Neuropeptide Y (NPY) is a peptide encoded by the NPY gene on human chromosome 7q15. This peptide affects multiple metabolic processes, including regulation of energy balance, insulin release, and lipoprotein lipase activity, and administration of NPY in the central nervous system of rat has been shown to be a powerful stimulant of feeding behavior. Therefore, NPY was analyzed as a candidate gene for obesity in Pima Indians. The coding region and ~2 kb of the promoter region of the NPY gene was sequenced in 96 non-first degree related extremely obese Pima Indians (body mass index [BMI]=50.5-79.6kg/m2). Seven single nucleotide polymorphisms (SNP) were identified, including two synonymous SNPs (Ser50Ser, Ser68Ser) and five promoter SNPs. These variants were genotyped for a family-based association analysis in 1037 Pima Indians. The Ser50Ser (A/G), with a minor allele frequency of 0.07 (G), was associated with BMI (p=0.03 under an additive model, p=0.05 under a recessive [A/A vs. A/G+G/G] model, adjusted for age, sex, birth-year and Pima heritage). Among 252 non-diabetic, full-heritage Pima subjects who had undergone detailed metabolic testing, subjects with the A/G genotype (n=31) for Ser50Ser had a lower plasma glucose level at 30 min and 60 min during an oral glucose tolerant test compared to subjects with the A/A genotype (n=221) (1393 vs. 1482mg/dl, p=0.007; 1435 vs. 1522mg/dl, p=0.04, respectively, adjusted for age, sex, % fat and family membership). This SNP was additionally associated with 24-hour energy intake and energy balance in 176 non-diabetic, full-heritage Pima subjects, as measured in a respiratory chamber. Subjects with the A/G genotype (n=23) had a lower energy intake and were in more negative energy balance as compared to subjects with the A/A genotype (n=153) (223568 vs. 234229kcal/day, p=0.003; -110 48 vs. -5113kcal/day, p=0.04, respectively, adjusted for age, sex, % fat and family membership). These data indicate that a variant in the NPY gene may influence susceptibility to obesity by influencing energy balance.

Polymorphisms in the FAS and FASL genes in Type 2 diabetes and in phenotypic traits caused by demise in beta cell mass and function. *R. Nolsoe[1], Y.H. Hamid[1], F. Pociot[1], S. Paulsen[1], K.M. Andersen[1], K. Borch-Johnsen[1], T. Drivsholm[2], T. Hansen[1], O.B. Pedersen[1,3], T. Mandrup-Poulsen[1,4].* 1) Steno Diabetes Ctr, Gentofte, Denmark; 2) Research Centre for Prevention and Health, Copenhagen County, Glostrup University Hospital, Denmark; 3) Faculty of Health Science, University of Aarhus, Denmark; 4) Department of Molecular Medicine, The Rolf Luft Center for Diabetes Research, Karolinska Institute, Stockholm, Sweden.

Aims/hypothesis. Type 2 diabetes is caused by a failure of the pancreatic beta cells to compensate for insulin resistance leading to hyperglycemia. There is evidence for a central role of a decline in beta cell mass due to increased beta cell apoptosis in the pathophysiology of Type 2 diabetes. Elevated glucose concentration upregulates Fas in human beta cells and induces apoptosis due to constitutive expression of FasL. The aims of this study were to test if polymorphisms in the FAS and FASL genes were associated with Type 2 diabetes or with estimates of pancreatic beta cell function and mass in normal-glucose tolerant (NGT) Caucasians. Methods. We genotyped two functional promoter variants; FAS-670 G/A and FASL-844C/T as well as a microsatellite in 3'UTR of FASL in 549 Type 2 diabetic patients and 525 normal-glucose tolerant subjects. Fishers exact test was applied to examine differences in allele frequencies and genotype distributions between Type 2 diabetic and NGT subjects. Phenotypic differences between the genotype groups among NGT subjects were tested with a general linear model including gender and genotype as fixed factors and age and BMI as covariate factors. Results. We found a significant association to Type 2 diabetes for the most frequent allele (16-repeat) of the FASL microsatellite (p value 0.04).There were no significant difference in genotype distribution between type 2 diabetic patients and normal-glucose tolerant subjects for the FAS-670G/A and FASL-844C/T polymorphisms (p values 0.16 and 0.4) or in the allele distribution for these two polymorphisms (p values 0.3 and 0.4). We found no overall significant association of any of the phenotypic traits to any of the polymorphisms tested in the FAS and FASL genes. Conclusion. We conclude that there is an association of the 16-repeat allele of the FASL microsatelitte to Type 2 diabetes in Danish Caucasian subjects.

Association of genetic variants in *VLDLR* with Type 2 Diabetes Related Traits in Mexican Americans. *V.S. Farook[1], S. Puppala[1], R. Arya[2], J. Schneider[1], S. Fowler[2], T.D. Dyer[1], S.A. Cole[1], L. Almasy[1], J. Blangero[1], M.P. Stern[2], R. Duggirala[1].* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) University of Texas Health Science Center, San Antonio, TX.

The incidence of metabolic syndrome (MS), a predictor of type 2 diabetes (T2DM) and coronary heart disease, continues to increase worldwide. Linkage between a broad region on chromosome 9 and susceptibility to T2DM-MS related traits has been established in several family studies including ours. One of the positional candidate genes in this region is *VLDLR* (very low density lipoprotein receptor) which plays an important role in triglyceride and cholesterol metabolism. To assess if variants in *VLDLR* may contribute to T2DM-MS related traits, we chose 9 single nucleotide polymorphisms (SNPs) from the public databases and genotyped ~720 individuals who participated in the San Antonio Family Diabetes/Gallbladder Study. All SNPs are in HW equilibrium. We performed association analyses on these SNPs for 10 diabetes related phenotypes using measured genotype analysis [MGA], quantitative transmission disequilibrium test [QTDT], and quantitative trait linkage disequilibrium [QTLD] test within the variance components analytical framework (SOLAR). All techniques yielded similar results; only QTLD results (p 0.05) and, in the case of population stratification QTDT results are reported. Of the 9 SNPs studied, 3 (rs10967213; rs2290465; rs8210) showed significant association with insulin (p = 0.028-0.043), 2 (rs1551411; rs2290465) with MS (p = 0.025 and 0.010) and 1 (rs8210) with HDL-cholesterol (p = 0.012). Interestingly, one of the SNPs (rs10967213) showed strong associations with 6 phenotypes: adiponectin (p = 0.004), insulin (p = 0.028), leptin (p = 0.002), triglycerides (p = 0.033), BMI (p = 0.005), and waist circumference (p = 0.011); and, a moderate association with MS (p = 0.066). Although, an association between T2DM and a variant in *VLDLR* has been reported in a Japanese population, we show here for the first time a variant in *VLDLR* to be associated with several metabolic traits. In conclusion, variants in *VLDLR* are significantly associated with T2DM-MS related phenotypes in Mexican Americans.

Association Between Sequence Variants in the Positional Candidate Gene *GNAT3* Near *CD36* Region and Metabolic Syndrome in Mexican Americans: Preliminary Findings. *S. Puppala[1], V.S. Farook[1], R. Arya[2], J. Schneider[1], S. Fowler[2], T.D. Dyer[1], S.A. Cole[1], L. Almasy[1], J. Blangero[1], R. Duggirala[1].* 1) Southwest Fndn for Biomed Res, San Antonio, TX; 2) Univ of Texas Health Sci Ctr, San Antonio, TX.

We identified a major gene for Metabolic Syndrome (MS, NCEP/ATPIII) on chromosome 7q21 between the markers D7S2212 and D7S821 in Mexican Americans, previously. Other studies also implicated a broad region on chromosome 7q to influence MS related phenotypes. One of the important positional candidate genes in the 7q21 chromosomal region that has functional relevance to MS is *CD36* or *FAT* (fatty acid translocase). We have started exploring several genes in or around *CD36* gene region that are within the 1 LOD-unit support interval of our major linkage peak on 7q21. In the present study, we have screened the *GNAT3* (Guanine nucleotide binding protein, alpha transducing 3) gene, which is located upstream of *CD36* to identify the sequence variants that may explain our initial MS linkage findings in Mexican Americans. We obtained SNP information from public databases, and typed 5 SNPs (rs799975, rs6942728, rs1473122, rs11760281, and rs10234980) from the *GNAT3* region using data from the San Antonio Family Diabetes/Gallbladder Study (SAFDGS) (N = ~720). We performed association analyses between MS and the 5 SNPs, using the measured genotype analysis within the variance components (threshold model) framework (SOLAR). All 5 SNPs are in HWE. The minor allele frequencies ranged from 3% to 40%. Of the SNPs examined in the *GNAT3*, 4 SNPs showed significant or suggestive association with MS after adjusting for significant age effects: rs799975 ($p = 0.058$), rs6942728 ($p = 0.088$), rs1473122 ($p = 0.028$), and rs11760281 ($p = 0.0006$). Given evidence for association of variants in the *CD36* region with MS related phenotypes in other studies, it is interesting to find a highly significant association between MS and rs11760281 (minor allele frequency = 40%). In summary, our preliminary data signify the important association of variants in the *GNAT3* with MS in Mexican Americans, and the regions in or around *CD36* are being investigated further.

Association of *ACDC, PPARG* and *LEP* gene polymorphisms in type 2 diabetes and obesity among the Samoans.

S.R. Indugula[1], S. Viali[2], J. Tufa[3], H. Xi[1], R. Kaushal[1], P. Pal[1], G. Sun[1], D. Smelser[1], L. Jin[1], D.E. Weeks[4], S.T. McGarvey[5], R. Deka[1]. 1) Dept Environmental Health, Univ of Cincinnati, Cincinnati, OH; 2) Tupua Tamasese Meaole Hospital, Apia, Samoa; 3) Dept of Health, Pago Pago, American Samoa; 4) Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 5) International Health Institute, Brown Univ, Providence, RI.

Type 2 diabetes (T2DM) and obesity have reached epidemic proportions on a global scale. Both phenotypes result from a complex interaction of genetic and environmental factors. We have tested for association of variants in three plausible candidate genes (*ACDC*, *PPARG*, *LEP*) with T2DM and obesity among the Samoans of Polynesia, who have a very high prevalence of both diseases. We analyzed eight Single Nucleotide Polymorphisms (SNPs) in *ACDC* encoding for adiponectin, which is expressed in adipose tissue and is correlated with the severity of insulin resistance; seven SNPs in *PPARG*, which regulates adipocyte differentiation, lipid metabolism and insulin sensitivity; and six SNPs in *LEP* encoding for leptin known for its role in body weight regulation. For T2DM, we recruited 166 cases and 216 controls; and for obesity, we chose phenotypically extreme obese (mean BMI = 44.04, N = 96) and lean (mean BMI = 23.73, N = 87) subjects. To evaluate for any possible population stratification, we genotyped 30 null SNPs spanning the genome in all our samples. A -value of 0.97 was obtained negating any spurious association from population substructure. In *ACDC*, we observed significant association at the haplotype level ($P = 0.014$) with T2DM. No significant association was observed either at genotypic or allelic level with T2DM and obesity. In *PPARG*, rs10510411 showed association ($P = 0.039$) with obesity, and also significant association was observed at the haplotype level ($P = 0.006$) with T2DM. In *LEP*, association at haplotype level was observed ($P = 0.039$) in the diabetes group although none was observed at genotypic or allelic level with T2DM and obesity. Our study demonstrates a possible role of variants in *ACDC*, *PPARG* and *LEP* in the pathogenesis of T2DM and obesity related phenotypes among the Samoans. Supported by grants DK59642, DK55406.

Association of *CAPN10* Haplotypes with Type 2 Diabetes in the Saudi Population. *K. Al-Rubeaan[1], F. Imtiaz[2], O. Alsmadi[2], S.M. Wakil[2], P. Carroll[2], M. Rajab[2], S. Al-Katari[1], M. Al-Katari[1], B.F Meyer[2].* 1) Diabetes Center, King Abdulaziz University, Riyadh, Saudi Arabia; 2) Aragene, KFSH, Riyadh, Saudi Arabia.

The biological function(s) of CAPN10 is/are unknown. One role for CAPN10 is believed to be triggering of insulin exocytosis from beta cells. Variations in CAPN10 were found to associate with type 2 diabetes (T2D) in various populations. Inheritance of a specific haplotype combination defined by three single-nucleotide polymorphisms (SNP 43, 19, and 63) was found to associate with a threefold increased T2D risk. SNP 43, 19, and 63 are in non-coding regions of CAPN10 and are believed to affect the transcriptional regulation of CAPN10. To date there has been no reported studies of the association of CAPN10 haplotypes with T2D in Arab populations. We used fragment analysis and sequencing for genotyping of SNP 19 and SNPs 43/63 respectively. Alleles for SNPs 43, 19 and 63 are G/A, 2/3-32bp repeats, and C/T respectively. SNP alleles were assigned either 1 or 2 in the order mentioned for each pair. 480 patients diagnosed with T2D according to WHO criteria were studied along with a normal control set (age >60 with fasting blood glucose <7mM). Haplotypes (SNP 43, 19, 63) were ascertained where no ambiguity was present or deduced on a most likely basis. Frequencies of the eight possible haplotypes were identified and haplotype combinations assigned for each patient. 111/111 was the most common combination seen in both patients and controls. Previous studies indicated the 112/121-haplotype combination to be most strongly associated with T2D in several populations. However, this is not the case in the Saudi population where the 111/121-haplotype combination was significantly increased in T2D patients compared with normal controls (p=0.006). SNP-44 (C/T) of CAPN10 was also typed for all patients/controls and similarly to results seen in UK T2D patients, the C allele was shown to be associated in our population (p=0.019). In addition, frequencies of various other haplotypes and their combinations in the Saudi T2D patients are significantly different to those reported in other populations.

A functional NFB1 promoter polymorphism and type I diabetes in Norwegian trio families. *M.C. Eike[1], G. Joner[2], K. Dahl-Jørgensen[2], K.S. Rønningen[3], D.E. Undlien[4], E. Thorsby[1], B.A. Lie[5].* 1) Inst. of Immunology, Rikshospitalet Univ. Hospital and Univ. of Oslo, Oslo, Norway; 2) Dep. of Pediatrics, Ullevål Univ. Hospital, Oslo, Norway; 3) Div. of Epidemiology, Norwegian Inst. of Public Health, Oslo, Norway; 4) Inst. of Medical Genetics, Faculty Div. Ullevål Univ. Hospital, Univ. of Oslo, Norway; 5) Inst. of Immunology, Rikshospitalet Univ. Hospital, Oslo, Norway.

Nuclear Factor-B1 (NFB1) encodes two proteins, one of which (p50) is a transcription factor involved in regulation of both adaptive and natural immune responses, as well as a number of non-immunological responses. Significant changes in expression and function of NFB1 have been shown in studies of non-obese diabetic (NOD) mice, a murine model of type I diabetes (T1D) in humans. A -94delATTG promoter allele has been shown to cause lower promoter activity in reporter gene assays. The opposite allele (-94insATTG) has been reported associated with T1D in North American and UK families. In an effort to replicate these findings, 434 Norwegian T1D trio families were genotyped using fragment length analysis. Preliminary results, before confirming the genotyping results with an alternative method, shows a moderately significant positive association with the -94insATTG allele (RR = 1.276/p = 0.01933 by the transmission disequilibrium test (TDT) and OR = 1.264/p = 0.02098 by the test of haplotype-based haplotype relative risk (HHRR)). Together with earlier findings, these results strengthen the possibility that NFB1 is involved in the development of type I diabetes in humans.

In addition to the results on NFB1, genotyping results in the same material of a functional FCRL3 polymorphism (-169 C/T) will be presented. FCRL3 is a member of the Fc receptor-like family, with as yet unknown functions. However, FCLR3 lies in a region (1q21-23) showing linkage to multiple autoimmune diseases. The -169 C/T polymorphism alters the binding affinity for NFB1 and regulates FCLR3 expression, and has recently been reported associated with several autoimmune diseases in a Japanese population.

Association of the PPAR P12A polymorphism with type 2 diabetes in the Saudi population. *S.M. Wakil[1], O. Alsmadi[1], K. Al-Rubeaan[2], F. Imtiaz[1], P. Carroll[1], M. Rajab[1], S. Al-Katari[2], M. Al-Katari[2], B.F. Meyer[1].* 1) Aragene, KFSH&RC, Riyadh, Central, Saudi Arabia; 2) Diabetes Center, King Abdulaziz University Hospital, Riyadh,Saudi Arabia.

The Peroxisome Proliferator-activated receptor- (PPAR) is a ligand-activated transcriptional factor involved in lipid and glucose metabolism, fatty acid transport, and adipocyte differentiation. PPAR has a common polymorphism designated Pro12Ala (P12A) that leads to a non conservative change from proline to alanine at codon 12. In a study conducted on Japanese and Finns, the P12A allele was found to associate with metabolically deleterious phenotypes, such as decreased insulin sensitivity, obesity, and type 2 diabetes. However, in other studies in Caucasians, no similar association was found. To date there are no reports regarding the association of P12A polymorphism with type 2 diabetes in Arab populations. We developed a molecular beacon based real time PCR assay for the genotyping of this polymorphism. We studied a group of 1348 patients diagnosed with type 2 diabetes based on WHO criteria and 219 normal control subjects (age >60 with fasting blood glucose <7mM). The PPAR P allele frequencies were 0.96 and 0.94 in type 2 diabetics and controls respectively. The PPAR A allele frequencies were 0.04 and 0.06 in type 2 diabetics and controls respectively. P12A allele frequencies were not significantly different in type 2 diabetics and controls (p=0.164). The very high incidence of the risk allele in this population (0.96) requires further analysis of a much larger sample population to identify relative risk significance. The risk allele is present in the Saudi population at one of the highest frequencies observed in any study. Whilst risk associated with P12A may contribute to development of type 2 diabetes in this population, the relative risk (diabetics vs normals) is low and indicates the likely presence of other genes and/or environmental factors which may have a greater influence upon the development of type 2 diabetes in this population.

Modest T2D association of HNF4A P2 promoter SNPs observed in meta-analysis of more than 18,000 T2D individuals and controls. *L. Scott[1], K. Mohlke[2], F.S. Collins[3], M. Boehnke[1], for the HNF4A Meta-Analysis Consortium.* 1) U Michigan, Ann Arbor, MI; 2) UNC, Chapel Hill, NC; 3) NHGRI, NIH, Bethsda, MD.

SNPs near the P2 promoter of HNF4A were previously reported to be associated with type 2 diabetes (T2D) in Finnish (FUSION) and Ashkenazi Jewish samples (Silander et al. 2004 and Love-Gregory et al. 2004, multiplicative OR (95%C.I.) of 1.33 (1.06-1.65) and 1.46 (1.12-1.91), respectively). Now we have performed a meta-analysis of published and unpublished data for HNF4A SNPs genotyped in 19 additional case/control and 4 family-based samples. These samples consist of 9852 T2D individuals and 8833 controls from European, European-American, Hispanic, African-American, African, and American Indian backgrounds. We combined odds ratios (ORs) weighted by sample size for 4 associated P2 region SNPs observed to be in almost perfect LD in the original studies (rs4810424, rs1884613, rs1884614, rs2144908). The meta-analysis multiplicative OR for the non-original samples was 1.064 (95% C.I. 1.015-1.116, p=.01), in the direction of the original associations although considerably smaller. Including the FUSION or Ashkenazi samples increased the OR to 1.074 (95% C.I. 1.026-1.125, p=.003) and 1.074 (95% C.I. 1.026-1.135, p=.003), respectively. However, we observed significant heterogeneity in ORs for each analysis (p=.002, .001, and .0007, respectively). We next tested for study-wide correlation between the T2D OR and family history, study type, ethnicity, mean sample BMI, and mean sample age of diagnosis. Only older mean age of diagnosis showed a nominal trend toward association with the original risk alleles (p=.07). In addition, 8 HNF4A SNPs outside the P2 region were genotyped in at least 3 studies including the original ones. Of these, the C allele of rs3212183 (OR=1.15, 95% C.I. 1.04-1.28, p=.007, n studies =5) and the C allele of rs6031552 (OR=1.16, 95% C.I. 1.01-1.33, p=.04, n studies =3) showed significant association with T2D. Overall we found modest evidence for association of HNF4A SNPs with T2D in a large meta-analysis, and further observed significant between sample heterogeneity suggesting there may be sample-specific characteristics influencing the effect of HNF4A variants.

Contribution of Common PBX1 SNPs to Type 2 Diabetes Susceptibility in French Caucasians. *K. Duesing[1], P. Froguel[1,2], F. Gibson[1], International Type 2 Diabetes 1q Consortium.* 1) Imperial College London, UK; 2) CNRS 8090, Institut Pasteur de Lille, France.

Pre-B-cell leukemia transcription factor 1 (Pbx1) is a member of the TALE class of homeodomain proteins, which function as components of hetero-oligomeric transcription factor complexes. The interaction of Pbx1 with Pdx1, a master regulator of pancreatic development, has been shown to be essential for the normal proliferation of differentiated pancreatic cells and Pbx1 deficient mice exhibit pancreatic hypoplasia. The human PBX1 gene is located at chromosome 1q23, within the most consistently replicated type 2 diabetes (T2D) susceptibility locus in the human genome. We have examined the contribution of common PBX1 SNPs (frequency5%) to T2D susceptibility in the French Caucasian population. Sequencing of 1kb of the PBX1 promoter region, exons and flanking intronic sequence in 24 individuals identified 12 SNPs. In addition, we selected 21 SNPs from dbSNP, of which 18 were in ultra-conserved non-coding regions. These 33 SNPs were genotyped in 744 T2D cases and 894 normoglycemic controls. We identified 4 SNPs in intron 2 (P=0.046-0.006) and a non-synonymous coding SNP (G21S) in exon 1 (P=0.028) that were associated with T2D. Interestingly, the G21S variant is located in the Meis1 interaction domain of PBX1 that has been shown to influence its nuclear localisation. We employed various methods (linkage partitioning, GIST, LAMA) to analyse the associated SNPs for contribution to the linkage signal at 1q in French T2D families. The results of these analyses consistently indicated that the G21S variant, but not the intron 2 SNPs, is associated with the evidence for linkage (P=0.02-0.03). Furthermore, we observed that the frequency of the associated S allele increases progressively from controls (0.20)cases (0.23)probands from T2D families (0.35)probands from families showing linkage to 1q (0.42). In summary, common variation in the PBX1 gene is both associated with T2D and contributes to the linkage signal at 1q in the French Caucasian population.

Insulin Promoter Factor 1 Variation is Associated with Type 2 Diabetes in African Americans. *S.C. Elbein[1,2], M.A. Karim[1], T.C. Hale[1,2], X. Wang[1,2].* 1) Division of Endocrinology and Metabolism, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Medical Service, Central Arkansas Veterans Healthcare System, Little Rock, Arkansas.

Defective insulin secretion is a key defect in the pathogenesis of type 2 diabetes (T2DM). The -cell specific transcription factor, insulin promoter factor 1 gene (IPF1), is essential to pancreatic development and the maintenance of -cell mass. We hypothesized that regulatory or coding variants in IPF1 contribute to T2DM. We screened 71 Caucasian and 69 African American individuals for genetic variants in the promoter region, three highly conserved upstream regulatory sequences (PH1, PH2 and PH3), the human -cell specific enhancer, and the 2 exons with adjacent introns. We identified 8 variants, including a 3 bp insertion in exon 2 (InsCCG243) in African Americans that resulted in an in-frame proline insertion in the transactivation domain. No variant was associated with T2DM in Caucasians (192 cases and 192 controls). However, SNPs at -3766 in the human -cell enhancer, at -2877 bp in the PH1 domain, and at -108 bp in the promoter region were associated with T2DM in African American subjects (341 cases and 186 controls; $p<0.01$), both individually and as haplotypes ($p=0.01$ correcting by permutation test). No SNP altered a binding site for the expected -cell transcription factors. The rare alleles of InsCCG243 in exon 2 showed a trend to over-representation among African American diabetic subjects ($p<0.1$). The common alleles of regulatory variants in the 5' enhancer and promoter regions of the IPF1 gene increase susceptibility to type 2 diabetes among African American individuals, likely as a result of gene-gene or gene-environment interactions. In contrast, IPF1 is not a cause of type 2 diabetes in Caucasians. The InsCCG243 variant was previously shown to alter insulin secretion in cell lines, is present in up to 20 percent of African American individuals with T2DM, and may contribute to diabetes susceptibility in this population. However, this coding variant is of much lower penetrance than previously suggested.

FOXO1A as a Candidate Gene for Type 2 Diabetes. *M. Karim[1], X. Wang[2,3], R.L. Craig[2,3], S.C. Elbein[2,3].* 1) Pediatrics, Arkansas Children's Hospital, Little Rock, AR; 2) Division of Endocrinology and Metabolism, College of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Medical Service, Central Arkansas Veterans Healthcare System, Little Rock, AR.

The human forkhead box O1A (FOXO1A) gene, located on chromosome 13q14.1, is a key transcription factor in insulin signaling in liver and adipose tissue and controls key pancreatic beta cell genes including IPF1. Thus, sequence variants of FOXO1a could contribute to defects in hepatic and peripheral insulin action and altered beta cell compensation that characterize type 2 diabetes (T2DM). To test this hypothesis, we used a combination of DHPLC and fluorescent sequence analysis to screen for sequence variants in the three exons and 3' untranslated region, and 1.5 kb of the 5' flanking region for sequence variants in Caucasian and African American individuals with early onset (<45 years) T2DM. We identified 6 variants, but none altered the coding sequence and all but one in the 3 untranslated region was rare or absent in Caucasians. We also selected 7 SNPs in the large first intron and 5 flanking region. Together, the 13 SNPs spanned 116.4 kb. We selected 8 SNPs to type in a Caucasian population comprising 192 unrelated nondiabetic control individuals and 192 individuals with T2DM, and 10 SNPs to type in 182 controls and 352 diabetic individuals of African American ancestry. No variant was associated with T2DM (African Americans, p>0.08; Caucasians, p> 0.09). Of the 8 Caucasian SNPs, 6 fell in a single haplotype block spanning over 100 kb and including most of the large first intron. In contrast, only SNPs at -7747 and -54 formed a block in African Americans. No haplotype was associated with T2DM. FOXO1 variation is rare, and is unlikely to contribute to T2DM in either Caucasian or African American populations.

Endothelial nitric oxide synthase (eNOS) plays a key role in regulating vascular tone. The Glu298Asp (G/T) substitution of eNOS gene has been reported associated with coronary heart disease and hypertension. Another polymorphism, a 27bp insertion/deletion polymorphism was also reported associated with hypertension, type 2 diabetes, diabetic retinopathy and nephropathy. We genotyped 385 subjects with type 2 diabetes and 191 controls from five West Africa centers for both the G/T polymorphism and the insertion/deletion polymorphisms. No association was found between the two polymorphisms and type 2 diabetes or hypertension. However, we found that the GG genotype was significantly associated with increased creatinine clearance in diabetic subjects($p=0.043$) and diabetic subjects with hypertension($p=0.034$). The aa genotype was significantly associated with increased creatinine clearance in diabetic subjects with retinopathy. The bb genotype of the insertion/deletion polymorphism is also significantly associated with diabetes retinopathy with OR=2.4(95% CI=1.39-4.09). In conclusion, both of the polymorphisms studied were associated with increased creatinine clearance but not associated with type 2 diabetes or hypertension; Whereas, the insertion/deletion polymorphism was associated with both diabetic retinopathy and increased creatinine clearance in this West African cohort.

Association of the Thr92Ala variation in the DIO2 gene with young-onset diabetes in Pima Indians. *S. Nair, YL. Muller, E. Ortega, S. Kobes, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institute of Health, Phoenix, AZ.

The Pima Indians of Arizona have a high prevalence of obesity and type 2 diabetes mellitus (T2DM), and physiologic candidate genes that might explain increased susceptibility for these diseases are being investigated. The Type 2 Deiodinase (DIO2) gene encodes a deiodinase (DIO2), that converts the thyroid pro-hormone thyroxine (T4) to the more active form triiodothyronine (T3). Since thyroid hormones have important roles in the regulation of energy balance (in particular by stimulating thermogenesis) and may also influence glucose metabolism, variation in the DIO2 gene could affect susceptibility to obesity and /or T2DM. Indeed a Thr92Ala variation in DIO2 has previously been reported to be associated with insulin resistance in non-diabetic Caucasian women and in patients with T2DM. We have genotyped this variation in a diabetes case vs. control group of non-first degree related Pima Indians (146 diabetic subjects with an age of onset 25years vs. 147 non-diabetic subjects who are at least 45 years of age). The Thr92Ala (minor allele frequency = 0.19) was associated with T2DM ($p = 0.01$, odds ratio = 1.7, 95% CI = 1.1-2.6, additive model). However, in an obesity case vs. control group (362 obese subjects with a mean BMI = 51.7 6.2 vs. 127 lean subjects with mean BMI = 26.3 2.7) there was no association of the Thr92Ala with obesity, nor was there an association of this variant with BMI in a family-based association analysis (N = 1200). The Thr92Ala was further analyzed for associations with metabolic predictors of T2DM in 256 non-diabetic, full-heritage Pima subjects who had undergone detailed metabolic testing. The Thr92Ala was modestly associated with total triglyceride concentrations and hepatic glucose output ($p = 0.04$ and $p = 0.02$, respectively, adjusted for age, sex, percent fat and nuclear family membership). We are currently scanning the DIO2 gene by direct sequencing to search for additional polymorphisms that might substantiate an association between the DIO2 gene and T2DM.

Genotyping of 4608 SNPs across a 10Mb region of chromosome 20q in four UK and an Ashkenazi population suggests additional type 2 diabetes (T2D) candidate genes. *I. Barroso[1], J. Luan[2], P. Whittaker[1], E. Zeggini[3], S. Hunt[1], N. Walker[4], B. Glaser[5], A. Hattersley[6], M.A. Permutt[7], M. McCarthy[3], P. Deloukas[1], N.J. Wareham[2].* 1) The Wellcome Trust Sanger Institute, Hinxton, UK; 2) MRC Epidemiology Unit, Cambridge, UK; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; 4) JDRF/WT Diabetes and Inflammation Laboratory, Cambridge, UK; 5) The Hadassah Hebrew University Medical Center, Israel; 6) Peninsula Medical School, Exeter, UK; 7) Washington University School of Medicine, St. Louis, MO, USA.

Susceptibility to T2D has been identified in a broad region of chromosome 20q by genome scans in Caucasian, Ashkenazim, Chinese Han, Japanese and West Africans. SNPs in the proximal promoter region of *HNF4A* have recently been shown to associate with T2D predisposition in Caucasian and Ashkenazi populations. It remains unknown whether *HNF4A* explains all of the linkage signal or whether additional genes on 20q contribute to T2D susceptibility. We used a dense linkage disequilibrium (LD) map of chromosome 20 constructed at the Sanger Institute to select SNPs from 10Mb within the linkage peaks, for genotyping in four UK and an Ashkenazi population. We typed 4608 SNPs (38.1Mb-48.2Mb NCBI build 35, 1 SNP per 2Kb on average) in 1231 T2D patients and 1277 controls using the Golden Gate assay (Illumina platform). Meta-analysis for single SNP associations was performed in the four UK populations and 704 SNPs were shown to associate with T2D risk with $p<0.15$. A number of SNPs in *HNF4A* were associated at this significance level in the UK and Ashkenazi populations. More interestingly, a number of SNPs clustered in different genes (between 40.1Mb-41.7Mb) were more significantly associated with T2D in all populations than *HNF4A* SNPs. These 704 SNPs as well as 50 SNPs that associated with T2D risk in Ashkenazim ($p<0.01$) and that were not associated in the four UK populations at $p<0.15$ have been selected for Phase II of this study. Phase II will comprise replication testing of these SNPs in an independent group of samples comprising approximately 1300 cases and 1300 controls from the same populations used in Phase I.

