISH testing, additional screening of interphase nuclei to look for the duplication would seem reasonable. A systematic evaluation of more diverse patient population, including normal individuals will better characterize the frequency and phenotype for microduplication 22q11.2 syndrome and define a more appropriate target population for testing.

Complete trisomy 17p syndrome in a girl with der(14)t(14;17)(p11.2;p11.2). *F.M. Mikhail, D. McIvried, R.L. Holt, L. Messiaen, M. Descartes, A.J. Carroll.* Department of Genetics, University of Alabama at Birmingham, AL.

Complete trisomy of the short arm of chromosome 17 has been previously described, but is quite rare. It has been suggested to comprise a new syndrome owing to the similarities in phenotype. The phenotypic findings include, pre- and post-natal growth retardation, mental and motor retardation, skeletal anomalies, clinodactyly of fingers, short neck and peculiar facial abnormalities including, microcephaly, down slanting palpebral fissures, hypertelorism, poorly shaped ears, smooth philtrum, micrognathia and high-arched palate. Here we report a seven year old girl with multiple congenital abnormalities and dysmorphic features. She was first studied cytogenetically immediately after birth and was reported to have a 46,XX,add(14p) karyotype. Parental chromosomes were normal. At age 7 the patient was re-evaluated for history of chromosome abnormality. High resolution banding analysis demonstrated that the extra material on 14p was suggestive of 17p. FISH confirmed this with both the Smith-Magenis region probe (17p11.2) as well as the 17p subtelomeric probe seen to hybridize to the p arm of der(14) indicating near complete 17p trisomy. Also, a chromosome 17 centromeric probe did not hybridize to the der(14) suggesting that the breakpoints were p11.2 for both chromosomes 14 and 17. The final karyotype of this patient was 46,XX,der(14)t(14;17)(p11.2;p11.2)de novo. On physical examination she displayed remarkable similarities with the previously reported complete trisomy 17p phenotype. These included, growth and mental retardation, decreased reflexes with a mixture of hypotonia and hypertonia, microcephaly, receding forehead, low anterior and posterior hairlines, flared eyebrows, slanting palpebral fissures, cupped ears, smooth philtrum, high-arched palate, triangular and coarse facies, short neck, scoliosis, 5th finger clinodactyly and no speech. She also had a history of bilateral cataract as well as club feet. Our findings strongly support the distinctive phenotype of a Complete trisomy 17p syndrome. We are currently conducting molecular studies using microsatellite markers to determine the parental origin of the extra 17p as well as recombination events.

Microdeletion and Microduplication of Chromosome 22q11.2: Four-Years Experience. *J. Lee[1], N. Sebastian[2], S. Hassed[1], R. Seely[1], J. Mulvihill[1], S. Li[1].* 1) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Oklahoma School of Science and Mathematics, Oklahoma City, OK.

Microdeletion of chromosome 22q11.2 is responsible for a broad spectrum of developmental disorders including DiGeorge syndrome, velocardiofacial syndrome, and conotruncal cardiac defects. Although a microduplication of 22q11.2 has many manifestations, these patients have distinctive facial anomalies including widely spaced eyes, down-slanting palpebral fissures, and superiorly placed eyebrows. Since 2000, our laboratory has provided fluorescence in situ hybridization (FISH) testing for microdeletion/microduplication of chromosome 22q using a commercial DNA probe, TUPLE1. 259 consecutive patients with clinical features suggestive of a microdeletion 22q11.2 have been referred by clinical geneticists, cardiologists, or pediatricians. Thirty-five patients had a microdeletion of the TUPLE1 gene; three index patients had microduplication of TUPLE1. Two patients with the microdeletion also had a loss or gain of other chromosomal material due to unbalanced translocations involving chromosome 22. As expected, variable clinical features were found in the patients with the microdeletion or microduplication of chromosome 22.

Microduplication 22q11.2 syndrome : a cause of cognitive problems - report of 2 families. *W. Courtens[1], W. Wuyts[1], A. Laridon[2], I. Schramme[3], R. van Luijk[1], S. Scheers[1], N. Peeters[1], J. Wauters[1].* 1) Department of Medical Genetics, University Hospital Antwerp, , Antwerp, Belgium; 2) Department of Child Neurology, University Hospital Antwerp, Antwerp, Belgium; 3) Centre for Developmental Disorders Antwerp, Antwerp, Belgium.

We report on two unrelated families where the probands presented with psychomotor retardation. In the first family the proband was an 8-year-old boy referred because of psychomotor retardation, behavioural problems and mild facial dysmorphism, in whom a microduplication 22q11 was discovered. The standard karyotype of the patient was normal 46,XY but FISH analyses 22q11.2 showed the presence of three signals for TUPLE1 probe in all interphase nuclei. Complementary investigations showed that the patient had, in addition to his developmental delay and behavioural problems, asymmetric perceptive hearing loss and a small right kidney. His father and one brother, also presenting with mental retardation and behavioural anomalies, had the same microduplication. In the second family only the proband presented with mild psychomotor retardation. The same microduplication was discoved in her asymptomatic mother. Further FISH studies allowed to identify a duplication between 2.1 and 3.4 Mb in both families. Microduplications of the 22q11.2 region have only recently been observed examining interphase cells by FISH with TUPLE1 in patients referred for DG/VCFS by Ensenauer et al. [2003] who found a duplication in 1.5% of unrelated patients. This finding has been verified in a prospective study on 200 cases referred for DG/VCFS, in which one patient (0.5%) with three copies of TUPLE1 was found. Since then only a few patients with microduplication 22q11.2 were described. We compare the clinical findings of our cases with those of other published cases in an attempt to further identify common phenotypic aspects.

Analysis of achiasmate bivalents in pachytene cells from 8 normal men. *F. Sun[1,2], M. Oliver-Bonet[1,2], T. Liehr[3], H. Starke[3], P. Turek[4], E. Ko[2], A. Rademaker[5], R.H. Martin[1,2].* 1) Medical Genetics, University of Calgary, Calgary, Canada; 2) Genetics, Alberta Children's Hospital, Calgary, Canada; 3) Institute of Human Genetics and Anthropology, Jena, Germany; 4) Urology, Obstetrics and Gynecology and Reproductive Sciences, University of California, San Francisco; 5) Northwestern University, Chicago, USA.

Meiotic exchange, or recombination, is required to ensure the proper disjunction of homologous chromosomes to opposite poles at the first meiotic division. Bivalents with no recombination foci (future achiasmates) are unable to orient properly on the metaphase plate or to segregate chromosomes to daughter cells. Achiasmate bivalents are known to lead to meiotic arrest in various organisms. We identified individual nonexchange bivalents in pachytene cells from testicular biopsies of 8 normal human males (3 cancer patients with normal spermatogenesis and 5 vasectomy reversals). An immunocytogenetic approach allowed analysis of pachytene cells by using antibodies to detect the synaptonemal complex (SC),centromere and sites of recombination (MLH1).698 pachytene cells and 16,054 individual bivalents were identified with centromere-specific multicolour FISH. A total of 26 achiasmates (SCs with 0 MLH1 foci) were found and of these chromosomes 21 (34.6%) had a significantly higher proportion than chromosome 10 (0%), 12 (3.8%), 13 (0%), 15 (7.7%), 16 (3.8%), 17 (7.7%), 18 (3.8%) and 20 (3.8%) ($P<0.05$, Fishers exact test). Chromosome 14 (11.5%) and 22 (23%) also had lower frequencies of achiasmate bivalents but this did not reach statistical significances. This suggests that chromosome 21 is most susceptible to having no recombination foci and thus would be more susceptible to nondisjuction during spermatogenesis. This is consistent with previous observations from sperm karyotyping and FISH analysis which demonstrate that chromosomes 21 has a significantly increased frequency of aneuploidy compared to other autosomes. Chromosome 21 has the lowest mean frequency of recombination sites of all the autosomes (1.000.23) and thus it is most susceptible to having an achiasmate bivalent which can subsequently result in a sperm aneuploidy for chromosome 21.

Cytogenetic Approaches to Identifying Genes for Hearing Impairments: Gene Discovery in an inv(7)(q21.3q35) and an inv(5)(q15q33.2). *K. Kocher[1], C.C. Morton[1,2].* 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA.

Hearing loss is a common sensory disorder with an estimated incidence of 1 in 1000 human births. Approximately half of these cases are attributed to environmental factors, while half are due to genetic causes. Genes with a role in the auditory system have been identified through both genetic linkage studies of families with heritable deafness and positional candidate gene approaches. Another method for gene discovery is to ascertain deaf individuals that carry balanced chromosomal rearrangements and identify disrupted or disregulated genes at the site of rearrangement. Here, FISH experiments were performed to map the breakpoint regions of a family with moderate hearing loss and of an individual with profound deafness. The family with moderate hearing loss consists of five affected members spanning three generations who carry a balanced paracentric inversion, inv(7)(q21.3q35). Successive FISH experiments were performed to map the 7q21.3 breakpoint within BAC RP11-879e11 and the 7q35 breakpoint within BAC RP11-643a21. Further analysis showed that the 7q21.3 breakpoint lies approximately 67 kb and 80 kb centromeric of the *DLX6* and *DLX5* genes, respectively. *DLX5/6* are important for proper development of the middle and inner ear and disregulation of these genes are likely to cause hearing loss in this family. The individual with profound deafness carries a *de novo* paracentric inversion, inv(5)(q15q33.2). FISH mapping has narrowed the 5q15 breakpoint to approximately 300 kb and the 5q33.2 breakpoint to approximately 500 kb. *NR2F1*, a gene highly expressed in human fetal cochlea, lies within the 5q15 breakpoint region and may contribute to the etiology of hearing loss in this individual.

A girl with an apparently balanced chromosome inversion (5)(p13q13) and atypical autism and mental retardation. *Z. Chen[1], H.Y. Li[1], X.H. Li[2], C.N. Huang[1], X.M. Son[1], J. Xu[3].* 1) Medical Genetics; 2) Neurology, First Affiliated Hospital, Zhongshan Medical College, Sun Yat-sen University, Guangzhou, PR China; 3) Cytogenetics, London Health Sciences Centre and University of Western Ontario, Canada.

Our recent reviews (Xu et al, Current Genomics, 2004, 5(4):347-364) showed that chromosome anomalies were found in ~7.4% (129/1749) of autism patients. There is an increased rate of apparently balanced chromosomal rearrangements (ABCR) in autism and 65% (17/26) of the breakpoints of ABCR have cryptic chromosomal rearrangements (CCR) of potential significance. This finding indicates that positional cloning of breakpoints is a very promising strategy in autism. We present a case of chromosome 5 inversion associated with atypical autism and mental retardation (MR). The female patient was born following an uncomplicated pregnancy at 39 weeks gestation with a birth weight of 2750g. She first walked at age 14 months and was found with moderate MR (IQ 48) and abnormal functioning in social interaction at age 2 years. She was diagnosed with atypical autism at age 6 years. She is shy, plays by herself, and lacks initiatives to share enjoyment, interests, achievement and reciprocity with other people. She has no speech and language development. Her vision and hearing are normal. The magnetic resonance imaging of her brain showed no anomalies. The family history is uneventful with regard to neurodevelopmental conditions. Routine cytogenetics (at ~550 G-band level) of the peripheral blood revealed a female karyotype with an apparently balanced and de novo pericentric inversion, 46,XX,inv(5)(p13q13). The breakpoints 5p13 and 5q13 have been previously reported to be implicated in 3 and 2 autism cases, respectively. This case waits for further molecular cytogenetics study of the breakpoints. More case reports and use of cytogenomics (e.g. microarrays) for detecting and screening for CCR in ABCR should help gene discovery in autism and/or MR.

Subtelomeric familial translocation t(8;12)(p23.1;p13.1) leading to deletion 8pter-p23.1 and duplication 12pter-p13.1: molecular cytogenetic analysis and clinical phenotype in two siblings. *A. Blumenthal[1,2], D. Verbaan[1], J. Halbgewachs[1], E. Kolomietz[1,2].* 1) Laboratory Medicine and Genetic Services, Lakeridge Health Corporation, Oshawa, Ontario, Canada; 2) Department of Pathology and Lab. Medicine, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

Unbalanced cryptic subtelomeric chromosomal rearrangements represent a significant cause of unexplained moderate to severe mental retardation. The use of subtelomeric FISH probes has greatly supplemented conventional chromosome analysis in detecting submicroscopic anomalies in patients with seemingly normal karyotypes. We report on two siblings of different sex and apparently normal karyotypes who had the same syndrome of minor anomalies: macrocephaly and global developmental delay. Neither have cardiac or renal abnormalities or any behavioural concerns at present. Family history revealed multiple first trimester miscarriages. Parental chromosomes studied in mid nineties appeared to be normal. These findings raised suspicions of a cryptic chromosome rearrangement. A translocation t(8;12)(p23.1;p13.1), balanced in the mother and the same unbalanced adjacent -1 segregation variant in the sibs with loss of terminal 8p and gain of terminal 12p regions, was verified by FISH using whole chromosome painting and subtelomeric probes. Some of the features observed in affected individuals are characteristic of known syndromes involving either 8p (upslanting palpebral fissures, short nose with a wide bridge and prominent colemma, thin upper lip, moderate mental retardation in 8pter deletion syndrome) or 12p (macrocephaly, large for gestational age, full cheeks in distal 12p trisomy). This familial case demonstrates the value of subtelomeric FISH in the diagnosis of submicroscopic chromosome abnormalities in those patents for whom routine chromosome analysis does not reveal result adequate to explain clinical findings.

Emerging evidence for a novel microdeletion syndrome at 15q24 with autism/PDD. *C.Lese Martin[1], L.F. May[1], K. Muralidharan[1], B-M. Anderlid[2], J. Schoumans[2], D. Rita[3], M. Smith[4], D.H. Ledbetter[1].* 1) Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA; 2) Dept Molecular Medicine, Karolinska Institute, Stockholm, Sweden; 3) Lutheran General Hospital, Park Ridge, IL; 4) Dept Pediatrics, Univ California, Irvine, CA.

With the increasing use of molecular cytogenetics in the investigation of individuals with unexplained mental retardation or developmental delay, microdeletions and microduplications across the genome are being unveiled. We have evidence for a novel microdeletion syndrome involving the *PML* locus on chromosome 15 at band q24. To date, we have ascertained 5 cases with *de novo* deletions of this region that were referred for clinical testing by Fluorescence *In Situ* Hybridization (FISH) for telomere analysis or to rule out Prader-Willi (PWS) or Angelman syndromes (AS). All 5 cases were serendipitously detected: a clone corresponding to the *PML* locus, which is included as a control in a commercially available assay for telomere screening and PWS/AS, was deleted in all individuals. We have begun to characterize the size, genomic content and parental origin of this deletion. Three deletions have been mapped using a combination of FISH and array Comparative Genomic Hybridization using a custom chromosome 15 array with clone coverage at a density of ~600 kb in the region of interest. Two deletions were ~3 Mb in size and the third was ~9.4 Mb. This region includes multiple copies of duplicon sequences which may mediate these imbalances. In addition, there is preliminary evidence to indicate a parent of origin effect. Of the three cases studied, two are paternally inherited and one is maternally inherited. The individuals with paternally derived deletions are markedly fair, well below normal curves for height and weight and have autism. The patient with a maternally inherited deletion exhibits hyperpigmentation, has been noted to be obese and is in the 97th centile for height; he has pervasive developmental delay (PDD). Detailed clinical and molecular cytogenetic characterization of additional individuals with this deletion will add to the growing description of genomic imbalances that are delineating new clinical syndromes.

A girl with 22q13.33 subtelomeric deletion and very friendly personality! *C. Prasad[1], C. Campbell[1,2], S. Conachar[1], J. Jung[1], J. Xu[3].* 1) Pediatrics and Genetics; 2) Neurology; 3) Cytogenetics, London Health Sciences Centre, University of Western Ontario, Canada.

Deletion of 22q13.33 or McPhelan-McDermidt syndrome is reported in more than 75 cases. The common clinical features of the syndrome include developmental delay (DD, in particular speech), hypotonia, relatively well preserved growth and pervasive developmental disorder. A 4 year old girl presented with severe DD, including significant speech delay (vocabulary of approximately 40 words). She had Dandy Walker variant. The parents are non consanguineous with no positive family history. The proposita had an extremely friendly personality and was giving hugs to strangers. Parents reported a high threshold to pain. There were no seizures. She had significant microcephaly with a head circumference of 45.8 cm (below 3rd centile); weight and height were on the 50th centile at 15.3 kg and 99.2 cm, respectively. Facial features revealed a narrow forehead, normal ears and no cleft palate. She had clinodactyly of 5th fingers bilaterally. The cardiovascular and abdominal examinations were normal. Neurological examination was significant for central hypotonia with a wide based ataxic gait. Numerous investigations including metabolic work up were normal. Cytogenetics of the peripheral blood showed a normal female karyotype (~650 band level). FISH for Angelman/Prader-Willi region at 15q11-13 detected no anomalies. FISH screening using a set of 41 subtelomeric probes identified a deletion of the probe at 22q13.33. This deletion is confirmed by FISH using probe N85A3 at 22q13.3. It is de novo deletion since the parents had a normal karyotype by G-banding and the telomere FISH. The microcephaly and Dandy Walker variant along with an extremely friendly personality are strikingly unusual findings for this syndrome, which is usually associated with autistic features and poor social interactions. Overlapping findings with Angelman syndrome are previously described by Precht et al 1998. This case emphasizes significance of telomere FISH screening and other cytogenomics studies in patients with idiopathic mental retardation and other clinical findings.

Mosaic Variegated Aneuploidy (MVA) with intact spindle checkpoint. *V. Jobanputra[1], J. Rockey[1], M. O'Driscoll[2], P. Jeggo[2], D. Warburton[1].* 1) Columbia Univ, New York, NY; 2) Univ of Sussex, East Sussex,UK.

MVA is characterized by growth retardation, severe microcephaly and constitutional mosaicism for aneuploidy involving multiple chromosomes. A defective mitotic-spindle checkpoint was demonstrated in 2 cases after treatment of cells with colcemid (Matsuura et al. AJHG, 2000). Recently mutations of both BUB1B alleles have been described in 5 families with MVA. Each case carried 1 missense mutation and 1 mutation that resulted in protein truncation or absent transcript (Hanks et al, Nat Genet, 2004). However, it is not known what proportion of MVA is due to BUB1B mutation.

In 1991 we described a 17-year-old girl with MVA who had clinical features resembling Seckel syndrome (Warburton, Ann Genet, 1991). We recently tested the mitotic spindle checkpoint in a fibroblast (GM09814) and a lymphoblastoid (GM09703) cell line from our patient. Both lines accumulated mitotic cells normally after treatment with nocadozole, indicating an intact spindle checkpoint. Direct sequencing of the entire coding region also did not reveal any mutations in BUB1B. Since GM09703 was designated as Seckel syndrome in the Coriell database, it was also analyzed by Alderton et al. (HMG, 2004) in a study of the ATR-dependent DNA damage response in Seckel patients. Previously a synonymous hypomorphic mutation of ATR, a gene in the repair pathway that responds to replication stalling, was found in two related Seckel syndrome families (O'Driscoll et al. Nat Genet, 2003). Our MVA cells exhibit many of the same features as the ATR-mutant cells, including reduced UV-induced H2AX formation, defective UV-induced G2/M arrest, and increased levels of nuclear fragmentation and micronuclei formation after treatment with agents that induce replication stalling. Chromosome breakage was not increased by aphidocolin treatment. However, no mutations were found in ATR and its binding partner ATRIP, or in H2AX, RPA1, RPA2 and RPA3.

Our data show that MVA can arise through mutations other than in BUB1B, and may involve errors in the G2/M checkpoint rather than the spindle checkpoint.

Marker chromosomes: New insights and worries. *L.F. May, C. Works, C. Lese Martin, D.H. Ledbetter.* Dept Human Genetics, Emory Univ, Atlanta, GA.

Common assumptions regarding nonacrocentric supernumerary marker chromosomes (SMC) include 1) they arise by breaks in the p and q arms, and could contain genes from one or both arms; 2) phenotypic severity is positively correlated with percentage mosaicism; and 3) that SMCs are found in association with two structurally normal homologs. We present a family and review the literature on marker chromosomes associated with pericentromeric deletions which challenge these assumptions. Prenatal analysis for an elevated serum screen identified a fetus mosaic (33%) for a SMC identified as chromosome 4. The same mar(4) was identified in the mother (66% of cells) who had unilateral ear deformities and blurred vision. FISH studies with clones for proximal 4p and 4q showed the childs marker to be positive only for BAC clones from the p arm, resulting in partial trisomy for a 5 Mb segment. FISH studies of the mother showed the same hybridization results for the mar(4), but revealed a deletion of these probes on one of her chromosome 4 homologs, indicating a balanced carrier state for a cryptic pericentromeric deletion corresponding to the mar(4). Ironically, in the presence of a deleted homolog, clinical severity will be *inversely* related to the percentage of cells with the extra marker chromosome present. Review of the literature revealed eleven similar cases of interstitial deletions involving centromeric alpha satellite associated with the formation of a SMC. Although this mechanism has been considered rare, other lines of evidence suggest that a majority of marker cases are positive for unique sequences from only one arm, consistent with one break within centromeric alpha satellite. If true, accurate determination of copy number and clinical prognosis are dependent upon molecular assessment with unique clones near the centromere. Variable phenotypes from identical SMCs within families are usually attributed primarily to level of mosaicism, yet these data suggest additional important factors. This new complexity to the origin of SMCs suggests more thorough molecular cytogenetic investigation is necessary to develop genotype-phenotype correlations to improve our prognostic capabilities.

Origin of structural chromosome rearrangements: Less frequency of paternal origin for unbalanced rearrangements. *E.J. Seo[1,2,3], J.S. Kim[1], J.Y. Lee[1], S.E. Lim[1], E.Y. Choi[1], E.M. Kwon[1], H.W. Yoo[1,2,4].* 1) Medical Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 3) Dept. of Laboratory Medicine, Univ. of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 4) Dept. of Pediatrics, Univ. of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

About 1 in 375 live births has a structural chromosome rearrangement. They might be appeared de novo or originated from a gamete of parent with a chromosome rearrangement. We investigated the origin, frequency, clinical and chromosomal characteristics of structural chromosome rearrangements for the cases in our hospital. Total 132 cases with structural chromosome rearrangements including 54 prenatal and 78 postnatal cases were analyzed. The number for balanced and unbalanced rearrangements respectively were 51 and 81. Seventy-four out of 132 (56.1%) were inherited cases of which paternal origin was 26 and maternal origin was 48. Forty-five of 58 de novo (77.6%) had unbalanced rearrangements while 36 of 74 inherited cases (48.6%) had unbalanced forms. The types of unbalanced rearrangements showed different characteristics between de novo and inherited cases. In cases with balanced rearrangements, the risk for an abnormal phenotype was higher in de novo than inherited cases. Although the number of balanced rearrangements was equal to the parental origin, the number of unbalanced forms was 7 of 26 (26.9%) for paternal origin and 29 of 48 (60.4%) for maternal origin. In summary, the frequency of structural rearrangements was higher in inherited cases than in de novo. For unbalanced rearrangements, the frequency is significantly higher in de novo than in inherited cases (P=0.0017), and interestingly higher in maternal origin than in paternal origin (P=0.0132). This finding suggests that the opportunity to be fertilized with a sperm having an unbalanced rearrangement is less frequent.

Detection of cryptic chromosomal alterations by genome-wide array comparative genomic hybridization (array-CGH) with 21,600 BAC clones. *B. Nowakowska[1,2], A. Kutkowska-Kazmierczak[2], S.J. Noblin[3], Y.F. Li[1], H. Northrup[3], D. Corzo[4], A. Weise[5], A. Patel[1], E. Bocian[2], S.W. Cheung[1], W.-W. Cai[1].* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston TX; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Dept. of Pediatrics and Ob/Gyn, The University of Texas Medical School, Houston, TX; 4) Div. of Clinical Genetic, Childrens Hospital, Boston, MA; 5) Institute for Humangenetics and Anthropolgy, Jena, Germany.

Development of array comparative genome hybridization has increased the resolution of detection of chromosome rearrangements more than 50 fold. Genome-wide BAC clone arrays have been developed using chemically modified DNA attached efficiently to an unmodified glass surface (Cai et al. 2002). To minimize clone repeat sequence content, a computer program was applied to select a set of 21,658 BAC clones with unique sequences at both ends. The selected clones have tightly distributed insert size and completely cover the entire human genome. We have identified the cryptic unbalances, subsequently confirmed by FISH analysis. Array-CGH analysis in a 2½-year-old boy with developmental delay, hypotonia, esotropia, paroxysmal alternating torticollis, movement abnormalities, elevated CK values and an apparently balanced de novo translocation t(3;10)(p26.2;q26.3) revealed an additional 3.7 Mb deletion at 10q26.3. An ~1 Mb deletion in 9q22.32 was identified by microarray in a 13-year-old girl with clinical features of Gorlin-Goltz syndrome and a normal 46,XX karyotype. In a third case, an unbalanced 46,XX,add(9)(q34.3) karyotype was found in a child with hypotonia, an anteriorly-placed anus, elevated testosterone, an unusual cry, plagiocephaly and developmental delay. In addition to the loss of the subtelomeric region on 9q, the array-CGH analysis revealed a gain of ~13.2 Mb of 12q24.3 and a gain of the 9q34 region, pending on FISH verification. Overall, we were able to precisely define the sizes of detected deletions or duplications. The results of the array-CGH demonstrate its huge potential for high-resolution, high-throughput molecular karyotyping and precise phenotype-genotype correlations.

Cytogenetic characterization of Y chromosome structural anomalies in two patients presenting with short stature. *J. Lavoie[1], J. Xu[2], M. Shago[3], R.F. Carter[1], A.A. Khan[4].* 1) Department of Pathology & Molecular medicine, McMaster University, Hamilton, ON, Canada; 2) London Health Sciences Centre, University of Western Ontario, London, Ontario, Canada; 3) Department of Pediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Pediatrics, McMaster Childrens Hospital, Hamilton, Ontario, Canada.

We report the results of cytogenetic studies of structurally rearranged Y chromosomes identified in two patients who were investigated for short stature. Patient 1 was an 18-year-old male referred with a provisional diagnosis of hypochondroplasia. Testing for FGFR3 mutation was normal. Subsequent cytogenetic analysis revealed the existence of an isodicentric Y chromosome for the long arm in all cells analyzed. The isodicentric showed only one primary constriction, which would explain the apparent stability of the dicentric during cell division. The SRY gene was detected using fluorescence in situ hybridization (FISH), consistent with the fact that the patient presented with normal external genitalia. Patient 2 was a 14-year-old boy referred for investigation of mesomelic limb shortening with confirmed Madelung deformity of the forearm on radiographs. G-banding and FISH analysis of lymphocytes revealed a mosaic karyotype with evidence of an unstable ring derived from the Y chromosome. The karyotype of skin fibroblasts was 45,X[6]/46,X,r(Y)[13]. The ring was lacking the long arm heterochromatic region and the tip of the short arm extending from a breakpoint distal to the SRY gene. Further FISH studies are in progess, including assessment for deletion of the SHOX gene located in the pseudoautosomal region on the short arm of the Y; SHOX haploinsufficiency is implicated in Leri-Weill Dyschondrosteosis, which is characterized by mesomelic short stature and Madelung deformity. These cases underline the importance of karyotyping patients with unexplained short stature and to characterize the chromosome constitution as part of the clinical assessment. These results will also be useful in determining whether SHOX haploinsufficiency should be included as a diagnostic consideration for causes of short stature in patients with Y-chromosome anomalies.

Complex chromosome rearrangements in 17p are associated with genomic architecture involving low-copy repeats. *P. Stankiewicz[1], L.E.L.M Vissers[2], S.A. Yatsenko[1], E. Crawford[3], H. Creswick[4], E.M. Gutter[4], B.B.A. de Vries[2], R. Pfundt[2], C. Marcelis[2], J. Zackowski[4], J.R. Lupski[1], J.A. Veltman[2].* 1) Dept. Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Sentara Cytogenetics Laboratory, Norfolk VA; 4) Children's Hospital of the King's Daughters, Norfolk, VA.