Association of the Gly482Ser Polymorphism in the Peroxisome Proliferator-Activated Receptor Coactivator-1 with Excess Weight Gain by Male Subjects with Type 1 Diabetes upon Intensive Diabetes Therapy. *S.S. Deeb*[1], *J.D. Brunzell*[2], *DCCT/EDIC Investigators.* 1) Dept Medicine/Med Genetics, Univ Washington, Seattle, WA; 2) Dept Medicine/Endocrinology, Metabolism, and Nutrition, Univ Washington, Seattle, WA.

The Diabetes Control and Complications Trial (DCCT) involved intensive diabetes therapy for an average period of 6.5 years. A subset of these patients gained excessive weight, mainly due to accumulation of visceral fat. Patients with a family history of type 2 diabetes mellitus (T2DM) were among those who gained more weight. To identify genetic factors that contribute to excessive weight gain in these patients, we investigated the association of one sequence variant in each of 7 candidate genes for association with this trait by comparing allele and genotype frequencies between quartile 1 (low weight gain) and quartile 4 (high weight gain). The Gly482Ser polymorphism in the gene encoding the peroxisome proliferator-activated receptor coactivator-1 (PGC-1) was the only one that was significantly associated with weight gain in men ($p = 0.0045$) but not in women. The Ser allele was associated with more weight gain than the Gly allele ($p = 0.005$). Those with the Gly/Gly genotype were overrepresented in quartile 1 ($p = 0.0054$), whereas carriers of the Ser allele (Gly/Ser and Ser/Ser) were overrepresented in quartile 4 ($p = 0.013$). These data support the previous findings that genetic variation in PGC1 may modify the effects of physiological and environmental factors that predispose to the metabolic syndrome and T2DM.

A novel -192c/g mutation in the proximal P2-promoter of *HNF4A* co-segregates with early onset diabetes. *J. Ek[1], S.K. Hansen[1], M.L. Jensen[1], S. Pruhova[2], A. Johansen[1], T.W. Boesgaard[1], A. Albrechtsen[1], J. Lauenborg[3], M. Parrizas[4], S.F. Boj[4], L. Bjørkhaug[5], P.R. Njølstad[5], T. Jørgensen[6], K. Borch-Johnsen[1,6,7], P. Damm[3], J. Ferrer[4], J. Lebl[2], O. Pedersen[1,7], T. Hansen[1].* 1) Steno Diabetes Center, Gentofte, Denmark; 2) Department of Pediatrics, Third Faculty of Medicine, Charles University, Prague, Czech Republic; 3) Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark; 4) Endocrinology unit, Hospital Clinic Universitari, Institut dInvestigacions Biomédiques August Pi I Sunyer, Barcelona, Spain; 5) Section for Medical Genetics and Molecular Medicine, Department of Clinical Medicine, University of Bergen, Norway; 6) Research Centre for Prevention and Health, Glostrup University Hospital, Denmark; 7) Seventh Faculty of Health Science, University of Aarhus, Denmark.

Recently, it has been shown that mutations in the P2-promoter of the -cell expressed isoform of hepatocyte nuclear factor-4 (*HNF4A*) cause MODY. In this study we have examined the P2-promoter and the associated exon 1D of *HNF4A* for variations associated with various forms of early-onset non-autoimmune diabetes. We examined 1189 bp upstream of the ATG site of the P2-promoter and exon 1D in 114 T2D patients of whom 47 patients had age at diagnosis < 40 years, 72 MODYX probands and 85 women with previous gestational diabetes (GDM). A -192c/g mutation was found in one MODY proband and in one early-onset T2D patient, and in 2 GDM probands. Also, the variant co-segregated with diabetes in the GDM families. Carriers of the -192c/g mutation had an impaired glucose stimulated insulin secretion compared to matched diabetic subjects and the insulinogenic index was significantly decreased (p=0.02). Two novel completely linked polymorphisms in the P2-promoter at positions -1107g/t and -858c/t, respectively, were identified. There was no difference in allelic frequency of the variants among 1430 T2D patients and 4812 normal glucose tolerant (NGT) subjects. In conclusion, a novel -192c/g mutation of *HNF4A* are a rare cause of early-onset diabetes among Danish Caucasians, highlighting the importance of this region when investigating the genetics behind diabetes.

Fine Mapping of a Putative Type II Diabetes Susceptibility Gene on 1q in Native American Pimas. *J.M. Singer[1], V. Ossowski[1], M.I. McCarthy[2], P. Deloukas[2], E. Zeggini[2], W. Rayner[2], C. Bogardus[1,2], M. Prochazka[1,2].* 1) Phoenix Epidemiology and Clinical Research Branch NIDDK NIH, Phoenix, AZ; 2) International Type II Diabetes 1q Consortium.

Previous genome-wide scans in different populations (including Native American Pimas, Caucasians, and Chinese) detected linkage of chromosome 1q21-q25 with type 2 diabetes mellitus (T2DM). Currently, an international collaborative effort (International Type II Diabetes 1q Consortium) is underway to fine map this region as a first step in detecting causative genes and mutations contributing to T2DM. So far, analysis of over 2000 SNPs in Pima samples has revealed 3-4 loci potentially associated with the disease. One association signal is at 159.9 Mb (NCBI build 35), between known genes *RGS5* and *CDCA1*. Family based association p-values for these SNPs range from 0.05-0.0009 (T2DM onset before the age of 45yr), and the original LOD score (2.6) is reduced by up to 20% when the linkage analysis is conditioned on SNP genotypes. The region flanked by *RGS5* and *CDCA1* contains at least three additional UniGene clusters, representing transcripts with unknown function. We have performed deep resequencing of the exons and promoter regions of these transcripts, and also included *RGS5* and *CDCA1* in our analysis. The most significantly associated SNPs are clustered within 60 kb, and do not overlap with either *RGS5* or *CDCA1*. Several of them are located in exons of the novel UniGene transcripts and have the potential of altering the predicted ORFs. We have also determined the expression profiles of these UniGene transcripts by PCR using cDNAs from 16 various organs and tissues, and they appear to be ubiquitously distributed. A complete deep resequencing of approximately 70 kb encompassing the significantly associated area is in progress to define all variants in this region and complete a thorough association analysis.

Fine mapping and association study for Graves' disease in Chinese Hans. *X. Chu[1], L. Sun[1], R. Lei[1], Z. Niu[1], L. Xu[1,3], K. Zhang[1,3], Y. Wang[1], Y. Dong[1], Y. Wang[1], H. Song[2], Z. Chen[1,2], L. Jin[1,4], W. Huang[1].* 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) Ruijin Hospital, SSMU, Shanghai, China; 3) Shanghai South Gene Technology Co., Ltd., Shanghai, China; 4) Institute of Genetics, Fudan University, Shanghai, China.

Graves' disease (GD) is an organ-specific autoimmune disorder and its etiology is believed as the results of interaction of inheritance and environment. Despite the human leukocyte antigen and cytotoxic T lymphocyte antigen 4 have been reported with a strong association with the GD trait, more susceptibility genes observed to be associated with its pathogenesis remain to be revealed. To identify susceptibility genes on chromosome 5q31, we carried out a genome-wide scan on 322 individuals from 54 Chinese Han multiplex GD pedigrees combined with a SNP genotyping design, leading to the fine mapping and the identification of a risk-conferring SNP haplotype. The result showed the strongest evidence for linkage at D5S436 on chromosome 5q31. A fine mapping using four additional markers around D5S436 was then performed and a maximum multipoint LOD score of 4.12 were obtained for marker D5S2090, among which regions containing several interleukin genes cluster arose our interests. Finally, 20 candidate genes including all the cytokine genes in 40Mb region flanking D5S2090- D5S436 were resequenced in a set of 48 unrelated Chinese Han subjects and more than 200 SNPs have been identified. Using LD analysis, we selected 50 tagSNPs and genotyped them in 380 cases and 690 controls collected from China. A nonsynonymous SNP(P27S) and another SNP at nt ¨C16 (T/C) in the 5' flanking region of the same gene showed a strong association with the disease. The further related investigation to explain function and interaction of SNPs in pathogenesis of Graves' disease will be continued.

Variation in PDGF-C and PDGFR and Nonsyndromic Cleft Lip and Palate. *B.T. Chiquet[1], S.H. Blanton[2], J.T. Hecht[3].* 1) University of Texas Dental Branch at Houston; 2) University of Virginia, Charlottesville; 3) University of Texas Medical School at Houston.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common birth defect with a birth prevalence of 1/700 live births. NSCLP is a complex disorder postulated to be caused by multiple genes and environmental factors. The region on chromosome 4q31 to 4qter has been implicated in multiple genome scans to harbor a clefting gene. Platelet-derived growth factor C (PDGF-C) on chromosome 4q32 and its receptor, platelet-derived growth factor receptor alpha (PDGFR) on chromosome 4q12, both play a role in normal palate fusion and epithelial degradation and are biological plausible candidate genes. Variation in these genes may play a role in NSCLP. Single nucleotide polymorphism (SNP) analysis of PDGF-C and PDGFR was undertaken using TaqMan SNP Genotyping Assays. Six SNPs in PDGF-C and five SNPs in PDGFR were selected for this study using 51 multiplex families and 184 simplex parent-child trios. All SNPs in both genes were in Hardy-Weinberg equilibrium. The SNPs within PDGFR were largely in linkage equilibrium, while most of the SNPs in PDGF-C were in extreme linkage disequilibrium. Nonparametric analysis of the SNPs with Genehunter yielded an NPL score of 1.4 ($p=0.05$) for one of the SNPs in PDGF-C. Transmission disequilibrium analysis with PDT found suggestive evidence for an altered transmission of two SNPs in PDGFR under a genotypic model ($p=0.0485$ and $p=0.0406$) and for one of the same SNPs under a generalized model ($p=0.01$). These results suggest that PDGF-C and PDGFR may play a role in nonsyndromic clefting and warrants additional studies.

A gene for speed: The *ACTN3* R577X polymorphism influences human muscle performance. *D.G. MacArthur[1], N. Yang[1], A.J. Kee[2], E.K. Kettle[2], J. Hook[3], F. Lemckert[3], E.C. Hardeman[2], P.W. Gunning[3], K.N. North[1].* 1) Neurogenetics Research Unit, Children's Hospital at Westmead, Sydney, NSW, Australia; 2) Muscle Development Unit, Children's Medical Research Institute, Sydney, NSW, Australia; 3) Oncology Research Unit, Children's Hospital at Westmead, Sydney, NSW, Australia.

The protein -actinin-3, encoded by the *ACTN3* gene, is a highly conserved component of the contractile machinery in fast skeletal muscle fibres. Intriguingly, a common nonsense variant in the human *ACTN3* gene (R577X) results in complete deficiency of -actinin-3 in ~18% of the general population who are homozygous for the X allele. We have recently demonstrated a significantly lower frequency of XX homozygotes amongst elite Australian sprint athletes than controls, suggesting that the presence of -actinin-3 is required for optimal fast fibre function. This finding has been supported by a number of recent studies demonstrating associations between R577X genotype and muscle strength and response to training. The *ACTN3* R577X polymorphism thus represents a genetic factor influencing muscle performance in humans.

We are currently investigating the evolutionary history of the 577X allele in humans. Analysis of the pattern of genetic variation in the R577X region in different ethnic groups suggests that the X allele is ancient and was maintained at low frequency, possibly by balancing selection, in the African ancestors of modern humans. The high frequency of 577X in many non-African ethnic groups may indicate more recent positive selection on the X allele in these populations.

We have also generated an *Actn3* knockout mouse to explore the mechanisms by which -actinin-3 deficiency affects muscle function. The loss of -actinin-3 results in the upregulation of a closely related protein, -actinin-2, in fast muscle fibres, which may partially compensate for the deficiency of -actinin-3. However, a marked increase in sarcomeric damage following eccentric exercise in knockout mice compared to wild-type suggests that -actinin-3 protects muscle from exercise-induced damage, potentially explaining the association between R577X and muscle function in humans.

Gender stratified linkage analysis for premature coronary artery disease (CAD). *B.R. Pedersen[1], C. Haynes[1], D. Crossman[2], J. Haines[3], C. Jones[4], W.E. Kraus[1], E.R. Hauser[1].* 1) Duke University Medical Center, Durham, NC; 2) University of Sheffield, Sheffield, UK; 3) Vanderbilt University, Nashville, TN; 4) University of Wales, Cardiff, UK.

Gender and family history are well-known risk factors for CAD, particularly when combined with an early age of onset. There is also a suggestion that some genetic effects may be gender-specific (McCarthy et al. Hum Genet. 114:87-98). We examined whether differences in linkage exist between gender-stratified affected sibling pairs (ASPs). A genomewide scan of linkage using 395 microsatellite markers was performed in 493 ASPs from 420 families. Families were stratified into 61 female, 279 male, and 157 mixed gender ASPs. Affected status was defined as CAD before the age of 51 years for males and 56 years for females. Evidence for linkage to specific regions was taken as nonparametric multipoint LOD score>1.0. LOD scores were reported at DECODE cM and were specific to the results for overall, male, female, and mixed gender pairs (LOD, MLOD, FLOD, and XLOD, respectively). We continue to observe evidence for linkage on chromosome 3 (Hauser ER et al. Am. J. Hum. Genet. 75:436-47) but not specific to gender (LOD=2.58, 134.5 cM; MLOD=0.97, 150.4 cM; FLOD=0.78, 132.2 cM; XLOD=0.72, 213.8 cM). Enhanced peaks were found on chromosome 5 in males (LOD=1.31, 200.8 cM; MLOD=1.91, 208.0 cM; FLOD=1.18, 138.0 cM; XLOD=0.39, 173.7 cM). Only females and overall pairs demonstrated linkage on chromosome 7 (LOD=1.30, 83.0 cM; MLOD=0.61, 39.1 cM; FLOD=1.99, 39.1 cM; XLOD=0.91, 80.7 cM). New linkage peaks were observed on chromosomes 6 for both genders, roughly 35 cM apart (LOD=0.92, 158.7 cM; MLOD=1.39, 157.5 cM; FLOD=1.93, 192.0 cM; XLOD=0.47, 73.9 cM). Chromosomes 8 (MLOD=1.19, 97.3 cM), 12 (LOD=1.0, 121.8 cM), 14 (FLOD=1.24, 4.5 cM), and 18 (XLOD=1.18, 49.6 cM) also revealed new evidence for linkage. These results indicate variable genetic effects by gender for premature CAD, reflecting the sampling scheme or genetically predicted CAD risk factors that differ between men and women such as HDL, LDL, and hypertension.

A PDFGC regulatory region SNP that decreases PDGFC promoter transcriptional activity is associated with CL/P. *T.C. Hart[1], S.J. Choi[1], P.S. Hart[2], P.P. Sulima[1], M.L. Marazita[3].* 1) Section on Craniofacial & Dental Genetics, NIDCR, NIH, Bethesda, MD; 2) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD; 3) University of Pittsburgh, Pittsburgh, PA.

The murine pdgfc-/- knockout is associated with a complete cleft of the secondary palate, demonstrating PDGF-C is necessary for palate formation. Human linkage and association studies support a gene(s) for nonsyndromic cleft lip with or without cleft palate (CL/P) on chromosome 4q31-q32 at or near the PDGFC gene locus. Linkage support is greatest in Chinese families. To evaluate the role of PDGFC gene mutations in CL/P Methods: We sequenced the PDGFC gene in 108 Chinese CL/P cases and 113 controls to evaluate its role in human CL/P. We also performed transfection assays of PDGFC four different promoter constructs to evaluate the effect of a novel -986C>T regulatory region SNP on PDGFC promoter activity. Results: No coding region mutations were identified, however a novel -986C>T SNP was significantly associated with CL/P (p=0.01) in Chinese cases from families that showed evidence of linkage to 4q31-q32. Database search demonstrate that the -986T allele abolished six overlapping transcription factor regulatory motifs (Sp1, USF, WT1, EGR-1, HEB, and ETF). Transfection assays of PDGFC promoter reporter constructs in 3 different cell types indicate that the -986T allele is associated with a significant decrease (up to 80 percent) of PDGFC transcriptional activity. Conclusion: A novel -986C>T SNP in the PDGFC promoter is significantly associated with human CL/P in Chinese cases from families linked to 4q32.1. This promoter polymorphism disrupts a potential cytosine-rich regulatory motif and is associated with a significant decrease in transcription of PDGFC reporter constructs. This functional polymorphism acting on a susceptible genetic background may provide a component of CL/P etiology in humans.

Dementia in the Amish: A follow-up linkage study. *J.L. McCauley[1], A.E. Crunk[1], L.L McFarland[1], P.C. Gaskell[2], L. Jiang[1], P.J. Gallins[2], W.K. Scott[2], K.A. Welsh-Bohmer[3], S.R. Johnson[3], C.E. Jackson[4], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine; 3) Joseph & Kathleen Bryan ADRC/ Division of Neurology, Duke University Medical Center, Durham, NC; 4) Scott & White, Temple, TX.

Alzheimers disease (AD) is the leading cause of dementia in the elderly. The underlying genetics of AD has proven to be challenging to understand and elucidate. While a role for the APOE gene in late-onset AD is clear, it accounts for less than half of the susceptibility and thus other genetic factors are likely to be involved. Genetic heterogeneity is a major complicating factor hindering further gene identification. With this in mind, we previously performed a genomic linkage screen using microsatellite markers on families ascertained from the genetically isolated, well-defined Amish population. Due to the complexity of these pedigrees, we employed both linkage analysis and combinatorial mismatch scanning. These approaches identified several regions of interest across the genome. Within these regions we have performed follow-up linkage in a set of 364 individuals (82 with AD) using single nucleotide polymorphisms. Regions demonstrating 2-pt lod scores 1.0 in the follow-up analysis included chromosome 3q(~209cM) at markers rs710446(Lod=1.1), rs1136644(Lod=1.5), and rs2169244(Lod=1.2) and chromosome 5q(~183cM) at marker rs628857(Lod=1.9). Our most promising results lie on chromosome 4q, which contains nine markers (rs2174080,rs3755896, rs2952886, rs1396009, rs1014107, hcv1718090, rs6826476, rs1993656, rs1388083) between 130-150 cM demonstrating average lod scores of 1.7. Interestingly, the most studied regions on chromosomes 9, 10, and 12 show little to no evidence of linkage in these families. However, our 3q, 4q, and 5q results do overlap with previous findings from other genome scans in AD. Our findings suggest that these regions harbor yet unconsidered susceptibility genes, and that the many previously reported regions of linkage should not be ignored.

Candidate Gene Studies of Dementia in the Amish. *N. Schnetz-Boutaud[1], J.L. McCauley[1], A.E. Crunk[1], L.L. McFarland[1], P.C. Gaskell[2], L. Jiang[1], P.J. Gallins[2], W.K. Scott[2], K.A. Welsh-Bohmer[3], S.R. Johnson[3], C.E. Jackson[4], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine; 3) Joseph & Kathleen Bryan ADRC/ Division of Neurology, Duke University Medical Center, Durham, NC; 4) Scott & White, Temple, TX.

Alzheimers disease (AD) is the leading cause of dementia in the elderly. While there is a strong genetic component and four genes have been identified, three of these (APP, PS1, PS2) are involved primarily in rare early-onset AD and the fourth (APOE) explains less than half of the more common late-onset Alzheimers disease (LOAD). One difficulty has been the underlying genetic heterogeneity. To reduce both genetic and environmental heterogeneity, we have been studying dementia in the Amish communities of northern Indiana and central Ohio. The Amish are socially and genetically isolated from the surrounding population and have more homogeneous education and environmental exposures.

There have been over 90 candidate genes in AD with at least one positive report of association. We investigated nine of these candidate genes (AGT, NCSTN, LTA, UBQLN, GAPD, PZP, LIPC, ACE, APOE) in a sample of 364 Amish individuals (82 with AD) in five large pedigrees. A total of 40 SNPs were genotyped. Genetic linkage (using SIMWALK v. 2.0) gave modestly interesting lod scores for AGT (Lod=1.0), UBQLN (Lod=1.4), LIPC (Lod=1.9) and APOE (Lod=2.26)(see Virdagamo et al., this conference). The AGT and APOR results were derived primarily from one very large pedigree centered in Ohio. Nominally significant association results were observed for AGT (p=0.03), NCSTN (p=0.05), GAPD (P=0.02), PZP (P=0.01), and LIPC (P=0.03). None of these survive a correction for multiple comparisons. Only AGT and LIPC gave interesting results in both the linkage and association tests, suggesting that these two genes should be investigated further.

A Follow-Up Genome Scan in Lithium Responsive Bipolar Disorder Families. *I. Jaitovich Groisman[1], F. Mamdani[1], T. Hajek[2,5], P. Grof[3], G.A. Rouleau[4], M. Alda[1], G. Turecki[1].* 1) McGill University, Montreal, Quebec, Canada; 2) Dalhousie University, Halifax, Nova Scotia,Canada; 3) University of Ottawa, Ottawa, Ontario,Canada; 4) Montreal University, Montreal, Quebec,Canada; 5) Charles University, Prague, Czech Republic.

Attempts to identify susceptibility genes for bipolar disorder (BD) require confirmation. We have been using a pharmacogenetic strategy in the study of genetic factors involved in BD, which has been based on the investigation of subjects who respond to long-term treatment to lithium. There is substantial evidence suggesting that lithium response may help define a more homogeneous BD phenotype. We have previously published a genome scan in families selected through excellent lithium responders (Turecki et al. 2001). Here we report on a follow-up genome scan on a larger sample of families using a total of 811 microsatellite markers spaced at an average of 5 cM. The clinical sample consisted of 36 families with a total of 282 subjects (135 affected with BD or recurrent unipolar disorder). The data was analyzed by the lod score method and NPL analysis. Similar to our previous study, we have detected suggestive evidence of linkage (multipoint lod scores 1) in 6p, 21q, 4q and 9q regions, some of which have been also reported by other groups. In addition, we identified linkage on 2 chromosomal regions with multi point LOD scores 2: 3p24-22 and 3p12-11, and another one 3 at 14p13-11. We have not found additional support for linkage on 15q and 7q, as suggested by our first study. In conclusion, our data add to the view of BD as a heterogeneous condition associated with multiple susceptibility loci. Further fine mapping would allow for the identification and study of candidate genes involved in 14q13-11. References: Turecki G et al. (2001). Mapping susceptibility genes for bipolar disorder: a pharmacogenetic approach based on excellent response to lithium. Molecular Psychiatry 6: 570 - 578.

A Novel Mutation in GCAP1 in Autosomal Dominant Cone Dystrophy. *Y. Zhao[1], X. Li[1], D. Birch[2], Z. Yang[1], J. Baird[1], D. Gibbs[1], D. Wheaten[2], K. Zhang[1].* 1) Department of Ophthalmology and Visual Science, and Program in Human Molecular Biology & Genetics, Eccles Institute of Human Genetics, University of Utah Health Science Center, Salt Lake City, UT 84112; 2) Retina Foundation of the Southwest, Dallas, TX 75231.

Purpose: The cone dystrophies are characterized by progressive dysfunction of the photopic (cone-mediated) system, presenting with photophobia, loss of color vision and reduced central visual acuity. Cone dystrophy is genetically heterogeneous and may present as an autosomal dominant, autosomal recessive, or X-linked recessive trait. In this study, we are trying to investigate the clinical features and gene mutations in one family with an autosomal dominant form of cone dystrophy. Methods: Ophthalmologic examinations were performed and genomic DNA extracted from bloods using the Puregene DNA isolation kit under consent. DNA samples were amplified by the polymerase chain reaction using primers corresponding to each exon of GCAP1. The PCR products were screened for mutations by direct sequencing. Results: Of 20 members in this family, with 5 generations, there are 5 affected patients. Clinical findings in this family include photophobia, decreased visual acuity and color vision abnormalities typical of cone dystrophy. Sequencing analysis revealed one novel mutation in exon2, which is at nucleotide C312A, and the corresponding amino acid change Asn104Lys. Conclusions: We identified a novel mutation in the GCAP1 gene in one family with autosomal dominant cone dystrophy. Genetic and functional studies of this mutation will aid our understanding of underlying pathogenetic mechanism.

Distribution of DNA sequence variants in the WDR36 gene in primary open angle glaucoma patients. *R.R. Allingham[1], L. Linkroum[2], J. Wang[1], K. Larocque-Abramson[1], F.L. Graham[1], E.A. del Bono[2], J.L. Haines[3], M.A. Pericak-Vance[1], M.A. Hauser[1], J.L. Wiggs[2].* 1) Duke Univ Medical Ctr, Durham, NC; 2) Harvard Medical School, Boston, MA; 3) Vanderbilt University, Nashville, TN.

Primary open angle glaucoma (POAG) is a complex inherited disease that is likely to result from defects in multiple susceptibility genes as well as environmental factors. WDR36 is a WD40 repeat protein that may be involved in T cell activation. Recently DNA sequence variants in the WDR36 gene have been identified in patients with high and low tension glaucoma (Monemi et al., 2005, Hum Molec Genet 14:725). To evaluate the role of this gene in familial high tension primary open angle glaucoma, we screened the probands from a set of 86 adult-onset POAG families, as well as probands from 6 early-onset primary open glaucoma families. Criteria for inclusion include elevated intraocular pressure 22mm Hg in both eyes, optic nerve damage, and corresponding visual field loss in at least one eye. Adult onset probands had an age of onset after age 35, while early-onset probands had an age of onset before age 35. All of the 23 coding exons and flanking introns were sequenced in 92 probands and 88 age and ethnically matched controls. Pools of genomic DNA were initially sequenced using ABI sequencing chemistries and run on an ABI-3100 automated DNA sequencer. Pools displaying DNA sequence variants were resequenced. Nine nonsynonymous SNPs, 7 synonomous SNPs and 13 intronic variants were identified. None of the intron changes would be expected to affect splice sites. Four of the 86 adult-onset probands and 2 controls had nonsynonomous changes previously identified as disease causing, while none of these changes were found in the early-onset POAG probands. In the adult-onset families, the disease causing nonsynonomous SNPs did not segregate with the disease. These results indicate that DNA sequence variants in WDR36 do not significantly contribute to early-onset or adult-onset primary open angle glaucoma in this population. Further studies of patients with normal or low tension glaucoma may help define the role of WDR36 in this blinding disease.

Evaluation of Complex Inheritance of Bardet-Biedl syndrome in a Puerto Rican BBS Cohort. *A.S. Cornier[1], D. Nishimura[2], A. Quintero-Del- Rio[1], C. Searby[2], E. Berg[2], G. Cox[4], S. Carlo[1], N. Ramirez[1], J. Acevedo[5], V. Franceschini[1], N. Arciniegas[1], V. Sheffield[2,3].* 1) Genetic Division, Ponce Sch Medicine, Ponce, PR; 2) Departemnt of Pediatrics, Univ of Iowa, Iowa City, IA; 3) Howard Hughes Medial Institution,Univ. of Iowa, Iowa City, IA; 4) Genetic Division Childrens's Hospital, Boston, MA; 5) Department of Nursigng, Univ. of Puerto Rico, Arecibo, PR.

Bardet-Biedl Syndrome (BBS) is a pleiotropic, autosomal recessive disorder characterized by retinal dystrophy, obesity, polydactyly, hypogenitalism and learning disabilities. BBS is genetically heterogenous with eight genes identified to date and evidence for additional loci. It has been suggested that in some cases, BBS may be inherited in a complex manner with three disease alleles (two at one locus and a third at a second locus) required for complete penetrance. The BBS1 gene was initially identified by studying a large Puerto Rican BBS cohort. Within this population, three distinct BBS1 mutations were found to segregate in different nuclear families. However, in two families, no BBS1 mutation could be found within the BBS1 coding sequence. We therefore decided to perform linkage studies on these families to determine if other BBS loci were involved. Genome-wide SNP genotyping indicated linkage to the BBS7 locus. Sequencing of BBS7 revealed a homozygous T211I mutation in all eight affected individuals from both of the non-BBS1 families. This mutation has been reported previously and T211 is highly conserved. Although the Puerto Rican population segregates mutations in both BBS1 and BBS7, inheritance of BBS in all individuals in the families studied is consistent with autosomal recessive inheritance.

Evidence for linkage and association on chromosome 1q21 in Mexican families with familial combined hyperlipidemia. *A. Huertas-Vazquez[1, 2], C. Aguilar-Salinas[2], J. Lee[1], A. Lusis[1], R. Cantor[1], S. Canizales-Quinteros[2], T. Tusie-Luna[2], P. Pajukanta[1].* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Unidad de Biología Molecular y Medicina Genómica del Instituto de Investigaciones Biomédicas de la UNAM y del INCMNZS, Mexico City, Mexico.

Familial combined hyperlipidemia (FCHL) is a common genetically heterogeneous disorder, characterized by the presence of multiple lipoprotein phenotypes that increase the risk of premature coronary heart disease. A recent study of Finnish FCHL families reported an association between specific alleles of upstream transcription factor 1 (USF1) on chromosome 1q21 and the FCHL and high triglyceride (TG) traits. USF1 encodes a transcription factor known to regulate several genes of glucose and lipid metabolism, providing an excellent candidate gene for the complex FCHL phenotype. Previously seven extended multigenerational Mexican FCHL families have been linked to the chromosome 1q21 region for the FCHL and TG traits. We analyzed these seven and 17 additional extended Mexican FCHL families with 314 genotyped individuals, 144 of which were affected, for association with SNPs in the USF1 gene region. Three SNPs in the USF1 region (hCV1459766, rs3737787 and rs2073658) resulted in significant p-values (0.05-0.001) when tested for association with high TGs. To elucidate the potential role of USF1 as a causative gene for FCHL, probands of the four most strongly linked Mexican FCHL families and 4 normolipidemic spouses were sequenced for 11 exons and the exon-intron boundaries of USF1. Seven variants were identified, however none of these results in an amino acid change. The potential functional role of each associated variant is currently under evaluation with cross-species sequence comparisons and functional studies in relevant tissues to assess if any of these variants alter regulation of USF1 in cis. These Mexican data provide further evidence for the role of USF1 in FCHL.

Evidence for linkage on chromosome 3q25-27 in a large autism extended pedigree. *H. Coon[1], N. Matsunami[2], J. Stevens[2], J. Miller[1], C. Pingree[1], L. Krasny[1], J. Lainhart[1], M.F. Leppert[2], W. McMahon[1].* 1) Neurodevelopmental Genetics Project, Dept Psychiatry, Univ Utah, Salt Lake City, UT; 2) Dept Human Genetics, Univ Utah, Salt Lake City, UT.

Though autism shows strong evidence for genetic etiology, specific genes have not yet been found. We tested for linkage in a candidate region on chromosome 3q25-27 first identified in Finnish autism families (Auranen et al., 2002). The peak in this previous study was at D3S3037 (183.9 cM). We tested this region in seven affected family members and 24 of their relatives from a single large extended Utah pedigree of Northern European ancestry. A total of 57 single nucleotide polymorphisms (SNPs) were analyzed from 165 cM to 200 cM. The maximum lod score was 3.40 (empirical p-value = 0.0004) across three SNPs from 184.6 - 184.9cM, close to the Finnish peak. We tested for alterations in a candidate gene in this region, the fragile X autosomal homolog, FXR1. No mutations were found in the coding sequence, exon-intron boundaries, or the promoter region of this gene.