Recent data show that complex chromosomal rearrangements (CCRs) are more complex and common than initially thought; however, the molecular mechanisms remain elusive. G-banding and FISH analyses in a 4-month-old boy with developmental delay, hypotonia, growth retardation, coronal synostosis, mild hypertelorism, and bilateral club feet revealed a duplication of the Charcot-Marie-Tooth disease type 1A (CMT1A) and Smith-Magenis syndrome (SMS) chromosome regions, inverted insertion of the Miller-Dieker lissencephaly syndrome (MDLS) region into the SMS region, and the terminal deletion of 17pter. Each of the chromosome breakpoints have been mapped at the BAC clone resolution and the patients karyotype has been designated as: ish der(17)(17qter17p11.2::17p13.317p13.2::17p11.217p13.2::17p11.217p13.2:)*de novo*. Interestingly, the MDLS region was inserted into the SMS LCR, middle SMS-REP. High-resolution genome profiling by tiling resolution array CGH in a 6-year-old girl with mental retardation, short stature, microcephaly and mild dysmorphic features showed a non adjacent ~5 Mb duplication in 17p13.1-p13.2, an ~3 Mb duplication in 17p12 involving *PMP22*, and an ~1.7 Mb duplication in 17p11.2. The duplications were confirmed by MLPA and shown to be *de novo*. *In silico* analysis demonstrated that the proximal breakpoint of the 17p12 duplication maps to the LCR17pA; known to be an unstable genomic region and the breakpoint for uncommon but recurrent SMS deletions. The 17p11.2 duplication is flanked by the middle SMS-REP and the proximal SMS-REP. In both patients, the LCR-evolutionary burden in proximal 17p likely stimulated and mediated the formation of CCRs. We propose that genome architecture involving LCRs may be mechanistically important for the origin of CCRs.

Replication timing of loci repositioned near centromeric heterochromatin after ring (14) formation. *K. Schlade-Bartusiak, D.W. Cox.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Ring chromosome 14 is associated with growth and mental retardation, characteristic facies and retinitis pigmentosa. Seizures are present in all cases. In our previous study we established that seizures are not due to deletion of a specific locus on one homologue in the preterminal region of 14q. Lack of mosaicism in the studied cultures made mitotic instability of the ring as a main cause of seizures also unlikely. Therefore, the cause of seizures is probably the formation of the ring itself. The new nuclear position of the preterminal region of 14q, together with the local protein environment of centromeric domain could determine different gene activity. The largest deletion detected so far on r(14) encompasses 5 Mb. The region in 14q32 adjacent to the breakpoint contains imprinted genes, as well as genes expressed and not expressed in lymphocytes. The present study focused on the analysis of replication timing (RT), as an approach to study gene expression in this region. Early replicating regions are usually transcriptionally active while late replicating sequences are generally silent. Imprinted regions are characterized by asynchronous replication. We expected r(14) cultures to show significantly changed RT, when compared with controls, as a sign of different gene activity in this region. We used FISH to analyze RT of 1 Mb region of 14q32 in lymphoblast cultures of three r(14) and three controls. We observed a significant level of asynchronous replication throughout the region, in both groups, which was comparable with that of a control imprinted region (SNRPN) in 15q11. Presence of known imprinted genes in the region can explain this observation. RT of a not expressed gene was not significantly different in ring cultures, as compared with controls. However, in ring cultures, we observed slightly delayed RT of a gene that is expressed in lymphocytes. In conclusion, RT of the 14q32 region in r(14) cell cultures is not significantly different from controls. Therefore, gene activity in this region in lymphocytes is either not changed due to ring formation, or changed gene activity is accompanied by only subtle differences in replication timing.

Cytogenetic Effects of Ethanol in Chronic Alcohol Users. *O. Demirhan[1], D. Tastemir[1], Y. Sertdemir[2].* 1) Medical Biology and Genetics, University of Cukurova, Adana, Turkey; 2) Biostatistics, University of Cukurova, Adana, Turkey.

Alcoholism is a significant public health problem that is also a complex genetic trait, and being relevant to study the induction of chromosomal aberrations by ethanol. The fragile sites (FS) are very interesting subjects for the study of clinical disorders. Still, it is unknown whether individuals with heritable FS have an increased risk of alcohol dependence. However, chromosomal abnormalities may be helpful in identifying disease genes. To search susceptible folate-induced common FS for chronic alcoholics, we have performed chromosomal examinations by using the GTG banding technique for 80 chronic alcoholics and 57 controls. Chromosome rearrangements were observed higher frequency among alcoholics, who revealed a significantly higher frequency of structural and numerical chromosomal aberrations. The most frequent exchange type was inv(9)(p11;q13), 9qh+, and deletion (22)(q13), followed by single cell deletions and aneuploidies. The 22q11 region is involved in chromosomal rearrangements that lead to altered gene dosage, resulting frequently in psychotic symptoms. Two cases with inv(9) (2.5%) and twenty-two cases with 9qh+ (27.5%) detected in this study. This inversion is usually known about 1% in the general population. Although, inv(9) and 9qh+ has been considered to be a normal variant, our observation implies a possible association between the pericentromeric region of chromosome 9 and alcoholism. It is suggested that a susceptibility locus for the alcohol abuse may be located at pericentromeric region of chromosome 9. We also observed a small number of additional karyotypic changes. The FS analyses of the study population provided evidence of genetic susceptibility loci for alcohol dependence on chromosome 1,2,4,3,7,9,5,6,11,12,X,13,14 and 17, in decreasing order. When compared with age matched controls, significant differences in the incidence of FS frequency were detected. But, there were not statistically differences between smoker and non-smoker in healthy control individuals, and smoking as modulating factors had no added effect on the frequency of FS. The results showed that long-term ethanol intoxication can lead to chromosome damage.

Characterization of the first isotricentric chromosome Y. *J. Xu[1], E. Drozd-Borysiuk[1], J.C. Hsu[1], H. Whitby[1], E. Aston[1], M. Mintz[2], Z. Chen[1], A.R. Brothman[1].* 1) Dept Pediatrics, Cytogenetics, Univ Utah, Salt Lake City, UT; 2) Bancroft Neurosciences Institute, Cherry Hill, NJ.

Tricentric chromosomes are extremely rare events in human beings. We report the detailed molecular-cytogenetic studies of an isotricentric Y chromosome identified in a 23-year old male. The patient was referred for cytogenetic assessment because of aggressive, severe outbursts, large bones and mild facial dysmorphology. He has been diagnosed with " Impulse Control disorder " and has borderline to mild mental retardation with a full scale IQ of 67. FISH and array-CGH revealed an abnormal karyotype: 46,X,itrc(Y)(pterq11.221::q11.221cenq11.221::q11.221pter). ish itrc(Y)(WCPY+,DXYS129++,SRY++,DYZ3+++,DYZ1-,ESTCdy16C07-). arrcgh(Y)(p11.31p11.2)(RP11-400O10RP11-375p13)x2,(Y)(q11.21q11.221)(RP11-350I10RP11-71M14)x4,(Y)(q11.22q11.23)x0. This represents a duplication of Yp, partial quadruplication of Yq (cenq11.221) and partial deletion of Yq(q11.221qter). So far, to our knowledge, no tricentric chromosome Y has been reported in the literature. The formation of this complex rearrangement appears to have involved two separate breakage events, the first resulting in the production of an isodicentric Y chromosome and the second leading to the tricentric isochromosome Y. There was no evidence of mosacism in 50 metaphases and 1000 interphase nuclei scored indicating the stability of the isotricentric Y chromosome. The clinical findings of our case share some common features with other reported cases of tetrasomy Y.

A deletion on chromosome 11 detected by array CGH in a patient with pulmonary fibrosis: an example of why balanced cytogenetic translocations should be scrutinized. *M. Scholand[1], E. Aston[1], H. Whitby[1], J. Xu[1], R. Selzer[2], T. Richmond[2], N. Singh[1], J. Pell[1], N. Matsumori[1], J. Carey[1], A. Brothman[1].* 1) University of Utah, Salt Lake City, UT; 2) NimbleGen Systems, Inc. Madison, WI.

Pulmonary fibrosis (PF), which results in progressive scarring of the lungs, is a devastating disease which is often fatal despite treatment. While there are environmental risk factors and systemic diseases that are associated with forms of PF, the majority of cases are without a known etiology. Moreover, specific genetic loci associated with pulmonary fibrosis are largely unknown. A woman with a history of pulmonary fibrosis with no known risk factors presented with progressive dyspnea despite aggressive therapy. Conventional karyotyping was performed and this patient was found to have a t(4;11)(q34.2;q21). Characterization of DNA by CGH was done using the Spectral Genomics, Inc. (Houston, TX) SpectralChip 2600, which contains genomic BAC clones spaced at approximately 1 Mb intervals throughout the genome. This analysis detected loss of a single clone at 11q22.1 (RP11-775E2); this was confirmed by FISH using the same clone. Further characterization was then done using a NimbleGen Systems Inc. (Madison, WI) human whole genome CGH array which contains approximately 393,000 oligonucleotides. Probes are masked for repetitive elements and have a median spacing of 6 kb. This high-density tiled approach enables high resolution mapping of both genic and intergenic regions, providing unbiased mapping of DNA breakpoints and copy number polymorphisms. This analysis revealed that the deleted region was 2.6 Mb in size and contained 13 transcripts. Genes within this deleted region may contribute to the pulmonary fibrosis phenotype. CGH array is a powerful technique showing greatly enhanced resolution in the analysis of the human genome. Stepwise analysis by two array platforms allowed for rapid and precise characterization of the region. Several candidate genes associated with pulmonary fibrosis have been identified by this approach. This case demonstrates how further study of an apparently balanced translocation may yield critical information in further understanding disease pathogenesis.

PURE TRISOMY 4p SUBTELOMERE: AN APPARENT NORMAL FAMILIAL VARIANT. *I. Gadi, L. Wisniewski, S. Griffin, V. Jaswaney, C. Bullen, P. Papenhausen, J. Tepperberg.* Dept Cytogenetics, Laboratory Corp America, Res Triangle Pk, NC.

In our laboratory, the Vysis ToTelvision Multi-Color chromosome specific subtelomere FISH panel has detected various subtelomere rearrangements in 2-4% of patients referred because of idiopathic MR/DD. In a number of these cases, follow up studies demonstrated that apparent unbalanced subtelomere abnormalities in the probands were actually inherited from clinically normal unbalanced carrier parents. We have ascertained 4 unrelated families with an unbalanced derivative chromosome 22 secondary to a translocation between the short arm subtelomere region of chromosome 4 and the short arm of chromosome 22. In each family, FISH testing demonstrated that the breakpoint on 4p was located distally to the Wolf-Hirshhorn syndrome (WHS) critical region. Case 1: B.A. is a 28 yr. old male with idiopathic MR. Case 2: J.A. is a 4 yr. old boy with developmental delay. Case 3: B.S. is a 1 yr. old boy with developmental delay Case 4: H.T. is a 7 yr. old female with asthma, rhinitis, otitis, sleep disturbance and morbid obesity. In two of the 4 cases (case 1 and case 2), parental subtelomere FISH analysis revealed the identical unbalanced rearrangement in a clinically normal parent. Parental FISH studies on case 4 are pending and case 3 was lost to follow-up. Various hypotheses can be offered to account for the observations reported here. First of all, the subtelomeric region of chromosome 4 translocated in these families may not share common breakpoints resulting in trisomy for variable amounts of 4p DNA. Clearly, some of the DNA localized in this region may have no phenotypic expression in a trisomic state and is probably inactive. A more proximal breakpoint, however, may begin to encompass expressed genes. Second, while no imprinted loci have been assigned to 4p, both normal carriers identified were female and the possibility of UPD or another form of regulatory disruption may exist. Finally, it is conceivable that any clinical stigmata observed in the probands may be due to another etiology.

INVERTED DUPLICATION OF CHROMOSOME 18 SHORT ARM ASSOCIATED WITH MILD PHENOTYPE. *G. Calabrese[1,2], A. Sensi[3], P. Guanciali-Franchi[1,2], E. Morizio[2], D. Fantasia[2], C. Nuzzi[1,2], V. Aiello[3], A. Bonfatti[3], V. Gatta[1], L. Stuppia[1], E. Calzolari[3], G. Palka[1,2], B. Dallapiccola[4].* 1) Scienze Biomed/Genetica Medica, Univ G D'Annunzio, Chieti; 2) Serv. Genetica Umana, Spirito Santo Hospital, Pescara; 3) Genetica Medica, Univ. di Ferrara; 4) CSS-Mendel, Rome, Italy.

Pure 18p duplication phenotype, with absent or mild malformations and mild mental retardation, has been rarely reported (6 cases), and FISH characterization of dup(18p) was performed in only two cases. We report on two unrelated infertile women, aged 36 and 37, respectively, who were referred to cytogenetic units for karyotyping as candidates for IVF treatment. Both patients were single offspring with normal auxologic parameters and menarche at 12 yrs with normal rhythm. The older patient presented with borderline intelligence. Physical examination disclosed mild common dysmorphisms: high palate, micrognathia, long philtrum, and bulbous tip of the nose. Parents were apparently normal. Both patients showed a diploid karyotype with an add(18)(p11.3) de novo. FISH analysis with a chromosome 18 painting probe showed a complete decoration of rearranged chromosome. FISH with alphoid D18Z1 probe unraveled a signal on the tip of the short arm of the der(18) in addition to the normal signals at both chromosome 18 centromeres. MultiTelomere FISH test disclosed chromosome 18p subtelomere deletion on der(18) short arm in which no other subtelomeric region was found. FISH with a panel of RP11 BAC clones mapped at both telomere and centromere breakpoints detected duplicated regions on der(18) in addition to a single signal on normal chromosome 18. FISH experiments on interphase nuclei displayed that duplicated distal clones hybridized closer each other than more proximal clones, confirming the presence of an inverted duplicated segment estimated 13 Mb in size. Although inv dup(18p) is possibly underreported because of the normal or near normal phenotype, an accurate prognosis remains difficult when this anomaly is incidentally found de novo at prenatal diagnosis. Molecular characterization of a larger series of patients could provide better classification and prognostic information for recurrent inv dup(18p) abnormalities.

A recombinant chromosome 14 derived from 2 maternal inversions: Delineation of a complex karyotype by high resolution comparative genome hybridization. *B. Levy[1,2,3], O. Nahum[2], R.D. Clark[4].* 1) Dept Human Gen,Mt Sinai Medical Ctr, New York, NY; 2) Dept Pediatrics, Mt Sinai Medical Ctr, New York, NY; 3) Dept Obstetrics, Mt Sinai Medical Ctr, New York, NY; 4) Division of Medical Genetics, Dept Pediatrics, Loma Linda School of Medicine, Loma Linda, CA.

We report a case of a complex recombinant chromosome 14 derived from a mother with two different pericentric inversions in chromosome 14. This dysmorphic male infant weighed 1768 g at term. Dysmorphic features were large fontanelles, hypertelorism, micrognathia, large downturned mouth, clinodactyly, adducted thumbs, overlapping digits, undescended testis. He had an irritable high-pitched cry, absent gag, incomplete Moro and weak suck. Amniocentesis for IUGR and abnormal MSAFP showed an apparent proximal duplication of 14p10-14p12, a distal duplication of 14q31-14q32.3 and a distal deletion from 14pter to 14p13. The mother was mosaic with two cell lines: 46,XX (78%) and a cell line (22%) that contained a different pericentric inversion in each chromosome 14: inv(14)(p11.2q13) and inv(14) (p12q31).

High-resolution comparative genomic hybridization (CGH) on the patient indicated a gain of chromosomal material in two places on the long arm of chromosome 14 at 14q13-14q21.1 and 14q31-14qter. This was confirmed by FISH using the sub-telomeric 14q probe and multiple BAC probes, which indicated that proximal 14q11.2-q21.1 (containing one of the duplicated regions), was inverted and inserted into the short arm. The apparent loss of 14pter-p13 was reconciled in the GTG image but was not detected by CGH as this region is suppressed using Cot-1 due to its repetitive nature. Based on the GTG image, CGH and FISH results, the orientation of the derivative ch14 was qterq31::q21.1q11.2::p11.1q11.2::q13qter. Possible mechanisms by which this complex derivative was formed will be reviewed. We conclude that high resolution CGH can be an important tool for the accurate delineation of complex derivative chromosomes.

Definition of a deletion phenotypic map of chromosome 14 to search for gene-disease in the ring 14 syndrome. *L. Seminara[1], G. Matarrelli[1], G. Gobbi[2], E. Della Giustina[3], A. Scarano[3], G. Neri[1], M. Zollino[1].* 1) Genetica Medica, Università Cattolica , Rome, Italy; 2) Unità Ospedaliera NPI Ospedale Maggiore Pizzardi, Bologna, Italy; 3) Struttura Complessa Neuropsichiatria Infantile Ospedale Santa Maria Nuova, Reggio Emilia,Italy.

The ring 14 syndrome is a rare condition with mental retardation, epilepsy, retinal anomalies and craniofacial dysmorphisms. It is caused by rearrangements of chromosome 14 to form a ring, usually associated with 14q deletions of variable extent. Clinical manifestations are only in part justified by the terminal 14q deletion. Positional effects, mitotic instability of the ring and mosaicism with a monosomic cell line can also be responsible for some clinical manifestations. With the purpose of looking for gene-disease in the ring 14 syndrome, we tried to define a deletion phenotypic map of chromosome 14, by means of a clinic-genetic analysis of a total of 12 families with different chromosome rearrangements, including ring (14) (6 cases de novo and 1 familial); interstitial deletions (total 4) affecting 14q11.2, 14q12, 14q24.3q32.12 and 14q31q32 regions, respectively, and one balanced translocation t (10;14) (q25.3; q12). Genetic analysis was performed by conventional cytogenetics, by FISH with a total of 61 molecular probes specific for chromosome 14q and by microsatellite segregation analysis (to look for parental origin of the rearrangement). Relevant results are about: 1) familiarity; 2) genotype-phenotype correlations with respect to degree of mental retardation, facial characteristics, epilepsy and retinal anomalies. 3) Comparative analysis of cases with ring 14 and cases with interstitial deletions of different 14q regions led us to tentatively map some clinical signs to very restricted chromosome regions. Supported by International RING 14 Association (info@ring14.com).

Interstitial duplication 8q 22.2-24.3 in a patient with congenital malformations and normal psychomotor development. *D. Concolino[1], M.A. Iembo[1], M.T. Moricca[1], E. Rossi[2], R. Marotta[3], P. Strisciuglio[1].* 1) Department of Pediatrics, University of Catanzaro,Italy Catanzaro, Italy; 2) Department of Human Genetics, University of Pavia, Italy; 3) Department of Psychiatry, University of Catanzaro, Italy.

We report a new case of de novo partial duplication of 8q in a child with short stature, facial dysmorphisms and heart malformations. The clinical signs associated to 8q duplication are variable and correlated with the size of duplicated segment. The dysmorphic signs include: broad face, downslanting palpebral fissures, hypertelorism, depressed bridge and anteverted tip of the nose, long philtrum, micrognathia, small and posteriorly rotated ears, cryptorchidism, clinodactyly. Almost all had heart malformations. Mental deficiency is severe with frequent occurrence of seizures. PG is second child of healthy and unrelated parents; the family history, the pregnancy and the delivery were unremarkable. Physical examination at age of 6 months of age showed weight and length < 5 centile, typical facial dysmorphic features, frontal epydermoid, clinodactyly, cryptorchidism. The echocardiography showed atrial and ventricular septal defects. The neurological examination and the evaluation of psychomotor development at 3 years of age were normal. No other malformations were present. Chromosome analysis showed 46,XY,dup(8)(p22-tel) de novo. The subtelomeric probes specific for chromosome 8 showed normal signals in both telomeres, so the duplication is interpreted as direct interstitial duplication. Molecular analysis by FISH was performed and the duplicated region was included from 8q 22.2 to 8q24.3 (from 100Mb at 144.3 Mb). Recently a de novo 2.3 Mb inverted duplication of 8q24.3 in a subject with profound psychomotor retardation and epilepsy has been described suggesting that small subtelomeric de novo duplications may be responsible for mental retardation. Our patient presents mild phenotype with normal mental development, although the presence of a large direct interstitial duplication 8q. The absence of subtelomeric regions duplication in our case could be explain the absence of psychomotor retardation in this patient.

Parental 4p16.3 inversion polymorphism is not a risk factor for WHS-associated genomic rearrangements. *M. Zollino, M. Murdolo, R. Lecce, I. Mancuso, D. Orteschi, G. Marangi, G. Neri.* Dept Medical Genetics, Univ Catt Sacro Cuore, Rome, Italy.

Wolf-Hirschhorn syndrome (WHS) is a MR/MCA contiguous gene syndrome, resulting from partial 4p deletion. Genomic rearrangements represent de novo events in most cases. Although they are expected to be isolated deletions, there is increased evidence of their complexity. In addition, the role of a parental 4p16.3 inversion polymorphism is still unclear. A total 61 WHS families were analysed both clinically and genetically. Genetic analyses included: a) conventional and molecular cytogenetics (a total of 70 molecular probes 4p-specific and all telomeres); b) microsatellite segregation analysis, c) multiple colour FISH (detection of 4p16.3 inversion polymorphism). We found that a) the basic genomic rearrangements were de novo events in 55 out of 61 patients (90%); de novo rearrangements were isolated deletions in 44/55 patients (80%), unbalanced translocations in 7 (12,8%), consisting of t(4p;8p) (5 cases), t(4p;11p) (1 case), t(4p;7p) (1 case); dup/del(4p) in 3 (5,4%); double intrachromosomal rearrangement in one (1,8%). A total of 29 families were simultaneously tested for type of rearrangement, parental origin and parental 4p16.3 inversion polymorphism. Rearrangements were paternal in origin in 22 out of 29 cases (76%). Nearly the totality of them were isolated deletions (21/22). The 4p16.3 inversion polymorphism was absent in both parents in each case. Genomic defects were maternal in origin in the remaining 7 cases (24%), of which four were de novo unbalanced t(4p;8p), one t(4p;7p) and two isolated deletions (one interstitial, one terminal). The 4p16.3 inversion polymorphism was detected in the mother in 3 out of 7 cases of maternally derived rearrangements. They all were t(4p;8p). It was absent in both parents in one case of t(4p;8p), in the two isolated deletions and in the t(4p;7p). We conclude that the 4p16.3 inversion polymorphism is not a risk factor for WHS-associated genomic rearrangements. Supported by Telethon, grant GGP030253.

A Centromeric Translocation Diagnosed by FISH. *A. Zaslav[1], J. Jacob[1], R. Kazi[1], S. Allan[2], K. Probherbs[3], J.E. Fox[2].* 1) Dept Laboratory Medicine, Long Island Jewish Medical Ctr, New Hyde Park, NY; 2) Department of Pediatrics, Schneider Childrens Hospital, The Long Island Campus of The Albert Einstein College of Medicine, New Hyde Park, NY; 3) Department of OB/GYN, Antepartum Testing Unit, Long Island Jewish Medical Center, The Long Island Campus of The Albert Einstein College of Medicine, New Hyde Park, NY.

Centromeric translocations have been extensively reported. However, these translocations have rarely been ascertained by FISH alone. Here we report a prenatal case with this type of translocation. Amniocentesis was performed on a 40-year-old African American woman for AMA and late gestational age (21 weeks). Direct interphase analysis using the Aneu Vysion X/Y/18cen TM probe and the LSI 13/21 probe (Vysis, Downers Grove, IL) revealed a signal pattern consistent with one normal X centromere signal, one X centromere signal half the size of the normal X, and one normal Y centromere signal. FISH results were ambiguous and cytogenetic analysis was expanded to rule out the presence of a ring X, mar X and/or sex chromosome mosaicism. Patients were counseled to wait for the cytogenetic results to definitively determine the karyotype of the fetus. Cytogenetic analysis revealed a normal 46,XY male karyotype in 50 metaphase spreads from five in situ culture vessels. FISH was repeated on 10 metaphase spreads. The above probes were used and revealed a signal pattern consistent with one X centromere signal, one Y centromere signal, and one 19 centromere signal hybridizing with the X centromere probe. Parental chromosome analysis and FISH revealed that this was an apparently balanced paternally inherited reciprocal translocation [i.e., t(X;19)(p10;q10)]. A full term infant was delivered and had normal physical findings. To our knowledge, this is the first report of a centromeric translocation ascertained by direct prenatal FISH interphase analysis. This finding reinforces the policy that FISH analysis should not be used as the basis for irreversible therapeutic action. This case illustrates the importance of reporting unusual FISH results in conjunction with standard cytogenetic analysis for patient management and genetic counseling.

Comprehensive analysis of WHS using CGH microarray. *S.T. South[1], J.C. Carey[1], H. Whitby[1], A. Battaglia[1,2], A.R. Brothman[1].* 1) Dept Peds/Div Med Genetics, University of Utah, Salt Lake City, UT; 2) Inst of Neurology & Psych, Stella Maris Clinical Research Inst, Univ Pisa, Pisa, Italy.

Wolf-Hirschhorn syndrome (WHS) is a multiple malformation syndrome with a broad range of clinical manifestations. The minimal diagnostic criteria include mild to severe mental retardation, hypotonia, growth delay, and a distinctive facial appearance. Variable clinical manifestations include severe feeding difficulties, seizures, antibody deficiency, and major congenital anomalies such as skeletal anomalies, heart lesions, oral facial clefts, sensorineural deafness and genitourinary tract defects. WHS is caused by deletions involving chromosome region 4p16.3. Clinical variation may be explained by variation in the size of the deletion. However, in addition to having a deletion involving 4p16.3, at least 15% of WHS patients are also duplicated for another chromosome region due to an unbalanced chromosome translocation. Therefore, we hypothesize that some of the variation in clinical phenotypes may be due to the additional material from another chromosome. Furthermore, it is likely that the prevalence of unbalanced translocations resulting in WHS is underestimated since many unbalanced translocations can be missed using conventional chromosome analyses such as karyotyping and standard FISH. In contrast, CGH microarray will comprehensively evaluate the entire genome at a high resolution for unbalanced rearrangements, including unbalanced translocations. Using CGH microarray we are conducting a study to access the prevalence and associations of unbalanced translocations among WHS patients. Within the first six months of this study we have enrolled 15 participants with WHS in the study. Thus far, CGH microarray has been completed on 7 patients and 3 of these patients have a derivative chromosome 4 due to an unbalanced translocation. Results of each participants genomic analysis and comparison of their clinical manifestations will be presented.

Prenatal diagnosis of heterokaryotic monozygotic twins discordant for Turner syndrome in a recurrent familial dizygotic twin history. *M. Gadji[1], K. Krabchi[1], M. Ferland[1], M. Bronsard[1], A. Bastide[2], J.L. Ardilouze[3], C. Caron4[4], A. Langevin[4], R. Drouin[1].* 1) Serv. of Genetics, Dept of Pediatrics, Fac. of Medicine and Health Sciences, Univ. de Sherbrooke, Sherbrooke, Québec, Canada; 2) Department of Obstetrics and Gynecology, CHUL, University of Laval, Quebec, Canada; 3) Service of Endocrinology, Department of Medicine, Faculty of Medicine and Health Sciences, University of Sherbrooke, Québec, Canada; 4) Lac St-Jean Clinic of Obstetrics and Gynecology. Alma, Québec, Canada.