Association of TNF/LTA polymorphisms with Crohns disease in a Korean population. *K. Song[1], S. Lee[2], J. Lim[1], Y. Cho[3], S. Yang[3].* 1) Dept of Biochemistry & Molecular Biology, Univ of Ulsan College of Medicine, Seoul, Korea; 2) Dept of Biotechnology, College of Agriculture & Life Sciences, Chonnam National University, Gwangju, Korea; 3) Dept of Internal Medicine, Univ of Ulsan College of Medicine, Seoul, Korea.

The tumor necrosis factor-a (TNF) and lymphotoxin-a (LTA) are proinflammatory and immunoregulatory cytokines. Promoter polymorphisms of the TNF have been shown to affect TNF production and to be associated with Crohns disease, however, the actual alleles associated with the disease were variable among populations. Five TNF promoter polymorphisms (-1031, -863, -857, -308, and -238) and two LTA polymorphisms (intron 1 and Thr60Asn) were analyzed in 288 patients with Crohns disease and 399 unrelated healthy controls. Carriers of an individual polymorphism of TNF at -1031C, -863A, and -857T, showed statistically significant association with Crohns disease (adjusted OR = 1.51, 95 % CI = 1.08-2.10, P = 0.016; adjusted OR = 1.44, 95 % CI = 1.02-2.02, P = 0.038; adjusted OR = 1.60, 95 % CI = 1.13-2.27, P = 0.008), respectively. Following the haplotype analysis, carriers of the haplotype consisted of the -1031C, -863A, and -857C alleles showed statistically significant association with Crohns disease (adjusted OR = 1.58, 95 % CI = 1.10-2.23, P = 0.014). Our results are similar to those of two Japanese case-control studies, however different from Caucasian data. The carriers of the polymorphism at Thr60Asn of LTA had age/sex-adjusted odds ration of 0.61 (95 % CI = 0.43-0.87, P = 0.007), showing protective effects on Crohns disease. Our data support the hypothesis that the TNF/LTA genotypes play an important role in the pathogenesis of Crohns disease.

MMP7 promoter polymorphisms -181A/G and -153C/T are not associated with chronic pancreatitis in the United States. *J. Lamb[1,5], Y. Zhang[2], J.J. Martinson[3], L. Wang[2], B.D. Elinoff[1,5], D.C. Whitcomb[1,3,4,5].* 1) Dept Medicine, Div Gastro, Hep & Nutrition; 2) Div PACC; 3) Dept Human Genetics; 4) Dept Cell Biol & Phys, Univ Pittsburgh; 5) UPCI Hillman Cancer Ctr, Pittsburgh,PA.

Chronic pancreatitis (CP) is an inflammatory disease of progressive fibrosis and calcification leading to destruction of the pancreas. Smoking is a strong risk factor for CP and appears to accelerate progression of pancreatic fibrosis and insufficiency. Clinical imaging and functional tests can only detect CP at an advanced stage when functional recovery is minimal. An understanding of the etiology of the disease will allow earlier identification and intervention for those at risk.

Matrix metalloproteases (MMPs) are a family of proteases involved in extracellular matrix homeostasis and pathologic remodeling. MMP7 is associated with idiopathic pulmonary fibrosis (IPF). Pathologically similar to CP, IPF is a disease also characterized by progressive fibrosis and tissue distruction. Two functional polymorphisms have been identified in the MMP7 promoter at -181 (-181 A/G) and -153 (-153 C/T). Moreover it has recently been shown that a -181 A allele increases susceptibility to IPF in smokers.

We have investigated whether functional polymorphisms in the MMP7 promoter are associated with CP in smokers and non-smokers. Ninety-one CP, 49 recurrent acute pancreatitis (RAP) and 206 healthy control (HC) samples were genotyped by PCR RFLP analysis. Haplotypes were determined and analyzed using PHASE software. No significant differences were found between CP and RAP (which is not associated with fibrosis), $p = 0.9$; or CP and HC datasets, $p = 0.54$. Comparison of haplotypes of CP smokers and HC smokers similarly gave a non-significant result $p = 0.47$. Considering only the -181A/G polymorphism a ^{2}test showed no association of the A allele in CP smokers, $p = 0.84$. We therefore conclude that there is no association between the MMP7 -181G/A and -153C/T promoter polymorphims and chronic pancreatitis. Further, unlike IPF, the -181 A allele does not appear to increase susceptibility to CP in smokers.

Interferon-inducible gene family *HIN200* and lupus susceptibility. *L.J. Flinn[1,3], D. Xu[2], M. Lee[2], M-C. King[1,2].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Medical Genetics, Medicine, University of Washington, Seattle, WA; 3) Molecular and Cellular Biology Program, University of Washington, Seattle, WA.

Systemic Lupus Erythematosus (SLE) is a complex disease influenced by genetic background and environment. In order to identify genes that contribute to lupus susceptibility, we chose to examine a candidate gene family, the *HIN200* genes, clustered in a 250-kb region within 1q23. These genes are homologous to the *Ifi200* genes in mouse, implicated in the *Nba2* mouse model of SLE. The human gene family consists of four genes: *MNDA*, *IFIX* or *PYHIN*, *IFI16*, and *AIM2*, all similar in protein structure. We used genomic sequencing to detect a frameshift mutation in the first coding exon of *AIM2* in one SLE case, resulting in protein truncation. This mutation was not seen in 500 additional SLE cases and controls. We are currently sequencing the coding regions and flanking UTRs of all four genes in a series of 69 SLE cases and matched controls, and have not yet detected any other obviously pathogenic mutations. We are searching for variants altering gene function in other ways, in addition to those that affect protein sequence. We use linkage disequilibrium (LD) analysis to determine haplotype blocks with this region, and then use haplotype-tag SNPs (htSNPs) to further identify disease-associated alleles. Variants with potential regulatory effects will be in LD with htSNPs, and haplotypes associated with disease examined more closely. This method also tests for association of the entire gene cluster with disease. We have identified four major haplotype blocks; the largest, at nearly 80 kb, harbors *MNDA* and is defined by 14 SNPs (MAF0.10). The most common haplotype in this region occurred at decreased frequency in SLE cases (p0.005), and cases had a corresponding increase in frequency of rarer haplotypes. Our next steps will be to examine variation in this block, by sequencing potential regulatory domains and genotyping more SNPs. We hypothesize that a regulatory variant in this region may influence expression levels, which may predispose certain individuals to lupus susceptibility.

Association analysis of 47 candidate genes in 200 attention-deficit/hyperactivity disorder(ADHD) trios. *M.N. Ogdie[1], J. Ishii[1], S.L. Smalley[2], S.F. Nelson[1].* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, UCLA Neuropsychiatric Institute, David Geffen School of Medicine at UCLA, Los Angeles, California 90024.

Attention-deficit/hyperactivity disorder (ADHD) is a pervasive neurobehavioral disorder characterized by childhood onset and impairment in multiple settings. ADHD affects ~5% of children and adolescents, and ~3% of adults. We have conducted transmission-disequilibrium analyses of 47 candidate genes in 200 ADHD trios. Over 400 SNP markers were selected and genotyped in a set of genes comprising both functional candidates and positional candidates located in previously linked regions. Transmission-disequilibrium tests (TdT) of singleton SNPs and haplotypes in two genes, prolactin-inducible protein (PIP) and the serotonin transporter (5-HTT), yielded evidence of association to ADHD. Singleton SNPs in PIP present two-fold over-transmission to cases and nominally significant evidence of association (P = 0.0002). Additionally, a haplotype in PIP is four-fold over-transmitted to affected individuals (P = 0.0004). The serotonin transporter, located within the previously linked region on 17q11, presents nominally significant association (P = 0.0035). In the current study, we report an exhaustive analysis of all 47 candidate genes and discuss putative associations to ADHD.

Investigation of DGCR8 and the miRNA pathway in schizophrenia. *S.E. Bruse, M.A. Azaro, I.V. Tereshchenko, L.A. Goff, R.P. Hart, L.M. Brzustowicz.* Department of Genetics, Rutgers University, Piscataway, NJ.

Linkage analyses have repeatedly identified the 22pter-q12.3 chromosomal region as linked to schizophrenia. DGCR8 is a positional candidate given its location at 22q11.21. It was recently discovered that DGCR8 functions in the microRNA (miRNA) pathway. miRNAs are important in regulating protein expression and are abundant in mammalian neurons. Perturbation of these regulatory pathways could conceivably contribute to the etiology of schizophrenia. We wish to determine whether DGCR8 is associated with schizophrenia using family-based genetic analysis. In addition, we are investigating the expression patterns of miRNAs in post-mortem brain samples of schizophrenic patients. 22q11.21 contains other strong candidate genes, and a simultaneous investigation of DGCR8, COMT, and ZDHHC8 was performed. A SNP tagging strategy was used which utilized the r2 measure of LD to select one tag SNP from each of 26 LD bins spanning these three genes. Thus, 26 SNPs were genotyped in a set of 37 extended pedigrees of Caucasian descent. Single-marker analysis was performed using the Pedigree Disequilibrium Test. At least one SNP in all three genes showed nominal evidence for association ($p<0.05$). SNP rs2255497, located within the 3 UTR of DGCR8, showed the strongest association with schizophrenia ($p<0.0045$), and was the only SNP with significant association after correction for multiple testing. Interestingly, this SNP is located within a predicted conserved miRNA binding site (has-mir-221). Ongoing studies include an attempt to replicate this finding in an independent Caucasian sample of 24 extended pedigrees. We have also begun an miRNA microarray study of post-mortem schizophrenic brain samples using a microarray containing 218 known human miRNAs (mirMAX, Rutgers University). A pilot study examined post-mortem samples from the medial temporal lobe of three schizophrenics compared to three controls. Though some striking individual expression differences were observed, no miRNAs showed significant expression differences after correction for multiple testing. Ongoing studies include miRNA microarray analysis of multiple brain regions in a larger set of samples.

Further evidence in support of allelic and haplotypic association of GABAA receptors and alcohol dependence in an Irish sample. *G. Kalsi[1], P-H. Kuo[1], J. Vittum[1], P.F. Sullivan[2], E.J.C.G. van den Oord[1], D.G. Patterson[3], D. Walsh[4], K.S. Kendler[1], C.A. Prescott[1], B.P. Riley[1].* 1) Molecular Genetics Lab, Virginia Commonwealth Univ., Richmond, VA; 2) Dept of Genetics, University of North Carolina, Chapel Hill, North Carolina; 3) Shaftsbury Square Hospital, Belfast, Northern Ireland, UK; 4) Health Research Board, Dublin 2, Ireland.

Animal and human studies suggest that GABAA receptors play a role in the neurochemical pathways involved in alcohol use, abuse and dependence. GABAA receptor subunits have been tested in several association studies, which have supported their role as candidates for alcohol dependence. The current case-control study was conducted in a subset of the larger Irish Affected Sib Pair Study of Alcohol Dependence (Prescott et al, 2005). 328 unrelated cases and 328 controls of matched ethnicity were genotyped with 21 SNPs localized to GABRG1, GABRA2, GABRA4 and GABRB1 subunits on chromosome 4p12. The results were analyzed using the WHAP program. Four of the nine GABRA2 SNPs tested in our sample revealed allelic association with alcohol dependence. Furthermore, one of the SNPs for GABRB1 produced a highly significant association (p=0.000012). Computing all nine GABRA2 SNPs for haplotype analyses using WHAP produced a disease associated haplotype with a p-value of p=0.02. Thus, our result replicates previously reported studies. Additional joint haplotype analyses of the nine 2 subunit SNPs and the most significantly associated 1 subunit SNP produced an enhanced disease association, with p value of 0.000067. This result may be indicative of an epistatic effect which could have functional implications, however further tests are required to verify whether a true interaction does exist. Prescott et al (2005) Alcohol Clin Exp Res. 29(3):417-29 This work was supported by NIH grant AA-11408.

A detailed study of the serotonin pathway in autism. *B.M. Anderson[1], L. Jiang[1], N. Schnetz-Boutaud[1], H.H. Wright[3], R.K. Abramson[3], M.L. Cuccaro[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine, Duke University Medical Center, Durham, NC; 3) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Classic autism is characterized as one of the Pervasive Developmental Disorders (PDDs) of childhood, a spectrum of often severe behavioral and cognitive disturbances of childhood development. The high heritability in autism has driven multiple efforts to identify susceptibility genes, but to no avail. Numerous studies have suggested that deficits in the peripheral and central metabolism of serotonin may play a role in the pathophysiology of autism. We hypothesize that multiple variations in the serotonergic pathway genes are involved in autism.

We assembled a dataset collected through the collaborative efforts of Vanderbilt and Duke Universities. Our sample includes 284 total autism families consisting of 155 parent-child trios and 129 multiplex families, a screening subset of our overall dataset of 333 trios and 158 multiplex families. We prioritized our initial work to include 10 prominent serotonin pathway candidate genes for detailed study within our autism families.

Sixty evenly spaced SNPs were genotyped in our candidate genes: HTR1A, DDC, TPH1, TPH2, SLC6A4, ITGB3, AANAT, FLJ22341, MAOA and MAOB. Parametric two-point analyses identified peak LOD scores > 2.0 for the subset of families containing only affected males within AANAT, LOD=2.63, and SLC6A4, LOD=2.04 for the complete Vanderbilt subset. Another marker within SLC6A4, demonstrated a parametric two-point LOD of 2.61 in the Vanderbilt male-affected-only families and a highly significant association in the Vanderbilt trio subset(0.006). However, there was little evidence of linkage or association in the Duke subset suggesting that underlying heterogeneity remains. These results warrant further investigation of the serotonergic pathway including a specific examination of gene x gene interactions (underway).

Investigation OF *LAMB1* as an Autism candidate gene. *D.A. Skaar[1], J.M. Jaworski[1], J.L. Benton[1], E.R. Martin[1], H.H. Wright[3], R.K. Abramson[3], J.L. Haines[2], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Center for Human Genetics Research, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 3) University of South Carolina, Columbia, SC.

Multiple studies indicate an area on chromosome 7q as potentially contributing to autism susceptibility. Several microsatellite markers on 7q, d7s1813 (102.82cM), d7s821 (109.1cM), d7s477 (111.79cM), and d7s496 (119cM), have shown significant linkage. In addition, haplotype and recombination analysis has identified the region 119.8-122.5cM as being predominantly shared among families with autistic individuals. These indications, combined with the candidate gene *RELN* also located in this area of 7q, led us to perform a fine-mapping study of this region (111.3-121.4cM/98.8Mb-108.5Mb) with SNPs spaced approximately 100kb apart. Three areas with multiple association peaks were identified with this screen. One of these significant regions (~107-108Mb) contains the *NRCAM* and *LAMB1*, which have been previously examined as candidate genes. Multiple SNPs in these genes have been tested by two different groups, with both groups finding significant associations in *LAMB1* SNPs. One group found significance for a missense mutation in exon 30 that changes a conserved isoleucine (I1547) to threonine, while the other group identified a significant SNP in intron 3.

We therefore examined the *LAMB1* SNPs tested by the other groups in our dataset. Twelve SNPs were typed on 501 Caucasian families. No significant association results were seen for any of these SNPs for this dataset. Several SNPs showed marginally significant linkage scores (LOD1.0), but neither of the SNPs that were found associated in the previous studies had linkage approaching significance.

This lack of replication indicates that *LAMB1* is probably not contributing to Autism susceptibility in these data. However, our association results in this region of 7q continue to support the presence of a susceptibility factor.

Genetic polymorphisms in catechol O-methyltransferase gene (COMT) affect acute post-surgical pain in humans.
H. Kim, D. Mittal, J. Brahim, J. Rowan, R. Dionne. Dept PNMB, NIDCR/NIH, Bethesda, MD.

Candidate gene studies on the basis of biological hypotheses have been a practical approach to identify relevant genetic variation in complex traits such as pain. Based on their roles in pain pathways, we have examined the effects of variations of loci in the human catechol O- methyl transferase gene (*COMT*) and cyclooxygenase 1 and 2 genes, also known as prostaglandin G/H synthase genes (*PTGSs*), on acute clinical pain responses in humans. In the responses to clinically induced acute pain, haploblocks from COMT showed significant association with maximum post-operative pain ratings. Further analysis revealed that homozygous SNP7 (rs165722) T/T patients in the *COMT* haploblock 2 (HB2) showed significantly lower pain ratings than C/C homozygous patients (t-test, $p = 0.031$) while no significant association was found between clinically induced acute pain responses and haploblocks in *PTGS1* and *PTGS2*. However, the association between *COMT* genetic variations and pain sensitivity in our study differ from previous studies with small sample sizes, population stratification and artificial pain phenotype from combining different types of pain stimuli. The association between *COMT* SNP7 and persistence in psychological temperament suggests interactions between genetically influenced psychological trait and acute clinical pain perception.

Association of a SNP in the *PTPN22* gene with multiple autoimmune diseases. *S. Onengut-Gumuscu[1], D.K. McCurdy[2], C. Pihoker[3], J.H. Buckner[1], C. Greenbaum[1], P. Concannon[1].* 1) Benaroya Research Institute, Seattle, WA; 2) Division of Rheumatology, Mattel Children Hospital, Los Angeles, CA; 3) Children's Hospital and Regional Medical Center, Seattle, WA.

The *PTPN22* gene at chromosome 1p13 encodes a 110 kDa lymphoid specific tyrosine phosphatase, Lyp, that negatively regulates the response of T cells to antigen stimulation. A coding SNP in *PTPN22* (1858T) (R620W) has been reported to be a general risk allele for autoimmunity possibly due to its effects on the interaction of Lyp with the Csk kinase during T cell activation. To evaluate the role of variation at the *PTPN22* 1858C/T SNP in autoimmunity we have genotyped independent populations with adult rheumatoid arthritis (RA) (N = 68), pauci-articular juvenile rheumatoid arthritis (PJRA) (N = 79), and type 1 diabetes (T1D) (N = 244) and compared allele frequencies in these cases to a single control population (N = 167). The frequency of the T allele in controls was 0.086 (95% CI = 0.0590.12). The RA population had a significantly higher T allele frequency when compared to controls (0.169, 95% CI = 0.110.243) (P = 0.008). In the PJRA population, the frequency of the T allele was increased (0.127, 95% CI = 0.0790.189), but was not significantly different from controls (P = 0.1). The frequency of the T allele among T1D cases was significantly elevated relative to controls (0.158, 95% CI = 0.1260.193) (P = 0.001). We confirmed the association with T1D by genotyping 406 multiplex T1D families. There was significant evidence of association between the 1858T allele and T1D by pedigree disequilibrium testing ($P = 2.5 \times 10^{-5}$). T1D families from this analysis in which affected siblings share alleles identical by descent at microsatellite markers flanking *PTPN22* are being screened for additional coding variants that may contribute to autoimmunity.

The importance of non - invasive genetic analysis of Col4a5, Col4a4 and Col4a3 genes in the initial diagnostics of Alport syndrome and familial benign hematuria. *D. Glavac[1], M. Ravnik-Glavac[1], M. Slajpah[1], P. Furlan[2], A. Meglic[3].* 1) Department of Molecular Genetics, Institute of Pathology, Medical Faculty, Korytkova 2, 1000 Ljubljana, Slovenia; 2) Department of Nephrology, General Hospital Novo mesto, Smihelska c. 1, 8000 Novo mesto, Slovenia; 3) Pediatric Nephrology Department, Childrens Hospital, University Medical Center Ljubljana, Stare Pravde 4, 1000 Ljubljana, Slovenia.

Alport syndrome is a hereditary disease, characterized by progressive hematuric nephritis with structural changes of glomerular basement membrane, frequently associated with sensorineural hearing loss. The distinction between Alport syndrome and familial benign hematuria is sometime difficult in young patients, sporadic cases and small families. Major changes in glomerular basement membrane are associated with mutations in Col4a5 gene which encodes for a5 collagen chain. However the disease was also associated with Col4a3 and Col4a4 genes. DNA was extracted from peripheral blood lymphocytes of five children (three boys, two girls) aged 10 months to four years. Col4a3, Col4a4 and Col4a5 genes were amplified in PCR and analyzed using non-isotopic high resolution single stranded conformation analysis (SSCA) and sequenced on ABI PRISM 310 Genetic Analyzer. Clinical data were obtained from clinician who performed precise urine tests, hearing and ocular examinations. Three novel mutations, G198E, G3189D and G669R, were detected in Col4a5 gene and one new mutation 3145del5b in Col4a3 gene. On the basis of the results of our study and the existing national register of Alport syndrome patients, we demonstrated that non-invasive methods such as the genetic analysis of collagen genes, particularly in the case of young patients with undefined clinical features, may be of great importance and could diminish the need for invasive skin and renal biopsy. Some patients affected with familial benign hematuria are carriers for autosomal recessive Alport syndrome. Our study showed the importance of molecular genetic data for the purpose of providing quick and precise diagnoses to affected family members and their offspring.

Prediction of radiation morbidity from polymorphisms in candidate genes among prostate cancer patients treated with carbon ion therapy. *M. Iwakawa[1], T. Suga[1], S. Noda[1], H. Tsuji[2], Y. Ohtsuka[1], M. Kohda[1], M. Sagara[1], A. Ishikawa[1], H. Suzuki[1], J. Mizoe[2], H. Tsujii[2], T. Imai[1].* 1) Frontier Research center, National Institute of Radiological Sciences, Chiba, Chiba, Japan; 2) Research Center for Charged Particle Therapy, National Institute od Radiological Sciences, Chiba, Chiba, Japan.

Heavy ion beams possess high linear energy transfer components and a prominent Bragg peak in the human body. These properties promote higher relative biological effectiveness and a favorable dose distribution. Some patients, however, develop adverse effects in the rectum and /or bladder/urethra. Using DNA samples collected from 95 Japanese prostate cancer patients who underwent radiotherapy with the Heavy Ion Medical Accelerator in Chiba, 905 SNPs were genotyped from 127 candidate genes for radiation susceptibility. These genes were selected from our previous gene expression analyses of cultured human cell lines and mouse strains that had exhibited variable radiosensitivities. The SNPs in the candidate genes were selected from jSNP and dbSNP databases and their allele frequencies were examined using 133 healthy controls. The acute and late radiation morbidities were scored using Late Effects of Normal Tissues-subjective, objective, management, and analytic criteria. Significant differences were observed of genotype frequencies for SNPs in candidate gene loci. Area under the curve of the Receiver Operating Characteristic Curve (ROC) was estimated for each SNP marker for radiation morbidity to construct a predictive score. The top 7 markers were used in constructing predictive scores for dysuria within 3 months, and the top 5 markers at 6 months after starting radiotherapy. The top 10 markers were used in constructing predictive scores for polyuria within 3 months, and the top 11 markers at 6 months after starting radiotherapy. The distribution of ten predictive scores according to response values showed the potential discriminating power of these analyses.

Association Genome Scanning for Addiction Vulnerability: Convergent Results Using 98,398 SNPs and Four Samples. *G. Uhl[1], Q. Liu[1], T. Drgon[1], C. Johnson[1], D. Walther[1], I. Sora[2], H. Ujiki[2], T. Inada[2], M. Yamada[2], N. Iwata[2], M. Iyo[2], I. Ozaki[2], Y. Sekine[2], H. Yoshimoto[2], M. Harano[2], T. Komiyama[2].* 1) Molec Neurobiology, NIDA/NIH & JHUSM, Baltimore, MD; 2) Japanese Genetics Initiative on Drug Abuse (JGIDA).

About half of human vulnerability to substance abuse and dependence comes from polygenic allelic variants, including common alelic variants that are likely to contribute to vulnerability to many addictive substances. To identify the chromosomal regions likely to contain such variants, we have validated and used pooled microarray-based association genome scanning to compare allelic frequencies at 98,398 autosomal SNP markers in four samples European American and African American polysubstance abusers/controls recruited in Baltimore, European-American alcohol dependent and control individuals from a multicenter US sample, and Japanese methamphetamine abusers/controls (ca 160 million person/ genotypes determined in quadruplicate). SNPs that display 1) the largest allelic frequency differences between substance abusers and controls and 2) the largest nominal statistical significance for these differences are found much more closely clustered in several chromosomal regions than expected by chance. Regions that contain these clustered, positive SNPs in multiple samples contain haplotypes that include interesting genes involved in cellular information processing, transcriptional and translational/posttranslational regulation, other interesting neuronal functions. These results, and other ongoing efforts to elucidate the molecular genetic underpinnings of human addictions, add additional powerful suport to the idea that common allelic variants contribute to individual differences in vulnerabilities to human addictions in individuals from a number of different racial/ethnic groups.

Sib-pair analysis in Brazilian families with non syndromic cleft lip with or without cleft palate. *F. Poerner[1,2,3], M. Bicalho[2], T. Hiekkalinna[4], M. Passos-Bueno[1].* 1) Biology, USP, São Paulo, Sao Pulo, Brazil; 2) Genetics, Biology, UFPR, Curitiba, Brazil; 3) CAIF, Curitiba, Brazil; 4) National Public Health Institute, Department of Molecular Medicine,Helsinki, Finland.

Cleft lip with or without cleft palate (CL/P) is one of the most common congenital malformations, occurring in 1:200 to 1:2000 live births, depending on the ethnic group. It is an heterogenous condition and the multifatorial model of inheritance is the most acceptable. To date, there is still no consensus which are the candidate genes involved with the predisposition of this condition. Therefore, our major aim is to identify susceptibility loci for non syndromic CL/P in the Brazilian population. For this purpose, we have applied the sib pair approach using microsatellite markers of 14 chromosomes (1, 2, 4, 6, 8, 11, 12, 13, 14, 16, 17, 19, 22 and X) that were previously found associated with CL/P through others methods of analysis (Carinci et al, J. Craniof. Surg., v.14, n.2, 2003). We have so far included 50 affected sib-pairs with nonsyndromic CL/P from 44 families which were ascertained in CAIF - Center for Integral Care to Cleft Lip and Palate Patient, Curitiba, PR, Centrinho, Joinville, SC and Center of Studies in Human Genome, SP. A total of 232 microssatelites markers have been analyzed and the results were analyzed using the GeneHunter software. The major evidence of linkage was found in chromosome 1 region between markers D1S2868 e D1S484 (max lod score of 3.24). The present data will also be analyzed with the software Pseudomarker. Other regions with smaller values of lod score will be discussed.

Genome-wide association for Atypical Antipsychotic Treatment Emergent Weight Gain and Replication in an Obesity Cohort. *S. Kirkwood[1], R.D. Hockett[1], N. Mukhopadhyay[1], D.J. Fu[1], D. Ballinger[2], R.A. Price[3], Y. Yue[1], L. Gelbert[1], S. Li[1], D. Cox[2], A. Breier[1].* 1) Res Tech/Experimental Med, Eli Lilly & Co, Indianapolis, IN; 2) Perlegen Sciences, Inc, Mountain View, CA; 3) University of Pennsylvania, Philadelphia, PA.

Treatment-emergent weight gain observed with atypical antipsychotic therapy continues to be a clinical concern with genetic factors likely playing a role. The genetic contribution to weight gain has been investigated using candidate gene methodology. Although significant associations with candidate genes such as the Serotonin 5-HT2c Receptor Gene have been reported, negative results have also been. The lack of consistent findings has led to uncertainty as to the significance of reported associations. Therefore, we completed a genome scan followed by a replication in a cohort of individuals selected for obesity. Using a cohort of adult patients diagnosed with schizophrenia, schizoaffective, or schizophreniform disorder who had taken oral olanzapine for a minimum of six months, cases and controls were chosen from the 20% tails of the weight-gain distribution, weight gainers (n=255) and non-weight gainers (n=258) as measured by change in body mass index. A genome-wide association study using the Perlegen Sciences platform was performed using pooling in phase I and then individual genotyping in phase II for all 513 individuals for 30,000 SNPs. Association analyses between the 30,000 SNPs and weight-gain phenotype were completed using Fishers exact test. Following the genome scan, an algorithm was developed using linkage disequilibrium map information and the association results from the treatment emergent weight gain scan (SNP significance level, frequency, and clustering information) to select SNPs for follow up (n=3000). Using a cohort of more than 340 parent child trios selected for an obese proband, these SNPs were then associated with obesity using transmission disequilibrium methodology.The SNPs (n=311 at p=0.001) and genes identified as significantly different in the first cohort between weight gainers and nongainers and those that replicated in the obesity cohort will be presented.

Analysis of a QTL for diabetes related traits identified through a genome scan in large extended pedigrees. *J. Jowett[1, 5], J. Curran[4], K. Shields[1], J. Wang[1], S. Dennis[1], R. Kotea[2], S. Kowlessur[3], P. Chitson[3], P. Zimmet[1], J. Blangero[4, 5].* 1) Genetics Research, Intl Diabetes Inst, Melbourne, Australia; 2) SSR Centre, Mauritius; 3) Ministry of Health, Mauritius; 4) Southwest Foundation for Biomedical Research, San Antonio, TX; 5) ChemGenex Pharmaceuticals, Grovedale, Australia.

The prevalence of Type 2 diabetes and obesity continues to increase in both developed and developing countries presenting major public health issues impacting a wide variety of social and economic measures. Substantial evidence supports a major role of genetics in development of the disease together with modifying effects of the environment. To improve our understanding of the molecular mechanisms underpinning the metabolic abnormalities associated with disease development, we conducted a genome-wide scan to identify chromosomal regions likely to harbour disease-influencing genes. Using large multigenerational pedigrees to improve statistical power of susceptibility gene detection/localization we undertook a 10 cM genome scan on a cohort of 450 individuals in 20 families. We identified two quantitative trait loci (QTL) for fasting plasma glucose and uric acid with significant lod scores. To assist with prioritisation of candidate genes, we developed a data-mining software program that interrogates online databases for information relating each gene under the peak to the trait phenotype. To begin dissection of the QTL for fasting plasma glucose at 12q24, we selected SNPs from within and juxtaposing the top ranked genes and from intergenic regions showing conservation among mammals. Preliminary association analysis of SNPs typed in a set of founders identified 30 associated variants in 15 genes. The overall best signals (p-value = 0.0000192) were seen in novel genes that are now being assessed in the total sample.

A genome-wide association study in sporadic ALS using DNA microarrays. *C.L. Simpson[1], V. Hansen[1], J. Powell[2], I. Fogh[1], M. Turner[1], C. Shaw[1], J. Knight[3], P. Sham[3], P. Leigh[1], A. Al-Chalabi[1].* 1) Dept Neurology, Inst Psychiatry, London, United Kingdom; 2) Dept Neuroscience,Inst Psychiatry, London, United Kingdom; 3) MRC SGDP Centre, Inst Psychiatry, London, United Kingdom.

Most cases of ALS occur sporadically, but twin studies suggest a genetic contribution of up to 85%. Previous association studies using candidate genes have yielded few positive, reproducible associations. DNA microarrays allow the genotyping of larger numbers of SNPs than is feasible with microsatellites and combining this approach with DNA pooling provides a quick and efficient method of performing a genome-wide association study. Our objective was to perform a genome-wide screen for susceptibility and phenotype modifier genes for sporadic amyotrophic lateral sclerosis (ALS), using DNA pools genotyped on Affymetrix GeneChip microarrays. We have previously analysed DNA pools with the 10K microarrays, and here present the results of this technique using the denser Affymetrix GeneChip 100K Mapping Set.

Pools were constructed of 300 cases and 300 controls matched for sex and age withing 1 year. 100 individual genotypes were used to calculate data correction values. Each pool was hybridised to the microarrays in 6 replicates and mean values used for analysis. 99,776 SNPs were analysable and had correction factors available. Using a modified chi square which allows for measurement and sampling error, 11,895 markers were significant at $P < 0.05$, 42 were significant at the Bonferroni corrected $P < 5 \times 10^{-7}$. The largest effect sizes were seen for SNPs on chromosome X (OR = 12, $P < 10^{-8}$) and chromosome 13 (OR = 8.3, $P = 10^{-15}$).

DNA microarrays provide the high-throughput technology which genome-wide association studies require. This work shows that genotyping DNA pools on microarrays is a useful method for first-pass screening which has quickly and efficiently identified regions associated with ALS to target with fine-mapping studies.

Mitochondrial Genotypes Associated with Healthy Aging. *T.A. Donlon[1,2,3,4], J. Grove[2,3,4], B.J. Wilcox[2,3,5], K. Yano[2,3], R. Chen[2], B.L. Rodriguez[2,3,5], K.H. Masaki[2,3,5], C. Ceria[2,6], J.D. Curb[2,3,5].* 1) Queen's Genetics Laboratories, The Queen's Medical Center, Honolulu, HI; 2) Pacific Health Research Institute, Honolulu, Hawaii; 3) Honolulu Heart Program, Kuakini Medical Center, Hawaii; 4) Cancer Research Center of Hawaii, University of Hawaii, Honolulu; 5) Department of Geriatric Medicine and Medicine, John A. Burns School of Medicine, University of Hawaii, Honolulu; 6) Department of Nursing, School of Nursing & Dental Hygiene, University of Hawaii, Honolulu.

As our society ages it becomes imperative to identify causes of morbidity and decline in order to improve the quality of late life. The mitochondria plays a major role in many age-related chronic diseases and may play an important role in healthy aging and longevity. Healthy aging was measured using hand grip strength at two separate exams in an elderly male Japanese population and shown to be associated with common polymorphisms in the genes for three mitochondrial proteins, one mitochondrial- and two nuclear-encoded; NAD Dehydrogenase, subunit 2 (NAD2 C1578A), Uncoupling Protein 1 (UCP1; G/T in 5 UTR), and Uncoupling Protein 2 (UCP2; V55A). These results show that common variation in mitochondrial genes can have a significant effect on healthy aging, even in late life and identify an important physiologic pathway for future investigations.

Haplotype-based sequencing methodology to identify strongly associated SNPs in regions with strong LD, applied to EBV positive Hodgkin Lymphoma. *M. Niens[1], A. van den Berg[2], A. Diepstra[2], I. Nolte[3], G. van der Steege[3], S. Poppema[2], G.J. te Meerman[1].* 1) Department of Medical Genetics; 2) Department of Pathology; 3) Department of Medical Biology, University Medical Center Groningen, Groningen, Netherlands.

Various studies have indicated that the human leukocyte antigen (HLA) region is associated with Hodgkin Lymphoma (HL). We recently demonstrated association of the HLA class I region with Epstein-Barr virus (EBV) positive HL cases. The positively associated haplotype was characterized by alleles 126 and 284 of the consecutive microsatellite markers D6S265 and D6S510 while the negatively associated haplotype was characterized by alleles 130 and 302. Further fine mapping of this region is necessary to identify the causal SNP(s). To select the most promising candidate SNPs for screening the total study population, known SNPs were sequenced in an individual homozygous for the positively associated haplotype and an individual homozygous for the negatively associated haplotype. Four SNPs (rs2523972, rs4713276, rs2256543, and rs6457110) that were selected on the basis of displaying different alleles in these two individuals where analysed in the total study population and revealed a much stronger association than the microsatellite markers (-log p difference = 2). The associated region was delimited from 310 kb in the original study to a region comprising less than 60 kb in the present study. Of the genes mapping to this candidate region, HLA-A represents the most interesting target because of its consistent expression in EBV positive HL cases and its ability to present EBV derived peptides to cytotoxic T cells. We demonstrated that sequencing homozygous individuals selected for positively and negatively associated haplotypes is an efficient way to identify candidate SNPs.

Identifying genes for optimal brain aging: translational gene mapping of complex phenotypes. *B. Wilmot[1], S. McWeeney[2], R. Nixon[3], J. Laut[4], J. Kaye[4], P. Kramer[1,4].* 1) Dept Mol. & Med. Genetics, Oregon Health & Sci Univ, Portland, OR; 2) Div. of Biostatistics, Dept of Public Health and Prev. Medicine, Oregon Health & Sci Univ, Portland, OR; 3) Dept of Pathology, Oregon Health & Sci Univ, Portland, OR; 4) Dept of Neurology, Oregon Health & Sci Univ, Portland, OR.

Healthy brain aging is a complex phenotype subject to both genetic and environmental influences. Natural variation across individuals in the ability to sustain cognitive function in the presence of brain injury is known as cognitive reserve. Based on the hypothesis that cognitively healthy individuals carrying a severe neuropathologic burden may be utilizing cellular pathways in a different manner, we designed a case/control study in which the controls were classified into defined phenotypic groups based on severity of neuropathology (Braak stage) and were compared to patients with Alzheimers disease (AD), the most common cause of dementia in the elderly. Global gene expression profiling was conducted on nine cognitively intact individuals and five AD patients in postmortem frontal cortex tissue. Of the 4556 transcripts that were differentially expressed (q-value < 0.05) between control subjects and AD subjects, 58% were downregulated in AD subjects. 487 genes were located in previously identified linkage regions. 1655 genes in the list of differential expression candidates were statistically overrepresented in Gene Ontology (G0) categories for biological process when compared to the expected proportion based on the distribution of GO categories on the gene array. Genes implicated in cognitive reserve were identified using trend analysis across all groups. Of the 82 transcripts identified, 51 transcripts were upregulated in controls with Braak stage V/VI as compared to AD subjects. Comparison of the differentially expressed genes involved in AD with those implicated in cognitive reserve revealed only 5 genes common to both suggesting the presence of unique cellular processes in brain tissue of cognitively healthy individuals with severe neuropathology. Multiple Attribute Decision Making theory was used to create a priority score to identify genes for further study.

Polymorphism 5 of the Leptin Gene Results in Sex-Specific Trends in Birth Weight and Cord Leptin Levels. *R.M. Adkins[1], C.K. Klauser[2], J. Fain[3], J. Magann[4], J. Morrison[2].* 1) Le Bonheur Child Med Ctr, Univ Tennessee-Hlth Sci Ctr, Memphis, TN; 2) Department of Obstetrics and Gynecology, Univ. MS, Jackson, MS; 3) Department of Molecular Sciences, Univ. TN Hlth Sci Ctr., Memphis, TN; 4) Department of Obstetrics and Gynecology, Naval Medical Center - Portsmouth, Portsmouth, VA.

Objectives: Leptin levels are positively correlated with adult BMI and birth weight, with female serum levels nearly twice those of males. Postnatally, SNPs in the leptin gene have been shown to exhibit sex-specific associations with BMI and circulating leptin levels. These relationships, as they affect fetal birth weight, remain undefined. The purpose of this study is to test the association between leptin polymorphism and both birth weight and cord leptin levels.

Study Design: Subjects were recruited at three sites. At one site, Caucasian newborns were recruited in a case-control design, while African-Americans were recruited in a cross-sectional design at two additional sites. Genotype at 5 SNPs in the leptin gene was determined for all newborns. Using either birth weight Z score or log(leptin) as dependent variables, ANOVA was performed using a model composed of potential correlates of birth weight or leptin levels (gestational age, gender, size for gestational age, SNP genotype) with an interaction term included to detect a differential association between the dependent variable and genotype, depending on newborn gender.

Results: Leptin levels were about twice as high in females as in males (14.8 vs. 7.0 ng/ml; $p<0.001$), and leptin levels positively correlated with birth weight ($r2=0.33$; $p<0.001$). Relative to homozygotes for the major allele at a SNP upstream of the leptin gene, heterozygous males exhibited an increase in birth weight and cord leptin levels, while females exhibited a decrease in both variables ($F=4.7$, $p=0.01$ for gender x genotype interaction).

Conclusions: Upstream polymorphism in the leptin gene is associated with opposite trends in birth weight and cord leptin levels in male and female newborns.

PDE4D and _ALOX5AP_ genes are associated with ischemic stroke. *R. Kaushal[1], D. Woo[2], P. Pal[1], H. Xi[1], K. Alwell[2], P. Sekar[1], M. Haverbusch[2], C. Moomaw[2], B. Kissela[2], L. Sauerbeck[2], R. Chakraborty[1], J. Broderick[2], R. Deka[1].* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Dept Neurology, Univ Cincinnati, Cincinnati, OH.

Stroke is the third commonest cause of death and the leading cause of disability in the United States. It is a complex phenotype with both genetic and environmental risk factors interacting in its etiology. Genetic variations in the phosphodiesterase 4D (*PDE4D*) and the 5-lipoxygenase activating protein (*ALOX5AP*) genes have been shown to be associated with stroke and its sub-types in Icelandic and European populations. We report the results of association of six SNPs in *PDE4D* and five SNPs in *ALOX5AP* with various subtypes of stroke in Caucasians. We enrolled cases (N = 252 ischemic subtypes that include cardioembolic, large vessel, small vessel and unknown; 87 subarachnoid and 185 intracerebral hemorrhage), and race and age matched population controls (N = 519) from the greater Cincinnati area. Allelic variant *rs152312* in *PDE4D* is associated with cardioembolic (*P* = 0.006) and small vessel stroke (*P* = 0.026). We inferred haplotypes using the HelixTree software and detected significant association of *PDE4D* haplotypes with cardioembolic and large vessel stroke (*P* 0.0001). No association is observed with the subtypes of hemorrhagic stroke. In *ALOX5AP*, SNP *rs4769874* is significantly associated with ischemic stroke (*P* 0.0001) and subtypes cardioembolic (*P* 0.0001) and large vessel stroke (*P* = 0.0005). This variant was also found significantly associated with ischemic stroke in the Icelandic and a Central European population. We found nominal association of *ALOX5AP* SNP *rs9579646* with ischemic (*P* = 0.022) as well as subarachnoid hemorrhage (*P* = 0.02) stroke. Haplotype analysis showed strong association of *ALOX5AP* with cardioembolic and large vessel stroke (*P* 0.0001); however, we do not observe any association with hemorrhagic stroke. Our study confirms that polymorphisms in *PDE4D* and *ALOX5AP* significantly contribute to the risk of ischemic stroke among the Caucasians. This study was supported by NIH grants NS36695 and ES06096.

Hemorrhagic stroke and variants in the *ACE* gene. *P. Pal[1], D. Woo[2], R. Kaushal[1], H. Xi[1], M. Haverbusch[2], P. Sekar[1], C. Moomaw[2], L. Sauerbeck[2], R. Chakraborty[1], J. Broderick[2], R. Deka[1].* 1) Department of Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Department of Neurology, Univ Cincinnati, Cincinnati, OH.

Hemorrhagic stroke, which results from rupture of intracranial vessels, is subdivided into intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH). ICH has an incidence of 15-19 per 100,000 and SAH has an incidence of 6-8 per 100,000 persons in Western Europe and North America. Both ICH and SAH has a 30-day mortality rate exceeding 40%. Environmental and genetic factors are associated with the occurrence of both ICH and SAH. Association of the ACE gene (*ACE*) with hypertension, a proven major risk factor for both ICH and SAH, has been demonstrated. *ACE* has also been implicated in hemorrhagic stroke. However, most studies have reported only the insertion/deletion (*I/D*) polymorphism and the results of association are inconsistent. We tested for allelic and haplotype associations using six variants in *ACE* with hemorrhagic stroke in a sample of Caucasian cases (N = 185 ICH and 112 SAH) and population-based race and age-matched controls (N = 367 ICH and 217 SAH) from the greater Cincinnati region. The *I/D* polymorphism as well as the other SNPs showed no association with ICH or SAH either at allelic or genotypic level. However, haplotypes inferred using the HelixTree software showed significant association with both SAH ($P = 0.011$) and ICH ($P = 0.008$). When ICH cases were divided into lobar (N = 65) and non-lobar (N = 115) cases, no significant associations were found either at allelic or genotypic level; however, significant haplotype associations were observed for both subtypes (lobar $P = 0.005$; non-lobar $P = 0.019$). Our study suggests that *ACE* plays a plausible role in the pathogenesis of hemorrhagic stroke and warrants a rigorous examination of larger number of variants within the gene. Supported by NIH grants NS36695, ES06096.

Association study of OPRM1 with smoking initiation and progression to nicotine dependence. *L. Zhang[1,2], K.S. Kendler[1], X. Chen[1].* 1) Virginia Institute for Psychiatric and Behavioral Genetics and Department of Psychiatry , Virginia Commonwealth University, Richmond, VA; 2) Psychiatry Department, West China Hospital, Sichuan University, Chengdu, China.

The gene encoding the mu-opioid receptor (OPRM1) has been reported associated with a range of substance dependences. Experiments in knockout mice implicate that the mu-opioid receptor may mediate reinforcing effects of nicotine. In human, opioid antagonist naltrexone may reduce the relative reinforcing effects of nicotine via cigarette smoking.The OPRM1 is thus a plausible candidate gene influencing smoking behavior. To investigate whether OPRM1 contributes to the susceptibility of smoking initiation and progression to nicotine dependence, we selected 6 haplotype-tagged single nucleotide polymorphisms (SNPs) in this gene and genotyped 688 subjects of lifetime smokers and nonsmokers. We performed chi-square tests for both allelic and genotypic associations and failed to find significant results for neither smoking initiation nor nicotine dependence. Haplotype analyses based on expectation-maximization algorithm showed no significant associations. These preliminary results provide no support for the hypothesis that OPRM1 contributes to susceptibility to smoking initiation and progression to nicotine dependence.

Promoter polymorphisms in the apolipoprotein H (APOH) gene and the risk of systemic lupus erythematosus. *E. Jacobs[1], Q. Chen[1], M. Kenney[1], P. Shaw[2], A. Kao[2], C. Kammerer[1], F. Bontempo[3], S. Manzi[2], M.I. Kamboh[1].* 1) Department of Human Genetics; 2) Division of Rheumatology & Clinical Immunology; 3) Department of Medicine, University of Pittsburgh, Pittsburgh PA.

Systemic lupus erythematosus (SLE) is a complex systemic autoimmune disease. Almost 50% of the SLE patients have antiphospholipid autoantibodies (APA) in their sera. APOH is a major autoantigen for the production of APA and thus genetic variation in the APOH gene may affect the risk of SLE. In this study we tested the hypothesis that single nucleotide polymorphisms (SNPs) in the APOH promoter are associated with SLE, the severity of SLE, and the presence of APA. Three hundred and eighty women with SLE (334 Caucasians and 46 African Americans) and 497 healthy control women (455 Caucasians and 42 African Americans) were genotyped for 6 SNPs in the APOH promoter using pyrosequencing. The presence of APA was determined using fluorometric assays. Association studies were carried out using the 2 distribution and Z-tests. The EH program was used for the haplotype analysis. The distribution of four of the 6 SNPs differed significantly between Caucasians and African Americans. Individually, none of the promoter SNPs differed significantly between cases and controls in Caucasians; however the SNPs at positions -700 and -759 had differences in genotype distributions between cases and controls in African Americans (-700, p=0.035; -759, p=0.022). Six-site haplotype analysis was performed among Caucasians only because of the relatively large number of cases and controls in this racial group. A total of 26 different haplotypes were observed and the overall haplotype distribution was significantly different between SLE cases and controls (p=0.00015). Additional analyses indicated that the -700 and -759 SNPs were associated with increased renal disease among Caucasian SLE patients (p=0.024; p=0.028, respectively). No significant associations were found between the promoter polymorphisms and the occurrence of APA.

In conclusion, our data suggest that genetic variation in the APOH promoter may be associated with SLE risk, especially risk of renal disease.

Association of the ubiquilin 1 (*UBQLN1*) SNPs with late-onset Alzheimers disease in a large case-control sample.

R.L. Minster[1], S.T. DeKosky[1,2], M.I. Kamboh[1]. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

In addition to the *APOE* gene on chromosome 19, several chromosomal regions have been implicated to harbor putative genes for late-onset Alzheimers disease (LOAD), but their identity is not known with certainty. The gene coding for ubiquilin 1 (*UBQLN1*) is located near a linkage peak on chromosome 9q22.2, and it also impacts the function of the presenilin 1 and 2 genes that cause early-onset AD. Thus, *UBQLN1* is both a positional and biological candidate gene for AD. Recently genetic variation in the *UBQLN1* gene has been shown to affect the risk of AD in two independent family-based samples (NEJM 2005; 352:884-894). The purpose of this study was to confirm the reported association in a large case-control sample. We examined the associations of three SNPs in the *UBQLN1* gene (rs2780995, rs12344615 and rs2781002) in 785 LOAD cases and 726 controls. All SNPs were in significant linkage disequilibrium ($p < 0.001$). Significant associations were observed with the rs12344615 and rs2781002 SNPs. The age, sex and *APOE* adjusted odds ratios between the less common allele carriers and wild type homozygous were 1.38 (95%CI: 1.06-1.80; $p = 0.016$) for the rs12344615 SNP and 1.28 (95%CI: 1.00-1.64; $p = 0.048$) for the rs2781002 SNP. These odds ratios are within the range recently reported in the family-based study. Three-site haplotype analysis identified one haplotype to be significantly more common in cases than controls (20.1% vs. 13.8%; $p = 0.0002$) and this haplotype was mainly defined by the risk allele of the rs12344615 SNP.

In summary, our data from a large case-control cohort indicate that genetic variation in the *UBQLN1* gene has a modest effect on AD risk and these results are similar to those found in a recent family-based association study.

Investigation of the relationship of candidate genes on chromosome 10 with the risk and age-at-onset of Alzheimers disease. *A. Ozturk[1], S.T. DeKosky[2], M.I. Kamboh[1].* 1) Department of Human Genetics; 2) Department of Neurology, University of Pittsburgh, Pittsburgh PA.

Late-onset Alzheimers disease (LOAD) is a complex and multifactorial disease with a substantial genetic component. The APOE*4 allele in the APOE gene is the only established risk factor in the development of LOAD that accounts for 20-30% of the disease risk. Recently, linkage studies in multiplex families with LOAD have provided evidence for the existence of additional putative genes for LOAD on several chromosomes, including chromosome 10. A broad linkage peak encompassing 50 cM region between chromosome 10q21 and 10q25 has been implicated that influence both disease risk and age-at-onset (AAO). There are a number of promising candidate genes in this region that are involved in either the production, processing or clearance of A peptide and include CHAT, PLAU, IDE, HHEX, GSTO1, GSTO2, and PRSS11. In this study, we have examined the role of these genes under the linkage peak on chromosome 10 to assess their role with AD risk and AAO. Association studies for 14 SNPs were performed in a large case-control cohort comprising 1012 white LOAD subjects and 771 white control subjects. No significant associations were observed with any of the SNPs examined in the IDE, HHEX, GSTO1, GSTO2 and PRSS11 genes. Of the 3 CHAT SNPs examined, we detected significant association of the intron 9 SNP with AD risk in both the total sample OR = 2.37, 95% CI: 1.19-4.73; p=0.01) and among non-APOE*4 carriers (OR=2.94, 95% CI: 1.33-6.51; p=0.007). Three-site haplotype analysis confirmed that haplotypes determined by the CHAT/intron 9 SNP were associated with either risk (p=0.0009) or protection (p=0.0082) among non-APOE*4 carriers. In the PLAU gene, we examined 3 tagSNPs and found a modest protective effect with one SNP in the 3UTR (OR=0.71, 95% CI: 0.53-0.95; p=0.02). Suggestive associations for AAO were observed with the PLAU/3UTR (p=0.036) and PLAU/intron 9 (p=0.01) SNPs. In summary, our data on a large number of AD cases and controls suggest that genetic variation in two positional candidate genes on chromosome 10 (PLAU and CHAT) or nearby genes may affect the risk and AAO of LOAD.

Association of paraoxonase-1 (PON1) polymorphisms with lupus nephritis. *L. Tripi[1], Q. Chen[1], M. Kenney[1], P. Shaw[2], A. Kao[2], C. Kammerer[1], F. Bontempo[3], S. Manzi[2], M.I. Kamboh[1].* 1) Department of Human Genetics; 2) Division of Rheumatology & Clinical Immunology; 3) Department of Medicine, University of Pittsburgh, Pittsburgh PA.

Systemic lupus erythematosus (SLE) is the prototypic systemic inflammatory autoimmune disease with a significant genetic component. About 50% of the SLE patients are positive for antiphospholipid antibodies (APA) and the risk of coronary artery disease (CAD) is up to 50 times higher than the general population. Several lines of evidence suggest the existence of a relationship between oxidative parameters of LDL and APA in SLE patients. PON1 inhibits LDL oxidation and thus may affect the risk of SLE by modifying susceptibility to CAD. In this study we examined the role of 9 SNPs in the PON1 gene in relation to SLE risk. DNA samples from 380 women with SLE (334 Caucasians and 46 African Americans) and 497 healthy control women (455 Caucasians and 42 African Americans) were studied. Association studies were performed using logistic regression. Haplotype analysis was performed using EH program. The genotype distributions of 7 SNPs were significantly different between Caucasians and African Americans. All SNPs were in significant linkage disequilibrium (LD) in the Caucasian sample and all except 2 were in significant LD in the African American sample. The SNP at position -1739 had a significantly different genotype distribution between lupus patients and controls in the Caucasian sample (OR) =0.66, 95% CI 0.45-0.97; p=0.03). The overall haplotype distribution in the Caucasian sample also differed between SLE cases and controls (p=0.051). Stratification of the lupus sample based on renal disease (n=81) and no renal disease (n=243) revealed significant associations with three additional promoter SNPs with ORs 3.82 (95% CI: 1.49-9.82; p=0.005), 3.41 (95% CI: 1.35-8.61; p=0.009) and 2.17 (95% CI: 1.01-4.65; p=0.049). Because these three SNPs were in high LD (|D| range 0.915-0.962), the significant effect is most probably derived from one functional SNP. In conclusion, our data suggest that genetic variation in the PON1 gene may affect the risk of developing lupus nephritis, especially among Caucasians.

Association of NOD1 Polymorphisms with Atopic Eczema and Related Phenotypes. *T. Illig[1], N. Klopp[1], L. Rummler[2], S. Wagenpfeil[3], N. Novak[4], HJ. Baurecht[3], W. Groer[2], U. Darsow[2], J. Heinrich[1], T. Schafer[5], T. Jakob[2,6], H. Behrendt[6], HE. Wichmann[1], J. Ring[2,6], S. Weidinger[2,6].* 1) Institute of Epidemiology, GSF National Research Center for Environment and Health, Munich, Germany; 2) Department of Dermatology and Allergy Biederstein, Technical University Munich, Germany; 3) Institute for Medical Statistics and Epidemiology, Technical University Munich, Germany; 4) Department of Dermatology and Allergy, University of Bonn, Germany; 5) Institute of Social Medicine, Medical University, Luebeck, Germany; 6) Division of Environmental Dermatology and Allergy GSF/TUM, GSF National Research Center for Environment and Health & ZAUM Center for Allergy and Environment, Technical University Munich, Germany.

Interactions with microbial pathogens are crucial for the maturation of the immune system. The nucleotide-binding oligomerization domain protein 1 (NOD1) is a cytosolic receptor sensing a muropeptide found mostly in gram-negative bacterial peptidoglycans. NOD1 is located on chromosome 7p14-p15, a region which has been linked with atopy. Within a large population-based cohort of German adults (n=1417), a case-control population for atopic eczema (n=454), and a large cohort of parent-offspring trios for atopic eczema (189 trios), we evaluated 11 NOD1 polymorphisms for associations with atopic phenotypes. Analyses revealed significant association of one NOD1 haplotype with atopic eczema in the population-based cohort (p=0.004) and the case-control population (p=0.003). Another NOD1 haplotype (p=0.008) was associated with increased total IgE. In addition, significant associations with total serum IgE levels were observed for polymorphisms rs2907748 (p=0.006), rs2907749 (p=0.012) and rs2075822 (p=0.018). These polymorphisms were significantly associated with atopic eczema and asthma in the family-based association analyses (p=0.001-0.043). Seven polymorphisms showed significant transmission distortion for total IgE levels (p-values < 0.0001 - 0.029). These data indicate that genetic variants within NOD1 are important determinants of atopy susceptibility.

Using HapMap methods and data in lung cancer study. *Y. Gao[1], T. Sun[2], S. Ma[1], W. Tan[2], Q. Zhang[1], D. Lin[2], C. Zeng[1].* 1) Beijing Genomics Institute, The Chinese Academy of Sciences, Beijing Airport Industrial Zone B6, Beijing, 101300, China; 2) Cancer Institute and Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, 17 Panjiayuan Nanli, Beijing, 100021, China.

In an attempt to mine genes and their polymorphisms correlated to lung cancer, 4 chromosomal regions were chosen for SNP genotyping and association studies in case and control samples from 1800 individuals. Initially, 97 SNPs were selected and genotyped in 192 case and 192 control samples. Then 58 SNPs with MAF>0.05 were chosen to genotype in enlarged samples from total of 923 case and 888 control individuals. In a 26 kb region on chromosome 10, 14 SNPs were genotyped whereas using various types of analysis neither SNP nor haplotype was shown to associate with the cancer. 22 SNPs were genotyped in chromosomal region 2 which spans 57 kb. Three SNPs appeared to be associated with moderately increased risk of the disease by comparing individual SNPs and haplotype patterns of case and control samples. However, after partitioning the haplotype blocks, a haplotype containing 13 typed SNPs, with a frequency of 19.5%, appears strongly associated with lung cancer. In a 9-kb region which contains only one gene, 8 novel SNPs were discovered by resequencing. Three SNPs and one haplotype were detected to be associated with cancer. Region 4 on chromosome 2 covers 200 kb. 14 SNPs which are defined as tag SNPs in HapMap data were selected for genotyping. 5 of 14 SNPs appear to correlate with the cancer. Moreover, 2 blocks, containing 18 haplotypes, were identified in all samples. One haplotype appears to correlate to lung cancer significantly.

Replicated linkage and association between *DRD3* and schizophrenia: Attempting to resolve a history of inconsistencies. *M. Talkowski[1], H. Mansour[1], J. Wood[1], S. Deshpande[2], B.K. Thelma[2], K.V. Chowdari[1], V.L. Nimgaonkar[1].* 1) Univ of Pittsburgh, Pgh, PA; 2) Dr. RML Hospital and Univ of Delhi, New Delhi, India.

Over forty studies have evaluated a single coding SNP, rs6280, at *DRD3* for associations with schizophrenia (SZ). Yet, the results remain inconclusive. Simulations have suggested variants in LD with an unidentified liability locus may produce inconsistent associations. Thus, we investigated additional SNPs within and flanking *DRD3*. Our results suggest replicated associations in two samples, and post-hoc LD analyses indicate the associations are independent of rs6280.

We initially analyzed 13 SNPs spanning 109kb in 331 SZ cases, including 151 case-parent trios, and 274 controls from the US. Subsequently, we evaluated 11 SNPs in an Indian cohort (141 trios). In the U.S. sample, we detected associations with eight SNPs, including rs6280 ($p=0.001$). Notably, five contiguous SNPs spanning intron 1 to the 3 region were associated with SZ. Associations were observed with haplotypes incorporating these SNPs, particularly a common haplotype in both case-control ($p=0.002$) and family-based designs ($p=0.00009$). In the Indian cohort, we detected associations with one SNP (rs10934254; $p<0.05$), and the identical haplotype spanning the gene ($p=0.009$). Global tests of transmission distortion supported associations in both samples ($p=0.009$ and 0.005).

To evaluate if our results were attributable to LD with rs6280, or other variants, we sought comprehensive LD analyses. Direct sequencing of 64.7kb (including 8.5kb 5, 12.9kb 3) in a pool of 400 people to identify polymorphisms is ongoing. At the time of submission, we identified 62 SNPs, including 13 novel SNPs. Sequencing of 30 CEPH individuals reveals rs6280 clusters with 4 SNPs ($r^2>0.8$), all 5 to exon 1, and was not correlated any common SNPs 3' to exon 1. We find that 18 tags would represent all common SNPs detected thus far. Our results indicate novel SNPs at *DRD3* may contribute to SZ pathogenesis. Post-hoc LD analyses suggest comprehensive evaluation of this gene has not yet been achieved in association studies. Such analyses are ongoing in a large cohort and may further characterize these results.

Insulin Resistance and Inflammation: Cause or Effects? *X. Guo[1], K.D. Taylor[1], M.J. Quinones[2], J. Cui[1], I. Bulnes-Enriquez[2], R.D.L Rosa[2], H. Yang[1], W. Hsueh[2], J.I. Rotter[1].* 1) Medical Genetics Inst, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Dept of Medicine, UCLA, Los Angeles, CA.

Recent data have shown that plasma inflammatory markers predict the development of diabetes and have supported the hypothesis that low-grade inflammation is part of the insulin resistance (IR) syndrome. The relevant question is whether the inflammatory process precedes IR. Support for this possible sequence would come from the demonstration of the association of variation in inflammatory genes with IR. Thus, the aim of this study was to investigate the role of genetic variants in the C-reactive protein (CRP) gene in IR. Families were ascertained via a coronary artery disease proband in the Mexican-American Coronary Artery Disease Project. Individuals from 167 Mexican-American families (n=894) were genotyped for 6 polymorphisms in the CRP gene using the Taqman MGB assay. Adult offspring and offspring spouses (423 individuals from 100 families) were phenotyped for insulin sensitivity by the gold standard for insulin resistance, the hyperinsulinemic euglycemic clamp. One SNP was not polymorphic in this population, so the analyses were performed on the remaining 5 SNPs. Association was tested using the general estimating equations methods. After adjusting for age, sex, and body mass index, SNP rs3093062 was found to be associated with both insulin sensitivity index (SI, p = 0.008) and glucose infusion rate (GINF, p = 0.003); while rs3093066 and rs2808630 were associated with GINF (p = 0.04 and 0.001, respectively). Haplotype analysis based on the 5 SNPs revealed that all 5 SNPs were in the same haplotypic block, and that the second common haplotype, which is distinguished by the rare variant in SNP rs2808630, was strongly associated with IR as indicated by a lower mean GINF (mean ¡À SE: 370 ¡À 13 for H2 carriers vs. 417 ¡À 12 for non-carriers, p = 0.0005). These results suggest that genetic variants in the CRP gene may contribute to IR and support the hypothesis that inflammatory genes may link chronic inflammation and insulin resistance.

Association of functional polymorphisms in neuronal tryptophan hydroxylase gene with bipolar affective disorder. *H.S. Sun[1], Y.M.J. Lin[2], S.C. Chao[1], T.J. Lai[3], T.M. Chen[2].* 1) Institute of Molecular Medicine, National Cheng Kung University Medical College, Tainan, Taiwan; 2) The Institute of Basic Medical Sciences, National Cheng Kung University Medical College, Tainan, Taiwan; 3) Department of Psychiatry, Chung Shan Medical University Hospital, Taichung, Taiwan.