Turpin et al. (1961) reported the first case of heterokaryotic monozygotic dichorionic twins. We describe a similar set of monozygotic twins, one of whom presented a typical Turner Syndrome (TS) phenotype (twin 1) and the other a normal male phenotype (twin 2). Fetal ultrasonography at the 14th week of gestation showed a dichorial diamniotic pregnancy with a hygroma colli and other features associated with TS in twin 1 and no anomalies in twin 2. FISH (Fluorescent In Situ Hybridization) analyses performed on amniocytes showed a 45,X[70]/46,XY[30] mosaicism in twin 1 and a normal XY-male chromosome modality in twin 2. Whereas cultured amniocytes showed an homogeneous 45,X [100] karyotype in twin 1 and a normal 46,XY [100] karyotype in twin 2. At birth, twin 1 presented a typical TS phenotype and t win 2 had a normal male phenotype. Postnatal molecular (FISH) and conventional cytogenetic investigations of blood lymphocytes showed the same normal 46,XY chromosome constitution in both twins. However, the same approach performed on fibroblasts showed 100% of 45,X in twin 1 and 100% of 46,XY in twin 2. Monozygosity was confirmed by molecular analysis using a set of microsatellite markers of different chromosomes with DNA extracted from both lymphocytes and fibroblasts. The mechanism of this case could be explained by two events arising in the primary blastomeric step: one leading to a XY constitutional monozygotic twins (probably in the first day) and the second event, to the loss of the Y chromosome during mitotic division of blastocytes in twin 2. The rarity of heterokaryotic monozygotic twins in a familial history of dizygotic twins constitutes the novelty of this case report.

Independent mechanisms leading to two different sex chromosome deletions in one individual. *K. Hovanes[1], R. Falk[1], D. Jeandron[3], M. Karantza[2], M. Geffner[2,3], R. Schreck[1].* 1) Medical Genetics Institute, Cedars Sinai Medical Center, Los Angeles, CA; 2) Endocrinology, Diabetes, and Metabolism, Childrens Hospital Los Angeles, Los Angeles, CA; 3) The Saban Research Institute of CHLA, Los Angeles, CA.

A 13.5-yr-old boy referred for short stature had a generalized scaly rash. A similar rash was reported in male, maternal relatives, but no other reports of short stature. Height was 142.2 cm (-3.0 SD) (mid-parental target was 178.7 cm). Examination revealed Tanner Stage (TS) 1 pubic hair (PH). Bone age was age appropriate. Radiological exam revealed short 4^{th} and 5^{th} metacarpals. Testing showed normal hormone levels, chemistry panel, and urinalysis. A skin biopsy was consistent with ichthyosis. Six month follow-up showed height velocity of only 3.75 cm/yr but advance to TS2 PH. Molecular analysis of the *SHOX* gene revealed lack of heterozygosity at 27 intragenic SNPs, consistent with a deletion of the entire *SHOX* gene. The method used could not determine the chromosomal origin of the deletion. No mutations were found in the remaining allele. Thus, short stature was due to *SHOX* haploinsufficiency. The presence of both X-linked ichthyosis due to *arylsulfatase C (STS)* deficiency and a confirmed *SHOX* deletion suggested a contiguous gene deletion at Xp22.3. Cytogenetic analysis showed deletions on both his X and Y chromosomes. Karyotype was 45,X[6]/46,X,idic(Y)(p11.3)[14] with two different cell lines, one with an isochromosome of the Y and one which had lost the abnormal Y. FISH demonstrated the presence of the *SRY* gene on the isodicentric Y and deletion of the *arylsulfatase C* gene on the X chromosome. FISH analysis using two RP11-BAC clones, 91D5 and 132H11, 0.1 Mb and 0.9 Mb telomeric and centromeric to *SHOX* respectively, showed the *SHOX* gene present on the X chromosome but deleted from isodicentric Y chromosome. Thus, the phenotype is the result of a maternally inherited deletion of the X chromosome and a presumed de novo rearrangement of the Y chromosome. The additional information gained from cytogenetic analysis demonstrates that the confluence of rare events can explain an unexpected finding.

Array-CGH reveals a gain of proximal 15q associated with autism in a multiplex family with a familial cryptic translocation t(14;15)(q11.2;q13.2). *M. Koochek[1,5], C. Harvard[2,5], MJ. Hildebrand[1,5], M. VanAllen[1], JJA. Holden[3,4,5], MES. Lewis[1,5], E. Rajcan-Separovic[2,5].* 1) Depts. of Medical Genetics &; 2) Pathology, University of British Columbia, Vancouver, Canada; 3) Depts. of Physiology &; 4) Psychiatry, Queen's University, Kingston, Canada; 5) The Autism-Spectrum Disorders -Canadian American Consortium (ASD-CARC; www.autismresearch.ca).

Autism is a neurodevelopmental condition with a strong genetic etiology. In ~1% of cases, duplication of the 15q11-13 region is reported and most often it is due to interstitial duplication or supernumerary marker chromosomes 15. Here we report array-CGH, cytogenetic and clinical evaluations of a family with autism and at least two generations of a maternally inherited gain of 15q11-13 occurring as a result of abnormal segregation of a cryptic familial translocation with breakpoints at 14q11.2 & 15q13.2. The translocation was identified using the 1Mb resolution whole genome array (Spectral Genomics), as the affected family members had normal karyotypes. There was a gain of 7 clones from proximal 15q, loss of 2 clones from proximal 14q and gain of 2 clones from 6q. FISH analysis with chromosome 14 & 15 clones combined with DAPI reverse banding of the affected members showed an abnormal karyotype with one normal copy of 15 and the der(15)t(14;15)(q11.2;q13.2) resulting in the gain of proximal 15 and loss of proximal 14q. Two-color FISH using probes for 14qter and centromere 15 confirmed carrier status in the mothers of our probands, and ruled out this cryptic translocation in unaffected family members. The duplication of 2 clones from 6q in the affected subjects was familial in origin and detected via the array analysis. Our findings suggest that the gain of 15q in autism may be due in some cases to cryptic translocations with breakpoints in the pericentromeric regions of chromosome 15 and a different acrocentric chromosome. Close inspection of pericentric regions of all acrocentric chromosomes is therefore warranted, and any variation in their size may justify parental chromosome analysis and FISH analysis of the autistic proband using probes from the 15q proximal region as an important means of autism recurrence risk determination.

X CHROMOSOME ORIGINATES THE MAJORITY OF MARKERS AND RINGS CHROMOSOMES IN TURNER SYNDROME. *M.Y. Nishi, M.A. Medeiros, M.F.A. Funari, C. Rossi, A.E.C. Billerbeck, B.B. Mendonca.*
Laboratorio de Hormonios e Genetica Molecular LIM/42, Div Endocrinologia do Desenvolvimento, Disciplina de Endocrinologia - HCFMUSP, Sao Paulo, Brazil.

Introduction: The absence of genetic sequences of one of the sexual chromosomes is the cause of gonadal dysgenesis in Turner syndrome (TS). Around 6% of TS patients present a marker or a ring chromosome in their karyotype, whose chromosomal origin is rarely identified by classical cytogenetic analysis. Several studies, using molecular biology techniques, demonstrated that the marker/ring chromosomes (MRC) are derived from the X or Y chromosomes. The Y chromosome sequences in dysgenetic gonads are related to gonadal tumor development, especially gonadoblastomas, therefore prophylactic gonadectomy is indicated.

Aim: Identify the origin of MRC in TS patients using FISH or PCR techniques.

Material and Methods: Forty-nine patients, aged from 6 to 41 years old, were studied, 19 by FISH and 30 by PCR. Twenty-eight patients have a cell lineage with at least one marker chromosome and 21 with a ring chromosome. Genomic DNA was extracted from peripheral blood leukocytes and amplified with specific primers for 3 different pericentromeric *loci* of Y chromosome. The metaphase chromosomes were obtained from peripheral blood lymphocytes cultures nd hybridized with centromeric probes for the Y and X chromosomes (Vysis Inc.,Downers Grove, USA).

Results: FISH revealed that 15 MRC were derived from the X and 3 from the Y chromosome; in one patient the probes did not hibridize to the marker chromosome. PCR showed that the MRC were originated from the Y chromosome in 4 patients.

Discussion and Conclusion: Both techniques revealed that the majority of MRC in TS patients were originated from the X chromosome (86%) and not from the Y chromosome, therefore gonadectomy would not be indicated in these cases. Both techniques are good for such identification; however, FISH showed to be a faster and easier method, but more costly than PCR, whereas PCR showed a higher sensitivity compared to FISH.

De novo unbalanced cryptic chromosomal rearrangement involving subtelomeric regions 2q37 and 20p13 in a child with multiple congenital anomalies and dysmorphic features : Genotype phenotype correlation and literature review. *S.K. Murthy[1], A. Faquih[2], S. Mani[1], S. Naveed[1], A.K. Malhotra[1], A.I. Al-Khayat[3], M.T. AlAli[1].* 1) Department of Genetics,Al Wasl Hospital,DOHMS,Dubai, PO Box 9115, United Arab Emirates; 2) Department of Neonatology; 3) Department of Paediatrics.

We present here our cytogenetic observations in a one month old female child with dysmorphic features. The child presented with : odd facies, micro-opthalmia, epicanthal folds, low hair line, large and flat right ear, low set ears, high arch palate, arachnodactyly, hypotonia, cardiac murmer, left multicystic dysplastic kidney. Chromosome analysis by G-banding showed the presence of a derivative chromosome 2 with a cryptic chromosomal rearrangement involving 2q terminal region. FISH studies using ToTelVysion multicolor FISH probe (Vysis) showed deletion of 2q subtelomere and addition of 20p subtelomere at 2qtel in addition to the two normal chromosome 20s. Chromosome analysis and FISH studies of the parents showed normal chromosome complement. The final karyotype was interpretted as 46,XX,der(2).ish der(2)t(2;20)(q37;p13)(2ptel+,2qtel-,20ptel+) de novo, leading to a monosomy of 2q tel and trisomy of 20p tel in the patient. Common clinical findings as reported in the literature involving these two chromosomomal breakpoints include - development delay, macrocephaly, frontal bossing, depressed nasal bridge, cardiac anomaly, hypotonia and repetitive behavior/autism. Our patient shows several features corresponding to 2q37 deletion as well as of Allagile syndrome. Very rarely Allagille syndrome has been reported in patients with trisomy 20p with distinctive facies, cardiovascular anomalies, paucity of interlobular bile ducts, ocular anomalies and minor skeletal malformations. Further molecular studies would help to delineate the exact breakpoint and genes involved in the clinical manifestation of our patient. To our knowledge, this is the first report with such a rearrangement. Since complex cryptic rearrangements are extremely rare, our patient is of great interest to help us better understand the underlying genetic causes and its correlation with the clinical manifestations.

Efficiency of small CGH-array targeting regions between segmental duplications in detecting pathologic and polymorphic cryptic chromosomal imbalances. *I. Cusco[1], E. González[2], M. Vilardell[1], O. Villa[1], B. Rodriguez[1], X. Estivill[2], L. Sumoy[2], L.A. Pérez-Jurado[1].* 1) Unitat de Genetica, Univ Pompeu Fabra, Barcelona, Spain; 2) Centre de Regulació Genòmica, Barcelona, Spain.

Five to ten percent of the human genome consists of large blocks (5-400kb) of highly identical (95%) low copy repeats (LCRs) also called segmental duplications. These LCRs appear to have an important role in the dynamic evolution of chromosomes and can mediate chromosome rearrangements underlying genomic disease or genomic polymorphism (deletions, duplications or inversions) through non-allelic homologous recombination. We have constructed a microarray including 228 BACs covering single-copy regions flanked by LCRs and all the subtelomeric regions. Using this CGH-array, we have screened a collection of 94 samples of cytogenetically normal patients with a variety of conditions to look for candidate regions of sub-chromosomal aneusomy. Patient-specific rearrangements likely responsible for the disease were detected and confirmed in 6 samples (6.4%): two cases of Silver-Russell syndrome (dup~10Mb 7q36-qter/del~8Mb 10q26-qter; dup1Mb 7q14), one polymalformative syndrome (del~0,5Mb 18q23-qter/dup~3Mb 8p23-pter), and three with mental retardation and autistic features (dup~3Mb 15q12; del~0,5Mb 15q11; dup~4Mb 10q23). We also detected 61 abnormal signals (21 deletions, 8 duplications and 32 deletion/duplications) present in 2-9% of the samples that might correspond to copy number polymorphisms (CNPs). Almost half of these presumed CNPs (28/61) have also been described elsewhere (Iafrate 2004, Sebat 2004, Bejjani 2005, Sharp 2005). Alternative methods (FISH, MLPA, microsatellites) allowed us to confirm only half of the putative CNPs tested (n=12), suggesting false positive results of the array. Confirmation of the novel variable loci not previously reported is in process. Array-CGH is a powerful tool to detect sub-microscopic pathogenic rearrangements in patients as well as CNPs, although careful analysis and confirmation by other methods may be required due to some false positive results. The strategy of targeting putative hotspots located between LCRs has proven to be highly effective.

Routine MLPA screening for telomeric rearrangements : a low cost, high throughput substitute for multiFISH technology. *S. Drunat[1], A. Aboura[2], A.C. Tabet[2], O. Dupuy[2], C. Baumann[3], J. Elion[1], A. Verloes[3,4].* 1) Molecular Genetics Unit, Genetics Dept, Robert DEBRE Hospital, Paris, France; 2) Cytogenetics Unit, Genetics Dept, Robert DEBRE Hospital, Paris, France; 3) Clinical Genetics Unit, Genetics Dept, Robert DEBRE Hospital, Paris, France; 4) INSERM U676.

Cryptic telomeric rearrangements (CTR) are found in 5 % of patients with idiopathic mental retardation (MR) or Multiple Congenital Anomalies/MR syndromes, and apparently normal karyotype. Despite their clinical relevance, multiFISH screening remains difficult to apply widely, because kits are expansive and methodology extremely time consuming. Clinical presection criteria as De Vries scale are unsatisfying. Multiplex ligation-dependent probe amplification (MLPA) is a highly sensitive and rapid alternative to multiFISH. It can be used on any DNA source (blood, amniocytes, CVS, paraffin-embedded tissue...) The method allows batch screening of 20 patients per run. We used 2 commercial sets of probes, the SALSA P036B and P70 human telomere kits, to assay retrospectively patients with known dup/del syndromes. All were detected and, more importantly, there was no false negative tests. We will present results of MLPA to a series of more than 500 systematically collected patients referred to the genetic clinic for evaluation of MR or autism. In all cases with abnormal/dubious MLPA, confirmatory pantelomeric FISHing was performed. Detailed results of this ongoing study will be presented. Preliminary results (at the time of submission,) in a prospectively collected series of 240 samples: we were able to confirm 6 anomalies. Three further MLPA positive but FISH-negative cases were considered as polymorphisms. Nine further MLPA-positive cases are pending. Conclusion: subtelomeric MLPA screening can be done without preselection, and appears to be cost-effective, time saving, and clinically rewarding, as some of the positive patients would not have been selected on clinical grounds for multiFISH. Moreover, the drastic reduction in FISH-based screening demand allows buzy diagnostic laboratories to re-affect time to refining the cytogenetics/molecular definition of positive cases.

A locus for ano-sacral malformation maps to 6q25.3 in a 0.3 Mb interval region. *L. Titomanlio[1,2], I. Giurgea[3], M. Elmaleh[4], Ph. Sachs[2], F. Chalard[4], O. Dupuy[5], A. Verloes[1,6].* 1) Clinical Genetics Unit, Dept of Genetics, Robert DEBRE Hospital, Paris, France; 2) Dept of Child Neurology,Robert DEBRE Hospital, Paris, France; 3) Dept Biochemistry & Genetics and INSERM U654, Henri Mondor Hospital, Creteil, France; 4) Dept Medical Imaging, Henri Mondor; 5) Cytogenetics Unit, Dept of Genetics, Robert DEBRE Hospital, Paris, France; 6) INSERM U676.

Partial absence of the sacrum is a rare congenital defect which also occurs as an autosomal dominant trait; whereas imperforate/ectopic anus is a relatively common malfrormation, usually observed in polymalformative syndromes. We report on a girl born to healthy consanguineous parents (first cousins once removed). She was immediately admitted to a tertiary care center for surgical correction of an anal imperforation with an associated recto-vaginal fistula. At 3 years of age, imaging studies showed partial sacral agenesis and a tethered cord. Facial dysmorphism included a high forehead, epicanthal folds, downslanting palpebral fissures, hypertelorism, a depressed nasal root. Brain MRI showed a bilateral opercular dysplasia with an unilateral (right) pachygyria; MRI and X-ray imaging of the spine disclosed a tethered cord associated with a partial sacral agenesis. She showed a global and moderate developmental delay. Ophthalmologic examination evidenced bilateral microphtalmos (<20 mm) and relative microcornea. Terminal deletions of 6q (6q25à6qter) have been rarely reported in the literature and have been associated to a specific phenotype. Cytogenetic studies in our patient disclosed a pure de novo 6q25.3àqter deletion. By genotype analysis, we detected in our patient a maternal allele loss for the D6S1581, D6S264, D6S446 markers. Distal 6q deletions have been frequently reported in association with sacro-anal malformations (sacral agenesis, anal imperforation/ectopy). By comparing the reported cases of affected patients carrying a pure terminal 6q deletion, we delimited a critical region spanning 0.3 Mb. Thus we hypothesize that there is a gene in the deleted region whose haploinsufficiency impairs the normal development of these structures, possibly acting on the notochordal development.

Application of Whole Genome Amplification to Chromosomal Microarray Analysis for Genetic Disorders. *D. del Gaudio, T. Sahoo, J. Li, SH. Kang, P. Ward, CM. Eng, A. Beaudet, SW. Cheung, BB. Roa.* Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Molecular cytogenetic techniques have improved the diagnosis of chromosomal abnormalities. Comparative genomic hybridization on microarrays has demonstrated utility for detecting clinically relevant DNA dosage variations at high resolution, sensitivity and speed. We have developed a clinical microarray at Baylor College of Medicine that encompasses loci involved in over 55 genetic disorders, plus clones for 41 relevant sub-telomeric regions. Application of chromosomal microarray analysis (CMA) to prenatal testing is being evaluated. Limitations of DNA extracted directly from uncultured amniocytes and chorionic villi preclude rapid testing. Yields are improved by using fetal cell cultures, but this delays prenatal testing and reporting. One option is to incorporate whole genome amplification (WGA) into the CMA process. The WGA technology involves random fragmentation of genomic DNA and adapter ligation followed by PCR amplification with universal primers. We used a WGA kit developed by Rubicon Genomics and subsequently released by Sigma Aldrich. Our initial validation included 6 whole blood genomic DNA samples tested in parallel with the corresponding WGA products. CMA testing showed comparable results, with no significant amplification bias observed for genomic clones included in the microarray. This approach was then evaluated for prenatal testing by CMA analysis. Genomic DNA extracted from 35 prenatal samples (27 direct amniocytes and 8 direct CVS samples) were subjected to WGA. Comparable results were obtained on parallel CMA testing of fetal genomic DNA samples and corresponding WGA products, including positive controls. Results were usually obtained in 6 days or less. Comparative PCR analysis of multiple polymorphic STR loci ruled out maternal cell contamination on fetal DNA and WGA samples. We observed 100% concordance in this study on CMA analysis using genomic DNA and the corresponding WGA products. The use of WGA provides a viable approach to facilitate rapid prenatal testing on direct fetal samples.

Paucity of primary identification of new cryptic subtelomere rearrangements with subtelomere FISH: a three year retrospective analysis. *H.M. Saal, L. Bao, E.K. Schorry, R.J. Hopkin, N.D. Leslie, T.A. Smolarek.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

A review of the literature shows that in many cytogenetics laboratories the frequency of anomalies identified by subtelomere FISH panel ranges from 3-7%. The experience in our institution has not produced similar results; although, indications for testing have closely matched those reported in the literature. In the past three years we have performed 233 subtelomere FISH analyses, of which there were only five subtelomere abnormalities diagnosed (2.1%) which were not initially identified by cytogenetic analysis, usually high resolution. Significant among these five cases was one patient who had a 14q deletion which was also seen in the phenotypically normal father and a 22q deletion in which the FISH study was performed prior to completion of the chromosome study where the deletion was identified microscopically. Therefore, in only three of 233 cases (1.3%) were subtelomere studies essential for identifying pathologic chromosome abnormalities. Utilization of subtelomere FISH panels is a helpful adjunct to cytogenetic analyses; however, this technology should not be considered a replacement for high resolution chromosome studies, since interstitial deletions or duplications may also be missed. During the same period we have identified a greater number of interstitial rearrangements (24) than subtelomere rearrangements, many of which were very subtle. These data underscore a need for continued emphasis on high quality microscopic analysis in addition to continued development of new technologies, including comparative genome hybridization, for enhancing cytogenetic diagnosis.

CELL CYCLE DURATION IN A SECKEL SYNDROME PATIENT. *L. Bobadilla-Morales[1], J.R. Corona-Rivera[1], I. Cervantes-Luna[1], C.E. Monterrubio-Ledezma[1], R. Iñiguez -Rodruiguez[1], A. Corona-Rivera[1,2].* 1) Lab de Citogenetica Genotoxic, Univ Guadalajara, CUCS, IGH, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Hospital Civil de Belen Fray Antonio Alcalde,, OPD.

Seckel syndrome has been proponed as one chromosome instability syndrome. This nosological group includes genetic entities sharing short stature, developmental delay, immunodeficiency, high cancer risk, and autosomal recessive inheritance. This group includes also defects in the ways of DNA reparation and consequently spontaneous or induced breackages and chromosome instability. It was proposed that chromosome instability in this syndrome can be related to cell cycle impairement or apoptosis leading to reduction of cells in the organism and failure to thrive. Considering that altered cell cycle can be involved in Seckel Syndrome we performed cell cycle measurements in one patient with Seckel syndrome and paired control. Cellular proliferation kinetics was measured by the method called average generation time by differential sister chromatid stain of chromosome spreads from cultures at 60 and 72 h treated with 5'-BrdU. We found average generation times of 31.57 h at 60 hrs and of 28.45 h, at 72 hrs, meanwhile in control was of 34.6 at 72 h. Apparently differences in cell cycle duration can be involved in Seckel syndrome.

Chromosome 8p23 rearrangements. *G. Wenger[1,3], K. McBride[2,4], D. Bartholomew[2,4].* 1) Laboratory Medicine/Cytogenetics, Columbus Children's Hospital, Columbus, OH; 2) Division of Human and Molecular Genetics, Columbus Children's Hospital, Columbus, OH; 3) Dept. of Pathology, Ohio State University College of Medicine and Public Health, Columbus, OH; 4) Dept. of Pediatrics, Ohio State University College of Medicine and Public Health, Columbus, OH.

In recent years, repeated sequences located on the same chromosome have consistently been shown to be involved in the generation of recurring chromosome rearrangements including deletions, duplications, and inversions. Repeats located on non-homologous chromosomes are responsible for translocations including the constitutional t(11;22)(q23;q11.2) and t(4;8)(p16.1;p23.1). The olfactory receptor gene superfamily includes sequences located on almost all chromosomes, and has been implicated in the generation of recurring chromosome abnormalities including interstitial deletions, inv dup(8p), and a supernumerary marker chromosome. We describe a series of patients examined cytogenetically in our laboratory in the last five years, including two patients with interstitial del(8)(p21.3p21.3), three patients with duplication in the same region, a patient with duplication and deletion in the region, patients with the balanced translocation t(4;8) or resulting unbalanced karyotypes (two patients with der(8) and one patient with der(4)), and four patients with der(8) karyotypes as a result of inheritance of an unbalanced chromosome complement from a parental translocation in which the breakpoint for one translocation partner is 8p23.1. Olfactory receptor gene sequences have been found at the other translocation breakpoints. Clinical features included developmental delay and congenital heart disease. Studies in other labs have identified a maternal inversion polymorphism that favors the formation of rearrangements including inv dup(8p) and der(8p). Interstitial deletions and translocations may arise through this or other mechanisms also related to the presence of olfactory receptor gene sequences. Chromosome 8p23.1 rearrangements join the list of recurring microrearrangement syndromes as frequently encountered abnormalities in the clinical cytogenetics laboratory.

A unique interstitial deletion involving chromosome 20q in a child with microcephaly and behavioral difficulties.

M. Demos[1], M. Connolly[2], L. Armstrong[1], P. Eydoux[3]. 1) Dept Medical Genetics; 2) Dept Pediatric Neurology; 3) Dept Cytogenetics, CW Health Centre of BC, UBC, Vancouver, BC, Canada.

Constitutional interstitial deletions involving the long arm of chromosome 20 are not common. To our knowledge, a deletion involving 20q13.11-q13.13 has never been reported. We describe a 7 year old boy with congenital microcephaly, dysmorphic features, and behavioral abnormalities due to a deletion involving chromosome 20q13.11-q13.13. This patient was born at term following an uncomplicated pregnancy to nonconsanguinous Chinese parents. He was healthy but noted to have microcephaly at birth. Hyperactivity and poor attention span were first noted at 4 years of age. Episodes of disruptive and aggressive behavior also developed, but there were no episodes suggestive of seizures. Early developmental milestones were normal, but at 7 years of age he had mild fine motor difficulties and learning difficulties, particularly in the area of speech and language. On examination, his head circumference plotted just below the 2nd percentile, his height was at the 25th percentile and his weight was at the 10th percentile. Dysmorphic facial features included hypotelorism, prominent nasal bridge, slightly flat philtrum, and micrognathia. Neurological examination was normal except for mild clumsiness of fine motor movements. Brain MRI was normal. Electroencephalogram at 4 years of age was normal. At 6 years of age the EEG showed spikes in the bilateral frontal, parietal, and temporal areas, particularly in sleep. At 7 years of age it showed frequent spikes in the left temporal areas. There were also frequent spikes in the left central parietal area; right central sharp waves; and mid-central temporal sharp waves. His karyotype revealed a small deletion within chromosomal region 20q13.11-q13.13. Parental karyotypes are pending. Further characterization of the interstitial deletion will be performed using a Sub-Megabase Resolution Tiling-set (SMRT) array-CGH (aCGH). Further characterization of our patients imbalance may allow a better understanding of our patients phenotype.

PRENATAL DETECTION OF A PARTIAL MONOSOMY OF THE CHROMOSOME 13 AND PARTIAL TRISOMY OF THE CHROMOSOME 18 IN A FETUS WITH ALOBAR HOLOPROSENCEPHALY. *G. Razo-Aguilera, R. Báez-Reyes.* National Institute of Perinatology.

The holoprosencephaly (HPE) is a defect of the development of the previous brain and frecuently of the half face. It has a prevalence of 1:250 during the embriogenesis and 1:16,000 in newly born. It's associates with teratogen agents or genetic factors. The evidence for genetic causes of HPE for their heterogeneity comes of: 1) chromosomal anomalies, 2)family ocurrence and 3) genetic syndromes associates. The chromosomic aberrations are found in the 50% or more than the patients with HPE and exist already of 12 involved genes. The case of a couple of 35 years old both is presented, with 4 pregnancies, 1 alive son and 2 deaths with probably hidrocephaly, she is housewife and he is merchant, not consanguineous. They went to the consultation of Prenatal Diagnosis with 18 weeks of gestation for control and in the ultrasound of second level an unique ventricle was visualized in the brain, with adsence of thalamuses and the presence of a cardiopathy of the type CIV, the rest was normal. Genetic advice is given to the couple and we offered cytogenetic amniocentesis, they accepted and the result with G bands was reported: 46,XY,der(13)t(13;18)(q22;q23) desbalanced for a partial monosomy of the chromosome 13(q22-->qter) and partial trisomy of the chromosome 18(q23-->qter) of maternal origin, being carrier the lady of a balanced reciprocal translocation 46,XX,t(13;18)(q22;q23). The family study was completed. Most of the affected can to present alterations for desbalanced translocations; howewer, the reagment of this fetus is innusual, for what represents a special interest with regard to the segregation.

Familial balanced homozygous translocation, t(11;22)(q23.3;q11.2) in a male - Segregation and recurrence risk - A case report. *D. Krishnamurthy[1], F.M. Mohammed[2], M.A. Redha[3], L. Bastaki[3], S.A. Al-Awadi[3].* 1) Cytogenetics and Molecular Cytogenetics, Canadian Specialist Hospital, Dubai, United Arab Emirates; 2) Allied Healtah Sciences, Kuwait University, Kuwait; 3) Kuwait Medical Genetics Centre, Maternity Hospital, Kuwait.

A balanced/unbalanced reciprocal translocation, t(11q22q) is one of the most common, familial site-specific reciprocal translocation which seems to have recurred over and over again, creating numerous carriers. In the majority of the reported cases ascertainment has been through the birth of a child with the chromosomal constitution 47,XX,+der(22) or 47,XY,+der(22), i.e., tertiary trisomy. Homozygosity for major structural rearrangement is very rare. A normal healthy, male and female, seeking premarital genetic counseling because of family history of mental retardation and chromosomal abnormality was investigated to exclude possibility of balanced chromosomal rearrangement. Metaphase chromosome analyses prepared from peripheral blood culture showed balanced homozygous translocation, 46, XY, t(11;22))(q23.3;q11.2), t(11;22))(q23.3;q11.2), Karyotype of the female partner was normal 46,XX. Balanced carriers are at risk of having offspring with the derivative 22 syndrome owing to 3:1 meiotic non-disjunction. Clinical features of the der(22) syndrome include mental retardation, craniofacial abnormalities and congenital heart defects. Heterozygous carriers pf t(11;22) are phenotypically normal, but are at high risk of having children with tertiaray trisomy 22 or recurrent fetal loss. Majority of the carriers reported in the literature are female. The family history is remarkable. The couple had three children (2 males and 1 female) 2 were balanced carriers, and 1 was affected with supernumerary chromosome, der(22). The recurrence risk and segregation of the reciprocal translocation will be presented.

Cytogenetics of Idiopathic neurological conditions helped in identifying Glutamate and Gamma-amino butyric acid receptors as crucial genes in their etiology. *S. ponnala[1], V. Mohan[1], R.V. Alluri[1], S. Komandur[1], K. Chawda[2], K. Alladi[2], J.R. Chaudhuri[2], Y.R. Ahuja[4], Q. Hasan[2,3].* 1) Genetics and mol med, Kamineni Hospital, Hyd 500 068 India; 2) Dept of Neurology. Kamineni Hospitals, Hyd 500 068, India; 3) Dept of Genetics, BMMRC, Hyd 500 004, India; 4) Dept of Genetics, VMRC,Hyd 500 003, India.

Cases with learning disability, motor developmental delay with or without epilepsy pose diagnostic and therapeutic challenges to clinicians. In the present study idiopathic neurological cases were evaluated to define their genetic basis. 43 cases with delayed milestones, learning disorders with or without epilepsy were subjected to detailed neurological examination which included ENMG, EEG, CT scan and other relevant biochemical tests. cytogenetic evaluation was carried out. 27.9% patients showed chromosomal anomalies involving break points at 2q(2q23-24), 4q(4q21-26), 5q(5q31), 6q(6q21-24), 8p(8p22-pter), 8q(8q13-24), 15q(15q11-13) and 16q(16q22-24). Neurotransmitter receptor genes located at chromosomal break points were identified by OMIM search. 66.7% of the patients with chromosomal anomalies were associated with glutamate receptor and 33.3% with GABA receptor. L-Glutamate is the major excitatory neurotransmitter and its activation is responsible for basal excitatory synaptic transmission and plasticity, which is involved in cognitive functions. Disruption of the activity of this may be responsible for the clinical phenotype seen in 66.7% cases. While GABA receptor is a multi-subunit chloride channel receptor, which mediates inhibitory synapses in the brain and spinal cord. It plays a role in increasing or decreasing the cellular excitability by interfering with sodium, potassium and calcium influx, which may result in seizures or impaired neural functions. Altered function of GABA receptor may account for the phenotype seen in the remaining 33.3% cases. Loss or altered function of Glutamate and GABA receptors caused by chromosomal rearrangements appears to be a major factor for neurological dysfunction in the cases studied.

Multiple spontaneous miscarriages caused by a rare and complex derivative chromosome resulting from reciprocal translocations involving chromosomes 4,7 and 15 in a phenotypically normal male. *J. Yung, S. Hardikar.* Cytogenetic laboratory, LabCorp/Dynagene, Houston, TX.

We are reporting a case of a couple that requested cytogenetic evaluation due to multiple miscarriages. The 26-year-old woman and 31-year-old man have had two previous first trimester spontaneous abortions. The woman also has a normal child from a previous marriage. The womans cytogenetic finding was 46,XX normal female. The mans chromosomal study revealed two reciprocal translocations. It was determined that the man carried two apparently balanced chromosome translocations, t(4;7)(q33;q22) and t(7;15)(p15;q24). These rearrangements resulted in a very complex derivative chromosome 7, der(7)t(4;7)(q33;q22)t(7;15)(p15;q24), consisting of chromosomal material from 4,7 and15. Given the complexity of the rearrangement, FISH and high-resolution studies were performed. The result confirmed the above break points. The presence of two translocations in one individual is rare. The two translocations involving one common chromosome, as in this case chromosome 7, is even more unusual. Patients with one reciprocal translocation are known to give rise to abnormal unbalanced offspring due to segregation at meiosis and meiotic crossing-over. An individual with such complex and unusual rearrangements will be unlikely to generate any offspring with a balanced karyotype and the incidence of unbalanced conceptus will be very high. Genetic counseling is warranted to discuss the reproductive consequences of carrying this complex chromosomal aberration and to address the recurrence risk for other family members who may carry a similar chromosome abnormality.

Two infants with homozygous premature chromatid separation trait. *H. Numabe[1,2], T. Ikeuchi[3], T. Kajii[4], I. Kusakawa[5], I. Kato[5], S. Kosugi[1,2].* 1) Dept Clinical Genetics, Kyoto University Hospital, Sakyo-ku, Kyoto, Kyoto, Japan; 2) Department of Biomedical Ethics, Kyoto University Graduate School of Medicine, Kyoto, Japan; 3) Department of Molecular Cytogenetics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 4) Hachioji, Tokyo, Japan; 5) Department of Pediatrics, St. Lukes International Hospital, Tokyo, Japan.

We report two girls with homozygous premature chromatid separation (PCS) trait, chromosomally characterized by PCS and mosaic variegated aneuploidy (MVA). Case 1 had pre- and postnatal growth retardation, microcephaly, Dandy-Walker malformation, and minor facial abnormalities; and at age 22weeks developed generalized seizures controllable with phenobarbital. At age 4 months, bilateral multicystic Wilms tumors and rhabdomyosarcoma of the bladder were detected. She died of renal failure at age 9 months. Case 2 had pre- and postnatal growth retardation, malrotation of intestine, and duodenal stenosis caused by pancreas ring, but had not microcephaly nro Dandy-Walker malformation. At age 6 months, any tumor was not detected. All tissues and cells from the Case 1 analyzed showed a high frequency of PCS and MVA. On the other hand, blood cells from Case 2 and one of her parents analyzed showed a moderately high frequency of PCS, and MVA was observed only in Case 2. Case 2 and one of her parents had the same heterozygous mutation of *BUB1B* gene.

Severe phenotype in a female with non-mosaic, non-ring X chromosome with Xp and Xq deletions and complete skewing of X-inactivation. *S.A. Vaz, J. Lee, S. Li, J.J. Mulvihill, S.E. Palmer.* Dept. of Pediatrics, Section of Genetics, Univ. of Oklahoma HSC, Oklahoma City, OK.

Females with X chromosome deletions commonly have a Turner syndrome-like phenotype. Severe phenotype in females with X chromosome rearrangements are uncommon, mostly due to small ring X chromosomes (usually mosaic), or rarely translocations or duplications; phenotypes include multiple anomalies and brain abnormalities. We report a female with Xp and Xq deletions and severe phenotype. She presented with dysmorphic features, hypertelorism, craniosynostosis, orbital asymmetry with mild unilateral microphthalmia, optic nerve hypoplasia, complete cutaneous 2-3 syndactyly of hand, and urogenital abnormalities. Intractable seizures developed during early infancy. Chromosome analysis, subtelomere FISH, and whole X chromosome paint showed 46,X,rea(X)(pterp22.33::p21q21::p22.33pter), with two copies of Xpter subtelomeres, one on each end of the rearranged X chromosome with Xqter subtelomere absent, confirmed with Xpter probe DSYS129. *KAL*, which maps 8 Mb proximal to DXYS129, was absent by FISH. The abnormal X was non-mosaic with de novo inheritance. Although this patient shares phenotypic features of X-linked single gene disorders which map to regions near the rearrangements, including Lenz (OMIM 301590) and oculofacialcardiodental (OMIM 300166) syndromes, anomalies resulting from disruptions of these genes seem less likely. Study of this patient using androgen receptor methylation showed X-inactivation to be 100% skewed. This patient shares phenotypic features with some cases of ring X chromosomes with non-random X-inactivation and severe phenotype presumed due to gene dosage effects. In these females, skewing usually occurs due to deleted *XIST*, which maps to Xq13.2; this band is proximal to the deleted region in this patient. However, several patients with ring X and retained but non-expressed *XIST* have been reported. Due to the presence of Xp subtelomere on both Xp and Xq arms as revealed by FISH, an etiology of initial complex deleted ring chromosome with subsequent subtelomere duplication and separation is suggested, with *XIST* most likely present but non-functional.

Chromosome 10q deletion associated with diaphragmatic hernia. *L. Mehta[1], T. Vaughn[1], D.M. Barlev[2], D. Nedelea[1], J. Jacob[3], R. Kazi[3], A.L. Zaslav[3].* 1) Div Med Genetics,Schneider Children's Hospital at North Shore-NYU School of Medicine, Manhasset, NY; 2) Dept. of Radiology &; 3) Dept. of Laboratories, Long Island Jewish Medical Center, The Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY.

A 5 month-old male infant was evaluated for poor growth and dysmorphic features. Height, weight and head size were below 3rd % ile. Face was triangular with mild malar hypoplasia. Ears were lowset and overfolded. Premaxilla was prominent. There were bilateral single transverse creases on the palms and toes were overlapping. He had mild hypotonia and motor delays. He was hospitalized because of persistent mild respiratory distress. Chest X-ray showed a large, soft tissue mass in the right lower hemithorax with bowel loops occupying the right upper abdomen. CT scan confirmed anterior herniation of part of the liver into the right hemithorax, compressing the right side of the heart. Cardiology evaluation showed no structural heart defects. Standard cytogenetic analysis using G-banding revealed an abnormal karyotype of 46,XY,del(10)(q25). Parental chromosomes were normal indicating that the deletion was de novo. FISH analysis using 10p/q subtelomere probes (Vysis, Downers Grove, IL) confirmed the deletion in the patient and normal chromosomes in the parents. Phenotypic manifestations of chromosome 10q deletion include facial dysmorphisms, postnatal growth retardation, developmental and mental retardation, cardiac, and genitourinary defects. Our patient shows several of the described findings. To our knowledge this is the first case of del(10)(q25) presenting with a diaphragmatic hernia (DH). Most congenital DHs are posterolateral defects and left-sided. Anterior hernias (Morgagni), such as in our patient, are rare and typically right-sided. Most chromosome abnormalities associated with DH have been random. DH may occur in these cases as part of the generalized developmental disruption associated with genomic imbalance. This information will be of help in patient management and in defining the phenotype of chromosome 10q deletions.

Features of DiGeorge/Velocardiofacial syndrome in a patient with chromosome 15q26.3 subtelomeric deletion. *K. Casas, L. Williamson-Kruse, J. Saunders, S. Li.* Dept Pediatrics, Univ Oklahoma HSC, Oklahoma City, OK.

A 7-year-old female presented with mild developmental delay, seizures, history of esophageal atresia and thymic hypoplasia at birth, and craniofacial features of the DiGeorge/Velocardiofacial syndrome (small head size, middle ear anomalies, prominent nose, and bifid uvula). Karyotype and fluorescent in situ hybridization (FISH) probe for chromosome 22q11.2 yielded normal results. Subtelomeric chromosome analysis revealed a chromosome 15q26.3 deletion. The patient was also found to have 11 pairs of ribs with partial fusion of right ribs 5 and 6, scoliosis, coalition of the carpal bones, and shortening of metatarsals 4 and 5. While several patients with more proximal deletions involving 15q26.2 have been reported with congenital diaphragmatic hernia and growth retardation, this may be the first report of a chromosome 15q26.3 deletion syndrome.

Duplication 4p and autism: cytogenetic identification of a common region for autistic disorder. *J.J.D. Morrissette[1], L. Medne[3], R. McDaniell[3], A. Gupta[3], B. Parrish[2], C.E. Anderson[2], E.H. Zackai[3], N.B. Spinner[3].* 1) Div Path & Lab Med,; 2) Dept Pediatrics, St Chris Hosp for Children, Phila, PA; 3) Div of Human Genet, Childrens Hosp Phila, Phila, PA.

Autism is a behaviorally defined disorder believed to be heterogeneous. Autism has been found to run in some families, suggesting a genetic component to its etiology, and can be associated with genetic syndromes, and certain cytogenetic abnormalities. The most common cytogenetic abnormality observed is duplication of 15q11-q13, including the AS/PWS critical region, as well as several GABA-receptor genes. We identified three individuals with a diagnosis of Autistic Disorder based on DSM-IV criteria, who had chromosome abnormalities that resulted in partial duplication of 4p. Patient 1 is a 4 year old with a duplication of 4p14 to 4pter and a deletion of 8p21 [46,XX,der(8)t(4;8)(p14;p21)]. This individual had language and gross motor delays and had synophrys, cupped ears, high-arched palate, and self-injurious behavior. Patient 2 is a 21 year old who had a duplication of 4p12 to pter and a deletion of 4q28 [46,XY, der(4)t(4;4)(p12q28)]. This individual had bipolar disorder, cerebral palsy, hearing loss GE reflux, short stature, esotropia, and dysplastic finger and toenails. Patient 3 was a 17 month-old who had a duplication of 4p15 through 4pter [46,XX, dup(4)(p15)], with motor delays, prominent ears, delayed dentition, irregularily placed toes, with head circumference and length below the 5th centile. The smallest region of overlap includes 4p15 through 4pter. There are several genes of interest in this region, including SLIT2, a gene expressed in axons and growth cones during neural development, and dopamine receptor D5. A deletion involving 4q has been identified in another individual with PDD-NOS and a small, interstitial deletion comprising 4q31-q33. This deleted region contains genes that could be involved in the development of autism including a glutamate receptor, 2 glycine receptors and neuropeptide Y receptor. These 3 cases all share a region of overlap within 4p15 to pter, leading us to hypothesize that increased dosage of genes within this region leads to autism.

Clinical diagnosis of human chromosome aberrations using a new technique combining DAPI staining and image analysis. *M. Ji[1], J. Liu[2], X. Wang[3], X. Ren[2], M. Liu[2], Q. Wang[2,4].* 1) The Laboratory of Human Geneti, Institute of Tumour of Zhongshan in Guangdong, Zhongshan, Guangdong, China; 2) Human Genome Research Center, Huazhong Univ of Sci and Tech, Wuhan, Hubei, China; 3) The Laboratory of Human Genetics, Institute of Planned Parenthood of Nanyang, Nanyang; 4) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation.

In this study, human chromosome aberrations including several translocations, 46,XX,t(3;21)(12;18), 46,XX,t(11;22), 46,XY,t(7;22), and 46,XY,t(11;18) were identified by a new technique that combines DAPI staining and image analysis. The technique has been reported for analyzing plant chromosomes, but has not been applied to analyze human chromosomes yet. The staining method is conventional and the image analysis consists of only two steps: deconvolution and then three-dimensional reconstruction. The results showed that the karyotype of the 46,XX,t(3;21)(12;18) was 46,XX,t(3;21)(3q11.1;21p13), t(12;18)(12q15;18q23), and the karyotypes of the 46,XX,t(11;22), 46,XY,t(7;22) and 46,XY,t(11;18) were 46,XX,t(11;22)(11q23;22q13.1); 46,XY,t(7;22)(7q32;22q13.3) and 46,XY,t(11;18)(11q13.3;18q23), respectively. The derivative chromosomes involved in the translocations were also verified by chromosome painting as well as FISH with centromere probes. This new technique has two adavantages compared to the traditional G-banding technique: the results are more accurate and the procedure is more simple and convenient.

Polymicrogyria in a child with deletion 9p24-pter and microduplication 22q11.2. *P. Callier[1], L. Faivre[2], N. Marle[1], C. Thauvin-Robinet[2], N. Madinier[3], A.L. Mosca[1], S. Ragot[4], F. Huet[3], J.R. Teyssier[4], F. Mugneret[1].* 1) Laboratoire de Cytogénétique,CHU Le Bocage, DIJON, France; 2) Génétique médicale,CHU Le Bocage, DIJON, France; 3) Pédiatrie,CHU Le Bocage, DIJON, France; 4) Laboratoie de Biologie Moléculaire, CHU Le Bocage, DIJON, France.

We report on a 9-year-old girl presenting with polymicrogyria and an unbalanced chromosomal rearrangement. She was the unique child of non consanguineous parents. Measurements at birth were normal. She was referred at 8-year of age for mental retardation with speech delay and seizures. At clinical examination, measurements were normal except progressive microcephaly (OFC -2.5 SD). Facial dysmorphism included synophrys, up-slanting palpebral fissures, low implanted hairs, large ears and hypotonic face. Cardiac and renal ultrasounds were normal, but cerebral MRI showed polymicrogyria, affecting preferentially the occipital and temporal region. Conventional cytogenetic analysis revealed a 46,XX,add(9)(p24pter). FISH studies with Vysis To TelVysion specific probes showed 9pter deletion. Array-CGH (GenoSensor Array 300, Vysis/Abbott, 287 DNA clones) confirmed the deletion 9pter from two clones (9pter and D9S913), but also showed that three clones (GSCL, HIRA and TBX1) were duplicated in the 22q11.2 region. Molecular Cytogenetics studies with Bacs located in the 9pter region are in progress to better define the size of the deletion. Although FISH studies on interphase cells with a HIRA 22q11.2 specific probe did not permit to confirm this microduplication, quantitative PCR (ABI Prism SDS 7700) using primers of the TBX1 gene region was in favour of an overexpression of the gene. Maternal cytogenetic studies were normal whereas paternal samples were not available. This study demonstrates the utility of the Array-CGH technology to detect complex rearrangements as well as microduplications that are not easily studied using FISH. This observation is also of interest since it could be a clue in the search of the genes responsible for polymicrogyria.

Characterization by FISH of structurally abnormal Y chromosomes and of sex reversal cases: What are the implications on sex differentiation phenotypes? *M. Beaulieu Bergeron[1,4], M. DesGroseilliers[1,4], P. Brochu[3], E. Lemyre[2,4], N. Lemieux[1,3,4].* 1) Pathologie et biologie cellulaire, Université de Montréal, Montréal, Québec, Canada; 2) Pédiatrie; 3) Pathologie et; 4) Centre de recherche de l'Hôpital Sainte-Justine, Montréal, Québec, Canada.

Infrastructural rearrangements of the human Y chromosome are often seen in both males and females. These structurally abnormal Y chromosomes are unstable and can be implicated in male infertility, azoospermia and sex reversal. When found in female patients, rearranged Y chromosomes can lead to gonadal dysgenesis, sex reversal, and increased risk of developing gonadal tumors (gonadoblastoma/dysgerminoma). We present the FISH results of 27 patients, including 16 cases of isodicentric Y chromosome (6 males, 9 females and one individual with sexual ambiguity), 5 cases of translocations between sex chromosomes (4 XX males and 1 XY female) and 6 sex reversed females with a normal Y chromosome. FISH analyses were performed using commercially available probes of both X and Y chromosomes, as well as BACs (Bacterial Artificial Chromosomes). Of the 16 patients with an idic(Y), all are SRY+, with the exception of a female bearing an idic(Yq) SRY-, which explains her phenotype. A predominant 45,X cell line in blood lymphocytes and/or gonads seems to explain the female phenotype of 6 other cases of idic(Y). As for t(X;Y) cases, a DAX duplication was found in the female patient, explaining her sexual differentiation despite the presence of SRY. In the remaining t(X;Y) cases, at least one of the XX males has breakpoints below the molecular region frequently rearranged in such cases. Finally, of the 6 females with a normal Y chromosome, one was diagnosed with probable familial androgen resistance, thus possibly explaining her condition. Also, gonadal mosaïcism was excluded in at least one case. These results therefore highlight the necessity of further molecular characterization in cases of structurally abnormal Y chromosomes and/or sex reversal, as this not only help explaining the phenotype of these patients, but could also improve genetic counselling and cares offered. *Support : RMGA-FRSQ and Fondation de lHôpital Sainte-Justine.*.

Towards a molecular genotype-phenotype correlation of small supernumerary marker chromosomes (sSMC) by applying microdissected sSMC probes on a 21.5 k BAC array-CGH. *A. Weise[1], K. Mrasek[1], N. Kosyakova[2], T. Liehr[1], P. Stankiewicz[3], S.W. Cheung[3], W.W. Cai[3].* 1) Institute of Human Genetics , Jena, Thuringia, Germany; 2) Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow 115478, Russia; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Small supernumerary marker chromosomes (sSMC) are present in 0.043% of newborns and about 2.5 million humans are carriers of sSMC. In about 30% of sSMC carriers, an abnormal phenotype is observed. Clinical outcome of sSMC is difficult to predict as various phenotypic consequences can appear due to (i) differences in euchromatic DNA-content, (ii) uniparental disomy (UPD) of the sSMCs homologous chromosomes, and/or (iii) different degrees of mosaicism. To address point (i) we microdissected DNA of 23 different sSMC cases by glass needle, amplified the obtained DNA by DOP-PCR and hybridized the product to a 21.5 k whole genome BAC CGH-array. To confirm the array data, the suggested breakpoint spanning BAC clones were applied in FISH on metaphase spreads from the three patients, who are presented here in more detail. The first case belongs to the most frequently observed sSMC group, an inv dup(15) case. The second case was an isochromosome 12p, found in patients with Pallister-Killian syndrome and the third one was an unusual sSMC derived from chromosome X, inherited from the patients father. We demonstrate that DOP-PCR amplified samples from the microdissected sSMC hybridized on CGH-array is straightforward in terms of time, use of resources, and sensitivity. Almost 50 years after the description of the first sSMC, molecular cytogenetics combined with array CGH provides a comprehensive approach for the characterization of sSMCs. The new knowledge coming from that should lead to an improved genetic counseling of cases with de novo sSMC based on a molecular genotype-phenotype correlation. Supported by the Dr. Robert Pfleger-Stiftung, BCM postdoc fellowship, Boehringer Ingelheim funds and DFG (436 RUS 17/109/04).

One-hundred years of mental retardation and dysmorphic features solved: der(10)t(2;10)(q37;26)the phenotype described in 5 individuals over 3 generations. *R.L. Bennett[1], G.P. Jarvik[1], K.A. Leppig[2], C. Disteche[1].* 1) Div Medical Genetics, Univ Washington, Seattle, WA; 2) Group Health Cooperative, Seattle, WA.

The Medical Genetics Clinic at the University of Washington has followed the proband with MR and dysmorphic features since 1962. The 42 y.o. proband has a healthy older sister and two younger brothers, one of whom has a daughter with similar devleopmental delay and dysmorphic features. The proband's mother is healthy at age 66, and she had three similarly affected siblings, and two siblings with a more severe phenotype. The proband's maternal grandmother was unaffected, but she had a sister who died at age 21 and had a similar phenotype to the proband. Although the clinical and family history was compatible with a chromosome translocation, the chromosomal anomaly could not be identified by prometaphase G-banded cytogenetic analysis. Subtelomeric FISH analysis using the panel available from Vysis, Inc. identified an unbalanced .ish der(10)t(2;10)(q37;q26)(D2S447+,Z96139+,D102490+) result in the female proband and other affected family members. We review clinical data on affected relatives ranging in age from age 1 y. to age 71. Dysmorphic features include wide set eyes, broad and prominent nasal bridge, cupped ears, high palate, poorly aligned teeth, fifth finger clinodactyly, single palmar crease, short broad hands with shortened distal phalanges, IQ ranging from 60-70, overlapping of toes, flexion limitation at the elbows with limitations on supination and pronation, delayed motor and speech development, and seizure disorder. Two individuals within the family with a more severe phenotype with death during childhood likely inherited another unbalanced derivative chromosome. Subtelomeric FISH analyysis has permitted the identification of the etiology of approximately 6% of cases with MR of unknown cause as well as clarifying the basis of "private" family syndromes. It is for this reason that subtelomeric analysis has become a vital adjunct for routine cytogenetic analysis.

Aneuploidy screening in mature human sperm of 40 infertile men before ICSI treatment. *G. Schwanitz[1], U. Paetzold[1], R. Schubert[1], K. van der Ven[2], M. Montag[2].* 1) Inst Human Genetics, Univ Bonn, Bonn, Germany; 2) Dep of Obstetrics and Gynecology, Univ Bonn.

The frequency of aneuploidy of chromosomes 8, 9, 11, 13, 15, 18, 21, X, Y and diploidy in sperm nuclei of 40 infertile probands and 10 healthy men of proven fertility were compared. The patient group was subdivided by the type of spermatogenic abnormalities into OAT, OT, AT and T comprising each 10 probands. Aneuploidy and diploidy frequency were analysed by FISH using repetitive and single copy DNA probes. The efficiency of hybridization was higher than 99% for each probe combination after development of specific hybridisation protocols. The total number of aneuploid nuclei with aberrations of the sex chromosomes was significantly increased in patients (0.33%) compared to the controls (0.18%; p.lt. 0.001). Of the 3 possible disomy combinations - XY, XX, and YY - the XY karyotype was more frequent in patients and controls with highly significant differences between the two groups (0.14, 0.08%; p.lt. 0.001). The total amount of aneuploidy of the autosomes was significantly increased in patients (0.45%) compared to the controls (0.26%; p.lt. 0.05). An unequal interchromosomal distribution of hyperploidy was found. The highest frequencies of disomy and nullisomy were observed for chromosome 11 in both patients (1.41 and 0.28%) and controls (0.80 and 0.15%). The chromosomes 8, 9, 13, 15, and 21 showed comparable amounts of disomic (0.14 - 0.18%) and nullisomic (0.07 - 0.11%) nuclei. Striking were the low aneuploidy rates of chromosome 18 in patients and control group (0.17, 0.08%). The disomy rates were higher than those of the nullisomies for all autosomes investigated. The frequency of diploid nuclei was significantly higher in patients (0.04%) than in controls (0.02%, p.lt. 0.001) but comparing them to aneuploidies the latter group was more than ten times higher for sex chromosomes and autosomes. There were differences among the four subgroups with OAT patients showing the highest and T patients the lowest rate of diploidy. The different types of spermatogenic abnormalities revealed a different quantitative and qualitative distribution of aberrations.

A mosaic karyotype 47,XX,+r(Y)(p11.1?q11.2)/46,XX in a female patient referred to ICSI due to male factor infertility. *F. Dechend[1], B. Pabst[2], K. Miller[2], S. Schubert[2], G. Wilke[1], N. Graf[1].* 1) Humangenetik Hildesheim, GMP AJWG, Hildesheim, Hildesheim, Germany; 2) Institute of Human Genetics, Hannover Medical School, Hannover, Germany.

We report a case of a mosaic karyotype 47,XX,+r(Y)(p?11.1q11.2)/46,XX in a 27 year old female nullipara, who was cytogenetically diagnosed before performing ICSI. The woman is phenotypically and gynaecologically normal with the exception of an endometriosis uteri externa, but her 25 year old husband exhibits an OAT-syndrome. Chromosome analysis of lymphocytes from her subfertile husband revealed a normal 46,XY karyotype, while we found in about 60% of her lymphocyte cells a 46,XX karyotype and in 40% of her cells an additional ring chromosome Y. We were able to confirm these findings in fibroblasts from different tissues (ovar, skin and buccal mucosa). From FISH and PCR analysis it is suggested that the breakpoints of the ring chromosome Y are in p11.1, lacking most of the short arm, including SRY and the TSPY clusters; and in q11.2 between the AZFb and AZFc region. Although the TSPY clusters were deleted we could show by PCR and sequence analysis that at least one functional full-length TSPY copy is present. Whether the patient carries a risk for gonadoblastoma or has an increased risk for i.e. ovarian cancer is difficult to predict. To our knowledge, this is the first reported case of a chromosomal mosaicism with two X chromosomes and one ring Y chromosome. To elucidate the origin of the ring chromosome Y further studies are under progress.