Disturbances in serotonin neurotransmission have been implicated in the etiology of many psychiatric disorders including bipolar affective disorder (BPD). The tryptophan hydroxylase 2 gene (*TPH2*) encodes the rate-limiting enzyme in neuronal serotonin biosynthetic pathway, thus it is one of the leading candidate genes for psychiatric and behavioral disorders. This study was designed to investigate the role of *TPH2* gene in the pathophysiology of BPD. We have systematically screened the sequence of human *TPH2* gene and identified 10 sequence variants in Taiwanese Han population. Five SNPs that either with potentially functional relevance or moderate minor allele frequencies were selected for association study between 106 BPD cases and 105 matched control samples. Significant differences in single-locus allele distributions and haplotype profile of *TPH2* polymorphisms between case and control groups were found. The involvements of common variants on *TPH2* gene in BPD etiology were evidently by functional assays of two SNPs on promoter and coding region that affect the TPH2 expression level and the enzyme activity, respectively. Results of this study indicate the *TPH2* gene has biological and functional significance in BPD etiology, and provide the knowledge of common variants effect on the physiological status in vivo.

Genetic variations and disease-related genes in the Korean population studied by scanning the cytokine cluster region of chromosome 5q31-33. *B. Oh[1], J-K. Lee[1], H-J. Ryu[1], H-T. Kim[1], J-Y. Lee[1], H.D. Shin[2], C-S. Park[3], K. Kimm[1].* 1) Structural & Funct Genomincs, Natl Genome Research Inst, Seoul; 2) SNP Genetics, Inc., Seoul; 3) Genome Research Center for Allergy and Respiratory Diseases, Soonchunhyang University, Bucheon.

Numerous genetic studies have mapped disease genes to a region on chromosome 5q31-33 containing a cluster of cytokines. In order to determine the genetic variations and the haplotypes of genes in the chromosome 5q31-33 region, we resequenced all exons and the promoter regions of 130 genes in 24 unrelated Koreans. We identified a total of 1,829 genetic variants, including 1,560 single nucleotide polymorphisms (SNPs), 106 insertion/deletion polymorphisms and 163 microsatellites. Among these results the analysis of 289 SNPs derived from 29 genes was carried out. The standardized variance (FST) for allele frequency showed substantial differences among different ethnic groups. Using FST as a genetic distance, remarkable differences were observed between Korean and Caucasian or African (median FST=0.036; 0.038, respectively), whereas high similarity was found between Japanese and Korean (median FST = 0.002). Using these SNP information association study has been pursued to identify genes responsible for asthma. TaqMan and Illumina platform have been used for genotyping case and matched control DNAs. Among genes analyzed initially DCNP1 showed significant association with specific serum IgE levels in asthmatic patients. The minor allele of -1288C>T showed strong protective effects on the specific IgE production among asthmatic patients (P=0.0009, OR=0.63). On the other hand, two SNPs in 3'UTR (+1718C>T and +2666C>A) revealed the susceptibility on the IgE production (P=0.31-0.003, OR=1.37-1.82). 130 genes in 5q31-33 have been under the statistical analysis for their association to asthma and its subphenotypes such as IgE levels. Our results will provide the valuable evidence for gene-based analysis for association studies as well as the useful information for the identification of immune-related disease genes in the chromosome 5q31-33.

Epistatic effects in hyperserotonemia and autism. *A.M. Coutinho[1], G. Oliveira[2], I. Sousa[1], T. Morgadinho[3], C. Fesel[1], T.R. Macedo[3], C. Bento[2], M. Martins[1,5], C. Marques[2], A. Ataíde[4], T.S. Miguel[4], L. Borges[2], A.M. Vicente[1,5].* 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Hospital Pediátrico de Coimbra, Portugal; 3) Faculdade de Medicina da Universidade de Coimbra, Portugal; 4) Direcção Regional de Educação da Região Centro, Coimbra, Portugal; 5) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal.

One of the most studied subphenotypes in autism is platelet hyperserotonemia, which is likely influenced by several genes in a non-additive manner. A genome scan for QTLs determining serotonin (5-HT) levels found a linkage peak at 17q11-21, where the 5-HT transporter gene (*SLC6A4*) and the integrin 3 chain precursor gene (*ITGB3*) map, and a previous analysis of our autism sample showed an association of specific *SLC6A4* variants with hyperserotonemia. In this study, we further assess the genetic basis of hyperserotonemia in 103 autistic children. Epistasis among six candidate genes (*SLC6A4*, *HTR2A*, *HTR1D*, *HTR1A*, *TPH1* and *ITGB3*) was tested using the Restricted Partition Method (RPM). We found significant interactions between haplotypes in *HTR1A* and *ITGB3* (P=0.004) and between haplotypes in *SLC6A4* and *HTR2A* (P=0.005). While haplotypes in *SLC6A4* and *ITGB3* were independently associated with 5-HT levels, with specific variants increasing risk for hyperserotonemia, interaction between *SLC6A4* and *ITGB3* was more modest (P=0.015). This suggests that these genes may have an independent main effect and interact with others in the regulation of 5-HT levels. A strong linkage peak in this same 17q11-21 region has been reported for autism, suggesting that the occurrence of hyperserotonemia in autism may be mediated by genetic variation at the *SLC6A4* and *ITGB3* genes. We therefore used the Multifactor-Dimensionality Reduction (MDR) program to test for epistasis in autism among the markers shown to interact for the determination of 5-HT levels. In a sample of 167 autistic patients and 144 controls, we found a significant three-locus interaction among polymorphisms in *ITGB3* and *SLC6A4* (P=0.021). Our results indicate that the interaction of gene variants involved in hyperserotonemia is also significantly associated with increased risk for autism.

APOE in multiple sclerosis (MS) susceptibility and severity: meta- and pooled analyses. *R. Burwick[1], P.P. Ramsay[1], J.L. Haines[1], M.A. Pericak-Vance[1], S.L. Hauser[1], S. Schmidt[1], S. Sawcer[2], A. Compston[2], G. Savettieri[3], A. Quattrone[3], J. Zwemmer[4], S. Weatherby[5], F. Fazekas[6], R. Schmidt[6], C. Enzinger[6], J. Hillert[7], T. Masterman[7], P. Hogh[8], P. Maciel[9], L.F. Barcellos[1].* 1) US MS Genetics Group, UCSF; 2) Univ of Cambridge, UK; 3) Univ of Palermo and Magna Graecia, IT; 4) Univ Med Center, NL; 5) Derriford Hosp, UK; 6) Med Univ Graz, AT; 7) Karolinska Inst, SE; 8) Copenhagen Univ Hosp, DK; 9) Univ of Minho, PT.

Variation in MHC genes on chr.6p21, specifically the HLA-DRB1*15 haplotype, has been convincingly shown to confer MS risk. Whole genome screens have previously suggested chr.19q13 as a potential region harboring additional MS genes. APOE, a candidate gene located here, encodes a major lipid carrier protein in the brain and has long been associated with regeneration of axons and myelin. Previous studies have examined APOE variation in MS, but have shown conflicting results and have lacked statistical power to detect modest genetic influences. Because of the importance of identifying risk and prognostic factors in MS, we performed meta- and pooled analyses using large sample sizes to determine whether APOE variation influences risk, disease severity or other clinical outcomes. Using 2,900 (each) cases and controls, we observed no effect of e2 or e4 allele carrier status on MS risk (OR=1.10; 95% CI=0.94-1.30; p=0.24 and OR=0.89; 95% CI=0.78-1.02; p=0.09, respectively), nor were differences in genotypic distributions detected. Furthermore, results obtained from family-based analyses of APOE (1281 MS families/1152 trios/721 DSP) were also negative (PDT, p=0.62). Finally, results obtained from pooled analyses of 3,500 MS cases also argue strongly that APOE variation does not (1) distinguish a relapsing-remitting from primary progressive course, (2) influence severity, as measured by EDSS and duration, or (3) influence age of onset or gender distribution. While this study cannot exclude an APOE effect on other measures of progression that were not examined here, including subclinical MRI phenotypes; these findings do not support a role for APOE in MS, and highlight the need for adequate sample sizes, particularly in studies of genotype-phenotype relationships.

Association analysis of interleukin 4 receptor and interleukin 13 polymorphisms indicate a difference in development of atopy expression leading to atopic asthma or allergic rhinitis. *R.W.B. Bottema[1,2], I.M. Nolte[1], T.D. Howard[3], G.H. Koppelman[2], D.A. Meyers[3], A.E.J. Dubois[2], E.R. Bleecker[3], D.S. Postma[1,2].* 1) University of Groningen, Netherlands; 2) University Medical Center Groningen, Netherlands; 3) Wake Forest University School of Medicine, Winston-Salem.

Background: It is unknown why atopy is associated with asthma in one individual and with rhinitis in another. Genetic polymorphisms may explain this. We and others previously showed that single nucleotide polymorphisms (SNPs) of the interleukin 4 receptor (IL4R) and interleukin 13 (IL13) were associated with asthma and atopy traits. **Objective**: To study the IL4R and IL13 SNPs in relation to allergic rhinitis, asthma and atopy traits in rhinitis and asthma patients. **Methods**: 4 IL4R and 3 IL13 SNPs were studied in three independent Dutch populations: 1) 226 nuclear families ascertained through a proband with allergic rhinitis; 2) 407 nuclear families with an asthma proband; 3) 120 asthmatic individuals and 105 unrelated healthy controls. Family based association testing with atopy, asthma and rhinitis phenotypes was performed. Case-control analyses using 2 tests and Kruskall-Wallis tests were performed as appropriate. **Results**: IL13 SNP G870A was consistently associated with asthma, airway hyperresponsiveness (AHR) and serum IgE in both asthmatic populations ($p<0.05$). IL4R SNP E375A and S411L were associated with asthma and AHR in the asthma case-control population ($p<0.05$). All SNPs were not significantly associated with allergic rhinitis. Remarkably, within the rhinitis population there was no association with the traits AHR and serum IgE. **Conclusion**: Genetic polymorphisms of IL4R and IL13 are associated with asthma, AHR and atopy in an asthmatic population, but not in a rhinitis population. The results may indicate that atopy in asthmatics is genetically differently regulated from atopy in rhinitis patients. Further study is warranted, with high power to prove the absence of association in rhinitis patients.

The DRD2 C957T polymorphism and its interaction with COMT Val158Met polymorphisms in human working memory ability. *H. Xu[1], C.B. Kellendonk[2], E.H. Simpson[2], J.G. Keilp[3], G.E. Bruder[3], H.J. Polan[2], E.R. Kandel[2], T.C. Gilliam[1, 3].* 1) Department of Genetics and Development, Columbia University, New York, NY; 2) Center for Neurobiology and Behavior, Columbia University, New York, NY; 3) Department of Psychiatry, Columbia University, New York, NY.

Working memory impairment is a core cognitive deficit in schizophrenia, and dopamine neurotransmission plays a critical role in both normal cognitive processing and schizophrenia. In a sample of 402 healthy adults assessed on 4 working memory tasks, we observed the association of a polymorphism (Val158Met) of COMT, an enzyme essential for dopamine metabolism in the prefrontal cortex, with the performance on the WAIS-III letter number sequencing test (Bruder et al., in press). In a follow up study we genotyped a polymorphism in another dopaminergic gene, the human dopamine receptor D2 (DRD2) gene. The C allele of a synonymous SNP (C957T) in DRD2 has been shown to increase striatal DRD2 binding potential in vivo (Hirvonen et al., 2004) and to be associated with schizophrenia (Lawford et al., 2005). Our mouse studies indicate that over-expression of DRD2 in the striatum leads to impairments in working memory tasks (Kellendonk et al., submitted). We genotyped C957T in the Caucasian subset of our sample to assess its relation to human working memory ability. A significant impairment in the word serial position test (WSPT) performance was found in subjects with the C/C genotype versus the other two genotypes (ANOVA p=0.04). Among the 6 serial positions (varying in difficulty level) in the WSPT, only accuracy at the 5th position differed significantly between these two groups (ANOVA p=0.005). When interaction with the COMT Val158Met polymorphism is included in the analysis model, the relation of the C957T genotype to WSPT Performance (ANOVA p=0.01) and accuracy at the 5th position (ANOVA p=0.001) was strengthened. Our data suggest that the DRD2 C957T polymorphism affects human working memory. Further, they suggest that it is important to analyze genetic interactions between different polymorphisms for the understanding of complex phenotypes such as cognitive function.

Estrogen receptor polymorphisms and premature ovarian failure. *K. Bretherick[1], L. Currie[1], M. Fluker[2,3], W. Robinson[1].* 1) Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) Dept Obstetrics and Gynaecology, Univ British Columbia, Vancouver, BC, Canada; 3) Genesis Fertility Center, Vancouver, BC, Canada.

Although the average age of menopause is 51 years, approximately 1% of women will experience menopause before the age of 40, a condition known as premature ovarian failure (POF). POF is the cessation of ovulation and menstruation, caused by an absence of folliculogenesis in the ovary. Estrogen acts through estrogen receptor- (ER-) at the hypothalamus to stimulate the release of cyclic gonadotropins that regulate follicular proliferation, and through estrogen receptor- (ER-) in the ovary to directly enhance follicular differentiation. Genetic variants affecting expression or function of the ER- and ER- genes may therefore be associated with POF. We examined allele frequencies of a TA repeat in the promoter of the ER- gene and an intronic CA repeat in the ER- gene in women with idiopathic POF and control women using PCR amplification and fragment analysis on an ABI310 genetic analyzer. A clear bimodal distribution of ER- alleles is observed in both patient and control groups with short alleles (18 repeats) being significantly less common in the POF patient population (43%, N=108) than among the control women (60%, N=218) (p=0.004, ^{2}). Perhaps most striking is that genotypes consisting of two short alleles were found in only 3 of 54 (6%) POF patients and in 40 of 109 (37%) control women (p0.0001, ^{2}). This suggests that long repeats at the ER- gene may predispose to POF in a dominant fashion. The ER- TA repeat may have a direct effect on expression of the ER- gene or alternatively it may be in linkage disequilibrium with a functional variant in the ER- gene. The allele distribution of ER- CA repeats was not significantly different in the POF patient and control populations. These results support an association between POF and the ER- TA repeat but not the ER- CA repeat polymorphism, suggesting that the stimulatory affect of estrogen on the hypothalamus is critical in maintaining folliculogenesis.

Identifying the genetic factors involved in radiation-induced pulmonary fibrosis. *M. Begin, T. O'Brien, G. Dorion, C. Haston.* Dept Human Genetics, McGill Univ, Montreal, PQ, Canada.

Radiation treatment to the thoracic cavity results in a severe inflammatory and/or fibrotic response in 5% of exposed individuals. Identifying the susceptibility genes using a mouse model will allow for the identification of susceptibility loci in humans and will permit pre-radiation screening. Previous studies have shown that there are three potential susceptibility loci involved in the fibrosis response in C57Bl/6J x C3Hf/Kam F_2 mice; *Radiation-Induced Pulmonary Fibrosis 1* (*Radpf*) on chromosome 17, *Radpf2* on chromosome 1, and *Radpf3* on chromosome 6. In this study, the radiation responses of a cohort of 149 mice, bred to contain 6.25% C3H alleles, including the regions of *Radpf1-3* in a 93.75% C57Bl/6J background were measured. Mice were treated with 18 Gy of Cesium radiation to the whole thoracic cavity and sacrificed at 6 months post irradiation treatment or when moribund. Histological analysis of the left lung provided the percentage of the lung that contained the pulmonary fibrosis phenotype. Mice became sick between 11-26 weeks post irradiation and the average sacrifice time for the mice was 22 weeks. The mice had a range of 0%-30% pulmonary fibrosis on their lungs, with an average diseased area of 2.56%. Mice were genotyped using 25 markers on chromosomes 1,6, and 17 (7-10 markers each). At *Radpf1* the average pulmonary fibrosis area of mice with B6 alleles was 2.79%0.48, which was significantly greater then the average phenotype of mice with C3H alleles, 0.19%0.16, (P=0.024). Similarly, at *Radpf2* and *Radpf3* mice with B6 alleles had greater fibrosis than mice with C3H alleles (2.81%0.45 versus 0.47%.05, P=0.05) and (2.84%0.05 versus 0.73%0.32, P=0.01), respectively. The linkage on chromosome 6 was significant, after accounting for the linkage on chromosome 17 (P=0.0074). We have provided supporting evidence for the existence of 3 loci which influence the development of radiation-induced pulmonary fibrosis in mice.

Bleomycin-induced pulmonary fibrosis susceptibility genes in AcB/BcA recombinant congenic mice. *A. Lemay, C.K Haston.* Dept Human Genetics, McGill Meakins-Christie, Montreal, PQ, Canada.

The genetic basis of susceptibility to pulmonary fibrosis is largely unknown. Initially, in this study, loci regulating the response of bleomycin-induced pulmonary fibrosis were mapped using a set of recombinant congenic strains bred from pulmonary fibrosis-resistant A/J and susceptible C57BL/6J (B6) mice. Linkage was identified on chromosomes 9 and 6 (LOD= 4.9 and 2.4) and other suggestive loci were detected. The putative loci include alleles from both the B6 and A/J strains as increasing the fibrosis response of the congenic mice. To further investigate these putative linkages, chromosome substitution strains [C57BL/6J-Chr 6A/NaJ (n=9) and C57BL/6J-Chr 17A/NaJ (n=8)], were treated with the bleomycin protocol and were found to be resistant to bleomycin-induced pulmonary fibrosis (% fibrosis=0.35 0.36 and 0.02 0.06), supporting the existence of A/J-derived protective alleles on these chromosomes. Backcrosses of the recombinant congenic strain BcA84 (resistant to bleomycin-induced pulmonary fibrosis, n=28) were treated with bleomycin and linkage analysis revealed a potential locus on chromosome 6 (LOD=2.3) which was located in the region identified using the recombinant congenic mice. To identify potential fibrosis candidate genes in the putative linkage intervals, gene expression studies with microarrays were completed. This analysis revealed 3304 genes or expressed sequence tags to be differentially expressed ($p < 0.01$) in lung tissue between bleomycin treated B6 and A/J mice, and 246 of these genes to map to the potential susceptibility loci. Pulmonary genes differentially expressed between bleomycin treated B6 and A/J mice included those of heparin binding and extracellular matrix deposition pathways. A review of available genomic sequences revealed 809 (43% of total) genes in the linkage intervals to have variations predicted to alter the encoded proteins or their regulation, 68 (8.4%) of which were also differentially expressed. Genomic approaches were combined to produce a set of candidate genes which may influence susceptibility to bleomycin-induced pulmonary fibrosis in the A/J:B6 mouse model.

A common mutation in an organic anion transporter gene SLC22A12 is a suppressing factor for the development of gout. *N. Kamatani[1,2], A. Taniguchi[2], W. Urano[2], M. Yamanaka[2], S. Furihata[1,3], M. Hosoyamada[4], H. Endou[5], H. Yamanaka[2].* 1) Div Genomic Med, Tokyo Women's Med Univ, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Women'fs Medical University; 3) Genome Diversity Team, Japan Biological Information Research Center, Japan Biological Informatics Consortium; 4) Department of Pharmacotherapeutics, Kyoritsu University of Pharmacy; 5) Department of Pharmacology and Toxicology, Kyorin University School of Medicine.

Purpose: Previous studies have been suggested that various genetic factors are likely to determine the susceptibility of subjects to primary gout. However, studies of the genetic factors of primary gout have seldom been undertaken. Recently, urate transporter 1 (URAT1) encoded by SLC22A12, has been identified as a urate-anion exchanger in humans. It has been demonstrated that URAT1 plays a central role in reabsorption of urate from glomerular filtrate and may be the major mechanism for regulating blood urate levels. In this study, we examined SLC22A12 gene in patients with gout. The purpose was to analyze the roles of SLC22A12 in the development of gout. Method: 185 Japanese male patients with primary gout were randomly selected. The control group was consisted of 594 males and 386 females. The study was focused on G774A mutation in SLC22A12. This mutation leads to the substitution of a stop codon for tryptophan (W258X), and homozygous G774A mutation is the predominant cause of idiopathic renal hypouricemia in Japanese. Results: 25 males and 20 females in the control group were heterozygous for G774A. However, none of gout patients had the mutant allele. A homozygous mutation of G774A was found in neither of the groups. The heterozygotes were observed more frequently in male controls than in the gout patients (P = 0.001). The serum levels of uric acid were significantly lower in subjects with GA genotype than those with GG genotype both in male controls (3.9 '} 0.8 for G/A and 5.8 '} 1.1 for G/G, P0.0001) and female controls (2.9 '} 0.6 for G/A and 4.0 '} 0.8 for G/G, P0.0001). Conclusion: G774A mutation in SLC22A12 gene serves as a suppressing factor for the development of gout.

Smoking Influences the Association of LEPR SNPs with Body Composition and Bone Mineral Density. *U.L Fairbrother[1], A.J. Walley[1], L.B. Tanko[2], C. Christiansen[2], P. Froguel[1], A.I.F. Blakemore[1].* 1) Section of Genomic Medicine, Faculty of Medicine, Imperial College London, Hammersmith Hospital, Du Cane Road, London, W12 0NN, United Kingdom; 2) Centre for Clinical and Basic Research, Ballerup Byvej 222, DK-2750 Ballerup, Denmark.

Leptin is secreted by adipocytes and a range of other cell types, including osteoblasts. Like other cytokines, it is pleiotropic in its effects: reflecting and regulating adiposity; promoting inflammation and modulating bone turnover. Nonsense mutations in the leptin receptor gene (LEPR) cause monogenic obesity and non-synonymous LEPR SNPS have been associated with body composition in a range of studies. One SNP, Q223R, has also recently been associated with peak bone mass in young Chinese women and in young Korean men. We have analysed three SNPs in the extracellular region of the LEPR: K109R, Q223R and K656N, for associations with body composition and bone mineral density (BMD) in a large cohort of postmenopausal Danish women. There were no significant departures from HWE, for any SNP. Associations of Q223R were seen with total hip BMD and with central lean mass (p=0.03 and 0.046). The associations were strongest in smokers: Q223R was associated with BMD in total hip, femoral neck and spine (p=0.0009, 0.001 and 0.007). In addition, Q223R was associated with lean mass (p=0.046), particularly in smokers: peripheral and total lean mass (p=0.02 and 0.015). K109R was associated with hip BMD only in smokers (p=0.021). Overall, results with K656N were consistent with those of Q223R in that this SNP was associated with peripheral and total lean mass (p=0.029 and 0.01). Additionally in smokers, K656N was associated with peripheral and total lean/fat ratios and % fat (p=0.017, 0.008, 0.008). This study indicates that LEPR variation affects lean mass as well as adiposity and also influences bone mineral density in a European population and that this association is more pronounced in smokers. There have been previous reports of interactions of smoking status with LEPR SNPs in the regulation of adiposity, but this is the first report of a similar effect on BMD.

A spectrum of *PCSK9* alleles contributes to variation in plasma levels of LDL-cholesterol. *I.K. Kotowski, A. Pertsemlidis, J. Cohen, H.H. Hobbs.* UT Southwestern Medical Center, Dallas, TX.

Selected missense mutations in the proprotein convertase subtilisin/kexin type 9 serine protease gene *PCSK9* cause autosomal dominant hypercholesterolemia, whereas nonsense mutations in *PCSK9* are associated with reduced plasma levels of low density lipoprotein (LDL)-cholesterol (C). To define the contributions of other sequence variations in *PCSK9* to inter-individual differences in plasma levels of LDL-C, we performed large-scale sequencing and genotyping (113 SNPs; density 1 SNP per 500 bp) in an ethnically diverse population-based sample (n=3,543). A panoply of sequence variations with a range of frequencies (<1% to 45%), and various magnitudes of effects on plasma LDL-C level (from increasing by 10% to decreasing by 40%) that were often ethnic-group specific were identified. Neither sequencing alone nor high density SNP analysis alone revealed all the sequence variations at *PCSK9* contributing to variation in plasma LDL-C levels. One rare and two common missense mutations, as well as one common noncoding SNP, were found to be significantly and reproducibly associated with differences in plasma LDL-C levels. The presence of multiple alleles in *PCSK9* associated with increased as well as decreased LDL-C levels suggests that this gene is very sensitive to genetic variation. *PCSK9* provides a model system for the development of a comprehensive gene-focused approach to capture the genetic contribution to a complex quantitative trait.

CFH Y402H confers similar risk of soft drusen and both forms of advanced AMD. *K.P. Magnusson[1], S. Duan[2,3,4], H. Petursson[1], H. Sigurdsson[5,6], Z. Yang[2,3], Y. Zhao[2,3], P.S. Bernstein[2], J. Ge[4], F. Jonasson[5,6], E. Stefansson[5,6], G. Helgadottir[5,6], T. Jonsson[1], T. Thorlacius[1], G. Thorleifsson[1], A. Kong[1], H. Stefansson[1], J.R. Gulcher[1], K. Zhang[2,3], K. Stefansson[1].* 1) deCODE genetics Inc. Reykjavik, Iceland; 2) Dept. of Ophthalm and Vis Sci, Moran Eye Center, Univ of Utah; 3) Eccles Inst of Human Genetics, Univ of Utah, Salt Lake City, Utah, US; 4) Zhongshan Ophthalmic Center, Sun Yat-sen Univ, Gaung Zhou, China; 5) Dept. of Ophthalm, National Univ Hospital, Iceland; 6) Faculty of Medicine, Univ of Iceland.

Age-related macular degeneration (AMD) is the most common cause of irreversible visual impairment in the developed world. The two forms of advanced AMD, geographic atrophy (GA) and exudative AMD (Exu), represent different pathological processes in the macula that lead to loss of central vision. Soft drusen, characterized by deposits in macula without visual loss are considered a precursor of advanced AMD. Recently, it has been proposed that a common missense variant, Y402H, in the Complement Factor H (CFH) gene increases the risk for advanced AMD. However, its impact on soft drusen, GA, or exudative AMD or the relationship between them is unclear. We genotyped 581 Icelandic patients with advanced AMD (278 Exu, 203 GA, and 100 with mixed Exu/GA), and 435 with early AMD (of whom 220 had soft drusen). A second cohort of U.S. patients from Utah with advanced AMD (244 Exu and 78 GA) and 109 early AMD cases with soft drusen, were analyzed. We confirmed that the CFH Y402H variant shows significant association to advanced AMD in Iceland (OR 2.39, p-value = 5.9×10-12) and U.S. patients from Utah with advanced AMD (OR 2.14, p-value 2.0×10-9). Furthermore, we show that the Y402H variant confers similar risk of soft drusen as to both advanced forms of AMD (GA or Exu). Soft drusen occur prior to progression to advanced AMD and represents a histological feature shared by Exu and GA. Our results suggest that CFH is a major risk factor for soft drusen, and additional genetic factors and/or environmental factors may be required for progression to advanced AMD.

Haplotype-Based Association of a Type VII Adenylyl Cyclase Gene Polymorphism with Depression. *L.M. Hines[1], B. Tabakoff[1], L. Saba[1], A. Kaiser[1], B. Grant[3], L. Martinez[1], L. LeGault[2], M. Dongier[2], P. Hoffman[1].* 1) Department of Pharmacology, University of Colorado School of Medicine, Aurora, CO; 2) Department of Psychiatry, McGill University, Montreal, Quebec, Canada; 3) Division of Epidemiology, NIAAA, Rockville, MD.

Adenylyl cyclase is an enzyme that can regulate the physiologic effects of numerous drugs and hormones through the production of cyclic adenosine-3,5-monophosphate (cAMP). Reduced activity of the AC/cAMP signaling system has been implicated in the etiology of major depression. Previous work has shown low adenylyl cyclase activity in platelets and postmortem brain tissue of depressed individuals, and has indicated the heritability of platelet adenylyl cyclase activity. The Type VII isoform of adenylyl cyclase is a major isoform expressed in platelet precursor cells. In a population of 503 Caucasian subjects recruited from Montreal, Canada as part of the WHO/ISBRA Study on State and Trait Markers of Alcohol Use and Dependence, we have demonstrated a significant association, in women, between a tetranucleotide repeat polymorphism (the 7-repeat allele) in the 3'-untranslated region of the adenylyl cyclase 7 gene (ADCY7), and the phenotype of familial depression (history of DSM-IV depression in the subject and in a first-degree relative). A haplotype in the ADCY7 gene, which contains the repeat polymorphism, was also identified and found to be associated with a significantly higher risk (relative risk 5.1 for homozygotes and 2.1 for the heterozygotes) for familial depression in women. The microsatellite marker alone and the high-risk haplotype, were associated with a similar increased risk for familial depression, suggesting that the microsatellite marker may functionally contribute to familial depression in women, possibly through an effect on transcription or translation of adenylyl cyclase 7. Given the heterogeneity of depression, and the variable nature of response to antidepressant treatments, the presence of the ADCY7 repeat polymorphism may be useful for defining a subtype of major depressive disorder. We are currently investigating the potential role of other AC/cAMP pathway genes.

Evidence for association/linkage disequilibrium of DNA sequence variants with schizophrenia in the 3 region of neuregulin 1. *D.B. Wildenauer[1], B. Hoefgen[4], M. Albus[5], M. Borrmann-Hassenbach[5], M. Trixler[6], W. Maier[4], S.G. Schwab[2,3].* 1) CCRN, School of Psychiatry, UWA, Claremont, WA, Australia; 2) Centre for Medical Research, UWA, Perth, WA, Australia; 3) Western Australian Institute for Medical Research, Nedlands, WA, Australia; 4) Dept of Psychiatry, University of Bonn, Germany; 5) Mental State Hospital, Haar, Germany; 6) Dept. of Psychiatry, University of Pecs, Hungary.

Schizophrenia is considered to be a complex genetic disorder with several susceptibility genes contributing to its etiology. Association/linkage disequilibrium of DNA sequence variants with schizophrenia has been reported in the last few years for a number of candidate genes. Cumulative evidence has been obtained for neuregulin1, a plausible candidate involved in key neurodevelopmental processes in the central nervous system. The gene extends over more than 1Mb of genomic sequence. We have analyzed the exon dense 3 region of the gene, which extends over 160kb, in a sample of 125 trios with offspring affected with schizophrenia. We used 13 SNPs located in an average distance of 12.2kb. Transmission disequilibrium test revealed nominally significant P-values (0.05) for the three SNPs rs2466061, rs6988339, and hCV2870393. Haplotypes were constructed using the program FAMHAP. P-values of 0.0016 and 0.0008 were produced for a two-marker- and a three-marker haplotype, respectively. The markers are located approximately 1Mb distal from the previously reported (Stefansson et al AJHG 2002,72:83) and replicated association results, but in the same area as two of the markers for which association with schizophrenia has been reported recently by Yang et al (Mol Psychiatry 2003,8:706).

Detection of a variant in the DRD2 gene involved in schizophrenia using a phylogeny based method. *C. Bardel*[1], *C. Dubertret*[2], *E. Génin*[1], *P. Darlu*[1]. 1) INSERM U535, Villejuif, France; 2) INSERM U676, Faculté Xavier Bichat, Paris, France.

The gene coding for the D2 dopamine receptor (DRD2) is considered as one of the most relevant candidate genes in schizophrenia. Various studies have already been performed on this gene but they lead to conflicting results. In this study, we analyze a sample composed of 103 patients with DSM-IV criteria of schizophrenia and their two parents previously described by Dubertret et al. (2004). The individuals are genotyped for 8 markers (7 SNPs and 1 microsattellite) in the DRD2 region (either in the DRD2 gene or in the X-kinase gene, located downstream). The data are analyzed by a new method described in Bardel et al (2005) which is based on the reconstruction of the evolutionnary history of the haplotypes formed by the 8 markers through a phylogenetic tree. This method consists in looking for groups of haplotypes on the phylogenetic tree that contains an excess of case haplotypes. The polymorphisms defining these groups are likely to be susceptibility loci for the disease. Using this method, we identify the TaqI A1/A2 polymorphism, located in the exon 8 of the X-kinase gene as a potential susceptibility site for schizophrenia, thus confirming the results previsously published by Dubertret et al (2004).