Paternally inherited interstitial duplication of chromosome 13q. *J.H.M. Knoll, D.L. Bridges, A.J. Miller, M.L. Begleiter, H.H. Ardinger.* Children's Mercy Hospitals and Clinics, School of Medicine, University of Missouri - Kansas City.

Inherited interstitial duplications of chromosomes are extremely rare. Four members of a family with an inherited duplication of chromosome 13q were studied. The proband was a 4 year old female with developmental delay and mild facial dysmorphology whose clinical findings overlapped those observed in chromosome 22q11.2 deletion syndromes. The region 22q11.2 was normal by FISH. Chromosome analysis with GTG-banding revealed a duplication of chromosome 13q22.1q32. A similar duplication was observed in the probands father and one of her older sisters. All carriers of the duplication had a history of developmental delay. One sister with normal intelligence did not carry the duplication. By FISH with a whole chromosome 13 paint probe, we confirmed the chromosome 13 origin of the additional chromatin on the abnormal chromosome 13. The duplication did not extend into 13q34 as FISH with a chromosome 13q subtelomeric probe (D13S327) showed a normal hybridization pattern. The duplication includes 3 chromosomal bands at the 550 band level and we estimate that it spans ~15 million nucleotides of DNA. Given the size of this duplication, it seems surprising that the phenotype is not more severe. Chromosome 13q22.1 q32 is being clinically dissected by examining in silico the genes in the region and comparing the phenotypic findings between duplication carriers.

Craniosynostosis and distal 5q duplication. *J. Wang[1], M. Steinraths[1], B. Lomax[2], S.-L. Yong[2], M.I. Van Allen[2].* 1) Cytogenetics; 2) Medical Genetics, CW Health Centre of B.C., Vancouver, B.C.

Distal 5q duplication has been reported in less than 30 cases, with craniosynostosis present in six. We report two new cases with distal 5q duplication and craniosynostosis. The first case is a 6 month-old boy born at 39 weeks gestation by planned Caesarean section with low birth weight and length. He has an asymmetric skull and dysmorphic features including a long, flat philtrum and thin upper lip. Developmental delay is apparent at 6 months of age, primarily evident as gross motor delay. CT head at two weeks of age showed premature synostosis of sagittal, lamboidal and metopic sutures, with 3D reconstruction CT demonstrating multiple abnormal foramina. Cytogenetic and CGH analyses showed a karyotype of 46,XY,der(10)t(5;10)(q33.?2;q26.3). FISH analysis revealed both MSX2 and FGF4R genes to be duplicated. The second case is a 6 year-old girl born by emergency Caesarean section for failure to progress after spontaneous onset of labor at 39 weeks. Birth weight was 6 lb. 12 oz. (25-50th percentile). Prominence of the forehead and ridging of the metopic suture was noted from 5 months of age and a CT head demonstrated craniosynostosis of the metopic suture. Her height, weight and head circumference are all below the 5th percentile. She has facial dysmorphisms including bilateral epicanthal folds and ridging of the metopic suture. She has mild developmental delay, with notable delays in both expressive and receptive language. Bone age was advanced, with a bone age of 18-24 months at 14 months chronological age. Cytogenetic and CGH analyses showed a karyotype of 46,XX,der(17)t(5;17)(q35.1;p13.3). FISH analysis showed the Miller-Dieker critical region (17p13.3) to be intact. In consideration of our two cases and review of partial 5q duplication cases previously reported, including 7 cases with 5q31-qter, 6 cases with 5q32-qter, 5 cases with 5q34-qter, and 4 cases with 5q35.1-qter or 35.2-qter, we were able to refine genotype-phenotype correlations for distal 5q partial duplications. This will be of value in genetic counseling and clinical management of this previously diverse group of patients.

Supernumerary derivative chromosome 15 in one of two developementally retarded twins - longitudinal study. *D. Hansmann[1], E. Tuschen-Hofstätter[2].* 1) Inst Prenatal Diagnosis, Meckenheim, Germany; 2) St. Marien Hospital, Children's Department, Bonn, Germany.

Indication for the present cytogenetic and clinical examinations was the developmental retardation of twins after in vitro fertilization following sterilisation. Since the maternal age at pregnancy was not increased, no invasive prenatal investigation was performed, particularly because 3 ultrasound scans carried out at gestational week 12, 16, 20 showed a normal development of both foetuses and no evidence of malformations. Twin II was delivered first by secondary caesarean section at gestational week 39. Apgar scores for both twins: 9 /10 after 5 /10 minutes. After an infection at the age of 4 weeks twin II suffered from acute asphyxia, lactacidosis, two cardiac arrests, and multiple organ failure. He developed a postinfectious hydrocephalus, infantile cerebral palsy, symptomatic epilepsy and severe developmental delay. Twin I at that time was slightly retarded in his developmental milestones. Except mild muscular hypotonia he showed no malformations or dysmorphisms. At the age of 12 months both children were severely retarded and chromosome analyses were performed on lymphocyte cultures. Twin II showed a normal male karyotype (46,XY, GTG, 30 mitoses, 400 B/G). Twin I revealed a supernumerary derivate 15 (SMC) in 30 mitoses, which was dicentric and contained euchromatic material between the 2 centromeres. Karyotype: 47, XY,+der(15)ish(pterq13::q13pter (GTG,CBG,WCP15,SNRPN). Chromosome findings in the parents were normal, thus the marker chromosome originated de novo in the patient. At the age of 5 years the boy showed the phenotype of 15q13 triplication. The question of whether in vitro fertilization leads to an increase in structural de novo aberrations is looked into on the basis of our own findings in 350 prenatal cases.

Unusual case of double reciprocal translocation in a newborn. *O. Castro, K. Clark, G. Jervis, J. Moore.* Cytogenetics, Genzyme Genetics, Tampa, FL.

Cord blood from a newborn was studied for a maternally inherited t(1;16). Results showed a balanced t(1;16)(q12;q11.2)mat with an additional reciprocal translocation (rcp) involving the second chromosome 16 homologue, t(5;16)(p13;q24). FISH analysis showed these translocations to be apparently balanced. Chromosome analysis of the fathers blood showed the t(5;16)(p13;q24). Maternal testing had been performed previously (at another lab) due to a history of one healthy child and 4 spontaneous abortions (SAb). A search of Genzyme Genetics database from January 2002 through December 2004 showed 6 additional cases of double translocations (4 bloods and 2 amnios). Three cases (3/6) had 2 rcps; one case (1/6) involved the same homologue of chromosome 11 in both translocations. Three cases (3/6) had 1 rcp and 1 Robertsonian translocation (rob); two of the robs were unbalanced. Clinical indications were: Family history of translocation (4); Advanced maternal age (1); Failure to thrive (1) and Multiple congenital anomalies (1). Inheritance patterns of the 4 cases with 2 rcp (includes our original sample) showed that in 2 cases each parent contributed one translocation; these families also had repeat SAb. A third case had two maternal translocations following 2 abnormal amnios with 2 different translocations. The fourth case has unknown parental origin as maternal testing was normal and no paternal results are available. Two of the 3 rcp/rob cases showed paternal inheritance of the rcp with unbalanced de novo Robertsonian products. In the third case, the mother was a balanced carrier of both translocations, detected as the follow up to MCA in a child with the unbalanced rcp product. Clustering of translocations were seen with chromosome 11 (5 translocations); chromosome 13 (4 translocations); chromosome 16 (3 translocations) and chromosome 1 (3 translocations). Chromosomes 11 and 16 showed breaks in both arms; chromosome 1 and the acrocentric chromosomes only showed breaks in the long arm. Inheritance risk assessment may be available when each parent carries a translocation, but is extremely difficult to determine when an individual carries two translocations.

Cytogenetic analysis on the placenta using primary cultures established from Percoll gradient purified trophoblast cells. *K.K. Ho[1], Y.M. Chin[2], W.S. Ng[2], J.A. Tan[1].* 1) Dept Molecular Medicine, Fac. Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Div of Genetics, Fac. Science, University of Malaya.

Cytogenetic analysis on term placentas is not commonly performed as compared to chorionic villi analysis mainly due to the inherently low success rate in culture setup of placental cells. The difficulties in establishing viable and proliferating primary trophoblast cultures has caused some laboratories to move from conventional G-banding analysis to molecular techniques such as FISH and CGH.

Percoll gradient centrifugation is the standard method to obtain highly purified and viable trophoblasts for establishment of primary cultures, which can be later used for biochemical assays and cell-matrix interaction studies. However, this utility has never been adopted for cytogenetic analysis as the primary trophoblast cultures used have never progressed beyond the first passage.

In this study, the potentials and pitfalls of utilizing Percoll gradient centrifugation to purify trophoblasts and to establish viable primary trophoblast cultures for placental cytogenetic analysis were evaluated. Trophoblast primary cultures were established according to a modified protocol of Kliman *et al.* (1986). In addition, cultures of explanted and digested villi from termed placentas were used as comparisons. Cultures were harvested using either the standard trypsin-dispersion method or cell cycle synchronization in order to obtain high-resolution chromosomes.

Cultures established from Percoll gradient purified trophoblast were free from tissue debris but exhibited spontaneous cell fusion, indicating differentiation of cytotrophoblasts into syncytiotrophoblasts. Occasionally, viable and proliferating cultures were obtained after prolonged culture for 3 weeks compared to 2 weeks for tissue explant cultures. Cell cycle synchronization was successfully performed using a MTX block followed by a thymidine release protocol. Chromosomes of 800 band level were attainable. Further work on the optimization of trophoblast cultures is still being carried out to ensure feasibility of routine cytogenetic diagnosis on term placentas.

Developmental Genome Anatomy Project (DGAP): Characterization of Genes Critical to Specific Developmental Pathways. *D.J. Donovan[1], F.S. Alkuraya[1,2], G.A. Bruns[2,4], R. Eisenman[2], J.F. Gusella[3,4], D.J. Harris[2,4], A.W. Higgins[1,4], H.G. Kim[3,4], K.M. Kocher[4], S. Kulkarni[1], N.T. Leach[1,4], A.H. Ligon[1,4], W. Lu[1,4], R.L. Maas[1,4], S.D. Moore[1,4], F. Quintero-Rivera[3,4], I. Saadi[1,4], R.E. Williamson[4], B.J. Quade[1,4], C.C. Morton[1,4].* 1) Brigham & Women's Hospital, Boston, MA; 2) Children's Hospital, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA.

The Developmental Genome Anatomy Project (DGAP) is a collaborative effort to identify genes involved in human development and disease. By studying patients with apparently balanced *de novo* chromosomal rearrangements and at least one major congenital anomaly, we have correlated specific patient phenotypes to the disruption or dysregulation of genes at chromosomal breakpoints. From more than 180 cases, our progress to date includes over 130 FISH-mapped breakpoints from 64 cases. Of these, 80 breakpoints from 50 cases have been resolved to within a single BAC clone. Twenty-five breakpoints have been analyzed in detail and found to disrupt a gene directly. Attractive candidate genes for the autosomal form of Kallmann syndrome, seizures, behavioral disorders and hearing loss are among those recently identified. Eighteen breakpoints have been cloned, revealing nine microdeletions, one deletion, eight insertions, two duplications, and two balanced rearrangements at the nucleotide level. Most breakpoints fall within the intron of a gene, none fall within an exon, and one falls within a 3 UTR. Only three gene fusions have been found to date by RT-PCR. For the five instances in which the breakpoint fell outside of a gene, a gene appears to have been disrupted by the other breakpoint. Mutational analyses of individual collections with phenotypes similar to a DGAP case are ongoing in eight cases. We also are in the process of generating or characterizing mouse mutations in seven candidate genes from six DGAP cases. As the DGAP data collection has grown, we are working towards building a haplo-sufficiency map of the human genome for the developmental biology and medical genetic communities (http://dgap.harvard.edu).

Congential hypothyroidism, atrial septal defect, and hearing loss associated with 7q31.3q32 interstitial deletion.
R. Spaetgens, K. Bowser, J.E. Chernos, A.M. Innes. Department of Medical Genetics, University of Calgary and Alberta Children's Hospital, Calgary, Canada.

We describe a young girl with a *de novo* interstitial deletion 7q31.3q32, and congenital hypothyroidism, congenital heart defect, and hearing loss. Pregnancy and delivery were unremarkable. Hypotonia and mild dysmorphism prompted cytogenetic studies in the newborn period. Routine G-banded chromosome analysis revealed a normal female karyotype. Congenital hypothyroidism was diagnosed following a positive newborn screen and thyroid replacement commenced at 6 days of age. An atrial septal defect was also diagnosed in the newborn period. In addition, the patient later developed bilateral sensorineural hearing loss. She has mild dysmorphic facial features. Expressive language is markedly impaired and there are behaviour concerns that include hyperactivity and aggressiveness. Growth parameters are within the normal range. At nine years of age she was re-evaluated and studies were undertaken to rule out subtelomeric anomalies. Reassessment of the karyotype identified a subtle interstitial deletion of the long arm of chromosome 7. Small deletions in this region of 7q are very rare in contrast to the larger deletions seen at the proximal and distal regions of 7q which are associated with recognizable phenotypes. The 7q31q32 region is known to contain genes that are associated with speech and language disorders/autism (FOXP2), and autosomal recessive deafness (DFNB4 and DFNB17). In addition, the gene for Pendred syndrome (SLC26A4) which is characterized by sensorineural hearing impairment, abnormal iodine transport in the thyroid gland, and temporal bone abnormalities, is located within this region. Monosomy for these genes could account in part for our patients phenotype. There are no genes in this region that have so far been implicated in cardiac development; however there are a number of reports of patients with congenital heart defects, particularly ASDs, who have deletions involving the 7q31 region. This area therefore may be of interest in identifying genes involved in cardiac development.

Double paternal nondisjunction in an infant with transient neonatal diabetes mellitus and Klinefelter syndrome.
T.M. Felix, M.J. Tansey, S.R. Patil, J.C. Murray, J.M. Dagle. Department of Pediatrics, University of Iowa, Iowa City, IA.

Transient neonatal diabetes mellitus (TNDM) is a rare cause of severe hyperglycemia in infants with an incidence of approximately 1 in 400,000 live births. Insulin therapy is initially required with complete remission by 18 months of age. Approximately 40% of the patients developed diabetes mellitus type II later in life. TNDM is usually caused by over-expression of a paternally expressed imprinting locus on chromosome 6q24. This over-expression can be caused by paternal uniparental disomy (UPD), paternal duplication of the region 6q24 and loss of maternal methylation region at 6q24. Two genes, ZAC and HYMAI, located at 6q24, have relaxation of imprinting expression and are candidate genes for TNDM. We report on a baby who developed TNDM on the first day of life. He was born by cesarean section secondary to decreased fetal movements and poor fetal growth at 39 weeks of gestation. Birth weight was 1835 g and Apgar score 8 and 9 at the first and fifth minutes respectively. At day 1 he fed poorly and hyperglycemia with low levels of insulin was recorded. He was treated with intravenous insulin therapy with good resolution. At physical examination the baby was thin and macroglossia and hypertelorism were noticed. Karyotype showed 47,XXY chromosomes. DNA was collect from the baby and his mother. Microsatellite markers and the 50K XbaI GeneChip(Affymetrix) Mapping assay were analyzed. Both analyses showed no maternal contribution on chromosome 6. Using the 50K GeneChip, 405 out of 4100 markers on chromosome 6 were informative for UPD. The entire length of chromosome 6 showed no maternal contribution and 423 markers were heterozygous confirming paternal uniparental heterodisomy. The X chromosomes were one of maternal origin and the other of paternal origin. This suggests that both anomalies resulted from a double paternal meiosis I error, leading to paternal UPD6 and a sex chromosome anomaly. One previous case with XXX and UPD6 is also reported suggesting mechanisms predisposing to nondisjunction may be in play and that all cases of neonatal diabetes mellitus should be karyotyped.

Higher zinc concentrations in seminal fluid are associated with lower levels of single and double strand DNA breaks in human sperm. *F. Marchetti[1], T.E. Schmid[1,2], R.H. Weldon[2], A. Baumgartner[3], D.W. Killilea[4], L.M. Montelius[4], B.N. Ames[4], D. Anderson[3], B. Eskenazi[2], A.J. Wyrobek[1].* 1) Biosciences Directorate, Lawrence Livermore Natl Lab, Livermore, CA, USA; 2) School of Public Health, University of California in Berkeley, Berkeley, CA, USA; 3) Department of Biomedical Sciences, University of Bradford, Bradford, UK; 4) Childrens Hospital Oakland Research Institute, Oakland, CA, USA.

Zinc has essential roles in a wide range of biochemical and cellular processes, and zinc deficiencies have been associated with both chromosomal damage and infertility. Zinc is especially critical in sperm development, where it is predominantly located in the outer dense fibers of sperm flagella and in the nucleus where it binds stoichiometrically with protamine 2 during compaction of sperm chromatin. We examined the association between the levels of zinc in seminal plasma and the magnitude of sperm DNA strand damage in a cohort of 87 generally healthy non-smoking male volunteers with no history of fertility problems. Single sperm electrophoresis (Comet assay) under alkaline and neutral conditions was employed to measure single-strand DNA damage (breakage or alkali-labile sites) and double-strand DNA breakage, respectively. Zinc seminal fluid levels were determined using inductively coupled plasma-absorption emission spectroscopy (ICP-AES). Seminal zinc concentration was inversely associated with the magnitude of single- and double-stranded DNA damage, i.e., percent DNA in Comet tail under alkaline (=-0.018, p=0.008) and neutral conditions (=-0.026, p=0.003) after adjusting for age, duration of abstinence, and daily caloric intake. These findings suggest that men with lower levels of zinc in their seminal plasma carry more DNA breaks in their sperm. DNA breaks in sperm are expected to increase the risk for heritable chromosomal aberrations in the offspring, which would be expected to increase their risks for malformations and other developmental defects. This work was performed in part under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory, contract W-7405-ENG-48, with funding from NIEHS Superfund P42ES04705.

Vitamin C intake modifies the effects of aging on DNA strand damage in sperm. *T.E. Schmid[1,2], B. Eskenazi[2], F. Marchetti[1], S. Young[2], R.H. Weldon[2], A. Baumgartner[3], D. Anderson[3], A.J. Wyrobek[1].* 1) Biosciences Directorate, Lawrence Livermore National Laboratory, Livermore, CA; 2) School of Public Health, University of California in Berkeley, Berkeley, CA; 3) Department of Biomedical Sciences, University of Bradford, Bradford, UK.

The trend for men to have children at older ages raises concerns that age may increase the risk of transmitting germ-line mutations that will be detrimental for the genetic health of offspring. Lifestyle factors such as diet may reduce such paternally transmitted genetic risks. In particular, vitamin C (ascorbic acid), a known scavenger of reactive oxygen species (ROS), has been shown in prior studies to reduce oxidative stress in sperm in vitro. We hypothesized that advancing age induces DNA strand damage in sperm and that vitamin C intake reduces the impact of aging on sperm DNA damage. We used sperm electrophoresis to detect single-strand DNA damage (alkaline sperm Comet assay) in the sperm of 90 non-smoking men (range 22-80 years) with no known fertility problems. We found that the amount of DNA damage (i.e., percent sperm DNA in the comet tail) was higher in the 60-80 than in the 20-29 year age groups (50 vs. 43%; p=0.03); adjusting for covariates, there was a 0.2% increase in sperm DNA damage per year of age (p=0.003). Independent of age, men with high daily vitamin C intake had significantly less sperm DNA damage than men with low intake (38 vs. 45%; p=0.006). When we dichotomized the intake of vitamin C at the median, we observed an increase in DNA damage with increasing age among low consumers of vitamin C (p=0.004), but no increase with age in those who consumed higher levels of vitamin C (p-value on the interaction term of age and vitamin C intake = 0.03). These findings suggest that a component of sperm DNA damage seen with age is the consequence of increased oxidative stress in the male reproductive tract. [This work was performed in part under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory, contract W-7405-ENG-48, with funding from NIEHS Superfund P42ES04705 and European Community contract QLG4-CT-2002-51611.].

A neocentromere derived from a supernumerary marker deleted from the long arm of chromosome 6. *N. Qin[1], J. Bartley[1], J. Wang[2], J. Jogenson[1], P.E. Warburton[3].* 1) Genzyme Genetics, Orange, CA; 2) Genzyme Genetics, Pasadena, CA; 3) Mount Sinai School of Medicine, New York, NY.

Neocentromeres are new centromeres formed at previously non-centromeric locations. A neocentromere is a rare phenomenon; to date, 72 cases of neocentromeres involving 19 different human chromosomes have been described [1, 2, 3]. Chromosomes involved include X, Y, 1, 2, 3, 4, 5, 7, 8, 9, 10, 11, 12, 13, 14, 15, 17, 20, and 21. It has been assumed that the neocentromere can occur on any of the chromosomes. In the present study, we report a first case of a neocentromere derived from chromosome 6. Cytogenetic studies were performed on the parents of a phenotypically abnormal child with a balanced reciprocal translocation between chromosomes 4 and 15 (this test performed by another lab). The mother had normal karyotype. However, though phenotypically normal, the father had the same 4;15 translocation as his child. In addition, he had an interstitial deletion of the long arm of chromosome 6 between bands 6q16.2 to 6q22.2, as well as a supernumerary marker chromosome in every cell examined. FISH studies indicated that the marker was derived from chromosome 6 and contained no alpha satellite and no subtelomere sequences. Immunofluorescence analysis showed a positive signal for the CENP-C antibody, confirming the neocentromere formation. Review of the childs karyotype showed, in addition to the 4;15 translocation, an interstitial deletion in the long arm of chromosome 6 with no marker chromosome. Therefore, the abnormal phenotype of the child arises from the interstitial deletion, and not the translocation. Our case adds chromosome 6 to the growing list of chromosomes for which neocentromeres have been reported. In this presentation, we will also delineate the clinical phenotype associated with an interstitial deletion of 6q16 to 6q22.

A balanced de novo translocation t(15;16)(p11.2;q11.2) mediates a position effect in an Angelman-like patient. *P. Finelli[1,2], S. Russo[1], M. Masciadri[1], M.P. Recalcati[1], D. Giardino[1], F. Faravelli[3], L. Larizza[4].* 1) Lab Medical Genetics, Istituto Auxologico Italiano, Milan, Italy; 2) Dip. di Biologia e Genetica Università di Milano; 3) Struttura Complessa Genetica Umana, Ospedali Galliera, Genova; 4) Genetica Medica, Dip. di Medicina, Chirurgia e Odontoiatria, Università di Milano.

We report on a patient referred to our laboratory as affected with Angelman Syndrome. The more common known defects underlyng AS, as 15q11-q13 microdeletions, 15qpatUPD and IC microdeletions were ruled out. Cytogenetic analysis revealed the presence of a de novo balanced translocation t(15;16)(p11.2;q11.2). FISH characterization, by using -satellite and DNA/rRNA coding sequences allowed to locate the 15p bkp in 15p11.2, within heterochromatic sequences, while BACss contig (16q11.2), allowed to map the 16q bkp in the CDA08 gene interrupting it. Quantitative analysis performed by Real Time PCR showed the presence of a truncated transcript lacking the COOH-coding portion of the gene, confirming the previously identified bkp mapped between exons 11-12. As the 15 bkp is within heterochromatic region, we focused on 16q bkp region, selected genes flanking the bkp and investigated whether their expression profile and function might be related to the patients phenotype. Preliminary results of the in progress quantitative analysis of different gene transcripts, by Real Time PCR, evidenced a halved expression of the NETO2 gene, not disrupt, located at 11 Kb centromerically to CDA8. We aim at studyng other flanking genes to verify whether the patient's severe neurological phenotype might result from structural haploinsuffinciency of CDA8 and functional haploinsufficiency of NETO2 and additional genes. The latter effect may be mediated by the separation of cis-acting elements in 16p11.2 or by the local alteration of chromatin structure. Although it's currently unknown which mechanism disturbs the NETO2 transcriptional control, a further example of overthrow of gene expression through position effect caused by chromosomal rearrangement is delineated with potential disclosure of novel genes not involved in genetic diseases.

Study of meiotic segregation in three men with 14;22 Robertsonian translocation. *K. MORADKHANI[1,2], J. PUECHBERTY[1,2], S. BHATT[1,2], G. LEFORT[2], P. VAGO[3], P. SARDA[2], F. PELLESTOR[1].* 1) Cytogenetics of Human Gametes, Institut of Human Genetics, Montpellier, Languedoc, France; 2) Department of Medical Genetics, Arnaud de Villeneuve University Hospital, Montpellier, France; 3) Department of Cytogenetics, CHU Clermont-Ferrand, France.

Study of meiotic products by fluorescence in situ hybridization (FISH) in male carriers of Robertsonian translocations constitute an efficient tool for estimating the proportion of normal sperm (alternate segregation) in male patients with chromosome abnormalities. The information derived can be used as a key element in genetic counseling and decision making in the choice of assisted medical procreation (AMP) methods. To date, the meiotic segregation of rob(14q22q) has not been studied. We present the results of sperm analysis of three men heterozygous for 14;22 Robertsonian translocation. The three translocation carriers, with (1) oligoasthenoteratospermia, (2) teratospermia and (3) normospermia, were ascertained through fertility work-up. After fixation on slides, sperm nuclei were decondensed using 0.5M NaOH solution. Sperm analysis was performed by dual color FISH technique, using either directly labelled locus-specific probes (LSP) or whole chromosome painting probes (WCP). A mean of 5250 sperm nuclei were scored per patient by Locus specific probes (ranging from 5087, 5237 and 5428 respectively) and 4704 sperm nuclei per patient by WCP (3279, 5330 and 5504 respectively). The mean frequencies of normal and balanced spermatozoa ranged from 78.97% for LSP and 81.01% for WCP. When compared, both LSP and WCP probes gave similar results for segregation patterns, demonstrating the efficiency of the two procedures for sperm study in Robertsonian translocation carriers. This study shows that the segregation pattern of this rare Robertsonian translocation is identical to that of the rare and common Robertsonian translocations previously analysed. These data support the existence of similar meiotic behaviour for all the nonhomologous Robertsonian translocations. This study was supported by a French reseach project PHRC (N7732) from the C.H.U. of Montpellier.

Male intertility,45,X/46,X,del(Y)(q11.22)/46,XY mosaic karyotype, and Y chromosome microdeletions in a 42 year-old man. *L. Fan[1], R. Fetni[2], R. Mio[1], A. Chan[1], P. Scott[1].* 1) Montreal Children's Hospital, McGill University Health Center, 4060 ST-Catherine W, PT-420, Montreal, Quebec, Canada; 2) St-Justine Hospital, University of Montreal, 3175 Cote-St-Catherine, Montreal, Quebec,Canada.

We present the results of laboratory investigations, with emphasis on the Y chromosome, in a male referred for infertility. Cytogenetic analysis revealed the presence a mosaic karyotype of the following constitution: 45,X (50%); 46,XY (12.5%); 46,X,del(Y)(q11.22) (37.5%). Molecular analysis using PCR amplification of the AZF regions and band densitometry revealed partial deletion of the AZF regions -b and -c, consistent with cytogenetic findings. Unique to this patient is the observation of a normal cell line and a rearranged Y chromosome in the form of a deletion of the long arm following cytogenetic and molecular analysis. These findings support the use of PCR-based analysis of Y chromosome organization, in addition to cytogenetic analysis, in the diagnosis and clinical management of male infertility, even in the presence of mosaicism.

Characterization of a Xp11.22 microdeletion in a male patient presenting with failure to thrive, mental retardation, dysmorphic features, microgenitalia and tubulopathy of Dent's type. *V. Drouin-Garraud[1], F. Broux[2], P. Saugier-Veber[1,3], G. Joly-Helas[4], E. Bessenay[1], T. Frebourg[1,3].* 1) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Department of Pediatric, Rouen University Hospital, 76031 Rouen, France; 3) Inserm U614, Faculty of Medicine, 22 boulevard Gambetta, 76183 Rouen, France; 4) Laboratory of Cytogenetics, Rouen University Hospital, 76031 Rouen, France.

Dent's disease (DD) is a rare X-linked hypercalciuric nephrolithiasis resulting from inactivating mutations within the *CLCN5* gene located in Xp11.22 and which encodes a voltage-gated chloride channel. DD is characterized by low molecular weight proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, rickets and eventual renal failure. F. is a 13 years old boy born at term after an uneventful pregnancy with normal mensurations. He presented at birth with dysmorphic facial features and high vaulted narrow palate, hypogenitalism, ventricular septal defect and horseshoe kidney. He developed a tubulopathy with hypercalciuria and nephrocalcinosis at the age of seven associated with mental retardation and failure to thrive. Ophthalmologic examination was normal. At 13 years, he had no language, very short stature (1,15m, -6 SD) and dysmorphic facial features. His mother and one of his two sisters had obvious dysmorphic facial features. R-banding lymphocytes chromosomal analysis (550 bands level) was normal. The existence of a tubulopathy compatible with the diagnosis of DD in this boy in association with numerous unrelated symptoms led us to suspect a Xp11.22 microdeletion involving the *CLCN5* gene. Indeed, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments), we identified a microdeletion removing the entire *CLCN5* gene and spanning on at least 2 Mb. His mother and his two sisters also carried the microdeletion. This case report represents the first case of a DD associated with developmental and malformative syndrome in the context of a Xp11.22 microdeletion. Fine mapping of this Xp11.22 microdeletion would facilitate the positional cloning of a gene involved in X-linked mental retardation.

Unusual clinical features observed in a young girl having an inherited maternal translocation (13;14) with a mixed maternal uniparental hetero and isodisomy 14. *K. Krabchi[1], M. Ferland[1], F. Halal[2], L. Russel[2], A.M.V. Duncan[3], R. Drouin[1].* 1) Dept of Pediatrics & Service of Genetics, Sherbrooke Univ, Qc, Canada; 2) Div of Medical Genetics, McGill Univ Health Ctre, Mtl, Qc, Canada; 3) Lab of Cytogenetics, Montreal Childrens Hosp, Mtl, Qc, Canada.

We report a case of a 20-month-old girl who has inherited maternal balanced Robertsonian translocation detected by conventional cytogenetic techniques. Her phenotype included : growth retardation, hypotonia, significant feeding difficulties, hyperextensible joints, microcephaly, small anterior fontanel, prominent forehead, telecanthus and depressed nasal bridge. The probands clinical and cytogenetic features alerted us about the possibility of an uniparental disomy (UPD). By karyotyping her asymptomatic mother and sister, we identified in both the same balanced translocation. Concurrently, we excluded the possibility of a trisomy 14 mosaicism. In order to demonstrate UPD and to ascertain the parental origin of both chromosome 14, a molecular genetic study using microsatellite markers specific to chromosome 14 was performed. The distribution of the markers on the chromosome 14 suggested the presence of a heterodisomy of the proximal and distal long arm segments combined to an isodisomy of the median long arm segment. This UPD14 was of maternal origin and most likely resulted from a double meiotic chiasma between chromosome 14 homologues. The analysis using highly polymorphic markers specific for different chromosomes has confirmed the biparental origin of chromosomes 13 and excluded a false-paternity. Moreover, the sister presenting the rob t(13;14) has inherited the derivative 13;14 from her mother and the free chromosome 14 from her father. This particular form of UPD14 could be the consequence of a chromosome nondisjunction at the maternal meiotic stage I division which was followed by the loss of a chromosome 14 from a trisomic zygote. Furthermore, an imprinting effect resulting from the isodisomy segment of matUPD14 could possibly explain the bilateral nephrocalcinosis, the hypercalciuria and the myopathic electromyogram, three additional features observed in the proband and not previously reported in matUPD14.

Molecular cytogenetic study of a 45,X male with cryptic Y/15 translocation and deletion of IGF1R gene. *D. Mercer[1], C.T. Dvorak[1], D.L. Wesley[1], C. Techakittiroj[1], H.C. Andersson[1, 2], T. Dise[2], M.M. Li[1, 2].* 1) Human Genetics Program; 2) Dept Pediatrics, Tulane Univ Med Sch, New Orleans, LA.

A male newborn prenatally diagnosed with Turner Syndrome was referred for genetic evaluation due to the apparent phenotype/genotype discrepancy. He was born at term to a G2P1 28-year-old mother with normal male genitalia and bilateral descended testes. Physical examination revealed that his height, weight, and head circumference data were well below the 5th percentile. He also showed some minor dysmorphic features including mild midface hypoplasia, bilateral epicanthal folds, a depressed nasal bridge, bilateral preauricular pits, small year pits, and mildly puffy feet. No cardiac problem was observed. High-resolution chromosome analysis demonstrated a karyotype of 45,X. FISH with DNA probe for the SRY gene showed a positive signal on the telomere region of one chromosome 15q, which was negative for the 15q telomere probe and positive for the Xp/Yp telomere probe. FISH with the IGF1R probe (BAC clone RP11-262P8) demonstrated a deletion on one chromosome 15. Severe growth retardation was observed during follow-ups. At 4 months of age, his head circumference was 35cm (-4 SD), his height was 52cm (-3.66 SD), and his weight was 4.5kg (-2.2 SD). Cytogenetic study on the mother of the patient showed a normal female karyotype. The father was not available for study; however, two half-sisters from the same father were phenotypically normal. 45,X male has been rarely described in the literature. The chromosome rearrangements in these cases have usually involved translocation of all or part of Yp to an autosome. Most of these patients display sexual development delay and azoospermia due to the loss of some Y material. Additional manifestations vary significantly depending on the autosome involved. The growth retardation and mild dysmorphic facial features in our patient are consistent with the phenotype of patients with the deletion of 15q26.3. Although 100% of Turner patients display short stature, more than 50% of 45,X males are of normal height. Therefore, the severe growth retardation in our patient is at least partially resulted from the deletion of one copy of the IGF1R gene.

Autosomal imbalance enhances apoptosis during neuronal differentiation of mouse ES cells. *Y. KAI[1], Y. KAZUKI[1], S. ABE[1], M. TAKIGUCHI[1], S. KISHIGAMI[2], T. WAKAYAMA[2], C.C. WANG[3], M. OSHIMURA[1].* 1) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, Japan; 2) Laboratory for genomic Reprogramming Center for Developmental Biology, RIKEN, Japan; 3) Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Shatin, Hong Kong.

Most individuals with autosomal imbalance such as aneuploidy are associated with mental retardation, though the particular chromosomal syndromes are phenotypically and/or clinically distinct. In the case of Down syndrome (DS), the most common autosomal aneuploidy, a reduction in both the number and density of neurones in the brain is a common abnormal phenotype. Recently, we established an in vitro model system for neuronal differentiation using mouse ES cells to examine the early stage of neurogenesis. A model of DS was created by introduction of an extra human chromosome 21 into the ES cells [ES (hChr.21)]. Interestingly, we observed a higher incidence of apoptosis during the in vitro early neuronal differentiation in the ES(hChr.21) cells. Here, we ask if chromosomal imbalance commonly induces higher levels of the apoptosis. Toward that end, we isolated mouse ES cells with an introduced human chromosome 21, 11 and 6p, and with an additional mouse chromosome such as chromosome 1, 8, and/or 17. All the clones showed an elevated incidence of apoptosis during the in vitro neuronal differentiation. Loss of mouse Y chromosome, i.e., missing sex chromosome, does not have the effect. Our findings strongly support the hypothesis that autosomal imbalance is commonly associated with reduced number of neuronal cells. The reduction in the number of neuronal cells may result in mental retardation in patients with chromosomal aneuploidy syndrome. Our data further suggest that a common molecular event is present for recognition of autosomal imbalance and the consequence.

Metabolic decompensation in two unrelated children with small autosomal aberrations. *S. Wu, S. Yano, R. Boles.* Dept Pediatrics, Children's Hosp, Los Angeles, Los Angeles, CA.

Episodes of clinical deterioration associated with intercurrent illness and/or decreased caloric intake suggest the presence of a possible inborn error of mitochondrial metabolism, especially if associated with vomiting, altered mental status, metabolic acidosis or a rapid response to sugar intake.Potential diagnoses include the organic acidemia, fatty acid oxidation disorders and mitochondrial cytopathies. We present two infants with small chromosomal deletions, in whom intercurrent illness was associated with altered mental status and/or vomiting and metabolic acidosis, which resolved rapidly upon administration of sugar-containing fluids. The first Hispanic female presented at birth with cholelithiasis, arthrogryposis, severe symmetrical growth retardation and microcephaly. The patient has a karyotype of 46,XX, der(4)t(4;8)(p16.1;p23.1) with monosomy 4p16.1- pter and trisomy 8p23.1- pter. The second Hispanic female presented at age 3 months with dehydration, acidosis, growth retardation, down-slanting palpebral fissures, high arched palate, ezcema, lumbar kyphosis, hypercalcemia and significant lymphedema of the extremities. Peripheral blood karyotype revealed a small interstitial deletion between the bands 3q13.1 and 3q21. These infants may be predisposed towards metabolic decompensation under stress, possibly due to haploinsufficiency of one or more proteins involved in energy metabolism. Therefore, we recommend that individuals suspected to have mitochondrial disease, especially if associated with dysmorphic features or malformations, should be screened for potential chromosomal abnormalities.

Characterization of high-resolution G-banded chromosomes - Enhancement of banding pattern using different cell synchronization agents. *W.S Ng[1], K.K. Ho[2], Y.M. Chin[1], J.A. Tan[2].* 1) Div Genetics, Fac Science, University of Malaya, Malaysia; 2) Dept Molecular Medicine, Fac Medicine, University of Malaya, Kuala Lumpur, Malaysia.

G-banding remains the gold standard in clinical cytogenetics despite the introduction of new molecular techniques such as FISH, and CGH. Continuous development and research in banding protocols have lead to G-banding of high-resolution chromosomes with the application of special staining to enhance specific banding patterns. High-resolution chromosomes are obtained through cell-cycle synchronization and are useful to visualize minute aberrations on the chromosomes.

Several cell cycle synchronizing agents in various combinations were evaluated on trophoblast cell cultures, and specific agents were observed to have characteristic effects on the G-banding patterns. The chemicals evaluated were MTX, BrdU, FrdU, thymidine and uridine. Length of each treatment followed closely the timings used with high-resolution blood cultures. The banding patterns produced were compared and characterized.

BrdU was observed as the superior releasing agent for either MTX or FrdU/Ur blocked cell cultures. Higher percentage of high-resolution chromosome spreads of 800 band level was harvested using this treatment. The dark bands in the chromosomes were more intense and distinct when the Wrights stain was used. Sub-bands were observed as a result of further resolution of the minor bands, for example, the distal arm of chromosome 1p which is usually poorly stained was consistently banded with Wrights stain. Although colchicine treatment promotes chromosomal condensation, addition of colchicine 3 hours prior to harvesting did not affect chromosome length, but increased the mitotic index.

Staining enhancements observed in BrdU incorporated chromosomes may be due to interference of this nucleotide with normal chromosomal condensation as well as favorable interaction with Wrights stain. Therefore 2 advantages with cell cycle synchronization; high-resolution chromosomes as well as enhancing the G-bands.

A frequent partial AZFc deletion does not render an increased risk of spermatogenic impairment in East Asians.

F. Zhang[1], Z. Li[2], B. Wen[1], J. Jiang[3], M. Shao[1], Y. Zhao[1], Y. He[1], X. Song[1], J. Qian[1], D. Lu[1], L. Jin[1,4]. 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Renji Hospital and Shanghai Institute of Andrology, Shanghai Second Medical University, Shanghai, China; 3) Ningbo Haishu Mayuan Hospital, Ningbo, Zhejiang, China; 4) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH, USA.

The gene families in the AZFc region of the Y chromosome have been shown to be functionally important in human spermatogenesis. The gr/gr deletion, a partial AZFc deletion that reduced the copy numbers of all the AZFc gene families, was identified as a significant risk factor for spermatogenic impairment in Dutch, Spanish and Italian. However, the presence of this deletion in the healthy French and German questioned its importance in male infertility. In this study, we showed that the gr/gr deletion did not render an increased risk in Han Chinese. In fact, the gr/gr deletion is frequent (~8%) in our survey of 886 East Asians from 8 ethnic groups. Furthermore, the DAZ1/DAZ2 deletion was detected as the primary subtype of the gr/gr deletion in East Asians, though this doublet was considered to be crucial for normal spermatogenesis in Europeans. Our observations suggested that the functional difference between the AZFc gene copies was a likely cause of inconsistent associations of the gr/gr deletion with spermatogenic impairment across populations.

Pattern of human satellites on chromosome Yq12. *M. Babcock[1], S.A. Yatsenko[2], J.R. Lupski[2], P. Stankiewicz[2], B. Morrow[1].* 1) Albert Einstein Col Medicine, Bronx, NY; 2) Baylor College of Medicine, Houston, TX.

Satellite DNAs from the heterochromatic regions of the human genome comprise a class of tandemly repeated non-coding sequences that were originally identified by density gradient centrifugation. The breakpoints of the recurrent constitutional t(11;22) translocation cluster in satellite sequences within the LCR22-3a low copy repeat block on chromosome 22q11.2. Additional satellite sequences map in other LCR22s and they may be involved in chromosome rearrangements. We hypothesized that they could confer chromosome instability elsewhere in the genome. To determine their copy number, we performed Southern blot hybridization on human genomic DNA digested with different restriction enzymes. Genomic Southern blot analysis on SpeI digested human DNA using a satellite I probe revealed two fragments (5 and 2.4 kb) that were present in a very high-copy number. The 2.4 kb fragment was previously reported to be enriched in male DNA and was termed HSATI (PMID, 6324132). We performed FISH mapping with an HSATI probe and found that it painted the entire heterochromatin of the long arm of chromosome Y in human, Yq12. Interphase FISH mapping showed multiple hybridization signals on the periphery of the nucleus, a location where heterochromatic regions are known to reside. The structure of chromosome Y is highly variable in evolution, even among hominoid species. FISH mapping with human HSATI was performed on chimpanzee, bonobo, gorilla and orangutan cell lines and showed no fluorescence signal, indicating that it is specific to human chromosome Y. The Yq12 region also contains a pentamer repeat, (CATTC)n, referred to as HSATII. To determine the co-localization pattern of HSATI and HSATII on Yq12, we performed metaphase, interphase, and fiber FISH mapping. We found an interspersed pattern of these two satellite DNAs spanning Yq12, with HSATII being the predominant species. Taking classic molecular biological approaches, we have determined the pattern of interspersed satellites on human Yq12 that are missing from the human genome sequence.

Asynchronous replication of biallelically and monoallelically expressed loci in triploidy. *O. Reish, D. Cooltin, M. Mashevich.* Genetic Inst, Assaf Harofeh Medical Ctr, Zerifin, Israel.

Purpose: Triploidy results in vast majority of cases in fetal loss and in few cases in multiple anomalies with perinatal death. The secondary genetic effects resulting from the extra haploid chromosomal set havent been evaluated yet. Here the level of synchronization in replication timing of alleles and genomic instability associated with other anuepolidies were assessed in triploid cells. **Methods:** Fluorescence in situ hybridization was used for 4 loci in amniotic cells or lymphocytes derived from 4 trisomy 21 cases, 5 controls and 5 triploidies. **Results:** Biallelically expressed genes (21q, RB1 and c-myc), showed a significantly higher level of asynchronous replication in the trisomy 21, and triploid cells comparable to control group. Genomic instability as demonstrated by secondary aneuploidy, was significantly increased in both trisomic and triploid cells comparable to the control. Monoallelically expressed gene (SNRPN), showed an altered replication pattern in triploid cells, however, no alteration was detected in trisomy and control cells. **Conclusions:** Altered replication timing of biallelically expressed genes and secondary genomic instability were detected both in trisomic and triploid cells. However, alteration of monoallelically expressed genes that was detected in tripolid cells but not in trisomy cells may suggest a possible cellular replication control hierarchy where imprinted gene get affected only when severe cellular insult such as the presence of an extra haploid chromosomal set occur.

Identification of a specific interstitial telomere-like sequence (ITS) in human chromosome 22 at q11.2. *J. Yan[1], E. Bouchard[1], BZ. Chen[2].* 1) Department of Pediatrics, Faculty of Medicine, Université de Sherbrooke, Sherbrooke, PQ, Canada; 2) Services of medical genetics, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, PQ, Canada.

The presences of interstitial telomere sequences (ITSs) located in the intrachromosomal sites were reported in many eukaryotic species as well as in humans. The occurrence of ITSs was proposed to be a consequence of telomere-telomere fusion during the evolution of human chromosomes or to be involved in chromosome rearrangements or chromosome instabilities. By means of double-strand PRINS, we discovered a specific ITS on human chromosome 22 at q11.2, where the region was found to contain rearrangement breakpoints for multiple disorders. This ITS appeared only in the PRINS technique but could not be detected by FISH using PNA probe. Moreover, it is present only in the product of one DNA strand extension primed by a synthesized oligonucleotide (TTAGGG)7 although another complimentary primer (CCCTAA)7 was used for the same samples in the double-strand PRINS technique. As the maximum frequency of ITS from parallel analyzed chromosome 21 was 10%, which means that no second positive ITS can be found in analyzed 10 metaphases, we defined a cut-off for negative ITS as 10%. Based on this definition, the positive cases that contained ITS at 22q11.2 were determined in 11 out of 16 (69%). The average frequency of the metaphases containing ITS at 22q11.2 in the 16 cases is 24.7%, which is significantly different from parallel scored chromosome 21 (2.9%). Research on the genome database found a DNA segment with high density of telomere-like tandem repeat sequence composed of 9-base monomers and located at 22q11.2. As this sequence spans 909 bp and is unique in scanned 12.5 Mb sequences covered from 22q11.1 to 22q12.1, we suggest that the observation of ITS signals at 22q11.2 by PRINS should correspond to the telomere-like sequence found in the genome database. Further study may provide important information of the ITS at 22q11.2 related to the genomic instability and the chromosome rearrangements.

Molecular Ruler mapping and clinical correlations in seven patients with distal deletions of 9p. *G. Raca[1], X. Hauge[2], K. May[1], S. Cooper[1], R. Spiro[3], M. Adam[1], C.Lese Martin[1].* 1) Dept of Human Genetics, Emory Univ, Atlanta, GA; 2) Kennesaw State Univ, Atlanta, GA; 3) National Birth Defects Center, Waltham, MA.

Cytogenetically visible deletions of distal 9p have been reported in patients with cognitive impairment, trigonocephaly, characteristic facial features, hypotonia, cardiac abnormalities and abnormal genitalia. Previous studies have identified a critical region for the consensus phenotype to a region between 8 and 16 Mb from the 9p telomere, corresponding to bands 9p22.3 to 9p23. However, correlating genotype and phenotype findings has been difficult. Here, we report 7 new patients with deletions of the terminal portion of 9p. In one individual, the deletion was only detected by telomere FISH, while the six remaining individuals had cytogenetically visible deletions involving breakpoints in 9p23 or 9p24. Five patients had terminal deletions and two had unbalanced rearrangements involving additional material from another chromosome. Molecular Ruler clones, spaced 1 Mb apart and covering the most distal 14 Mb of 9p, were used as FISH probes to delineate the size of the deletions. In all 7 individuals, the deletion size was less than 14 Mb from the telomere, which is smaller than the majority of 9p deletion cases published in the literature. The smallest deletion was approximately 1 Mb and included at least 8 known genes. In order to develop genotype/phenotype correlations, the 6 individuals for whom clinical information was available were grouped into two categories based on their deletion size: 3 individuals had a deletion less than 7 Mb and 3 individuals had a deletion that was 10-14 Mb in size. Clinical evaluation and comparison showed little difference between these two groups for the physical features that were evaluated, suggesting that many of the genes contributing to the physical phenotype are located in the most distal 7 Mb of 9p. Gross motor skills appeared to be less severely impaired in the patient with the smallest deletion as compared to the remaining individuals. Language ability was uniformly poor, with sign language being the most common mode of communication in both groups.

A variant Kabuki phenotype and malabsorption syndrome in a subject with *de novo* cryptic microdeletion involving 8q21.2 detected using whole genomic array CGH. *G. Novelli[1], M. Frontali[2], A.M. Nardone[1], A. Novelli[3], F. Gullotta[1], G. Palmieri[1], L. Biancone[4], F. De Nigris[4], A. Antoccia[5], A. di Masi[5], A. Sgura[5], E. Giardina[1], M. Biancolella[1], F. Amati[1], C. Tanzarella[5], F. Pallone[4].* 1) Biopathology Department,University of Tor Vergata,Rome,Italy; 2) Neurobiology and Molecular Medicine Institute,CNR,Rome,Italy; 3) CSS-Mendel Institute,Rome,Italy; 4) Department of Internal Medicine,University of Tor Vergata,Rome,Italy; 5) Biology Department,University of Roma Tre,Rome,Italy.

Kabuki syndrome is characterized by typical facial features,skeletal anomalies,dermatoglyphic abnormalities,short stature,and mental retardation,which may be accompanied by other congenital anomalies and health disorders.We describe a 22 yrs old male with a mild mental retardation,with malabsorption syndrome since he was 19 and showed several dysmorphic features.The main findings were short stature,large palpebral fissures with long eyelashes and arched eyebrows,large ears,micrognathia,hypodontia and excess of ulnar loops.Neurological examination showed nystagmus on lateral gaze.MRI scan revealed a marked dilatation of aqueduct and IV ventricle.A pattern resembling acute graft-versus-host disease,with apoptotic bodies and lymphocytes in crypts,was seen in the colon,with gland loss and interstitial fibrosis.Lab test showed a deficit of IgA and IgE.A provisional diagnosis of Kabuki make-up syndrome was made even if a few frequent features were lacking like inferior eyelid eversion.Using a 1-Mb genomic microarray,we found a cryptic microdeletion in the 8q21.2 region confirmed using microsatellite analysis and fluorescence *in situ* hybridization.The 8q deletion encompasses approximately 2 Mb of genomic DNA where the family of exonuclease GOR genes maps.We investigated the functional effects of GOR genes hemizygosity in patients fibroblasts examining cell cycle checkpoints perturbation and genetic instability after treatment with different DNA damage-induced agents.To study the telomere structure,telomere length was analysed with Q-FISH hybridization.We conclude that haploinsufficiency of GOR genes may play a critical role in determining some of the phenotypic features of the patient.

MLPA: A Rapid and Sensitive Method for Detecting Copy Number Changes in 22q11.2. *G.R. Jalali, J.A.S. Vorstman, A. Hacker, B.S. Emanuel.* Dept. of Pediatrics, Div. Hum. Genet., Children's Hosp. of Phila., PA.

The 22q11.2 deletion causes a variable phenotype characterized by congenital and developmental abnormalities. About 87 % of deletions occur between Low Copy Repeats (LCR) A and D and 10% between LCR A and B or C. Sporadic deletions with atypical endpoints and other changes of 22q11 such as internal duplications, trisomy and tetrasomy have been observed. The diagnostic procedure often used for detection of copy number changes at 22q11.2 is Fluorescence In Situ Hybridization (FISH) with probes adjacent to the LCRs. The method is laborious and not sensitive enough to detect small deletions (40kb) within 22q11.2. A rapid, sensitive and less expensive method is necessary to detect these frequent 22q rearrangements. We have tested a commercially available MLPA kit (Multiplex Ligation-Dependent Probe Amplification) to assess copy number changes of 22q11.2. It is a novel method that allows the relative quantification of ~ 45 different target DNA sequences in a single reaction. The P023 MLPA kit has 9 probes specific for the 22q11.2 region. Multiple patients with variable deletion endpoints and other rearrangements of 22q11.2 have been characterized by FISH with cosmid or BAC clones. From this cohort numerous samples (50) were used in the current blinded study, including typical 22q11.2 deletions, various atypical deletions, duplications (trisomy and tetrasomy) and unbalanced translocations. MLPA findings were consistent with cytogenetic and FISH studies. No rearrangement went undetected. Repeated tests of the same samples gave consistent results. The number of false positive/negative calls correlated with the amount of variation within each sample (expressed as Standard Deviation, SD). At a SD in the range of 0.10 - 0.15, specificity and sensitivity were 0.96 (95%C.I.: 0.94 - 0.97) and 0.96 (95%C.I.: 0.90 - 0.98). At a SD below 0.10 both values improved (specificity: 0.99 (95%C.I.: 0.98 - 0.99) and sensitivity: 0.97 (95%C.I.: 0.94 - 0.98)). Thus, MLPA has proved to be a highly sensitive and accurate tool for detecting copy number changes in the 22q11.2 region, making it a fast and economic alternative to currently used methods.

Development of a set of unique pericentromeric clones for the investigation of chromosome imbalance by array CGH. *S.A. Hornor[1], B.C. Ballif[2], B.A. Bejjani[1,2], L.G. Shaffer[1,2].* 1) Health Research and Education Center, Washington State University, Spokane; 2) Signature Genomics Laboratories, LLC, Spokane, WA.

Most regions of the chromosomes are subject to rearrangement, but certain genomic segments appear more susceptible than others. For example, the use of subtelomere probes has led to the identification of deletions and rearrangements in patients with unexplained mental retardation. In addition, pericentromeric regions of chromosomes seem to be more susceptible to deletion than other internal segments of the chromosome arms based on the identification of deletions in Williams, Potocki-Shaffer, Prader-Willi/Angelman, and DiGeorge/VCF syndromes with deletions in proximal 7q, 11p, 15q, and 22q, respectively. Based on the susceptibility of these regions to rearrangement, it is likely that deletions and duplications of other pericentromeric regions occur. However, little effort has been put forth to develop FISH probes to all unique pericentromeric regions. To provide these critical reagents, we constructed a set of clones to the 43 unique human pericentromeric regions (excluding the acrocentric short arms). Overlapping BACs were selected to cover ~5 Mb regions immediately distal to the most centric ~1.5 Mb of DNA, adjacent to the centromeres. Each clone was screened for sequences shared with other chromosomes based on set criteria. Selected BAC clones were evaluated by FISH mapping under constant conditions. Possible FISH outcomes included cross-hybridization, mis-mapped clones, and usable, locus-specific clones. The average number of clones found usable for each pericentromeric region was approximately 70%. These reagents promise to be of great value for clinical applications with existing and newly developing platforms. Array CGH provides a platform for efficiently screening the pericentromeric regions of all chromosomes to uncover novel imbalances and centric marker chromosome identification. The identification of deletions and duplications in the pericentromeric regions may delineate new syndromes or uncover the etiology of known clinical syndromes. In addition, chromosomal origins of markers will be identified and the extent of euchromatin delineated.

Determination of a deleted region of an X-linked adreanal hypoplasia congenita with glycerol kinase deficiency.

K. Wakui[1], T. Nishikubo[2], Y. Fukushima[1]. 1) Dept Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Nagano, Japan; 2) Neonatal Intensive Care Unit, Nara Prefectural Nara Hospital, Nara, Nara, Japan.

X-linked adrenal hypoplasia congenita [X-linked AHC, MIM#300200] is caused by mutations or deletion of the *DAX1* (dosage-sensitive sex reversal, adrenal hypoplasia congenita, critical region on the X chromosome, gene-1) gene. The *GK* (glycerol kinase) gene, responsible for hyperglycerolemia [glycerol kinase deficiency (GKD), MIM#307030], and the *DMD* (dystrophin) gene, for Duchenne muscular dystrophy [DMD, #310200]/ Becker muscular dystrophy [BMD, #300376], are mapped at centromeric region to the *DAX1* gene in Xp21 (Xpter-*DAX1*-*GK*-*DMD*-Xcen). About 1/3 of all AHC patients have the deletion of *DAX1*, *GK* and *DMD* genes as part of an Xp21 contiguous gene syndrome. Many of the patients are the Xp21 contiguous gene syndrome involving *DAX1*, *GK* and *DMD*.