Evidence for sex-specific transmission of DNA sequence variants in the dysbindin gene to offspring affected with schizophrenia. *S.G. Schwab[1,2,6], T. Becker[3], M. Knapp[3], M. Albus[4], M. Borrman-Hassenbach[4], W. Maier[5], D.B. Wildenauer[6].* 1) WAIMR, University of Western Australia,Nedlands, WA, Australia; 2) Centre for Medical Research, UWA, Perth, Australia; 3) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Germany; 4) Mental State Hospital, Haar, Germany; 5) Dept of Psychiatry, University of Bonn, Germany; 6) CCRN, School of Psychiatry and Clinical Neurosciences, UWA, Perth, Austrlia.

Genetic vulnerability for schizophrenia has been demonstrated consistently in family-, twin- and adoption studies. One of the regions that might harbour susceptibility genes for schizophrenia is a region on chromosome 6p. We have been able to confirm the recently reported association of schizophrenia (Straub et al, AJHG 2002,71:337) with six single nucleotide polymorphisms from intronic regions of the dystrobrevin binding protein (DTNBP1) located in 6p22 in a chromosome 6p linked family sample (73 families with both parents and at least two affected offspring from Germany), as well as in an additional sample of small families comprising 125 parents and a single affected offspring (Schwab et al, AJHG 2003,72:185). Here we report analysis of these DNA sequence variants in the combined family sample for sex-specific transmission. A haplotype composed of rs1011313 (m2), rs760761 (m4), and rs1018381 (m6) produced a P-value of 2.09×10^{-6} for maternal transmissions which is an order of magnitude lower than the previously reported P-value (2×10^{-5}) for the marker combination m2 and m4. Parental asymmetry test for imprinting revealed $P = 4.82 \times 10^{-3}$ for the haplotype with markers m4 and m6. Gender differences in prevalence, age of onset, psychopathology, course, and outcome are well known to be present in schizophrenia and assumed to be due to genetic and/or environmental factors. Our data suggest a contribution of imprinting to these differences.

Progressive supranuclear palsy is associated with a conserved regulatory region in intron 0 of the tau gene. *S. Melquist[1], R. Rademakers[2], M. Cruts[2], M. Baker[1], R. Crook[1], J. Adamson[1], J. Crook[3], D. Dickson[4], G. Schellenberg[5,6], M. Hutton[1], C. Van Broeckhoven[2].* 1) Department of Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL; 2) Department of Molecular Genetics, University of Antwerp, Antwerpen, Belgium; 3) Biostatistics Unit, Mayo Clinic College of Medicine, Jacksonville, FL; 4) Department of Pathology, Mayo Clinic College of Medicine, Jacksonville, FL; 5) Department of Psychiatry and Genetics, University of Washington, Seattle, WA; 6) Geriatric Research Education and Clinical Center, Veterans Affairs Puget Sound Health Care System, Seattle, WA.

Two extended haplotypes exist across the tau gene (*MAPT*) - H1 and H2 - with the H1 haplotype associated with increased risk of progressive supranuclear palsy (PSP). We investigated whether risk for PSP could be narrowed down to a small region or a specific variant on the H1 haplotype. Using 15 haplotype tagging SNPs (htSNPs), capturing more than 90 % of the *MAPT* haplotype diversity, we performed association analysis in a cohort of 274 predominantly pathologically-confirmed PSP patients and 424 matched control individuals. In control individuals, we identified two ancestral extended H1 subhaplotypes, H1A and H1B that accounted for 39% of H1 haplotype diversity. We found that PSP risk is associated with H1B: increasing from 14% in controls to 22% in PSP patients ($p < 0.001$). Analysis of young PSP patients allowed us to narrow the PSP risk on H1B to a specific 22 kb region in intron 0 of *MAPT*. The association with H1 variants within intron 0 was replicated in a second PSP patient - control set. However, our analysis showed that H1 risk variants alone could not explain the overall differences in H1 and H2 frequencies in PSP cases and controls, not even in young patients. Therefore, both specific risk variants on H1 and the protective effect of H2 contribute to the overall population risk for PSP.

Investigating the Role of SLC6A4 in Response to the Antidepressant Citalopram Utilizing a Large Clinical Sample. *J.B. Kraft[1], E.J. Peters[1], S.L. Slager[2], G.D. Jenkins[2], M.S. Reinalda[2], P.J. McGrath[3], S.P. Hamilton[1].* 1) University of California, San Francisco; 2) Mayo Clinic College of Medicine; 3) New York State Psychiatric Institute and Columbia University.

The serotonin transporter is the target of many antidepressants, and the gene (SLC6A4) encoding this protein has been tested for association with phenotypes such as major depressive disorder (MDD) and response to selective serotonin reuptake inhibitors (SSRIs). Many studies have reported positive associations while others report no association. In previous studies utilizing a patient population with MDD (N=96) who were taking the SSRI fluoxetine, we failed to detect any association between SSRI response and the oft-studied length polymorphism (HTTLPR)in the promoter region. However, we did detect an association with two additional variants in the 5 region of the gene (rs25531/rs25533). We sought to further test the hypothesis that SLC6A4 is associated with SSRI response by using a larger patient population focusing on these 3 polymorphisms: HTTLPR, rs25531, and rs25533. We genotyped 1,953 subjects with MDD who have all taken the same SSRI, citalopram, as part of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study to investigate the role of SLC6A4 in SSRI response.

Genotyping was performed using RFLP analysis for the 2 SNPs and agarose gel separation for the HTTLPR. Single locus and haplotype analyses among the 3 markers were performed. Our analysis showed no association between the 3 markers and response to SSRIs (P values all >0.05), adjusting for ethnicity. A global score test of the association between 3-locus haplotypes and response was not significant (P=0.27). We observed extensive linkage disequilibrium in this 2kb region (d=0.93-0.99). These results fail to replicate findings showing HTTLPR association with SSRI response. Further, with our larger sample, we also failed to replicate our previous findings of association with 2 SNPs (rs25531/rs25533) and SSRI response. Our findings do not support an association between response to SSRIs and DNA variation at the serotonin transporter locus in the largest sample to date.

Allelic and haplotypic association of NOS2A with type 1 diabetes in Newfoundland. *K. Wang[1], M. Liu[1], B. Bharaj[1], M. Lu[1], H.T. Chen[1], J.A. Curtis[2], L.A. Newhook[2], A.D. Paterson[1,3].* 1) Dept Genetics & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Pediatrics, Memorial Univ. of Newfoundland, NF, Canada; 3) Dept. of Public Health Sciences, Univ. of Toronto, Canada.

Type 1 Diabetes (T1D) is an autoimmune disease which leads to destruction of insulin producing beta-cells in the pancreas. The NOS2A gene has been proposed to play an active role in this destructive process and might be a susceptibility gene for T1D. However, only one significant association between the T allele at Ser608Leu (exon 16) and T1D in HLA DR3/4-positive affected offspring has been reported (P=0.008, Johannesen et al. 2001). We genotyped six SNPs and (CCTTT)n around the NOS2A gene in 538 mulipex families from a relatively isolated population of Newfoundland (NF) which has a high incidence of T1D. The extended TDT (ETDT) was used to test for association between the markers and T1D. The Evolutionary Tree-TDT (ET-TDT), which takes advantage of grouping haplotypes through a cladistic analysis using their evolutionary relationships, was also carried out to test for excess transmission of haplotypes from parents to affected children. The affected offspring were stratified by the median age of diagnosis (AOD) into two groups: early (AOD <=10) and late (AOD>10). Interestingly, the T allele at Ser608Leu (exon 16) revealed significant transmission disequilibrium from unaffected parents to affected offspring (P=0.0033) in the whole dataset while allele 190 at (CCTTT)n demonstrated significant association to the early group (P=0.0011). Furthermore, one five-SNP haplotype was strongly associated with T1D for the whole dataset and the early group (P=0.0083 and 0.0018, respectively). Moreover, cladistic analysis confirmed that the same five-SNP haplotype was significantly associated with T1D both in the whole dataset and the early group (P=0.0026 and 0.0019, respectively). In addition, two clades based on the haplotypes inferred from (CCTTT)n and its two flanking SNPs were significantly associated with T1D in the early group (P=0.0016 and 0.0009, respectively), whereas only weak association was found using ETDT. In conclusion, our findings provide evidence for a role of the NOS2A gene in T1D in NF.

Association analysis of a LINE1 polymorphism in the gamma-aminobutyric acid A receptor, gamma 1 gene (GABRG1) in autism. *S. Horike[1], S. Choufani[1], J. Vincent[1, 2], S.W. Scherer[1].* 1) Department of Genetics and Genomic Biology, University of Toronto, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Autistic disorder (AD) is a neuro-developmental disease characterized by abnormalities in social, communicative, and behavioral functioning. We report here a family with two brothers diagnosed with AD each having inherited a paracentric inversion of the short arm of the chromosome 4 [46, XY, inv(4)(p12-p15.3)]. Molecular and cytogenetic analysis revealed that this inversion is inherited from the mother who inherited it from her father, neither of whom showed obvious symptoms. The proximal breakpoint (4p12) mapped within intron 7 of the gamma-aminobutyric acid A receptor, gamma 1 (GABRG1). Interestingly, we also discovered a LINE1 polymorphism located in the same intron of GABRG1. Studies have shown that LINE1 insertions can affect expression by acting as a 'gmolecular rheostat'h of target genes. Therefore, we hypothesized that this intron 7 LINE1-element may influence the level and timing of GABRG1 expression in other autism patients. Initially, we are investigating this hypothesis by testing the frequency of the LINE1 allele in autism patients and controls. Our preliminary data indicates the allelic frequencies in the autism patients (n=298) vs. control (n=182) to be: +/+ (34.9%; 25.8%), +/- (45.3%; 48.3%), -/- (19.8%; 25.8%), respectively. We are currently expanding these studies in a wider autism and control dataset (including family-based controls) and completing functional studies.

PRKCA shows association to multiple sclerosis in two populations and is flanked by elements of duplication superstructure. *J. Saarela[1], D. Chen[2], S.P. Kallio[1], A. Montpetit[3], E. Choi[2], T. Miettinen[5], R. Asselta[1], D. Bronnikov[1,2], M. Lincoln[4], A. Palotie[5], G.C. Ebers[4], T.J. Hudson[3], L. Peltonen[1,6].* 1) Dept Molecular Medicine, Natl Public Health Inst, Helsinki, Finland; 2) Dept Human Genetics, UCLA Medical School, Los Angeles, CA, USA; 3) McGill Univ and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Dept Clinical Neurology, Radcliffe Infirmary, Univ of Oxford, Oxford, UK; 5) Finnish Genome Center, Univ of Helsinki, Helsinki, Finland; 6) Dept Medical Genetics, Univ of Helsinki, Helsinki, Finland.

We have established linkage in Finnish MS families to 17q24, and identified initial association to the PRKCA gene. The gene with the 1 Mb flanking regions was explored in detail in two, large independent MS cohorts. A SNP haplotype analysis revealed an allelic variant of PRKCA being significantly over-represented in Finnish and Canadian MS cases (Odds Ratio 1.34, 95th CI 1.13-1.59). The expression level of PRKCA correlates with the copy number of the PRKCA risk allele, implying its biological relevance. Though the critical role of PRKCA in regulating immune responses makes it a strong candidate for MS susceptibility gene within this interval, we also observed some evidence of association to MS with SNPs mapping telomeric to PRKCA, within the interval flanked by duplications. To evaluate whether the SNPs associated with MS could be in LD with an yet unidentified chromosomal rearrangement polymorphism affecting several genes within the locus, we explored the complex structure of 17q in more detail. By blasting the exons of the genes mapping to the duplications at 63Mb and 66Mb on 17q, we observed highly homologous sequences to reside 13 times within 17q. A cross-species genome comparison revealed that the human and chimpanzee genomes have similar but not the identical duplication patterns, while the mouse genome has only one copy of the sequence. A retrotransposon-like element mapping almost exclusively to 17q was found in all copies of the superstructure, stimulating the hypothesis that the element might have contributed to the complex structure of 17q and can predispose to chromosomal rearrangements.

Novel Microdeletions and Microduplications in Subjects with an Autism Spectrum Disorder (ASD) Identified using 1 Mb Array-Comparative Genomic Hybridization (array-CGH). *C. Harvard[1,5], M. Koochek[2,5], Y. Qiao[1,5], C. Fawcett[1], P. Malenfant[3,4,5], SC. Creighton[2,5], MJ. Hildebrand[2,5], L. Armstrong[2], B. McGillivray[2], P. MacLeod[2], M. VanAllen[2], JJA. Holden[3,4,5], E. Rajcan-Separovic[1,5], MES. Lewis[2,5].* 1) Depts. of Pathology &; 2) Medical Genetics, University of British Columbia, Vancouver, Canada; 3) Depts. of Physiology &; 4) Psychiatry, Queen's University, Kingston,Canada; 5) ASD-CARC; www.autismresearch.ca.

ASDs are a group of neurodevelopmental disorders characterized by significant social, communication and behavioural impairments affecting 1/160-1/250 persons. Although current understanding of the complex genetic mechanisms underlying ASDs is limited, sub-microscopic/sub-telomeric chromosomal abnormalities have been reported in approximately 10% of individuals. Whole genome array-CGH is a powerful tool for identifying submicroscopic deletions and duplications undetectable by conventional cytogenetic techniques. We are using 1 Mb array-CGH (Spectral Genomics)to determine the prevalence of cryptic subchromosomal changes in subjects with an ASD. Four cases with known abnormalities, including mosaic and non-mosaic gain of 15q11-q13, del(22)(q13) and t(5,7)(p15.1p12.2) with inv(3)(p24q24), were used as positive controls. Twenty-two cases with normal high resolution karyotypes were studied. The del(22) and gains of 15q were confirmed via array-CGH. The case with structural rearrangements of chromosomes 3, 5 & 7 revealed 3 novel microdeletions undetectable by routine cytogenetic analysis. Of the karyotypically normal cases, 4 had novel submicroscopic changes. Two cases had submicroscopic imbalances not detected in unaffected family members (del of 2p in Case 1 & dup of proximal 15q/microdeletion of 14q in Case 2) as well as inherited rearrangements (del of Xp in Case 1 and dup of 6q in Case 2). In Cases 3 and 4 unique single clone changes were noted and their origin is under investigation. This pilot study identified novel cryptic subchromosomal changes in 18% of probands with an ASD, suggesting that the co-occurrence of autism with submicroscopic chromosomal abnormalities is significant and will be useful for localizing candidate gene regions for autism.

Gene Expression in Intracranial Aneurysm. *S. Weinsheimer[1], M. van der Voet[1], G.M. Lenk[1], M. Skunca[1], A. Ronkainen[2], H. Kuivaniemi[1], G. Tromp[1].* 1) CMMG, Wayne State University, Detroit, MI; 2) Department of Neurosurgery, University of Kuopio, Kuopio, Finland.

Frequently candidate regions from linkage analyses contain several hundreds of genes. An approach to reduce the list of positional candidate genes is to use gene expression data from diseased and healthy tissue. Genes that are not expressed, either in diseased or healthy tissue, may be excluded from the candidate list. Here we used this approach to assist in the identification of candidate genes for the complex disease intracranial aneurysm (IA). IAs may grow, rupture, and lead to subarachnoid hemorrhage. Each year about 30,000 individuals in the United States suffer ruptured IA. Despite evidence for a genetic predisposition for IA and previously reported linkage, including to chromosome 19q13, specific genes that contribute to IA have yet to be identified. **Methods**: Intracranial arteries from individuals with IA were obtained post-mortem and pooled (n=4) into sample sets to represent aneurysmal intracranial arteries and healthy contralateral vessels (controls) obtained from the same patients. Five pools of total RNA were amplified and hybridized to Affymetrix HU133 Plus 2.0 GeneChips. Samples were from aneurysms of the anterior communicating- and middle cerebral-artery, and from healthy intracranial arteries. Data were analyzed using the MAS 5.0, gcRMA, and RMA methods to identify expressed genes. **Results**: Several chromosome 19q13 positional and functional candidate genes were expressed in intracranial arteries. Some are known to be involved in important processes including extracellular matrix metabolism, apoptosis, and inflammatory response. A subset of the expressed positional candidate genes include: PLAUR, APOE, CARD8, HIF3A, NFKBIB, NOSIP, and several in the kallikrein gene cluster: KLK3, -4, -7, -13, and -15. **Conclusion**: These data suggest a role for kallikreins in the pathophysiology of IA. These gene expression data may be useful also for other diseases affecting intracranial arteries. Gene expression analysis is a useful approach for reducing a list of positional candidate genes.

Are Common Variants in APP Risk Factors for Late-onset Alzheimers Disease? *P. Nowotny[1], X. Simcock[1], A.L. Hinrichs[1], S. Smemo[1], J.S.K. Kauwe[1], S. Cherny[1], J. Morris[2], A. Goate[1,2].* 1) Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO; 2) Dept Neurology, Washing Univ Sch Medicine, St Louis, MO.

Linkage studies have suggested a susceptibility locus for late-onset Alzheimers disease (LOAD) on chromosome 21. A functional candidate gene in this region is the amyloid precursor protein (APP). Previously, coding mutations in APP have been associated with early onset Alzheimers disease (EOAD) and triplication of APP is associated with AD pathology in Downs Syndrome, suggesting that over-expression of APP may be a risk factor for LOAD. Although APP is a strong functional and positional candidate, to date there has been no thorough investigation using a dense map of SNPs across the entire APP gene. In order to thoroughly investigate the role of APP in the risk of LOAD, we genotyped more than 42 intronic SNPs, spanning 300 kb in and around APP. The SNPs were genotyped in a LOAD case-controls series of 270 cases and 270 controls from the ADRC at Washington University. We found significant associations with SNPs mainly in the region between introns 2 and 3, with rs2000989 (p-value= 0.0106) being the most significant. However, haplotypes including these SNPs showed no increase in association compared to the individual SNPs. We also stratified for presence or absence of the APOE 4 allele because the linkage to chromosome 21 was observed in the sibling pairs without an APOE 4 allele. This stratified analysis did not reveal a consistent trend in either stratum. We are currently genotyping SNPs in introns 2 and 3 in two independent case-controls samples and a case-control series derived from our linkage sample to try to replicate these findings.

Allelic heterogeneity at the serotonin transporter locus (SLC6A4) confers susceptibility to autism and rigid-compulsive behaviors. *J.S. Sutcliffe[1], R.J. Delahanty[1], H.C. Prasad[2], J.L. McCauley[1], Q. Han[2], L. Jiang[1], C. Li[1], S.E. Folstein[3], R.D. Blakely[2].* 1) Center for Human Genetics Research, Dept of Mol Physiology & Biophysics, Vanderbilt University, Nashville, TN; 2) Center for Molecular Neuroscience, Dept of Pharmacology, Vanderbilt University, Nashville, TN; 3) Dept Psychiatry, Johns Hopkins University, Baltimore, MD.

Autism is a spectrum of neurodevelopmental disorders with a primarily genetic etiology exhibiting (1) deficits in development of language and (2) social relationships, as well as (3) patterns of repetitive, restricted behaviors or interests, and resistance to change. Elevated platelet serotonin (5-HT) in 20-25% of cases, and efficacy of selective 5-HT reuptake inhibitors (SSRIs) in treating anxiety, depression, and repetitive behaviors points to the 5-HT transporter (SERT, 5-HTT) as a strong candidate. Association studies involving the functional insertion/deletion polymorphism in the promoter (5-HTTLPR) and a polymorphism in intron 2 are inconclusive, possibly due to phenotypic heterogeneity. Nonetheless, mounting evidence for genetic linkage of autism to the chromosome 17q11.2 region harboring the SERT locus (SLC6A4) supports a genetic effect at or near this gene. We confirm recent reports of sex-biased genetic effects in 17q by showing highly significant linkage (HLOD=8) driven by families with only affected males. Association to common alleles fails to explain observed linkage, therefore we hypothesized that preferential transmission of multiple alleles does. From 120 families most contributing to linkage at 17q11.2, we found 4 coding substitutions at highly conserved positions and 15 other variants in 5' noncoding and other intronic regions transmitted in families exhibiting increased rigid-compulsive behaviors. One coding variant, shows an increased frequency, substantial deviation from Hardy-Weinberg equilibrium, elevated transporter activity, and is refractory to PKG and p38 MAP kinase-mediated regulation. In the aggregate, these variants show significant linkage and association to autism. Our data provides strong support for a collection of multiple, often rare, alleles at SLC6A4 as imposing risk for autism.

Neural tube defects and folate pathway genes: family-based association tests of gene-gene and gene-environment interactions. *A.L. Boyles[1], A.V. Billups[1], D.G. Siegel[1], S.H. Slifer[1], M.C. Reed[2], H.F. Nijhout[3], T.M. George[4], A.G. Bassuk[5], J.A. Kessler[5], J.R. Gilbert[1], M.C. Speer[1], NTD Collaborative Group[1].* 1) Ctr Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) Dept Mathematics, Duke Univ, Durham, NC; 3) Dept Biology, Duke Univ, Durham, NC; 4) Dept Surgery, Duke Univ Med Ctr, Durham, NC; 5) Northwestern Univ Feinberg School of Med, Chicago, Illinois.

Folate metabolism pathway genes have been examined for association with neural tube defects (NTDs) due to the known ability of folic acid to reduce the risk of this birth defect. Studies of polymorphisms in these genes usually look at them individually often producing conflicting results. In 318 Caucasian American families with lumbosacral myelomeningocele we examined 10 folate transport and metabolism genes: 5,10 Methylenetetrahydrofolate Reductase (MTHFR), Methionine Synthase (MTR), Methionine Synthase Reductase (MTRR), Reduced Folate Carrier 1 (RFC-1), Cystathionine Beta-sythase (CBS), Methylenetetrahydrofolate Dehydrogenase 1 (MTHFD-1), Serine Hydroxymethyltranferase (SHMT), Folate Receptor Alpha (FolR), and Folate Receptor Beta (FolR). While no SNPs was significant singly using family-based association methods, combinations of 3 and 4 SNPs were significant using Extended Multifactor-Dimensionality Reduction (EMDR). The thermolabile C677T polymorphism in MTHFR was only significant in combination with two polymorphisms in CBS (p=0.01). Mathematical models of the folate pathway [Nijhout et al., 2004] show that reduced activity of MTHFR and CBS greatly increase homocysteine levels, but not in a synergistic manner. If the associated polymorphisms lower the efficiency of the pathway such that homocysteine levels rise above a threshold level, we would expect a similar effect from other folate pathway polymorphisms. More thorough interrogation of these genes as well as environmental influences on folate metabolism are needed. With the inclusion of maternal folate supplementation data, this study provides valuable insight into the significance of gene-gene as well as gene-environment interactions in the folate pathway and their role in neural tube defects.

Haplotypes over the APP gene that influence risk of Alzheimer's disease in women. *T. Jonsson[1], T. Thorlacius[1], H. Petursson[1], S. Bjornsson[2], P.V. Jonsson[2], J. Snaedal[2], A. Levey[3], A. Kong[1], J. Gulcher[1], K. Stefansson[1].* 1) Decode Genetics, Reykjavik, Iceland; 2) Landspitali University Hospital, Geriatric Department, Reykjavik, Iceland; 3) Emory University, Department of Neurology, Atlanta, GA.

Humans that reach extreme age have done so in part by avoiding or delaying the onset of Alzheimers disease (AD). Therefore, it is expected that the frequency of protective AD variants be greater in cognitively intact longevous individuals than in the general population.

We searched for such variants using linkage analysis in the Icelandic population. A locus for human longevity with a multipoint non-parametric LOD score of 2.4 on Chromosome 21 was identified in families containing cognitively intact longevous individuals. The gene encoding the Amyloid Precursor Protein (APP) resides within the linkage region. Haplotype analysis of single nucleotide polymorphisms (SNPs) within the APP gene reveals a haplotype conferring protection against AD in these longevous individiduals (allelic frequency 10.6% vs 4.9% in AD cases, nominal p-value 4.010^{-6}). Furthermore, a common at-risk haplotype for Alzheimers disease was identified (allelic frequency 42.4% vs. 34.9% in cognitively intact controls; p-value 7.010^{-4}). The observed effects appear to be largely female-specific, with an Odds Ratio (OR) for female heterozygous carriers near 1.7 (p-value 5.310^{-6}) and 3 (p-value 1.410^{-6}) for the at-risk and protective haplotypes, respectively. Expression analysis in human lymphoblastoid cell lines shows that homozygous carriers of the at-risk haplotype for AD have an isoform-independent decreased expression of APP.

Most studies of genetic variations in APP reported to date have focused on mutations in the open reading frame of the gene leading to mendelian phenocopies of AD. Our findings indicate that genetic variants in the APP gene play an important role in the development of the common, late onset, form of AD.

Haplotype analysis of the Androgen Receptor in Male Pattern Baldness using HapMap tag-SNPs. *J.A. Ellis, K.J. Scurrah, S.B. Harrap.* Department of Physiology, The University of Melbourne, Australia.

Androgenetic alopecia, or male pattern baldness (MPB), is a strongly heritable complex phenotype that requires the presence of androgen for expression. In 2001, we published the first evidence of a strong association between a synonymous SNP (*Stu*I RFLP or rs6152) in exon 1 of the Androgen Receptor (*AR*, X chromosome), and MPB[1]. This association has since been confirmed by two independent studies[2,3]. The SNP lies between two triplet repeat polymorphisms shown to have functional significance, however neither of these polymorphisms appear to be independently associated with MPB in our population. Sequencing of all exons, untranslated regions, and regulatory regions totalling 7 kb upstream of *AR* failed to reveal any polymorphisms associated with MPB. We used HapMap to determine patterns of linkage disequilibrium (LD) spanning over 500 kb in and around *AR*, and found almost all HapMap SNPs were contained in two strong LD blocks. We selected four tag-SNPs (LD block 1: rs4827542, rs 5964602; LD block 2: rs1415270, rs4827405), that defined all haplotypes observed in the HapMap data. These SNPs were genotyped in 56 cases (men aged 30 years with cosmetically significant baldness) and 107 controls (men aged 50 years with no evidence of baldness). Single SNP, and haplotype association analyses were performed using the Haploview program. Of the single SNPs, rs4827542, located more than 200kb upstream of *AR*, was the most strongly associated with MPB (T allele: cases 96% vs controls 72%; P = 0.0003). The most commonly identified haplotype was detected in 93% of cases, but only 65% of controls (P = 0.00004). In conclusion, single SNP association analyses suggest that more strongly associated SNPs may lie a significant distance upstream of *AR*, and that tag-SNP haplotype analysis better defines cases and controls than single SNPs. However we have yet to identify the functional variant(s) in *AR* that are contributing to MPB, which may lie some distance from the coding sequence.

Genomic studies of *FCGR3B* in SLE. *E. Petretto[1], C. Roberton[1], T. Aitman[2], T. Cook[1], T. Vyse[1].* 1) Imperial College, London, UK; 2) MRC CSC, London, UK.

Introduction: SLE is an autoimmune disease and complex genetic trait. The clinical manifestations include immune complex mediated glomerulonephritis. Linkage analyses in SLE have mapped a region around chromosome 1q23. Association studies have implicated functional polymorphisms in three of five IgG receptors that are encoded in tandem within this region. We have already shown that *FcR2A-H131R* and *FcR3A-F158V* act in concert to slightly increase the risk of SLE (submitted). In this study we have focused attention on the least studied member of this gene complex, *FCGR3B*. **Methods:** Patients with SLE and their siblings were taken from a UK SLE nuclear family collection. The study was ethically approved MREC 98/2/6. Quantitative real-time (qRT)-PCR was carried out using SYBR Green to estimate copy number at *FCGR3B*. To calculate the overall risk/protection associated with *FCGR3B* the data set were fitted with logistic regression model by SPSS 12.0. **Results:** 375 European nuclear SLE families were genotyped at two polymorphisms in the *FCGR3B* gene: one in the promoter and the second encoding the NA1/NA2 allotypes. In contrast with markers typed in the *FCGR2A* and *3A* genes, both *FCGR3B* markers generated significant Mendelian errors (n = 63) and deviated from HWE. Using these families we tested the hypothesis that the median copy number deviated significantly from the expected value in a diploid genome. This was rejected for the single-copy control, *CD36* ($p = 0.25$), but was significant for *FCGR3B* ($p = 0.0004$). We examined the *FCGR3B* copy number in all patients with nephritis (n = 74) compared with unrelated matched siblings (n = 153). A logistic regression analysis provided support for reduced *FCGR3B* copy number in lupus nephritis ($p = 0.001$, 95% CI 0.001-0.0008) and a stepwise model confirmed that *3B* copy provided a statistically reliable model ($^2 = 7.6$, $p = 0.006$) whereas the inclusion of *FcR2A-H131R* and *3A-F158V* produced poorer models. **Conclusion:** Reduced copy number of *FCGR3B* confers a greater risk to lupus nephritis than other associated polymorphisms at the *FcR* locus. This may reflect a role for neutrophils Fc receptors in immune complex removal from the glomerulus.

Association between *PADI4* and rheumatoid arthritis: a mata analysis. *K. Ikari, M. Kuwahara, T. Nakamura, S. Momohara, M. Hara, H. Yamanaka, T. Tomatsu, N. Kamatani.* Institute of Rheumatology, Tokyo Women's Medical University, Shinjuku, Tokyo, Japan.

Recently, the peptidylarginine deiminase type 4 gene (*PADI4*) was reported to be associated with rheumatoid arthritis (RA) in a Japanese population. The strongest association was observed for a single nucleotide polymorphism (SNP) located in intron 3 of *PADI4* (P = 0.000008). In a subsequent study, we confirmed the result with the large series of case-control samples using the same genetic markers within the same ethnic background as the original study (P = 0.0008). Despite the strong association results observed in a Japanese population, Barton et al. failed to replicate the observed association in a United Kingdom population. Our objective was to determine whether a reported association is caused by a common variance through different ethnicities, using a meta-analysis combining the results of three association studies from two different ethnic groups.

Meta-analysis was performed under a recessive model, assuming minor-homozygote versus other genotypes, as indicated in the original Japanese study. Since padi4_104 was the only SNP used in all three studies it was included in the meta-analysis. The Breslow-Day test for homogeneity was calculated and conditional independence was assessed using the Mantel-Haenszel test. The common odds ratio with a 95% confidence interval (CI) was also calculated using the Mantel-Haenszel method.

Meta-analysis confirmed the association (P = 0.0002). Common odds ratio calculated with the Mantel-Haenszel method was 1.40 (95% CI = 1.17 - 1.67). The result of a meta analysis provides strong support for the role of *PADI4* in RA. To conclude, we suggest that the association between *PADI4* and RA is attributed to a common variance, irrespective of ethnicity. More powerful validation studies of other ethnic populations are warranted to support this conclusion.

Association and interaction of the IL4, IL13, IL5, IL3, IL12B, IL9, CD14 and IL4R genes with asthma in Chinese population. *X. Kong, H. Zhang, L. Wang, H. Chen, W. Huang, L. Zhang, L. Hu.* Health Sci Center, Sibs, Shanghai, Shanghai, China.

Cytokines, having central functions in immunological and inflammatory process, are always expected to play important roles in the pathogenesis of various diseases, such as asthma. Genetic polymorphisms of those cytokine and cytokine receptor genes are the focus of genetic association studies. In an effort to identify gene(s) whose variant(s) are associated with the asthma, we screened all exons and their flanking regions, as well as the promoter region (1.5kb) of eight genes, including IL4, IL13, IL12B, IL5, IL3, IL9, CD14 and IL4R.We could identify 42 single nucleotide polymorphisms, 15 of which were novel. Then, we examined the genetic effects of 30 single nucleotide polymorphisms in eight cytokine and cytokine receptor genes on asthma in a Chinese asthma cohort (n=537). Genetic association analysis of polymorphisms revealed that six polymorphisms (SNP18685711¡¢SNP18686951¡¢ SNP18686994¡¢ SNP18687043 ¡¢SNP18687051 ¡¢SNP18687259) in IL4R gene, three of which resulted in an amino-acid change, showed significant association with the risk of asthma (P=0.00023). Further analysis indicates that these six polymorphisms segregated in strong linkage disequilibrium. This information about the genetic association of important genes with asthma might provide valuable insights into strategies for the pathogenesis of asthma.

Evidence that KIAA0319 is a susceptibility Gene for Developmental Dyslexia on Chromosome 6. *J. Williams[1], N. Cope[1], D. Harold[1], G. Hill[1], V. Moskvina[1], J. Stevenson[2], P. Holmans[1], L. Jones[1], M. Owen[1], M. O'Donovan[1].* 1) Psychological Med, University Wales Col Medicine, Cardiff, United Kingdom; 2) Faculty of Medicine, University of Southampton, Southampton, United Kingdom.

Developmental dyslexia, (DD), is a relatively common, complex cognitive disorder that affects 5-10% of school-aged children. Genetic linkage and association studies have implicated a number of chromosomal regions that may harbor susceptibility genes for the disorder. In particular, linkage between DD and chromosome 6p has been replicated in a number of independent samples. By performing a systematic, high-density linkage disequilibrium (LD) screen of genes with publicly available SNPs in the most consistently supported region on 6p, we have previously found evidence that variation in the KIAA0319 gene is associated with increased risk of developing dyslexia (Cope etal, AM.J.Hum.Genet. 76,2005) Logistic regression analysis showed that two SNPs, rs4504469 and rs6935076, best explained DD status (p=0.00001). While the haplotype composed of these two markers is significantly associated with DD, these results do not necessarily imply that these two SNPs are the direct susceptibility variants. As such, we have further analyzed the KIAA0319 gene by resequencing all exons and genotyping the non-redundant polymorphisms identified. In addition we have assessed the LD structure of the gene, and genotyped all tag SNPs within haplotype blocks containing an associated SNP. Additional SNPs in conserved non-coding regions were also typed. In total, 22 SNPs have been genotyped in a case/control sample of 223 subjects with DD and 273 controls, in addition to 4 SNPs typed previously. We report here the refined evidence for involvement of KIAA0319 in susceptibility to developmental dyslexia.

Test of association of *DTNBP1, NRG1, DAOA/G30, DAO,* and *DRD2* with schizophrenia in two US family samples. *J. Duan, M. Martinez, A.R. Sanders, C. Hou, A. Krasner, D.B. Schwartz, G.J. Burrell, P.V. Gejman.* Center for Psychiatric Genetics, Department of Psychiatry and Behavioral Sciences, ENH Research Institute and Northwestern University, Evanston, IL.

We report here a study of association of *dysbindin (DTNBP1)*, *neuregulin-1 (NRG1), D-amino-acid oxidase activator (DAOA)/G30, D-amino-acid oxidase (DAO)*, and the *dopamine receptor D2 (DRD2)* in a sample of 136 United States (US) schizophrenia families largely of European Ancestry (EA). Besides all the previously positively associated single nucleotide polymorphisms (SNPs), we selected additional SNPs to increase map coverage and to explore for a potential causative SNP by prioritizing for known coding variants. We assessed the data quality by testing the repeatability and reliability of our genotyping methods (Fluorescence-polarization detection (FP), TaqMan, and SNPlex), and by checking for Hardy-Weinberg equilibrium (HWE) departures, Mendelian errors, and unlikely recombinants. For *DTNBP1*, Family-Based Association Test (FBAT) analyses with 11 tag SNPs (r^2>0.8) showed evidence for association between rs7758659 and disease (P=0.004). This actually represents evidence for three highly correlated SNPs including rs7758659 (r^2>0.94), which span about 55 kilo base pairs (kb) of intron 7 containing 3 cryptic exons. The most significant haplotype C-A (P=0.001, global P=0.0015) consists of rs7758659, and the previously most replicated SNP, P1635 (rs3213207). For *DRD2*, the promoter -141C Ins/Del was observed to be associated in the EA subset (P=0.008). Though the synonymous C957T did not show significant association, when combined with Taq1A, the P value of the haplotype C-G reached modest significance (P=0.02, global P=0.07) in which C is the allele that previously was shown to have higher *DRD2* mRNA stability (Duan et al., 2003). Lack of association for the remaining tested genes might reflect disease allelic heterogeneity, inadequate statistical power deriving from sample size, or that previously reported associations actually reflect false-positives. A robust test will require a comprehensive set of markers and larger samples.

Missense mutation in a bitter taste receptor (hTAS2R16) influences risk for alcohol dependence. *A. Hinrichs[1], J.C. Wang[1], B. Bufe[2], J.M. Kwon[1], J. Budde[1], R. Allen[1], S. Bertelsen[1], W. Evans[3], D. Dick[1], T. Foroud[4], R. Crowe[5], V. Hesselbrock[6], M. Schuckit[7], L. Almasy[8], H. Begleiter[9], B. Porjesz[9], H.J. Edenberg[4], W. Meyerhof[2], L.J. Bierut[1], A.M. Goate[1].* 1) Dept Psychiatry, Washington Univ Sch Med, St Louis, MO; 2) Department of Molecular Genetics, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany; 3) Laboratory of Neurogenetics, National Institute of Aging, National Institute of Health, Bethesda, MD; 4) Indiana University School of Medicine, Indianapolis, IN; 5) University of Iowa School of Medicine, Iowa City, IA; 6) University of Connecticut School of Medicine, Farmington, CT; 7) UCSD School of Medicine, La Jolla, CA; 8) Southwest Foundation, San Antonio, TX,; 9) SUNY Health Science Center at Brooklyn, Brooklyn, NY.

The aim of the Collaborative Study of the Genetics of Alcoholism (COGA) is to find genes that modify susceptibility to alcohol dependence and related phenotypes. A linkage finding (LOD=2.9) on chromosome 7q for alcohol dependence is located near a cluster of bitter taste receptors (TAS2Rs). We genotyped three functional single nucleotide polymorphisms (SNPs) in TAS2R16, a gene, which encodes a receptor for beta-glucopyranosides. The non-synonymous SNP rs846664 showed strong association with DSM-IV alcohol dependence (p=0.00018) in the COGA linkage sample and an additional set of trios unrelated to the linkage sample. The risk allele is rare in Caucasians (MAF 0.6%), but is present in 45% of African Americans making it a significant risk factor for alcoholism in this population. The SNP results in an amino acid substitution (N172K) in the extracellular loop between transmembrane domains four and five. In G-coupled protein receptors such as the TAS2Rs this domain has been associated with ligand binding and suggests that this amino acid substitution may alter signaling/taste perception. Our functional assays show that constructs containing the rare allele, K172, exhibit a higher EC50 (half-maximal response) for each of the agonists tested supporting the hypothesis that this SNP is a functional allele that increases risk for alcoholism.

Identifying candidate coronary artery disease susceptibility genes through genomic convergence. *J.J. Connelly[1], T. Wang[1], A. Dobra[2], J. Rose[1], L. Wang[1], L. Huang[1], B. Pedersen[1], C. Haynes[1], J.M. Vance[1], W.E. Kraus[3], P. Goldschmidt-Clermont[3], E.R. Hauser[1], S.G. Gregory[1], for the GENECARD and AGENDA investigators.* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Institute of Statistics and Decision Sciences, Duke University, Durham, NC; 3) Department of Medicine, Duke University, Durham, NC.

We aim to characterize genes involved in the development of Coronary Artery Disease (CAD) using several different genetic methods. We have identified GATA2 as a transcription factor with an increased potential to be involved with CAD susceptibility. GATA2 is known to regulate hematopoiesis and the development of the cardiovascular system. We obtained evidence for the involvement of GATA2 in CAD from several independent lines of investigation: 1)GATA2 maps beneath our GENECARD (early onset CAD genome scan) linkage peak on Chromosome 3q, which meets the criteria for genome wide significance and, upon stratification, was significant for linkage to both Acute Coronary Syndrome and the absence of diabetes; 2)Analysis of differential gene expression within distal and proximal regions of the aorta identified GATA2 expression patterns as highly predictive of atherosclerosis susceptibility; 3)GATA2 DNA binding sites are significantly over-represented in the upstream region (3kb) of genes that are differentially expressed in atherosclerotic aortas when compared to controls. We further evaluated evidence for a role for GATA2 in CAD in an independent case-control data set including 1,037 subjects with catheterization data from the Duke Coronary Catheterization Lab (the CATHGEN study). We identified four SNPs within GATA2 that are significantly associated (p0.01) with affected status using logistic regression. Two of these SNPs were also significant (p.05) using family-based association methods in the GENECARD study. However,these SNPs do not account for the linkage observed in the GENECARD families. These data suggest a role for GATA2 in CAD as one of many genes increasing susceptibility to CAD. We present our data as a model for the integration of genomic methods to identify candidate disease genes.

Mutation Screening of Candidate Genes for the X-Linked High-Grade Myopia Locus (MYP1). *N.F. Wasserman[1], P.C. Paluru[1], E.N. Campbell[2], T.L. Young[1,2].* 1) Divisions of Ophthalmology and Genetics, Childrens Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania School of Medicine, Philadelphia, PA.

The first locus (MYP1) for high-grade myopia was mapped to chromosome Xq28 in a large Danish family with myopia and cone photoreceptor dysfunction. We previously performed analysis on a second Danish family also exhibiting high-grade myopia with definitive cone dysfunction, identifying a linked region at Xq27.3-Xq28. Reported mapping studies performed in two Indian pedigrees with X-linked high-grade myopia (no electrophysiology studies conducted) contracted the putative gene interval to 1.2cM at the telomeric end of Xq28. We sought to identify the causative gene(s) in our MYP1 family by direct sequencing of 7 known (CTAG1, CTAG2, CLIC2, H2AFB3, TMLHE, SPRY3 and SYBL1) and 2 hypothetical positional candidate genes in this reduced 1.2 cM region. Reverse-transcription PCR was performed to confirm gene expression in human ocular tissues. Gene sequence was elucidated using public databases. Exonic regions and exon/intron boundaries for all genes were sequenced using genomic DNA from affected, carrier, and unaffected family members. Polymorphic sites were compared to known variants from the NCBI dbSNP database. A total of 27 polymorphisms were identified; 2 were silent, 10 were not translated, and 15 were intronic. Two were homozygous insertions, 2 were deletions, and the remaining 23 were substitutions. Eight polymorphisms were novel. Two of the novel polymorphisms segregated with the affection status for all 24 family members - a 7 base pair deletion in the 5 untranslated region of the SPRY3 gene, and a single base pair intronic polymorphism 22 bases 5 of an alternatively spliced exon of the TMLHE gene. We screened 100 external controls using denaturing high-performance liquid chromatography (DHPLC), and found that 22% exhibited the SPRY3 polymorphism, while 3% contained the TMLHE variant. Further in depth analysis of this contracted interval is underway.

Association between pain response and an Endothelin Receptor A (EDNRA) polymorphism in children undergoing an IV insertion. *D.L. Schutte[1], C. Kleiber[1], M. Floria-Santos[1], K. Hanrahan[1], J.C. Murray[2], A.M. McCarthy[1].* 1) Col of Nursing, Univ Iowa, Iowa City, IA; 2) Pediatrics, Univ Iowa, Iowa City, IA.

Nearly one half of children report significant pain with IV insertion despite the correct use of topical anesthetics. The purpose of this project, conducted as part of a larger study to test a distraction intervention, was to identify factors that explain variation in topical anesthetic effectiveness used for IV insertion. Children (age 4-10 years), scheduled for an IV insertion, and their parents were recruited. A total of 128 participants met the following inclusion criteria for this subproject: 1) topical anesthetic applied according to recommendations, 2) DNA available, and 3) a completed Oucher scale (self-report measure of pain intensity). An Oucher score of 0-3 was defined as low pain; a score of 4-10 was defined as high pain. Predictor variables included child age and gender, number of previous painful procedures, child temperament (Dimensions of Temperament Scale-Revised), parent anxiety (State-Trait Anxiety Inventory) and alleles in three candidate genes for pain pathways influenced by topical anesthetics [Endothelin-1 (EDN1), Endothelin Receptor A (EDNRA), Endothelin Receptor B (EDNRB)]. All subjects were genotyped for a single SNP in each gene using Taqman methods. Statistically significant differences were found between high and low pain groups on age (high pain group, younger age, p=.0001), child task orientation (higher pain, less orientation, p=0.020), child general activity (higher pain, higher activity, p=0.017), and Endothelin Receptor A genotype (high pain group, TT 67.35%; low pain group, TT 39.47%; p=0.004). A backwards elimination logistic regression procedure identified the EDNRA SNP as the best predictor of the high pain phenotype [Adjusted Odds Ratio=4.13 (1.64-10.440)]. In a follow-up Transmission Disequilibrium Test (TDT), trends of overtransmission of the EDNRA-C allele and undertransmission of the EDNRA-T allele in the low pain response group were noted (p = .085). The identification of genetic and behavioral factors that influence pain response will aid in prescribing the most appropriate pharmacologic and non-pharmacologic interventions.

The LRRK2 G2019S mutation in Italian Parkinson's Disease. *D. Civitelli, P. Tarantino, G. Nicoletti, I.C. Ciro Candiano, F. Annesi, E.V. De Marco, D. Carrideo, F.E. Rocca, P. Spadafora, G. Annesi.* Inst Neurological Sci, National Research Council, Mangone Cosenza, Italy.

We assessed the frequency of the G2019S mutation of the leucine-rich kinase2 (LRRK2) gene in Italian patients suffering from familial or sporadic Parkinsons disease (PD). This substitution represents the most common causative mutation to date described, and was found in affected members of families with autosomal dominant parkinsonism linked to PARK8 locus (about 5-6%) and in sporadic PD patients (about 2%) in different populations. We screened 38 unrelated familial patients with autosomal dominant parkinsonism and 450 sporadic PD patients. Age at onset was 30-78 years. Moreover, we genotyped 180 healthy subjects from the same geographical area. PCR-RFLP assay of G2019S mutation was performed using Scf1. Among the 38 patients with familial PD, we identified two carriers (5.2%) of G2019S substitution. One of them was heterozygous and the second one, descending from a PD family with consanguineous mating, was homozygous for this mutation. A living affected sibling showed the same rare homozygous genotype. Moreover, we found the heterozygous G2019S mutation in 12 of 450 sporadic PD patients (2.7%). The mutation was absent in controls. Clinical findings were similar between carriers and non-carriers subjects, and included bradykinesia, asymmetric resting tremor and rigidity, and a good response to levodopa. The age at onset ranged 40 to 77 years. The age at onset of homozygous siblings was 47 and 49 years respectively. The LRRK2 gene encodes the dardarin protein. It is the first kinase involved in PD, although its precise function remains unknown. The residue 2019 lies in the highly conserved DYG motif, essential to catalytic function of the protein. The GlySer substitution at this position could result in an impairment of the kinase activity of dardarin. Our results confirm that Gly2019Ser mutation in LRRK2 gene is the most frequent cause of genetic PD in Italians as well as in other different populations. A molecular screening of all 51 exons of the gene could reveal a higher frequency of mutations and increase the weight of dardarin gene in PD.

A new resistant gene candidate for human narcolepsy identified by a genome-wide association study. *M. Kawashima[1, 2], G. Tamiya[3], H. Hohjoh[2], T. Juji[4], T. Ebisawa[1], Y. Honda[5], H. Inoko[3], K. Tokunaga[2].* 1) Dept Sleep Disorder Research, the Univ. of Tokyo, Tokyo, Japan; 2) Dept Human Genetics, the Univ. of Tokyo, Tokyo, Japan; 3) Department of Moleculer Life Science, Tokai University school of medicine, Kanagawa, Japan; 4) Japanese Red Cross Central Blood Center, Tokyo, Japan; 5) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Human narcolepsy is a sleep disorder that is affected with multiple genetic and environmental factors. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region. To find out associated genetic factors other than HLA, a genome-wide association study using about 23,000 microsatellite markers with pooled DNAs has been performed. The subjects were all Japanese living in the Tokyo area. From the 1st and 2nd screening, >90 microsatellite markers showed statistical significance with Fisher'fs exact test using 2 x 2 tables. Those associations were then assessed by individual typing (case: 228, control: 420), and >30 markers still showed significant differences. Then, a region with one microsatellite marker NA3.4 showing a strong association was subjected to high-density mapping using additional microsatellite markers. In the analysis, a microsatellite marker NA3.L, which is 70 kb distance from NA3.4 showed stronger association than NA3.4 ($p<0.0005$). In succession, a fine mapping using 80 SNPs with the average distance of 5kb was performed. As a result, eight SNPs around NA3.L showed significant associations. In particular, two SNPs located close to the NA3.L showed strong associations (C-4: $p < 0.0005$, C-7: $p < 0.001$). In this region, predicted genes were registered in databases, and we performed expression analyses. In the RT-PCR, we found that a gene tentatively named NLC1-A is expressed in human brain and hypothalamus, as well as spleen, lung, kidney, and skeletal muscle. Moreover, in the reporter gene assay, the expression level was shown to be lower in the constructs with the SNP C-7 and marker NA3.L resistant alleles compared to those with the common alleles. Those observations indicate that the NLC1-A is a resistant gene to human narcolepsy in Japanese.

Gene expression changes in postmortem brain samples of schizophrenia patients with comparison to matched controls. *H. Chen[1], C.A. Ross[1], M.G. McInnis[2].* 1) Department of Psychiatry & Behavioral Science, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, University of Michigan School of Medicine, Ann Arbor, MI.

Schizophrenia is thought to be due to brain malfunction. Normal brain function at the molecular level requires controlled genetic expression. Although variation in gene expression occurs naturally, there is cumulative evidence of aberrant gene expression in postmortem brains from patients with schizophrenia. Altered expression of genes in the brain that are related to schizophrenia is not fully understood. We performed microarray expression profiling of postmortem brain samples from 15 schizophrenia patients and 15 matched controls using the Affymetrix U133plus2 GeneChip platform. We processed and normalized microarray raw data (CEL files) using the RMA algorithms. Analysis of the normalized data identified 102 genes that showed greater than 40% changes in expression levels in schizophrenia brains compared to controls (nominal t-test p value < 0.05). We further performed TaqMan assay validation of 10 of the 102 microarray significant genes. We observed that expression changes in 7 of the 10 genes tested with TaqMan assays were in agreement with microarray findings, however, there were only three of them with statistical significance ($p < 0.05$). GO database search for functional classification of the 102 significant genes indicates that there are classes of genes involved in biological processes of central nervous system development, synaptic transmission, proteolysis, cell mortality, and small GTPase mediated signal transduction. Our data suggests that modest expression changes are common in most of the significant genes identified with microarray analysis, and a portion of the significant genes may contribute to the malfunction of the schizophrenia brain.

The aggrecan core protein of precise length is protective of osteoarthritis. *O. Kämäräinen[1], S. Solovieva[2], T. Vehmas[3], K. Luoma[4], P. Leino-Arjas[2], H. Riihimäki[2], L. Ala-Kokko[1], M. Männikkö[1].* 1) Collagen Research Unit, Biocenter and Dept. of Medical Biochemistry and Molecular Biology, University of Oulu, Oulu, Finland; 2) Dept. of Epidemiology and Biostatistics, Finnish Institute of Occupational Health, Helsinki, Finland; 3) Dept. of Occupational Medicine, Finnish Institute of Occupational Health, Helsinki, Finland; 4) Dept. of Radiology, Peijas Hospital, Helsinki University, Central Hospital, Vantaa, Finland.

Osteoarthritis (OA), a chronic joint disorder, is characterized by articular cartilage breakdown and joint destruction. It is a major reason for disabilities in the aging population. The imbalance between synthesis and degradation of extra cellular matrix (ECM) molecules is believed to result in the destruction of cartilage leading to pain, stiffness and structural changes in the affected joints. Our goal was to study the contribution of the aggrecan VNTR polymorphism in clinically differing manifestations of hand osteoarthritis. 530 Finnish females representing two academically similar occupations with diverse exposure to mechanical hand load were included. Radiographs of both hands were analysed from all subjects, OA findings were graded and subjects divided into a different categories according to the clinical manifestations. The aggrecan VNTR alleles were analysed by Southern hybridization. Statistical analysis was performed in OA categories comparing joint involvement and pathological findings with the prevalence of the different genotypes. Subjects homozygous for the most common aggrecan VNTR allele, A27 with 27 repeats (n=95), had significantly lower risk for hand OA with OR 0.46 (95% CI 0.27-0.78) for at least mild OA (grade 2 or more), 0.42 (95% CI 0.18-0.96) for severe OA (grade 3 or more), and 0.40 (95 % CI 0.20-0.83) for symmetrical OA. Our results show that carrying two copies of the alleles less than 27 repeats (n=50) exposes to severe forms of hand osteoarthritis (OR 2.45, 95 % CI 1.17-5.12). Carrying two copies of the alleles with more than 27 repeats (n=93) also increased the risk of the disease (OR 1.73, 95 % CI 1.03-2.89). Our findings suggest that a precise number of the repeats is necessary for the optimum function of the aggrecan molecule.

Identification of candidate gene polymorphisms associated with childhood-onset systemic lupus erythematosus in Mexican population. *R. Velazquez[1], L. Orozco[1], F. Espinoza[3], D. López[3], V. del Castillo[1], V. Baca[2].* 1) Department of Human Genetics, INP, SS, Mexico City; 2) Department of Pediatric Rheumatology, CMN SXXI, IMSS, Mexico City; 3) Department of Immunology, INP, SS, Mexico City.

Systemic lupus erythematosus (SLE) is a complex autoimmune disorder that predominantly affects women during their childbearing age. It is estimated that 15-17% of all SLE patients present in children younger than age 16. Susceptibility to SLE has been attributed to complex interactions between genetic and environmental factors. The sibling risk ratio, the disease concordance rate in twins, the identification of several susceptibility loci, and the genetic association to a number of candidate genes support a genetic component of the occurrence of SLE. Initial manifestations of childhood-onset SLE are diverse and often more severe than in adults. Moreover, It has been suggested that genetics may play a greater role in pediatric than in adult SLE. We genotyped 8 single-nucleotide polymorphisms (SNPs) located in genes encoding interleukin-6, interleukin-10, tumor necrosis factor-alpha (TNFA), the low-affinity receptor for the Fc region of IgG (FCGR2A) and the programmed cell death 1 gene (PDCD1), in 170 Mexican pediatric patients with SLE and 200 unrelated, healthy Mexican controls. Genotyping was carried out by the 5 nuclease assay ((TaqMan) or by restriction fragment longitude polymorphism. Genotype frequencies differed significantly between SLE patients and controls for the TNFA -308 and the PD-1.3 polymorphisms (P = 0.004 and P = 0.005 respectively). The A allele frequency of the TNFA -308 polymorphism was more frequent in SLE patients than in controls (8.0% versus 3.0 P = 0.005; OR = 2.56; 95% CI = 1.30-5.04). On the other hand, the frequency of the PD-1.3 A allele was more frequent in SLE patients when compared with healthy controls (5.8% versus 2%, P = 0.005; OR = 2.95; 95% CI = 1.33-6.57). Our results suggest that PD-1.3 and TNFA -308 polymorphisms could play an important role in childhood-onset SLE susceptibility in Mexican population; it also confirms previous associations of these polymorphisms in other populations. This project was partially supported by FOFOI: FP-2003/014.

Opioid genes and alcohol dependence: whats in and whats not? *X. Xuei[1], L. Flury[1], L. Bierut[2], R. Crowe[3], D. Dick[2], A. Goate[2], J. Nurnberger[1], J. Rice[2], T. Foroud[1], H. Edenberg[1].* 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) Washington Univ Sch Medicine, St. Louis, MO; 3) Univ of Iowa, Iowa City, IW.

Opioid receptors and their endogenous peptide ligands play an important role in neurotransmission and neuromodulation, and in the rewarding and reinforcing properties of drugs such as cocaine, heroin, and alcohol. There are three known classes of opioid receptors: mu, delta, and kappa. The interactions of the opioid receptors with their peptide ligands usually lead to the activation of neurotransmission. There have been reports that variations in OPRM1 are associated with alcoholism, but data were not consistent, some were positive while others were negative. To examine whether the opioid system is associated with the risk for alcoholism, we performed extensive SNP genotyping on OPRM1 (18 SNPs), OPRD1 (16 SNPs), OPRK1 (13 SNPs), OPRL1 (8 SNPs), PDYN (18 SNPs) and PENK (5 SNPs) genes in the large family-based Collaborative Study on the Genetics of Alcoholism. Analyses were done with the Pedigree Disequilibrium Test (Martin, 2000) using 1860 Caucasian American individuals from 218 multiplex alcohol families. The data did not support the association of OPRM1, OPRD1, and OPRL1 genes with alcohol dependence. However, 7 consecutive SNPs in intron 2 of OPRK1 were significantly associated with alcohol dependence (p 0.05). The kappa-opioid receptor has been reported to produce aversive states, thus may prevent the development of reinforcement. Eleven SNPs in the PDYN gene also were associated with alcohol dependence. Haplotype analysis using a three-SNP sliding window further confirmed the association of both genes, with p-values as low as 0.00009. Therefore, we conclude that the variations of OPRK1, encoding the kappa-opioid receptor, and PDYN, encoding its ligand, are strongly associated with the risk for alcoholism. The finding that both the kappa-opioid receptor and its ligand are associated with alcohol dependence makes biological sense.

Update on identifying drug targets associated with human disease. *P. St Jean, L. Li, D. Montgomery, R. Newton, D. Yarnall, M. Sumner, J. Stuart, L. Middleton, D. Burns, E. Lai, S. Chissoe, A. Roses.* Genetics Research, GlaxoSmithKline, Res Triangle Park, NC, Harlow and Stevenage UK, Upper Merion and Providence, PA.

Over the past decade the pharmaceutical industry has seen decreased productivity in drug discovery. The GSK HiTDIP program (High Throughput human-Disease specific target Program) was initiated to deliver drug targets genetically associated with human disease (a target is a protein thought to play a key role in disease pathophysiology and whose activity may be modified by drug therapy). The premise of this program is that identification of disease associated drug targets will reduce attrition in the drug discovery pipeline. Over the next several years, this premise will be borne out by a larger proportion of successful Phase IIA efficacy studies (Phase II is usually considered the stage at which the drug is evaluated for effectiveness in patients). The value of HiTDIP in enhancing drug discovery can then be evaluated against historical methods of target selection. The HiTDIP program, in conjunction with physician collaborators, has recruited large, well phenotyped case/control collections for many different common human diseases in respiratory, inflammatory, musculoskeletal, cardiovascular, metabolic, neurological and psychiatric disease areas. These collections of approximately 1000 cases and 1000 controls have been genotyped for SNPs in ~2000 target genes (such as 7TMs, kinases and ion channels) and then tested for association to disease status. The analysis design uses an initial test set and a replication set. To date the HiTDIP program has delivered results for 12 initial test screens and 4 replication screens. Some well-known associations have been identified such as the HLA region in Rheumatoid Arthritis and APOE in Alzheimers Disease. This poster will give an overview of the analytical methods applied and highlight interesting features of results from the some of the completed studies.

HLA risk haplotypes segregating in a multiplex family affected with systemic lupus erythomatosus (SLE). *P.R. Pacheco[1,2], M. Pereira[1], L. Mauricio[1], M. Baptista[1], A. Quental[1], C. Paiva[1], L. Mota-Vieira[1,2].* 1) Hospital do Divino Espirito Santo, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

SLE is a chronic autoimmune disorder, caused by the production of pathogenic autoantibodies with specificity for nuclear and other tissue antigens. Although the genetic basis for SLE susceptibility is not known, recent studies in several populations support a role for specific HLA alleles and extended haplotypes, spanning the class II region, as genetic risk factors for SLE expression. Here, we report the identification of one extended and one class II haplotypes segregating in an Azorean family from Sao Miguel island, in whom the propositus - a women (51y) with classical SLE - has all three sons affected with different expressions of the disease: the 29y has a asymptomatic SLE, the 24y has a lupus nephritis, and the youngest (20y) had an episodic exanthema. All four have or had a positive antinuclear antibodies. Blood samples were collected from all patients, as well as from two non-affected family members: the husbands and mothers propositus. The HLA genotyping for class I (A, B and Cw) and class II (DRB1, DQA1 and DQB1) was carried out using PCR-SSP from Olerup SSP. Segregation analysis revealed that the haplotype (A*01-B*08-DRB1*03-DQB1*02) strongly associated with SLE in Caucasians is present in the propositus and in the two oldest sons, but absent in the youngest one. Moreover, the three boys also inherited, from his father, a class II risk haplotype associated with SLE (DRB1*15-DQB1*06). These alleles have relatively low frequencies in Sao Miguel population (0.075% and 0.198%, respectively). Considering these results, we are now genotyping all class II alleles, with high resolution (4 digits), because it is known that the DRB1*1501-DQA1*0101 has a multiplying effect on the SLE expression and is implicated in lupus nephritis. Moreover, an extended familial study is planned with a particular emphasis for other propositus relatives. This type of familial study is very useful for the patients clinical follow-up, and essential for understanding the susceptibility of autoimmune diseases.

Association of *FOXP3* gene variants with Systemic Lupus Erythematosus (SLE). *M. Barreto[1], R. Ferreira[1], L. Lourenço[1], C. Fesel[1], J. Demengeot[1], R. Andreia[2], J.F. Viana[2], C. Vasconcelos[2], B. Martins[3,4], L. Mota-Vieira[5], C. Ferreira[2,6], A.M. Vicente[1,7].* 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Associação dos Doentes com Lupus, Lisboa, Portugal; 3) Instituto de Ciências Biomédicas Abel Salazar, Porto, Portugal; 4) Instituto Nacional de Saúde Dr. Ricardo Jorge, Porto, Portugal; 5) Hospital do Divino Espírito Santo, Ponta Delgada, Azores, Portugal; 6) Clínica Universitária de Medicina II, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal; 7) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal.

FOXP3 is a member of forkhead/winged-helix proteins, which is involved in the regulation of T-cell activation, and therefore essential for normal immune homeostasis. It is specifically expressed by $CD4^+CD25^+CD45RO^+$ regulatory T cells (Treg), which are crucial in the prevention of autoimmune disorders due to their ability to suppress deleterious immune responses against self-antigens. To examine the involvement of the *FOXP3* gene in SLE susceptibility, we tested the association of the disease with two polymorphisms in this gene: a microsatellite marker on intron 0 in the enhancer/promoter region, which has been previously reported to regulate FOXP3 mRNA levels, and another microsatellite in intron 5 in a population consisting in 157 patients and 98 healthy individuals. The polymorphism in intron 0 showed a significant association with SLE (P=0.036). Given the putative role of this polymorphism in FOXP3 expression, we compared FOXP3 mRNA expression levels in patients with healthy controls. SLE patients showed higher levels of FOXP3 mRNA than healthy individuals, although not reaching statistical significance, possibly due to the small number of tested individuals. No association was found between *FOXP3* polymorphisms and its expression levels. We therefore screened the *FOXP3* gene for polymorphisms in the promoter/enhancer region that could influence the observed difference in FOXP3 expression. Given that no other variants were found in this region, we believe that variation in the intron 0 microsatellite polymorphism may influence the binding of regulatory proteins and thus modulate susceptibility to SLE.

TNF polymorphisms and occupational respiratory disease in a rural cohort. *R.E. Slager[1], J.L. Meza[2], S.E. Puumala[2], D.J. Romberger[1], S. von Essen[1].* 1) Dept Internal Medicine, Univ. of Nebraska Medical Center, Omaha, NE; 2) Preventive & Societal Medicine, Univ. of Nebraska Medical Center, Omaha, NE.

The genetic contribution of tumor necrosis factor (TNF) polymorphisms to asthma and other complex airway diseases is controversial. The functional significance of several well-characterized single nucleotide polymorphisms (SNPs) within the adjacent genes for TNF- (*TNFA*) and lymphotoxin and TNF- (*LTA*) is also not well understood. Few studies have focused on the association between TNF SNPs and respiratory disease in adult farmers of midwestern American. These individuals have specific respiratory challenges, including exposure to potentially high levels of endotoxin and particulate matter from inhalation of organic dusts in the agricultural setting. We now report genotyping results for two TNF polymorphisms, the *TNFA* -308G>A promoter polymorphism (dbSNP rs1800629) and an *Nco*I restriction fragment length polymorphism (RFLP) within the first intron of *LTA* (dbSNP rs909253), as well as the demographic profile of our rural cohort (n=199), composed primarily of farmers from Nebraska. Health and occupational data was collected from questionnaires, lung function was measured by spirometry, and genomic DNA was isolated from whole blood. The median age of our cohort was 57 and 73% of participants reported central European heritage. The median FEV_1 % predicted was 94.0 and the median FVC % predicted was 99.0. Smoking history was also taken into account, as 9% of individuals were current smokers and 25% were former smokers (median pack years 15). Genotyping was performed by PCR and RFLP analysis and confirmed by sequencing. The allele frequency in our population at the *TNFA* -308 locus was: 0.82 allele 1 / 0.18 allele 2, which is consistent with published frequencies in Caucasian populations. The allele frequency of the *LTA* SNP was: 0.36 allele 1 / 0.64 allele 2. Phenotypic information will be used to determine if there is a correlation between specific TNF alleles and respiratory function or disease as well as to quantitate environmental exposure in order to define gene / environment interactions.

Interaction of CFH T1277C polymorphism and cigarette smoking in age-related macular degeneration. *W.K. Scott[1], S. Schmidt[1], M.A. Hauser[1], P. Gallins[1], S. Kwan[1], L.M. Olson[2], N. Schnetz-Boutaud[2], K.L. Spencer[2], J.R. Gilbert[1], A. Agarwal[2], E.A. Postel[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Duke University Medical Center, Durham, NC; 2) Vanderbilt University Medical Center, Nashville TN.

Age-related macular degeneration (AMD) is a complex disease influenced by genetic and environmental risk factors. A strong association between the CFH T1277C polymorphism and AMD was reported in several independent samples, making it the most widely replicated genetic risk factor for AMD. Cigarette smoking is the most consistently implicated environmental risk factor for AMD. Both CFH and smoking influence complement activation. Thus, we examined potential gene-environment interaction between these two strong risk factors for AMD. 438 people with AMD and 142 unrelated controls were ascertained from two university eye clinics. Standard criteria were used to rate severity of macular disease (grades 1-5) based on examination of fundus photographs. Individuals were classified as ever or never smokers based on self-reported smoking of 100 cigarettes. T1277C genotypes were determined by sequencing of the polymorphic site. Logistic regression analyzed the joint effect of smoking and genotype, controlling for age and sex and including two-way interaction terms for smoking and genotype. Borderline significant interactions between smoking and the TC genotype were detected overall (p=0.09) and when comparing 276 grade 5 (neovascular) AMD cases to 109 grade 1 controls (p=0.09). Compared to a referent of never smokers with the TT genotype, grade 5 cases were more likely than controls to carry the CC genotype regardless of smoking history (OR=15.3, 95% CI: 3.7-63.8 in never smokers; OR=27.8, 95% CI: 7.4-104.9 in smokers). However, grade 5 cases were only more likely than controls to carry the TC genotype among smokers (OR=10.6, 95% CI: 3.2-34.7); in non-smokers, the TC genotype was not associated with AMD (OR=1.7, 95% CI: 0.5-5.1). A similar, but less significant, pattern was observed when comparing all cases to all controls. These results suggest that cigarette smoking might modify the effect of the TC genotype on risk of AMD.

Parent-of-origin effects in Attention Deficit Hyperactivity Disorder (ADHD). *L. Goos, R. Schachar.* Brain & Behaviour Res Program, Hosp Sick Children, Toronto, ON, Canada.

Attention Deficit Hyperactivity Disorder (ADHD) is one of the most common neurological disorders of childhood, affecting approximately 3-7 percent of all school age children. Generally characterized by age-inappropriate and impairing levels of inattention, hyperactivity and impulsiveness, many children also display varying degrees of intellectual impairment, cognitive deficits, and comorbid psychopathologies. Despite no consistent sex differences in core symptoms, severity or level of impairment, ADHD is 2-9 times more prevalent in boys than in girls. According to threshold models of ADHD etiology, this disparity is due to sex differences in the burden of genetic and environmental risk factors required to produce clinically significant symptoms. Thus, ADHD in girls represents the accumulation of a greater number of risk factors; where these risks are genetic in origin, females with ADHD may also transmit a greater number of risk factors to their offspring. In this study, the influence of sex on the transmission and manifestation of ADHD was investigated. The behavioural, intellectual and emotional characteristics of girls and boys diagnosed with ADHD were evaluated for parent-of-origin effects. Maternal history of ADHD was significantly associated with greater behavioural symptoms in children of both sexes. Paternal history of ADHD interacted with proband sex on intellectual and emotional measures, resulting in greater impairment in girls relative to boys in these domains. Interpretations of these data in terms of environmental and genetic factors, including epigenetic and sex-linked hypotheses, are explored.

Identification of Novel Asthma Susceptibility Loci on Chromosome 12q. *B.A. Raby[1], R. Lazarus[1], J. Su[2], K. Schneiter[2], C. Lange[2], E.K. Silverman[1], S.T. Weiss[1].* 1) Channing Laboratory, Brigham & Women's Hospital, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Chromosome 12q is among the regions most commonly linked to asthma in both genome-wide and regional linkage studies, yet the gene(s) responsible for these linkages have yet to be identified. We have previously demonstrated evidence for linkage with asthma to this region in families ascertained through the Childhood Asthma Management Program (CAMP). We subsequently performed high-resolution linkage disequilibrium (LD) mapping across this region using 1472 LD-tagging SNPs in 395 Caucasian CAMP families and identified 31 regions with significant evidence ($p<0.05$) of association with asthma. We now present results of follow-up SNP genotyping in these associated regions at substantially higher resolution. 535 markers were genotyped in these 31 associated regions to achieve a target SNP density of 5kb. Of the 31 regions, only 8 demonstrated persistent evidence of association in the second round of genotyping, with 2 regions demonstrating very strong evidence of both single-SNP and haplotype transmission distortion. Region 1 spans 176kb and included 26 SNPs demonstrating significant transmission distortion (transmission:non-transmission ratio 1.6:1, $p_{min}=0.0006$). Haplotype analysis revealed transmission distortion of one common haplotype at 18% frequency (global haplotype test $p=0.002$; haplotype-specific $p_{min}=0.0005$). Region 2 spans 37kb and includes 8 SNPs demonstrating significant transmission distortion (T:U ratio 1.4:1, $p_{min}=0.0002$). SNPs in this region form only two common haplotypes of 28% and 69% frequency. Survival analysis of time-to-symptom-onset revealed that both regions were significantly associated with earlier onset of asthma symptoms ($p_{min}=0.008$ and 0.002, respectively). There are five known genes mapping to these associated regions, none of which has previously been implicated in asthma, suggesting they may provide new insights into the pathobiology of this disease.

Haplotype Analysis of Complement Factor H and the CFH-like Genes and Risk for Age-related Macular Degeneration. *K.M. Spencer[1], M.A. Hauser[2], S. Schmidt[2], W.K. Scott[2], L.M. Olson[1], P. Gallins[2], S.Y. Kwan[2], M. Noureddine[2], J.R. Gilbert[2], N. Schnetz-Boutaud[1], A. Agarwal[3], E.A. Postel[4], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine, Duke University Medical Center, Durham, NC; 3) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN; 4) Duke University Eye Center and Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Age-related macular degeneration (AMD) is the leading cause of blindness in the elderly. Estimates suggest that over 50 million people worldwide are affected with this disorder, including 15 million in the United States. Recently, Haines et. al (2005) and other groups reported a strong association between the Y402H variant in the complement factor H gene (CFH) and risk for AMD. The CFH gene and 5 related CFH-like genes all lie within the Regulator of Complement Activation (RCA) gene cluster on chromosome 1q32. Because these genes may play a role in control of the complement system and epistatic interactions may exist between polymorphisms in these genes, the CFH-like genes were also sequenced in a subset of our AMD dataset. Fifteen known SNPs were observed and 8 novel SNPs were discovered. Strikingly, in the 48 people sequenced we observed a marked reduction in variation within the CFH and CFH-like genes in cases compared to controls ($p < 0.0001$), which further implicates the Y402H polymorphism in AMD risk. This may also indicate that the AMD risk haplotype is of recent evolutionary origin. After genotyping 14 coding SNPs observed in our sequenced samples in our full AMD case-control dataset of 465 cases and 170 controls, the reduction in variation was confirmed ($p < 0.0001$). Evidence for a protective haplotype spanning the CFH gene was also obtained ($p < 0.01$). This haplotype is significantly underrepresented in cases versus controls, after taking into account the overrepresentation of the Y402H risk haplotype in the cases.

Identifying schizophrenia-associated non-coding variants in the CAPON gene. *N.S. Wratten[1], S.E. Bruse[1], M.A. Azaro[1], J. Simone[1], J.E. Hayter[1], L.M. Brzustowicz[1,2].* 1) Dept of Genetics, Rutgers University, Piscataway, NJ; 2) Dept of Psychiatry, UMDNJ-NJMS, Newark, NJ.

We have previously shown linkage between chromosome 1q23 and schizophrenia and detected significant LD between schizophrenia and markers that fall within the CAPON gene in a set of families of European descent. A mutation screen of these samples failed to identify any associated coding SNPs. An independent study in a Han Chinese sample found a different pattern of significant association between markers in this gene and schizophrenia[3]. CAPON spans 300 kb and a number of statistical analyses have indicated more than one region of the gene may be associated with the disease. Heterogeneity in disease associated markers is often seen in complex traits and could be explained by mutations in independent regulatory modules. Regulatory sequences are not constrained by position relative to coding sequences so it is important to examine markers throughout the gene, including 5 and 3 regions. Given the large size of CAPON, it was necessary to use an efficient tagSNP approach to survey the entire gene with a minimal set of SNPs. Since established tagSNP approaches have certain limitations, we combined two methods; the Perlegen database that groups SNPs into LD bins based on r^2 (http://genome.perlegen.com/) and the Applera SNP browser software that chooses SNPs based on LDUs created with the measure (http://www.applera.com/). We required that a SNP was chosen from each bin and at a density of 0.33 LDUs. Luminex assays were then developed for the resulting panel of 53 SNPs (including the 15 SNPs previously reported) using custom software to allow the multiplexing of 10 to 15 SNPs per PCR reaction, substantially reducing the cost and the time to genotype samples. Associated SNPs give an approximate location for potential regulatory sequences, with nearby conserved sequences then tested for regulatory function in Hela and neuronal cell lines. This analysis pipeline allows for the efficient and systematic evaluation of even a large candidate gene for potential causative regulatory mutations. [3]Zheng *et. al.*, Biochem Biophys Res Commun. 2005, 328(4):809-15.

Bipolar 1 disorder and schizophrenia: A 440-SNP screen of 64 candidate genes among familial Ashkenazi Jewish case-parent trios. *A.E. Pulver[1,2], M.D. Fallin[2], V.K. Lasseter[1], N. Cheng[1], J.A. McGrath[1], K.Y. Liang[3], G. Nestadt[1], D. Valle[4,5], D. Avramopoulos[1], P.S. Wolyniec[1].* 1) Dept Psychiatry, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Department of Epidemiology, The Johns Hopkins Bloomberg School of Public Health; 3) Department of Biostatistics, The Johns Hopkins Bloomberg School of Public Health; 4) McKusick-Nathans Institute, The Johns Hopkins School of Medicine; 5) Howard Hughes Institute, the Johns Hopkins School of Medicine.

Schizophrenia (SZ), schizoaffective (SZA), and bipolar 1 disorders (BP1) are common heritable psychiatric disorders, for which familial co-aggregation as well as epidemiological and genetic evidence suggest genetic heterogeneity and overlapping etiologies. In an attempt to reduce genetic heterogeneity, we have ascertained families of Ashkenazi Jewish descent. As an initial effort, a SNP screen of 64 candidate genes was genotyped with an average 6.9 SNPs per gene and an average of 1 SNP every 11.9 Kb in 274 SZ and SZA and 323 BP1 Ashkenazi case-parent trios. Using single SNP and haplotype-based transmission disequilibrium tests, we ranked genes based on p<.01. Six genes (DAO, GRM3, GRM4, GRIN2B, IL2RB, and TUBA8) were associated with susceptibility for BP1 and six genes (RGS4, SCA1, GRM4, DPYSL2, NOS1, and GRID1) were associated with SZ/SZA. In addition, several genes showed overlapping suggestive evidence of association in both datasets (DPYSL2, DTNBP1, G30/G72, GRID1, and GRM4). To further reduce heterogeneity, we have now completed a stratified analysis, i.e., we examined the subset of familial trios in the SZ/SZA and BP1 samples using the same methods as above. For the 126 familial BP1 trios, GRIN2B and GRID1 are associated at the p<.01 level. For the 112 familial SZ/SZA trios, 6 genes are associated at the p<.01 level: ADRA1A, SCA1, KIF13A, NRG3, HTR7, HTR2A, and PRODH. Despite the decreased sample size, stratifying the proband groups by family history of disease supports previously found associations and potentially identifies additional genes (ADRA1A, KIF13A, NRG3, HTR7, HTR2A, and PRODH) that may play a role in susceptibility to subgroups of the case populations.

Analysis of chromosome 10 LOD-1 linkage region to identify genes associated with late onset Alzheimer's Disease. *A.R. Morgan[1], L. Jehu[1], D. Turic[1], G. Hamilton[2], L. Busby[2], J. Powell[2], S. Lovestone[2], M. Owen[1], J. Williams[1].* 1) Cardiff University Dept of Psychological Medicine, University Hospital of Wales, Heath Park, Cardiff CF14 4XN; 2) Departments of Old Age Psychiatry and Neuroscience, Institute of Psychiatry De Crespigny Park London SE5 8AF, UK.

In our genome scan for linkage with LOAD we observed significant evidence of linkage to chromosome 10 spanning approx 44 cm from D10S1426 (59cM) to D10S2327 (103cM) (Myers et al., 2002). In this current study we have focussed on the Max LOD -1.0 region, defined as the area encompassed by all markers producing LOD scores between approx 2.83 and 3.83, flanked by markers D10S1220 (70cM) and D10S1670 (86cM). All known and predicted genes between these markers were downloaded from the Ensembl database, and SNPs were identified within the genes using db SNP.

Using the SNPs, with an average SNP density 5.5kb (862 SNPs in 80 genes), we tested for association with LOAD. SNPs were typed in pooled samples of 4 case and 4 control DNA pools, totalling 366 case subjects and 366 control individuals. We obtained results for 494 SNPs. 23 SNPs (in 13 genes) gave significant results after correction with het ratio: VR22 (5 SNPs), LCX (1 SNP), ANK3 (3 SNPs), PLEAKHA1 (1 SNP), EGR2 (1 SNP) JMJDIC (1 SNP), OGDHL (1 SNP), TIMM23 (1 SNP), TMEM23 (3 SNPs), ACF (1 SNP), CGK1 (1 SNP), Em: AC074327. 1 (1 SNP), PCDH15 (3 SNPs)

These 23 positive SNPs now require genotyping in additional pooled DNA to further support our significant associations.

Genetic variants in *IRF6* are strongly associated with orofacial clefts in a Norwegian Population. *F. Rahimov[1], A. Jugessur[1,3], AJ. Wilcox[2], RT. Lie[3], HK. Gjessing[4], JC. Murray[1].* 1) University of Iowa, Iowa City, IA; 2) National Institute of Environmental Health Sciences, Durham, NC; 3) University of Bergen, Norway; 4) Norwegian Institute of Public Health, Norway.

Recently, mutations in the gene encoding interferon regulatory factor 6 (*IRF6*) were shown to underlie Van der Woude syndrome (VWS), in which lower lip pits and occasional hypodontia are the only additional features distinguishing the syndrome from isolated clefts. To date, two studies have reported strong associations of *IRF6* variants with CL/P. In a population-based case-control study of orofacial clefts in Norway (1996-2001), DNA was available from babies and their parents, and occasionally from additional siblings. The study had a high participation rate of 88% in the case group (n=574) and 76% in the control group (n=763). Of these, 187 were complete CPO triads, 135 were CLO, 228 were CLP, and 372 were control triads. Five SNPs (rs669694, rs4844880, rs126280, rs2013162, and rs17015215) at the *IRF6* locus were selected based on preliminary results showing an association with isolated CL/P in a Danish and Filipino population. All analyses were performed using HAPLIN (see http://www.uib.no/smis/gjessing/genetics/software/haplin), which enables estimation of the effects of a single or double dose of an allele or haplotype. A major strength of HAPLIN is that both fetal and maternal effects can be assessed separately, which is especially relevant when studying birth defects. Whereas no significant effects, either fetal or maternal, were observed in CPO, the cleft lip categories, however, showed significant distortions in the transmission of alleles for several of the markers. Haplotype-based analyses revealed a high-risk haplotype C-T-A-C-C (SNP order as above) in the CLO subgroup of clefts. The fetal haplotype relative risk was 2.6 (95%CI: 1.4-4.7; $p < 0.01$) with a single-dose of this haplotype and 5.2 (1.3-20) (p=0.02) with two doses. Combining the cleft lip subgroups does not appreciably alter these estimates (single-dose, 1.8 (1.2-2.7), $p < 0.01$; double-dose, 2.8 (1.1-6.8), p=0.03). In conclusion, these findings confirm the role of *IRF6* variants in clefting of the lip in the Norwegian population.

Association between OPRM1 Gene Variants and Substance Dependence in European Americans. *H. Zhang[1,2], H.R. Kranzler[3], X. Luo[1,2], B.Z. Yang[1,2], J. Lappalainen[1,2], J. Gelernter[1,2].* 1) Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) VA Connecticut Healthcare System, West Haven, CT; 3) Dept. of Psychiatry, University of Connecticut School of Medicine, Farmington, CT.

Previous association studies of the -opioid receptor gene (*OPRM1*) in substance dependence have focused on a few gene variants without full coverage of the gene, and findings are inconsistent. In this study, we examined a more extensive set of *OPRM1* single nucleotide polymorphisms (SNPs) in a sample of 406 European Americans (EAs) affected with substance dependence (337 with alcohol dependence and 204 with cocaine and/or opiate dependence) and 328 EA healthy controls. 13 SNPs spanning *OPRM1* were selected and genotyped. The SNPs were found to be located in two haplotype blocks. The genotype distributions of all SNPs were in Hardy-Weinberg equilibrium (HWE) in controls; but in cases, 5 SNPs in Block I and 3 SNPs in Block II showed genotype distribution deviation from HWE. Significant differences were found between cases and controls in both allele and genotype frequencies for 4 SNPs in Block I and 2 SNPs in Block II. Association of one SNP in Block I with drug dependence and two SNPs in Block II with alcohol dependence remained significant after correcting for multiple testing. Logistic regression analyses also indicated that one SNP in Block I and another SNP in Block II were associated with drug and alcohol dependence, respectively, when the sex and age of subjects, two potential confounding factors, were considered. Haplotype case-control studies showed that the frequency distribution of haplotypes (constructed by either the 7 SNPs in Block I or the 6 SNPs in Block II) was significantly different between cases and controls (haplotypes in Block I: $P = 0.020$ and 0.030 for alcohol and drug dependence, respectively; haplotypes in Block II: $P = 0.010$ for both alcohol and drug dependence). Structured association analyses using 37 ancestry-informative markers (AIMs) excluded the possibility that the positive findings resulted from population stratification and admixture effects. These results strongly support that *OPRM1* variants are associated with substance (alcohol and/or drug) dependence.

Genome-wide scan for Adiposity-related Phenotypes in Adult Samoans. *F. Dai[1], E.D. Keighley[2], G. Sun[3], D. Smelser[3], S. Viali[4], J. Tuitele[5], L. Jin[3], R. Deka[3], D.E. Weeks[6,1], S.T. McGarvey[2].* 1) Dept of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) International Health Institute, Brown University, Providence, RI; 3) Center for Genome Information, Department of Environmental Health, University of Cincinnati, OH; 4) Tupua Tamasese Meaole Hospital, Apia, Samoa; 5) Tafuna Family Health Center, Pago Pago, American Samoa; 6) Dept of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

As part of a genetic epidemiology study of adiposity in Samoa and American Samoa, we conducted a genome scan to detect linkage with adiposity QTLs among 677 adults from large pedigrees in American Samoa. The probands and family members were unselected for obesity and were recruited from all regions of the Samoan archipelago. Adiposity was assessed by BMI, abdominal circumference (ABDCIR), percent body fat (%BF), measured by bioelectrical impedance, and fasting serum leptin and adiponectin. The distribution of all phenotypes was transformed to normality, and adjusted for the influence of age and sex. The self-reported pedigree relationships were checked and corrected after genotyping. Multipoint LOD scores were calculated using variance components methods and SOLAR/LOKI software. Adiposity QTLs with LOD2.0 were detected for the following regions: (A) 16q21-23: LOD = 2.44 for BMI, LOD = 2.25 for %BF (and LOD = 1.98 for ABDCIR, LOD = 1.53 for leptin); (B) 13q33: LOD = 2.25 for adiponectin; (C) 4p15: LOD = 2.07 for BMI. These preliminary linkage analyses indicate potential pleiotropy at 16q21-23. Our work is supported by NIH grant R01-DK59642 (S.M. PI).

Fine mapping and candidate gene screening of 3q25-27 in Finnish autism families. *K. Rehnström[1,2], T. Ylisaukko-oja[1,2], R. Vanhala[3], R. Alen[4], R. Riikonen[5], E. Kempas[2], H. Komu[1], L. Peltonen[2], I. Järvelä[1].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 3) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 4) Department of Child Neurology, Central Hospital of Central Finland, Jyväskylä, Finland; 5) Department of Child Neurology, Children's Hospital, University of Kuopio, Kuopio, Finland.

Linkage to 3q25-27 has previously been reported in a Finnish genome-wide screen for autism spectrum disorders. We have now fine-mapped this region by linkage and association methods using a dense set of microsatellite markers in an extended set of families (n=100) including the families from the original genome-wide screen. Linkage to the 3q25-27 region was maintained in this extended patient sample (D3S3037 resulting in a two-point LOD score exceeding 3) and suggestive association was observed at D3S3037 and at a polymorphic dinucleotide repeat intragenic to MCF2L2, a rho-family guanine exchange factor (PSEUDOMARKER p=0.018 and p=0.049, respectively). Possible candidate genes involved in neuronal development and function were identified in silico in the region. Four candidate gene regions containing six genes, neuroligin 1 (NLGN1), ephrin receptor EphB3 (EPHB3), fragile X mental retardation-related protein 1 (FXR1), and three serotonin receptor 3 subunits (HTR3C, HTR3D and HTR3E) were chosen for further analysis. Coding regions of these genes were screened for mutations by sequencing in a subset of patients. Sequence analysis of NLGN1 did not reveal any functional mutations, and only one SNP resulted in suggestive association (FBAT p=0.002). Therefore we conclude that our results do not provide strong evidence for the involvement of NLGN1 in the etiology of autism in the Finnish material. For the other candidate genes, a dense set of SNP markers will be genotyped in all families in order to detect susceptibility variants in non-coding regions. Family based association and haplotype association tests will be performed to assess their importance in autism spectrum disorders.

Genetic variation in 5-hydroxy-tryptamine receptor (5HTR2A) is associated with obesity in the NHLBI Family Heart Study. *I.B. Borecki[1], Y. Jiang[2], S. Williamson[2], K.E. North[3], D. Ma[1], M.A. Province[1], R.H. Myers[2].* 1) Div Biostatistics, Washington Univ Sch Medicine, St Louis, MO; 2) Dept Neurology, Boston Univ Sch Medicine, Boston, MA; 3) Dept Epidemiology, Univ NC, Chapel Hill, NC.

A genome-wide linkage scan of BMI in Caucasian pedigrees from the Family Heart Study (Feitosa et al. 2002) revealed evidence of QTLs on chromosomes 7q31.3 (lod=4.9) and 13q14 (lod=3.2); Black families were not genotyped in that project phase. To follow up on these signals, 82 families (N=518) and 130 families (N=1104) with the largest contribution to the respective lod scores on 7 and 13 were studied. The focus of the present study is to test the potential role of the 5HTR2A locus, which maps within the peak on 13 at ~45,250 kb. Serotonin (5-HT) is a key mediator in the control of satiety and is probably involved with weight regulation (Leibowitz 1990), and a polymorphism in the 5HTR2A gene has been shown to be associated with dietary energy and alcohol intake in obese subjects (Aubert et al. 2000). A preliminary study was carried out in the chromosome 7 set of families using a particular SNP in the 5HTR2A gene (dbSNP ID: rs6313) because it appears to be a functional mutation - it introduces a missense mutation (Arg(CGG)39Trp(TGG)) in the second exon of one spliced mRNA form, and it also introduces a silent mutation in other transcription forms. A significant association with obesity (BMI > ~ 30 kg/m2) was found (P=0.007) using a family-based TDT implemented in TRANSMIT. We have now typed 11 SNPs across the gene in the independent set of chromosome 13 families; all but one (rs1923885; p=0.04) were in Hardy-Weinberg equilibrium. We replicated an association with 5HTR2A, although for a different SNP (rs2770296, p=0.04) and a 3-SNP haplotype including its flanking markers (p=0.01). While the two associated SNPs are in linkage disequilibrium (r^2~0.4), these results make room for the possibility that there may be heterogeneity among the haplotypes harboring functional variants. Therefore, while we have replicated evidence for the association of variants in 5HTR2A with obesity, further work is necessary to understand precisely which variants are functional.

Association Study of Trace Amine Receptors in Bipolar Disorder. *C. Liu, J. Shi, H. Zou, J.A. Badner, S.L. Christian, E.S. Gershon.* Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL.

Trace amines including tyramine, beta-phenylethylamine, tryptamine, and octopamine are biogenic amines. Some of them have been recognized as neurotransmitters in invertebrates. A family of trace amine receptors has been discovered in a small region at human 6q23.2. 6q24 has been reported to link to both SZ and BD. Although their biological functions are mostly unclear, one of the trace amine receptors (TRAR4, named as TAAR6 by Lindemann et al. 2005) was reported to be associated with schizophrenia (SZ). Twenty-five SNPs were selected for association test in bipolar disorder (BD) samples from the ~122 Kb regions where all nine known human trace amine receptors located. 557 individuals from 177 Caucasian pedigrees with BD were studied. Transmission/disequilibrium test (TDT) and haplotype analysis were performed. None of the associated SNPs in SZ -- rs8192625, rs4305745, rs6903874 and rs6937506 -- showed association with BD. Two distal markers (rs9389008 and rs9321360) showed nominally significant association. rs9389008 is close to TAAR4; rs9321360 is 8 Kb upstream to TAAR1. None of the results were significant after correcting for multiple testing using permutations. Haplotype block and LD map data indicate that the selected markers provided adequate coverage for this genomic region. Thus, trace amine system may not play a major role in bipolar disorder on 6q.

***FOXO3A* is associated with human longevity.** *L. Pawlikowska[1], D. Lind[1], E. Lovins[1], T.J. Nguyen[1], J. Chen[1], C. Chu[1], S. Huntsman[1], W. Browner[2], W.C. Hsueh[1], P.Y. Kwok[1], E. Ziv[1].* 1) Ctr for Human Genetics & Dept of Medicine, University of California, San Francisco, CA; 2) California Pacific Medical Center Research Institute, San Francisco, CA.

Genes in the insulin/IGF1 signaling pathways affect lifespan in model organisms. In *C. elegans*, mutations in *daf-2*, the homologue of insulin/IGF1 receptors, lead to increased resistance to oxidative stress and longer lifespan. These mechanisms appear conserved through evolution: mice with IGF1 receptor haploinsufficiency have increased lifespan. In *C. elegans*, the effect on lifespan requires the transcriptional factor DAF-16. FOXO3A, a mammalian homologue of DAF-16, increases oxidative stress resistance. We hypothesized that common polymorphisms in *FOXO3A* may be associated with variation in human lifespan. To identify *FOXO3A* single nucleotide polymorphisms (SNPs), we sequenced 6.7 kb of genomic sequence including exons, exon-intron boundaries and 1kb of promoter. Haplotype tag SNPs (htSNPs) were selected by eliminating redundant SNPs (R^2=1.0). We genotyped six htSNPs in 896 Caucasian women from the Study of Osteoporotic Fractures, selected for near-normal (n=603, lifespan79y, mean=75.72.6y) vs. extreme long lifespan (n=293, lifespan92y, mean=95.32.1y). We tested the association of genotype with lifespan by comparing individual SNP allele frequencies and computationally predicted haplotype frequencies between long-lived individuals and controls. All p-values are unadjusted. Five of the six *FOXO3A* htSNPs were associated with lifespan ($p<0.05$). We observed the strongest effect for an intronic SNP (minor allele frequency 0.19 vs. 0.13, p=0.0015) and the Ala53 synonymous SNP (0.17 vs. 0.12, p=0.004). Global haplotype distribution differed between long-lived women and controls (p=0.01). One haplotype was overrepresented among long-lived cases (frequency 0.17 vs. 0.12, p=0.003); the most common haplotype was underrepresented (0.64 vs. 0.70, p=0.02). In conclusion, genetic variants in *FOXO3A* may be associated with longer lifespan in Caucasian women. Our results support the hypothesis that oxidative stress resistance pathways, which modulate lifespan in model organisms, also influence human longevity.

No association between severe obesity and ACE gene functional variants in French Caucasians. *C. Bell[1,9], D. Meyre[2], E. Petretto[3], C. Boyle[1], B. Jouret[3], D. Jaquet[4], C. Levy-Marchal[4], M.A. Charles[5], J. Weill[6], M. Tauber[7], C.A. Mein[8], T.J. Aitman[3], P. Froguel[1,2], A.J. Walley[1].* 1) Section of Genomic Medicine, Imperial College, London, W12 0NN UK; 2) CNRS, UMR 8090, Pasteur Institute, Lille, France; 3) Section of Physiological Genomics, London, W12 0NN UK; 4) INSERM U457, Robert Debre Hospital, Paris, France; 5) INSERM, U258-IFR69, Paris South Faculty of Medicine, Villejuif, France; 6) Paediatric Endocrine Unit, Jeanne de Flandre Hospital, Lille, France; 7) INSERM U563, Childrens Hospital, Toulouse, France; 8) Barts and the London Genome Centre, Queen Marys College, London, UK; 9) Department of Haematology and Genetics, Prince of Wales Hospital, Sydney, NSW, Australia.

For the Angiotensin-