We encountered a patient with X-linked AHC and GKD, but without clinical features of DMD. We performed fluorescent *in situ* hybridization (FISH) analyses using the BAC clones spanning the genes the *DAX1*, *GK* and *DMD*, and confirmed that this patient had a deletion including *DAX1* and *GK*, but had no deletion of the *DMD* gene. Some similar patients with AHC and GKD but without DMD had been reported. But, there are few reports described the precise breakpoints of the deleted region in such patients. We present the precise deleted region of this patient by molecular level.

Identification of 5q35 microdeletion in a Korean patient with Sotos syndrome. *S.J Park, J.N Yoon, S.Y Jung, H.J Kim.* Dept Medical Genetics, Ajou Univ Sch Medicine, Suwon, Korea.

Sotos syndrome (OMIM #117550) is an autosomal dominant overgrowth disorder with developmental delay, typical dysmorphic craniofacial features, and advanced bone age. The syndrome is caused by haploinsufficiency of NSD1(nuclear receptor binding SET domain protein 1) due to microdeletion and point mutations. NSD1 consists of 23 exons with gene size of 160 kb and encodes a protein of 2,696 amino acids. The function is known to be involved in histone modification and regulation and maintenance of chromatin states. We identified 5q35 microdeletion including NSD1 region in one Korean patient with Sotos synrome. Microdeletion of the NSD1 were confirmed by FISH analysis. FISH was performed with two colour probes, the specific 5q35 BAC probe labelled with Cy3 and the 5q31 control probe with FITC. The specific 5q35 BAC probe was constructed using BAC clone DNA (NCBI build35). FISH was performed on metaphase chromosomes and interphase nuclei of cultured peripheral blood lymphocytes from Sotos patient and normal control individuals. In the Japanese patients with Sotos syndrome, most common mutations (50%) are microdeletion of 5q35 region including NSD1, while in the UK, approximately 70% of Sotos patients are shown to have NSD1 point mutations and only 10% of the patients have a microdeletion of 5q35 region. Therefore, further analysis will be studied to elucidate the mutation type of the NSD1 in Korean patients with Sotos syndrome.

Severe non syndromic encephalopathy and microcephaly associated with Xq28 duplication in a male patient: MECP2 gene overexpression ? *C. Sibille, M. Ravoet, I. Abinet, Ch. Verellen-Dumoulin, N. Lannoy.* Centre de Genetique Medicale, Univ Catholique de Louvain, Bruxelles, Belgium.

Point mutations and large deletions in X-linked methyl-CpG-binding protein 2 gene(MECP2) have been found to be a cause of RETT syndrome in young girls. Mutations were also described in males patients having lethal encephalopathy with mental retardation. One large MECP2 genomic duplication was reported once in a female patient with preserved speech variant (PSV) suggesting a dosage effect of the protein. We present a 9 months old boy referred for mental and motor retardation, microcephaly (-2SD) and hypospadias. Weak dysmorphic features were present: bilateral anti-mongoloïd palpebral fissure with ptosis and wide ears. MRI showed a brain with reduced volume and dysmyelinisation. Echography of the heart showed small interatrial septum defect. At 5 years of age, his size was below the 3rd centile and head circumference below the 6SD. Clinical reports mentioned axial hypotonia. His mother is clinicaly normal but her half-brother died at 9 years old with major encephalopathy. Mother and son showed a normal karyotype without CGG expansion of FMR1 gene. However, multisubtelomeric FISH analysis identified in both a cryptic microdeletion of Xp22.3 (SHOX-, locus DXYS129-) associated to a duplication of Xq28 (locus ESTCdy16c07++, LAGE-1). Additional molecular analyses indicated that the Xpter deletion is confined within the PAR1 area while the duplication in Xq28 stretch over 3.200 kb (Xqter-DXS8061). Genomic duplication of the non-syndromic mental retardation MECP2 gene was shown by Multiplex Ligation-dependent Probe Amplification(MLPA). However, DNA of the mother using the (CAG)n polymorphism at the androgen receptor locus indicated that the abnormal X chromosome is preferentially inactivated. Moreover, quantitative RT-PCR showed a four fold overexpressed MECP2 mRNA in the peripheral blood mononuclear cells (PBMC) of the affected son versus normal control. We proposed that duplication of MECP2 gene might be implicated in a dosage-sensitive protein expression in major progressive encephalopathies accompagnied by mental retardation, microcephaly and severe encephalopathy .

Detection of atypical deletions in the DiGeorge/Velocardiofacial region by array-based comparative genomic hybridization (Array CGH). *Z. Ou[1], J. Li[1], M.L. Cooper[1], H.M. Rosenblatt[2], M. Patel[1], S.W. Cheung[1], C. Chinault[1], A. Patel[1].* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Pediatrics, Baylor College of Medicine, Houston, TX.

DiGeorge /Velocardiofacial (DG/VCF) syndrome is the most common genomic disorder often associated a microdeletion on chromosome 22q11.2 region, resulting from non-allelic homologous recombination between sets of low copy repeats(LCRs). The main clinical findings include characteristic facial appearance, velopharyngeal insufficiency, learning disabilities, conotruncal heart defects and occasionally a cleft palate. A more severe subset of patients has a reduced or absent thymus gland and hypocalcemia. Of the 83% of patients with a detectable deletion, 90% had a common 3 Mb deletion in the 22q11.2 region while 7% had a smaller proximal breakpoint with a nested 1.5 Mb deletion. Rare patients with atypical deletions in the 22q11.2 region have also been observed. We have developed a BAC/PAC microarray for the detection of majority of the microdeletion syndromes including the DG/VCF syndrome. The clones in the DiGeorge/VCFS regions have been selected to identify 1.5 Mb, 3 Mb, and >4Mb deletions. Screening over 780 patients with our current V 4.0 clinical microarray, we identified 6 patients with 3 Mb deletion , 1 with a 1.5Mb deletion and one patient with 1 clone deleted just outside the common 3 Mb deletion locus. Patient with the 1.5 Mb deleted patient was a 35 week premature female infant, diagnosed with a membranous VSD and mild heart defect, hypocalcaemic seizures and absence of thymus function. Patient with 1 clone deleted distal to the common 3 Mb deletion was a twin (A) , born prematurely at 32 weeks gestation with truncus arteriosus, cryptorchidism and mild facial dysmorphism. Additional features included global developmental delay, failure to thrive with severe microcephaly. Twin B died of SIDS at 6 mos. of age and a half-sib died at 12 days of age with hypoplastic kidneys and polydactyly. Parental studies on both the atypical deletion patients are pending. Array-CGH provides quick and accurate detection of typical and atypical deletions/duplications in the DGS/VCFS region.

Detection of genomic variations by array-CGH in 728 consecutive samples in a postnatal clinical cytogenetic diagnostics. *A. Patel, C. Shaw, P. Ward, K. Vonalt, M.L. Cooper, P.A. Lennon, P. Stankiewicz, C. Chinault, A. Beaudet, S.W. Cheung.* Dept Molecular & Human Genetics Baylor College of Medicine, Houston, TX.

Variations in the human genome of a few base pairs to a few hundred base pairs have been identified and correlations to health and disease have been studied. Genome wide identification of these variations has been hampered by a lack of high-resolution and high-throughput techniques. The development of array-CGH in recent years has provided such a tool for a rapid analysis of large scale human genome variation. Genomic variations of 250 Kb to over 1 Mb have been identified in normal individuals. Array-CGH is also quickly gaining acceptance in the clinical setting to identify disease causing genomic rearrangements and thus it becomes important to catalog and understand the clinical significance of these genomic variations. The Baylor College of Medicine Diagnostic Chromosome Microarray chip contains 366 FISH verified BAC/PAC clones spanning regions implicated in 55 known genomic syndromes and all the subtelomeric regions. In analysis of 728 patient samples by array-CGH for genomic rearrangements using a single reference male and female controls we found 47 patients with clinically significant and well characterized disorders. In addition, we also observed gains and losses of single clones in the 2qter, 4qter, 10qter, and 15q11.2 regions in 2-5% of the patients studied. Sequence analysis of these clones showed that they contained significant percentage of segmental duplications or had a high repeat sequence content. We also observed gain and loss of the region between BP1 and BP2 in the 15q11.2 region in 1.4% of the patients. Gain of genomic regions of the well-characterized microdeletion syndromes such as STS, SHOX, NF1 and NPHP1were also observed in less than 1% of the patients. For all of the above loci in at least 2 patients the gain or loss was confirmed in one of the parent. Array-CGH is proving to be a powerful tool in the analysis of genomic rearrangements but careful clinical correlations are needed to determine which genomic variations can be classified as polymorphisms and which may have a clinical significance.

Array CGH identifies a partial trisomy 2p14p16 owing to an insertion in the chr 2 long arm. *J. Lapierre[1], B. Keren[1], M. Prieur[1], J. Amiel[1], D. Genevieve[1], M. Jacquemont[1], A. Tarrico[1], A. Munnich[1], S.P. Romana[1], A. Aurias[2], C. Turleau[1], M. Vekemans[1], D. Sanlaville[1].* 1) Genetics and Cytogenetics , Hopital Necker-Enfants Malades, Paris, France; 2) INSERM U509, Institut Curie, Paris, France.

Chromosome 2 short arm duplications are associated with a distinct phenotype. Here, we report a 5 years 6 months old girl presenting with intra uterine and post natal growth retardation, macrocephaly, facial dysmorphism, anteriorly displaced anus and mental retardation. Facial features include prominent forehead, narrow palpebral fissures, flat nasal bridge, short nose with anteverted nostrils, hypertelorism, bifid uvula, low set posteriorly rotated ears, large mouth with short philtrum and retrognathia. Hands were small and broad. Ophthalmologic was normal. No visceral malformations were found on cerebral MRI, abdominal and cardiac ultrasound. High resolution chromosome analysis revealed extra material at the 2q32 region. Fluorescent *in situ* hybridisation (FISH), using a whole chromosome 2 painting probe, showed that the extra material derived from chromosome 2, suggesting a 2q32q33 duplication. However, the clinical phenotype was discordant with previously reported cases with this imbalance. To further characterize this rearrangement, we used a 1 Mb CGH microarray. It showed that additional fragment correspond to the 2p14p16 region, from 53 Mb (RP11-469J7) to 64 Mb (RP11-494E18), with a suspected 600 kb deletion near the proximal breakpoint. Based on these results, we concluded that our patient had a 9Mb chr 2p insertion into the 2q32 region. Clinical presentation of our patient is more relevant to trisomy 2p than trisomy 2q in accordance with the array-CGH results. This observation underlines the accuracy of array-CGH to characterize complex chromosome rearrangement and to perform genotype phenotype correlations. Further studies are in progress to further confirm the small interstitial deletion. A mechanistic explanation of this complex rearrangement will be provided.

Subtelomeric rearrangements in fetuses with congenital malformations: Two case reports. *J. Gignac[1,2,3], F. Tihy[1,2], E. Lemyre[1,2,3].* 1) Service de génétique médicale, Hôpital Sainte-Justine, Montréal, Québec, Canada; 2) Centre de recherche de l'Hôpital Ste-Justine, Montréal, Québec, Canada; 3) Faculté de médcine, Université de Montréal, Montréal, Québec, Canada.

Chromosomal anomalies are a frequent cause (20%) of fetal malformations. However, in over 50% of the cases, the etiology of these malformations remains unclear. This limits evaluation of the prognosis as well as the medical follow up of the affected fetuses. We are studying the implication of cryptic subtelomeric rearrangements in the development of fetal malformations. Subtelomeric analysis is performed by FISH on amniocytes cultured *in situ*. We present here two cases that we have identified through this study. In both cases, the fetus was diagnosed with severe malformations through ultrasound and had a normal karyotype. Subtelomeric analysis detected derivative chromosomes inherited from maternal translocations for both fetuses. In the first case, the foetus inherited a der(14)t(14;16). He presented gastro-intestinal, cardio-vascular, skeletal, lymphatic and cerebral anomalies as well as dysmorphic features. This phenotype correlates with the clinical descriptions of both 14qter monosomy and 16qter trisomy. In the second case, the fetus inherited a der(12)t(2;12). He presented renal, cardiac, cerebral and nucal fold anomalies as well as dysmorphic features. The clinical descriptions of 2qter trisomy reported in the literature do not include severe malformations other than cardiac anomlaies. Therefore, it is highly probable that 12qter monosomy is the cause of the abnormal phenotype of this fetus. To our knowledge, we provide here the first clinical description of 12qter monosomy. The detection of these subtelomeric rearrangements is important to understand the causes of congenital malformations and to better evaluate the prognosis of the affected fetuses. Moreover, this type of diagnosis has an extended impact on the families who will be offered appropriate genetic counselling. We now plan to characterize the breakpoints of these rearrangements with BACs in hope of establishing genotype-phenotype correlations. Support : *Fondation de l'Hôpital Ste-Justine.*

Fluorescence in Situ Hybridization in Suspension Applied to Interphase Aneuploidy Quantification. *X. Wu[1], Z. Chen[2], J. Lucas[1].* 1) ChromoTrax, Inc., Arlington, VA; 2) University of Utah School of Medicine, Salt Lake City, UT.

Detection sensitivity of FISH performed on slides is 1 in 100-1000 cells. PCR is very sensitive, but lack of very accurate quantification still is a problem. By contrast, our innovative approach will greatly facilitate accurate and quantitative detection of chromosomal aberrations with potential detection sensitivity of 1 in 1,000,000 cells. Our technique includes a novel approach of hybridizing chromosomes in suspension with fluorescently-labeled DNA probes, in combination with flow cytometric method of analysis or magnetic sorting, in order to sensitively, precisely and rapidly quantify chromosomal aneuploidy, translocations and rearrangements. In our technique, DNA probes are hybridized to a suspension of cell nuclei or isolated whole chromosomes. The resulting hybridized cells or chromosomes are free-floating in solution, and may be subjected to flow analysis or magnetic sorting. In a pilot experiment, we demonstrated the efficacy of our approach by detecting aneuploidy in trisomy 21 human cells after solution hybridization with DNA probe specific for chromosome 21q. Our method produced staining the majority of nuclei with excellent detection of chromosomal domains, demonstrating its utility for clinical genetics. After hybridization in suspension of trisomy 21 cells with the above probe, essentially all free-floating interphase cells showed three distinct signals. In a direct comparison using trisomy 21 cells from four Down syndrome patients, FISH in suspension showed a slight increase in both sensitivity to detect three signals in interphase cells and hybridization efficiency compared to conventional FISH on slides. Scoring three signals in 500 cells per sample, we observed 1610 32 to 1506 29 for FISH in suspension to FISH on slides, respectively. Overall, FISH in suspension and on slides showed comparable hybridization results. Our revolutionary methods offer a new tool to assay chromosomes and DNA and provide the possibility to develop new techniques for analyzing low frequency of abnormal chromosomes based on FISH signals, potentially significant for early detection and diagnosis of genetic diseases and cancer.

Detection of low-level mosaicism by array CGH in routine diagnostic specimens. *E.A. Rorem, B.C. Ballif, C.D. Kashork, K. Sundin, V.M. Schmitz, B.A. Bejjani, L.G. Shaffer.* Signature Genomic Laboratories, LLC, Spokane, WA, USA.

One of the challenges of conventional cytogenetics is detecting low-level mosaicism for chromosomal abnormalities that may be responsible for the clinical phenotype. Recently, array CGH with its ability to screen the genome rapidly at an unprecedented resolution has revolutionized the cytogeneticists and clinicians approach to molecular cytogenetic testing. However, the limit with which array CGH can accurately detect low-level mosaicism is not known. Our laboratory uses the SignatureChip which we developed for the detection of microdeletions, microduplications, aneuploidy, unbalanced translocations, and subtelomeric and pericentromeric copy number alterations. This targeted BAC microarray contains 831 clones in 3-6 clone contigs covering 126 genetic loci and 104 control loci throughout the human genome. Of 1300 cases submitted to our laboratory for routine diagnostic screening by array CGH a substantial number of cases were identified as having mosaic chromosomal abnormalities. These include one case of a mosaic marker 18 (68% of cells), two cases of mosaic trisomy 8 (70% of cells and 28% of cells, respectively), one case of mosaic trisomy 9 (10% of cells), one case of mosaic trisomy 13 (21% of cells), and one case characterized by a mosaic deletion of the TWIST locus at 7p21.1 (6% of cells). Four of the six mosaic cases were known to have had previous or concurrent cytogenetic testing. Of these four, two had concurrent cytogenetic testing and were found to be abnormal after the microarray analysis had already been completed: the mosaic marker 18 (68% of cells) and one case of mosaic trisomy 8 (70% of cells). Two cases had previous cytogenetic analysis in other laboratories: one case of mosaic trisomy 8 (28% of cells) was detected cytogenetically by amniocentesis but was reported as pseudomosaic, and one case of mosaic trisomy 13 (21% of cells) was reported as normal. These cases illustrate the utility and comprehensive nature of array CGH in detecting a variety of chromosomal abnormalities and suggest that array CGH is a powerful platform for the detection of low-level mosaicism in clinical diagnostic specimens.

Activation of DNA damage signaling by Shiga toxin in mammalian cells. *Y. Kabir[1], K.A. Talukder[2], S. Ahmed[2], A. Nur-E-Kamal[3].* 1) Kuwait University, Department of Family Sciences, College for Women, P.O.Box 5969,Safat-13060, Kuwait; 2) International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B), Mohakhali, Dhaka, Bangladesh; 3) University of Medicine and Dentistry of New Jersy, Department of Pharmacology, Robert ood Johnson Medical School, 675 Hoes Lane, Piscataway, NJ 08854, USA.

Ataxia telangiectasia (AT) is a rare autosomal recessive disorder due to defects in the ATM gene. Homozygous mutation in the ATM gene has been characterized by progressive cerebellar neurodegeneration, immunodeficiency, telagiectasia, radiation sensitivity and predisposition to cancer development. Mice heterozygous in the ATM gene have been reported to be susceptible to cancer. Recently, missense mutations have been found to be more prevalent in ATM heterozygous breast cancer patient. ATM is located primarily in the nucleus in dividing cells and involved in cell cycle regulation and maintenance of genomic stability. Shigella infection causes serious complications including CNS manifestation (seizures, and coma) and haemolytic uremic syndrome (HUS). It has been suggested that shiga toxin plays a critical role in developing clinical symptoms in Shegellosis. Shiga toxin (STX) has been shown to induce apoptosis in mammalian cells. Inhibition of protein synthesis by STX has been speculated to be the cause for induction of apoptosis. However, inhibition of protein synthesis by cycloheximide, which inhibits peptidyl transferase, is known to be anti-apoptotic. We have attempted to explore the molecular mechanism of shiga toxin-induced cell death. We have found that Shiga toxin activate DNA damage signaling (activation of ATM, H2AX and p53) in mammalian cells including a cerebellar granule neuron (primary) culture and induces cell death. STX is also known to deadenylate 28S ribosomal RNA (rRNA). We have also demonstrated that introduction of chemically synthesized RNA activates DNA damage signaling pathway and induces mammalian cell death. Results obtained in shiga toxin-induced activation of DNA damage signaling and apoptosis in mammalian cells will be presented.

Microdeletion 13q12: a possible new syndrome identified using SNP screening. *P. Eydoux[1], S.L. Yong[2], N. Ali Akbarli[1], D. Bailey[3], A. Baross[4], M. Brown-John[4], M. Cao[3], S. Chan[4], D.L. Charest[4], A. Delaney[4], N. Farnoud[4], K. Garbutt[1], A. Go[4], G. Kennedy[3], M. Krzywinski[4], H.I. Li[4], S. Langlois[2], J. Schein[4], M.A. Marra[4], J.M. Friedman[2].* 1) Pathology and Medical Genetics; 2) Medical Genetics, Children's & Women's Hosp, Vancouver, BC, Canada; 3) Affymetrix, Santa Clara, CA, USA; 4) Genome Sciences Center, BC Cancer Agency, Vancouver, BC, Canada.

Array-based genomic screening is a recent and powerful strategy to identify allelic imbalances. Among these techniques, whole genome sampling assay (WGSA) using high-density SNP genotyping oligonucleotide arrays may allow identification of yet unknown microdeletions and microduplications. We report on a patient with developmental delay, growth retardation with delayed bone age, microcephaly, frontal bossing, synophris, short philtrum, retrognathia, dental crowding, small hands and hyperpigmentation of gums and nails. The patients karyotype was normal. Whole genome screening using the Affymetrix GeneChip Mapping 100K Assay was performed. Data analysis using the dChip software revealed a microdeletion within chromosome band 13q12, spanning approximately 5 Mb. We confirmed this deletion by FISH using BAC probes mapping to the potentially deleted region. To our knowledge, no such deletion has been reported so far. Arguments supporting a causal relationship between this chromosomal deletion and our patients disease include 1) the phenotype, compatible with chromosomal imbalance; 2) de novo occurrence of the deletion; 3) the size of the deletion; 4) evolutionary conservation of the deleted region; 4) the gene contents of the deleted segment. New cases are needed to further define the microdeletion 13q12 phenotype. SNP WGSA studies may serve as a tool for precise mapping of imbalanced regions and chromosomal breakpoints, allowing for accurate correlation between phenotype and genotype. Furthermore, with the help of FISH and other molecular techniques, SNP WGSA studies may help characterize new microrearrangement syndromes, individualize regions of uniparental disomy and identify genes involved in chromosomal rearrangements phenotypes.

Two siblings with trisomy 9p derived from maternal translocation. *K.T. Abe, D.A. Cornélio, A.R. Benedetti, L.M. Formigli, N. Sakai Jr, A.F. Castro, I.M.P.O. Rizzo, C.E.S. Martins.* Laboratorio de Patologia-Citog, Rede SARAH de Hosp. de Reabilitação-Brasília-DF, Brazil.

INTRODUCTION: Characteristic clinical features of partial trisomy 9p include: mental retardation, short stature, hypertelorism, wide fontanelles, prominent ears, bulbous nose, down-turned corners of the mouth, hand and feet anomalies, simian crease, clinodactyly and hypoplastic phalanges of the fifth finger. More than 150 cases were reported with trisomy of many segments of the short arm of chromosome 9, and about 10% of these cases have entire or almost entire short arm involved in translocations. In the majority of these cases, the trisomic segment was transmitted from a parent carrying a reciprocal balanced translocation. Significant phenotypic variability occurs due to the various sizes of the trisomic segments and also due to concomitant involvement of other chromosomes. PATIENTS AND METHODS: Two siblings showing mental retardation, facial dysmorphisms, hand anomalies and congenital hip dislocation were examined. They were followed in our health service center since one was eleven day-old (patient 1) and the other one eleven month-old (patient 2). Nowadays, they are 8 year-old and 4 year-old, respectively. Chromosome analyses were performed by routine GTW-banding from peripheral blood on both patients and their mother (the father was dead). FISH study was performed using a whole chromosome painting (wcp) with a chromososme 9 and 22 specific probe and a chromosome 9 and 22 satellite probe. RESULTS: Chromosome analyses of the patients 1 and 2 showed 46,XY,+9,der(9;22)t(9;22)(9pter->9p10::22q10->22qter)mat,and 46,XX,+9,der(9;22)t(9;22)(9pter->9p10::22q10->22qter)mat, respectively,and the mother was 46,XX,t(9;22)(p10;q10). The GTW banding results were confirmed by FISH. DISCUSSION: The abnormal chromosomes in these cases were originated by adjacent I of 2:2 segregation during maternal gametogenesis. FISH performed on the metaphase of the patient 1 and his mother was helpful to characterize more precisely the familial translocation between 9 and 22. The clinical findings in our patients are similar to those reported cases described in the literature of trisomy 9p.

Evaluating individuals with mental retardation using subtelomeric FISH and MLPA analyses. *Y.C. Li[1], C.C. Lin[2], M.F. Chao[2], S.J. Liao[1], L.J. Hsieh[2], M.M. Shiu[3].* 1) Dept of Biomedical Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Dept of Medical Research, China Medical University and Hospital, Taichung, Taiwan; 3) Institution of Biochemistry, Chung Shan Midical University. Taichung, Taiwan.

Unbalanced subtelomeric rearrangements have been identified in 2-10% of idiopathic mental retardation (MR). Approximately half of the subtelomeric MR cases are familial with some physical abnormalities. We have undertaken a FISH study using a panel of 43 chromosome arm specific subtelomeric probe mixtures (Vysis Inc.) and performed MLPA (SALSA P019 and P020 human telomere test kits; MRC-Holland Inc.) to screen a population of 44 MR patients selected from Nan Tou Retardation and Rehabilitation Center, Taiwan for subtelomeric aberration. The criteria for patient selection are severe to moderate MR, with family history of MR and normal karyotype by routine G-banding analysis. One patient out of the 44 patients studied (2.2%) was identified to have an unbalanced rearrangement involving subtelomeric region which was not readily identified by conventional G-banding. The aberration involved the deletion of a subtelomeric region in one of chromosome 19p which was replaced by a subtelomeric region from 16q. The patient has moderate MR and his mother also has mild MR with similar subtelomeric aberration. The subtelomeric deletion of 19p has not been reported and therefore the present case identified is novel. The study was supported by grants from the National Health Research Institute (NHRI-EX92-9207SI) and from the National Science Council (NSC93-2320-B-040-055), Taiwan.

Persistent Trophoblastic Disease Following a Fetal Chimera Line (chi 46,XYpat[18]/47,XX,+mar1[8]) in One Twin. *M. Kolthoff, L. Hoffner, J. Dunn, T. Macpherson, J. Hunt, L. Sniezek, U. Surti.* University of Pittsburgh, Magee-Womens Hosp, Pittsburgh, PA.

A 25 year old female Gravida 2 Para 1 at 15.0 weeks with a dichorionic, diamniotic twin gestation presented to our Genetics Department due to abnormal obstetrical ultrasound findings. These findings included low amniotic fluid and poor growth for Twin A. In addition, Twin A's placenta appeared grossly enlarged and cystic. Twin B appeared normal as did its placenta. The patient developed heavy vaginal bleeding and cramping 48 hours later. She was diagnosed with an inevitable abortion and underwent a D&E procedure without complication. The pathological exam of Twin A's placenta showed large, hydropic villi with trophoblastic hyperplasia, consistent with a partial hydatidiform molar pregnancy. Both villi and skin cells from Twin A were analyzed and the karyotype showed two different cell lines: one biparental female cell line with an extra bisatellited marker chromosome derived from chromosome #13 determined by FISH and a second androgenetic 46,XY cell line based on DNA analysis. Paraffin FISH results also confirmed Twin A to be a fetal XX/XY chimera and Twin B results confirmed an XY conception. The maternal karyotype was found to be 48,XX,+mar x2.ish der(13)x2. Of note, the patient was of normal intelligence and without dysmorphic features. The patient's -hCG level remained elevated following the procedure. A pelvic sonogram showed a thickened endometrial lining with multiple cystic areas and vascular flow. Based on these findings, the patient was referred to gynecologic oncology for management of persistent trophoblastic disease. Methotrexate therapy was initiated and the -hCG levels have been undetectable since week 6. To the best of our knowledge, this is the first reported case of persistent trophoblastic disease following a fetal chimera. The most likely explanation for this phenomenon is the biparental and androgenetic genetic make-up of Twin A as based on our cytogenetic and DNA analysis.

Severe dysmorphic features in a fetus with an unpredictable cytogenetic result. *A. Perez-Juana, M. Artigas-López, B. Hernandez-Charro, A. Alonso-Sanchez, M. Aristu, M.A. Ramos-Arroyo.* Genetics, Hospital Virgen del Camino, Pamplona, Navarra, Spain.

Chromosomal abnormalities are a common finding in early spontaneous abortions. About 25% of miscarriages are trisomic. Common trisomies (21,18,13) have a phenotype easily diagnosed by an experienced dysmorphologist. A healthy 32-year-old-pregnant woman went for her first obstetric sonogram at 12 weeks of gestation. A severe developmental defect of the lower pole of the conceptus was observed and sirenomelia was suspected. Fetal beat was absent and growth corresponded to a gestation of 9 weeks. It was the second pregnancy of a non consanguineous couple, they had a healthy son. Family history was unremarkable. The products of conception were submitted to our Genetics laboratory for evaluation. The fetus's length was 1,6cm and several malformations were observed. Its face was significant for a sloping forehead, marked hypertelorism, protruding eyes with absent lids, macrostomia but micrognathia, that reminded the canine facies of Neu-Laxova syndrome described in the Smiths Recognizable Patterns of Human Malformations. Limbs were rhyzomelic and remarkably short, polysyndactyly was present in left hand and both feet, an ectrodactyly on the right hand. An abdominal wall defect was present, anus was patent and no external genitalia were identified. The neck was short and an open neural tube defect covered approximately from the last thoracic to the first sacral vertebrae. After the dysmorphologic evaluation a tissue sample was obtained for further chromosome analysis. A thorough database research was realized while waiting for the cytogenetic result. Except for the EEC syndrome no other feasible diagnoses were found. Etiologically we considered two possibilities: a dominant syndrome resulting from a new mutation, subsequently with a negligible risk, or a rare recessive syndrome, giving a maximum recurrence risk of 25% for future pregnancies. The result of the karyotype came as a surprise for the dysmorphologists, revealing a full trisomy 18. In this case, the cytogenetic finding provided a valuable information and significantly reduced the prior risk of this couple.

Cytogenetic and FISH studies on patients with recurrent spontaneous abortions. *C.W. Yu[1], C. Thompson[1], B. Cowan[2], W. Cleland[2], R. Hines[2].* 1) Dept Preventive Medicine; 2) Dept Obstetrics and Gynecology, Univ of Mississippi Medical Center, Jackson, MS.

Recurrent spontaneous abortions (RSA), defined as two or more consecutive pregnancy losses before 20 weeks of gestation, is one of the most significant issues in womens reproductive health, affecting an estimated 1-2% of all couples who wish to have children. The diagnostic evaluation of RSA is extensive, however in most cases, a clear cause is never found. Studies of one patient series concluded that the contributing factors for RSA could be grouped into five categories: anatomic, immunologic, hormonal, infectious and genetic. We report here the cytogenetic studies from 454 patients (both couples and individuals, ages ranging from 20 to 54) with a history of RSA losses from 1998 to 2004. Lymphocyte cultures were set up and harvested according to the routine laboratory procedures, and twenty G-banded metaphases were analyzed for each patient. If mosaicism of the X chromosome was suspected, an additional twenty to thirty cells were examined. Should the mosaicism still be indeterminate after the additional cells studied, a second blood specimen was requested for traditional cytogenetic as well as FISH studies. Eleven patients (2.4%) were found to have structural chromosome abnormalities; they are two Robertsonian translocations, seven balanced translocations, one inversion, and one mosaic marker chromosome. Forty-one patients (9.0%) had X chromosome mosaicism. Our data is compatible with the percentage of chromosome structural anomalies found in other reported studies. However, there are a greater percentage of patients who have X chromosome mosaicism in our study as compared to those in other reports. This may be attributed to the second blood study and the use of FISH for diagnosis. This study further demonstrates that the combination of tradition cytogenetics and FISH studies provide valuable diagnostic implements for patients with RSA.

Whole genome array analysis of a patient with chromosome Y rearrangement, multiple congenital anomalies and speech and language delay. *C. Fawcett[1], A. Dawson[2], C. Harvard[1], Y. Qiao[1], E. Rajcan-Separovic[1].* 1) Dept. Pathology, Cytogenetics, UBC,Vancouver, Canada; 2) Cytogenetics, Health Sciences Center, Winnipeg, Canada.

The human Y chromosome is best known for its role in sex determination and spermatogenesis. Rearrangements of the Y chromosome have been frequently associated with infertility, and only sporadically is the rearranged Y noted in individuals with dysmorphic features and/or developmental delay (DD). In these instances, the possibility that Y chromosome rearrangements and the abnormal phenotype are coincidental can not be excluded. We have previously described a child with speech and language delay, short stature, mild dysmorphism and Duane abnormality who has two derivative Y chromosomes (Bal et al, 2004). Extensive molecular and cytogenetic studies showed a loss of the Yq chromosomal material distal to AZFa, the absence of Yp and Yq subtelomeric ends from both derivatives, and the presence of SRY on one of the Y derivatives. The proband has 2 male siblings who have speech and language delay but no other abnormalities and a normal chromosome Y. Because of the family history and the yet unknown role of chromosome Y deletions in DD/dysmorphic features, we have performed a whole genome array analysis using the 1Mb resolution array (Spectral genomics), looking for additional sub-microscopic rearrangements. Our analysis confirmed the loss of the Yq material in the proband, and the deletion of Yp region homologous to the Xp. These deletions were confirmed by FISH and are de novo in origin. In addition a loss of a single clone from 1q44, which was also deleted in the father but not in probands siblings, was noted. This clone has not been previously reported as a common polymorphism and may represent a rare deletion variant or possibly may be imprinted. Our report shows that the whole genome array analysis successfully elucidated the rearrangement of the Y chromosome and identified a rare deletion variant on 1q44. Cataloguing of rare variants and their molecular characterization in families with affected children may ultimately lead to better understanding of their role.

Molecular cytogenetic characterization of an apparently balanced chromosomal rearrangement in an infant with severe craniosynostosis. *S. Shetty, K.M. Boycott, J.S. Parboosingh, F.P. Bernier, J.E. Chernos.* Dept Medical Genetics, Alberta Children's Hosp, Calgary, AB, and University of Calgary, AB, Canada.

Chromosome analysis by G-banded karyotyping is an important part of the investigation of children with physical and developmental disorders. When an unbalanced chromosomal rearrangement is identified, it is considered causative. However, when an apparently balanced rearrangement is detected, the causal link with abnormal phenotype is not so evident. We report an interesting case of craniosynostosis in a newborn girl with a clinically normal twin brother. All of her cranial sutures were fused and she had dysmorphic facial features. Routine cytogenetic analysis revealed a de novo balanced chromosome rearrangement: 46,XX,t(7;18)(p15.3;q11.2). Molecular cytogenetic characterization using Fluorescence In Situ Hybridization (FISH) with a panel of chromosome 7 BAC probes revealed a complex chromosome rearrangement with a refined breakpoint at 7p15.2 for the translocation and a cryptic interstitial deletion (7p21) distal to the translocation breakpoint. This deletion could be due to chromosome breakage secondary to the translocation or a concurrent breakage event. Candidate gene TWIST map to 7p21 region. Typically, craniosynostosis is associated with fusion of either coronal, metopic or saggital sutures. The greater severity of craniosynostosis in our patient may be attributable to a complete loss of candidate gene plus possibly other neighbouring genes leading to a unique contiguous gene syndrome. Microsatellite marker analysis will determine whether the locus encompassing TWIST gene is deleted and the role of TWIST gene will be looked into in our patient . Based on our experience with this case and recently published data a targeted molecular cytogenetics approach using BAC-FISH may be a useful adjunct to routine karyotyping for the detection of cryptic imbalances in individuals with an apparently balanced rearrangement and abnormal phenotype. The identification of an underlying genetic anomaly will improve diagnosis and genetic counseling for specific patients and contribute to a general understanding of the correlation between phenotype and genotype.

Euchromatic duplication 8p23.1. A benign variant? *G. Sekhon, A. Lamb, J. Horwitz, K. Garcia, B. Ravnan, T. Morris, M. Klickovich.* Dept Cytogenetics, Genzyme, Santa Fe, NM.

We identified 11 families (6 pre- and 5 postnatal) of 8p23.1 duplications by cytogenetic analysis and further characterized by FISH with a chromosome 8 painting probe and locus-specific probes for D8S7, D8S574 and 8p subtelomere in the 8p23 region. Chromosome analysis follow-up of the prenatal families showed that, in one family, the duplication was of maternal origin, in two families was of paternal origin and was de novo in two families. In the remaining family the father was unavailable for the study, and thus the inheritance in the family remains inconclusive. Follow-up studies of parents in postnatal cases were performed in three of the families, one was maternal, one was paternal, and one was de novo. Parents were unavailable for follow-up in two of the postnatal families. FISH with a chromosome 8 painting probe (wcp8; Vysis) revealed that the extra material on the chromosome 8 was of chromosome 8 origin. FISH with the locus-specific probes showed two signals, indicating that 8p23.1 was duplicated on the aberrant chromosome. In the probands, where the duplication was inherited, one parent also showed an approximately double signal for the locus-specific probes and can be assumed normal variant. The literature suggests that 8p23.1 duplications are normal variants. However, recent findings also suggest that in some families cytogenetic duplications that appear similar to the euchromatic variants may be clinically significant. In the reported cases a parent carrying the duplication had phenotypic abnormalities. FISH showed that the interval from REPP-REPD was duplicated. If the duplication is inherited from a phenotypically normal parent, it can be assumed that it is a cytogenetic anomaly with no clinical significance. However, if inherited from a phenotypically abnormal parent or de novo, then FISH is warranted to rule out a duplication of REPP-REPD. Documentation with region-specific probes will clarify the clinical significance of this duplication. These studies will also help to reassure patients during prenatal counseling if a normal variant is demonstrated.

A NEW CASE OF INTERSTITIAL 6q16.2 DELETION IN A PATIENT WITH PRADER-WILLI-LIKE PHENOTYPE AND INVESTIGATION OF SIM1 GENE DELETION IN 87 PATIENTS WITH SYNDROMIC OBESITY. *M.C. Varela[1], C.A. Kim[2], D.R. Bertola[2], A.Y. Simões-Sato[1], C.I.E.C. Fabris[1], C.P. Koiffmann[1].* 1) CEGH, Dept Genet and Evolut Biol, Inst Biosciences, Univ Sao Paulo, Sao Paulo, SP, Brazil; 2) Clinical Genetics Unit, Childs Institute, Hospital das Clinicas, Univ Sao Paulo School of Medicine, Sao Paulo, SP, Brazil e-mail: mcvarela@ib.usp.br.

The association of obesity, phenotypic abnormalities and mental retardation characterizes syndromic obesity. Its most common form is the Prader-Willi syndrome (PWS). A PWS-like phenotype (hypotonia, delayed psychomotor development, hyperphagia, obesity, mental retardation, small hands and feet) has been described in 4 patients with chromosome abnormalities involving the chromosome region 6q16.2 that includes the SIM1 gene. Herein we report cytogenetic and genetic studies, including a screening for the SIM1 gene deletion, performed on 87 patients with syndromic obesity and whose genetic tests were negative for PWS. All patients presented normal karyotypes, except for one who had a de novo deletion [46,XX,del(6)(q16.1;q21)]. Eighty-seven patients were analyzed with an intragenic polymorphic marker within the SIM1 gene: 74 cases presented biparental inheritance, 11 were uninformative and the deletion patient showed a paternal deletion. These patients with uninformative results were studied with other markers mapped to 6q16.2 region (D6S2418 and D6S475), and biparental inheritance was observed. In addition to the deletion of the SIM1 intragenic polymorphic marker, deletions of D6S2418 and D6S475 were also detected in our patient. This is the fifth case with an interstitial deletion of the chromosome segment 6q14-q21 presenting a PWS-like phenotype. In conclusion, deletions of chromosome region 6q14-q21 should be investigated in patients with hypotonia, developmental delay, obesity, hyperphagia, rounded face and full cheeks, strabismus, micro/retrognathia, small hands and feet and mental retardation, while SIM1 gene deletions or mutations should be investigated in individuals whose only characteristics are early-onset obesity and hyperphagia. Supported by: FAPESP, CEPID/FAPESP, CNPq.

Dramatic instability of ring chromosome 5: Cytogenetic behavior. *D.J. Niccum, J. Lee, K.A. Casas, J.J. Mulvihill, S. Li.* Section of Genetics, Dept. of Pediatrics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK.

A ring chromosome is a rare genetic anomaly which may cause phenotypic abnormalities even without loss of genetic material. The ring chromosome induces difficulties in sister chromatid exchange by the breakage-fusion-bridge cycle at cell division, resulting in increased cell cycle arrest or apoptosis through the generation of secondary aneuploid cells. We present cytogenetically dynamic mosaicism of ring chromosome 5, including entangled, broken, doubled, or disrupted chromosome 5, as well as tetraploidy, in a 4 year-old male with developmental delay, growth failure, and dysmorphic features. The patient also had gastrointestinal problems, recurrent fever, and frequent upper respiratory infections. .

Characterization of An Analphoid Supernumerary Marker Chromosome with A Neocentromere Derived from 15q2-->qter Using High Resolution CGH and Multiplex FISH Analyses. *X. Huang[1], M.I. Michelina[5], H.L. Mark[3], R. Harston[1], P.J. Benke[4], S. Price[2], A. Milunsky[1].* 1) Dept Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pathology, Boston University School of Medicine, Boston, MA; 3) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 4) University of Miami School of Medicine, Miami, FL USA; 5) Genetica S.C.R.L., Lima, Peru.

Supernumerary marker chromosomes(SMCs) without detectable alphoid DNA are predicted to have a neocentromere and have been referred to as mitotically stable neocentromere marker chromosomes(NMCs). We report the molecular cytogenetic characterization of a new case with analphoid NMC derived from15q25-->qter by using High Resolution CGH (HR-CGH) and multiplex FISH analyses with various alpha-satellite DNA probes, all- human-centromere probe(AHC),whole chromosome painting probes and a subtelomere probe. At age 3 months, the infant has been found to have bilateral sensorineural deafness. Chromosome studies showed that the propositus has a de novo extra SMC in 80% of cells examined. HR-CGH revealed rev ish enh(15) (q25qter). Molecular cytogenetic analysis and Molecular DNA polymorphism study demonstrated that this extra SMC is a NMC containing an inverted duplication of the distal long arm of chromosome 15(tetrasomy 15q25-->qter) which originated paternally i.e. ish der(15)(qter-->q25::q25[neocen]-->qter)(AHC-,CEP-,WCP15+, PCP15q x2)pat. This case represents a new report of a neocentromere on distal chromosome 15q suggesting that this region appears to be susceptible to the formation of neocentromeres.

Prenatal diagnosis of 22q11.2 microduplication. *C. de La Rochebrochard[1,2], A. Goldenberg[2], I. Durand[3], A. Laquerriere[4], V. Ickowicz[5], P. Saugier-Veber[2], D. Eurin[5], H. Moirot[1,2], A. Diguet[5], F. de Kergal[4], C. Tiercin[1], S. Ferenbach[2], B. Mace[1], T. Frebourg[2], G. Joly-Helas[1,2].* 1) Laboratory of Cytogenetics; 2) Department of Genetics; 3) Department of Paediatric; 4) Department of Pathology; 5) Department of Obstetrics and Gynaecology, Rouen University Hospital, France.

The 22q11.2 microduplication syndrome is a rare recently recognized condition, which clinical phenotype includes subtle facial features, congenital heart defects and learning disabilities. We report here on a 23 year-old, gravida 3, para 1 woman referred at 23 weeks gestation. An obstetric ultrasonographic examination detected a severe, non conotruncal, complex congenital heart malformation. The parents elected to terminate the pregnancy at 24 weeks of gestation. RHG banded foetal chromosome analysis on the cord blood lymphocytes was normal. FISH, performed with probes for the DiGeorge syndrome (Vysis), showed three TUPLE1 signals in 70 out 103 interphase cells, with two chromosome 22 specific ARSA signals. Parental FISH analysis disclosed the same duplication on the healthy fathers interphase cells. Using a QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) assay specific of the 22q11.2 region, we estimated the duplication size to 3 Mb. Post-mortem examination showed an eutrophic female foetus presenting superior placement of eyebrows and downslanting palpebral fissures, long philtrum, micrognathism and dysplastic ears. Autopsy confirmed the cardiovascular findings (single atrium, total anomalous pulmonary venous return [TAPVR], small left ventricle, transposed great arteries and subpulmonary ventricular septal defect) and abdominal *situs inversus totalis*. It revealed thoracic heterotaxia. To our knowledge, this is the first case of a 22q11.2 microduplication prenatal diagnosis. Interestingly, TAPVR is a typical feature of Cat-eye syndrome associated with 22q11 tetrasomy. Phenotypic variability of the 22q11.2 duplication syndrome, ranging from none to severe congenital heart defects, and the technical difficulties in detecting microduplications strongly suggest that this syndrome remains under diagnosed.

FISH analysis of sub-microscopic variability of the human genome. *Y. Qiao[1,2], C. Harvard[1,2], C. Fawcett[1], JJA. Holden[3,4], MES. Lewis[2], E. Rajcan-Separovic[1].* 1) Dept. Pathology, UBC, Vancouver, Canada; 2) Dept. Medical Genetics, UBC, Vancouver, Canada; 3) Dept. Physiology,Queen's University, Kingston, ON, Canada; 4) Dept. Psychiatry,Queen's University, Kingston, ON, Canada.

The variability of the human genome has been recognized since the introduction of chromosome banding analysis. It is now well-established that variation of chromosome band size in regions rich in repetitive sequences is not associated with a clinical phenotype. More recently, with the development and application of whole genome arrays, it is clear that the human genome also demonstrates tremendous variability at the sub-microscopic level, which is not restricted to regions containing highly repetitive DNA. We have used the commercial 1Mb resolution genomic array (Spectral Genomics) to identify novel sub-microscopic changes associated with autism, intellectual disability and cancer. During this process we identified recurrent changes in 60 affected and control individuals. In order to understand the sub-microscopic DNA copy number variability we are now using FISH to study copy number changes of polymorphic DNA clones and establish the pattern of their inheritance. Our analyses so far suggest the existence of several groups of polymorphic clones which map to interstitial regions: a) clones that show a wide copy number range (1~8 copies/chromosome); b) clones that show simple copy number variability (0-1 copies/chromosome); and c) clones which do not demonstrate changes by FISH, despite a gain/loss detected on the array, possibly due to the limited size of the sub-microscopic DNA change. The copy number changes for a group of selected clones were studied in 3 families and showed familial inheritance. Although at the present time microdeletions and microduplications found in normal individuals are thought to represent the natural variability of the human genome, the possibility exists that they may have future impact on an as yet unapparent, genetically influenced, disease susceptibility. Further studies of sub-microscopic polymorphisms, their cataloguing, inheritance and genetic significance promise to reveal exciting and new discoveries about our genome.

Chromosomal Segregation in Spermatozoa of Fourteen Robertsonian Translocation Carriers. *E. Van Assche[1], G. Ogur[1], W. Vegetti[2], G. Verheyen[3], H. Tournaye[3], M. Bonduelle[1], I. Liebaers[1].* 1) Centre for Medical Genetics, University Hospital, Dutch-speaking Free University of Brussels, Laarbeeklaan 101, 1090 Brussels, Belgium; 2) First Department of Obstetrics and Gynaecology, University of Milan, Via della Commenda 12, 20122 Milan, Italy; 3) Centre for Reproductive Medicine, University Hospital, Dutch-speaking Free University of Brussels, Laarbeeklaan 101, 1090 Brussels, Belgium.

Robertsonian (Rob) translocations are one of the most common structural chromosomal aberrations observed in humans with an incidence of 1.23 per thousand births (Nielsen and Wohlert, 1991). In general, carriers of Rob translocations are phenotypically normal, but are at increased risk for spontaneous abortions and chromosomally unbalanced offspring. In addition, male carriers of Rob translocations can have fertility problems associated with abnormal sperm parameters. In the present study, the meiotic segregation behavior in spermatozoa from 14 Rob translocation carriers (7 der(13;14), 2 der(13;15), 2 der(14;15), 2 der(14;21) and 1 der(21;22)), with abnormal sperm parameters, were determined by Fluorescence In Situ hybridization (FISH). For the segregation analysis dual- and triple- color FISH, using sub-telomeric, and/or locus-specific and/or centromeric probes for chromosomes 13, 14, 15, 21 and 22 was used. Between 500 and 2 663 spermatozoa were analyzed per patient. Finally, spermatozoa of 5 carriers were also screened by FISH for enumeration of the chromosomes 13, 18, 21, X and Y for investigation of possible inter-chromosomal effects. It was shown that in each type of Rob translocation, meiotic segregation behavior is similar, comparable and occurs non-randomly. The majority of the spermatozoa result from alternate segregation (range: 76 % - 89.40 %). There is, however, still a considerable amount of unbalanced spermatozoa resulting from adjacent segregation mode (range: 10.30 %- 23.40 %). These data provide useful information for genetic counseling purposes. Moreover, aneuploidy for chromosomes 13,18, 21, X and Y was studied in five patients and suggested an inter-chromosomal effect.

Single Chromosomal Copy Deletion Detection using the Affymetrix GeneChip Mapping Array in DiGeorge Syndrome. *C.M. Stanczak[1], Z. Chen[1], S. McGhee[2], S.F. Nelson[1], E.R.B. McCabe[1,2,3].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 2) Department of Pediatrics, David Geffen School of Medicine at UCLA and Mattel Childrens Hospital at UCLA, Los Angeles, CA 90095; 3) Molecular Biology Institute, UCLA, Los Angeles, CA 90095.

DiGeorge syndrome is estimated to occur in 1:4000 births and is the most common contiguous-gene deletion syndrome in humans. Deletions in the 22q11.2 DiGeorge syndrome chromosome region (DGCR) prevent proper neural crest migration resulting in thymic and parathyroid hypoplasia and heart outflow tract defects. The purpose of this investigation was to determine whether the Affymetrix GeneChip Mapping 50K Array (SNP chip) could be utilized to detect and to map breakpoints in patients with DiGeorge syndrome. The SNP chip is a high-density oligonucleotide array that allows a rapid, standardized, parallel genotyping of over 50,000 SNPs across the human genome. Genomic DNA was isolated from three well-characterized Coriell cell lines and from a DiGeorge syndrome patients blood and analyzed on the Affymetrix platform. We confirmed the deletion breakpoints in the three cell lines and identified the patients deletion to be in the 22q11.2 DGCR. In all four cases we detected a single copy of genomic DNA in this region compared with two copies in normal individuals. The data permitted us to specify minimum and maximum deletion intervals for the patient and these intervals compared well with the control cell lines and corroborated the independent FISH results from this patient. This study demonstrates the use of the 50K SNP Chips for molecular cytogenetic analysis, and shows that they have utility beyond the genotyping which these arrays were initially designed. With approximately 1% of live births (40,000 U.S. neonates annually) having cytogenetic disorders, we envision a significant need for such a platform to facilitate rapid, high-throughput, genomic analysis for molecular cytogenetic applications.

Megabase-scale variation at 8p23 inversion region indicative of genome hyperplasticity. *R.A. Ophoff[1,2], O. Lee[1], E. Slaten[1], J. Kung[1], N.B. Freimer[1,2], P.N. Rao[3].* 1) Ctr Neurobehavioral Genetics Univ California Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, Univ California Los Angeles, Los Angeles, CA; 3) Molecular Cytogenetics Laboratories, Department of Pathology, Univ California Los Angeles, Los Angeles, CA.

The region of chromosome 8p23 was reported to contain a submicroscopical inversion polymorphism encompassing almost 4 Mb of unique sequence, flanked by large blocks of duplicated segments. This region has been implicated in susceptibility of severe bipolar as well as with panic disorder. In order to understand the possible role of the common inversion polymorphism in these neurobehavioral traits, our studies focused on the molecular characteristics and the genomic history of the 8p23 region. The segmental duplications flanking the inversion region are in opposite (palindromic) orientation mediating recurrent inversion events as seen by the multiple haplotypes associated with the inversion. Combined analysis by fluorescent in situ hybridization (FISH) and pulsed-field gel electrophoresis (PFGE) revealed extensive variation within these flanking duplicated sequences ranging from 100-1,500 kb in size. In a series of 30 African-American and Caucasian individuals from the Human Variation Collections of the NIGMS Repository, all subjects could uniquely be identified by PFGE showing distinctive alleles for each individual. Metaphase and interphase FISH analysis of the same individuals using the same sets of probes showed that both the proximal and distal segmental duplications are involved in these types of variations, and not necessarily linked to inversion status. Currently we are investigating two large CEPH reference pedigrees with known recombinants within the 8p23 region to test the meiotic stability of this type of genome plasticity, which may explain the extreme diversity seen in the African-American and Caucasian subjects. It is very likely that these megabase-scale variations in gene-rich regions have functional consequences that may be associated with human phenotypic variation.

Delineation of deletion breakpoints in patients with monosomy 1p36 using a combination of Chromosomal Microarray Analysis and FISH. *S.-H.L. Kang, C.A. Bacino, J. Li, Z. Ou, C.A. Shaw, A. Patel, A.C. Chinault, S.W. Cheung.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Monosomy 1p36 is the most common human terminal deletion syndrome, with an estimated occurrence of 1 in 5000 live births. This chromosomal abnormality results in mental retardation, developmental delay, hearing loss, seizures, and cardiac anomalies, in addition to distinct facial features including large anterior fontanel, deep-set eyes, flat nasal bridge, asymmetric ears, and pointed chin. Previous analyses of 1p36 deletion syndrome patients revealed a large degree of variability in the location and size of the deletion. Furthermore, the molecular mechanism for generating these deletions still remains unclear. It is therefore important to finely map and characterize 1p36 deletion breakpoints in order to gain more insight into the molecular basis of the syndrome. We studied six patients, four with known 1p36 deletion syndrome based on initial karyotype and/or telomere fluorescence *in situ* hybridization (FISH) analyses, by an array-based comparative genomic hybridization technique known as Chromosome Microarray Analysis (CMA). Our version 4 clinical array contains eight non-overlapping BAC clones covering >10 MB of the distal end of chromosome 1p. The CMA analyses revealed three different classes of deletions. Three patients harbor telomeric deletions of sequences represented by four clones resulting in a loss of ~2-4 MB of genomic DNA; two patients harbor larger telomeric deletions of a region identified by seven clones resulting in a loss of ~7.6-8.7 MB of genomic DNA; and one patient harbors an interstitial deletion of a region detected by two clones resulting in a loss of ~0.5-3.0 MB of genomic DNA. Because the BAC clones on the microarray are not overlapping, we performed FISH analysis with overlapping BAC clones adjacent to the deleted regions detected by CMA in order to refine the deletion breakpoints. Further analyses of these genomic regions should aid in determining potential mechanisms for the generation of terminal deletions as well as improving genotype/phenotype correlations to locate candidate genes.

Angelman syndrome in a boy with familial 15q11.2 microdeletion detected by microarray CGH. *O. Shimokawa[1, 2, 3], N. Miyake[1, 2], N. Harada[1, 2, 3], N. Sosonkina[4], T. Ohta[4], S. Saitoh[5], M. Iwakoshi[6], K. Yoshiura[1, 2], N. Niikawa[1, 2], N. Matsumoto[2, 7].* 1) Department of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) CREST, Japan Science and Technology Agency, Kawaguchi, Japan; 3) Kyushu Medical Science Nagasaki Laboratory, Nagasaki, Japan; 4) The Research Institute of Personalized Health Sciences, Health Sciences University of Hokkaido, Hokkaido, Japan; 5) Department of Pediatrics, Hokkaido University School of Medicine, Sapporo, Japan; 6) Nishinomiya Municipal Wakaba-en, Nishinomiya, Japan; 7) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

A familial 1.6-Mb-sized 15q11.2 microdeletion involving *UBE3A* was detected in a boy with features of Angelman syndrome (AS) by microarray CGH. Microarray using 2,173 BAC clone DNAs with 1.5-Mb resolution including subtelomeric regions, genes responsible for known mental retardation (MR)/multiple congenital anomaly syndromes was used for detection of genomic copy-number changes in children with idiopathic MR. The microarray detected a heterozygous deletion of RP11-1081A4 that covers *UBE3A* in a boy with features of AS, such as severe MR, absence of speech, epilepsy, happy disposition, abnormal EEG, sleep disturbance, microcephaly, prominent mandible, large mouth, and small, widely spaced teeth, but lacked characteristic laughter and hypopigmentation. Detailed FISH analysis revealed that his 15q11.2 deletion was 1.6-Mb in size, and involved *UBE3A, ATP10A* and a part of *GABRB3A*. FISH also revealed the same deletion in his phenotypically normal mother and maternal grandfather. Although FISH studies were unavailable in parents of the grandfather, it is likely that his deletion may have come from his father (great-grandfather).
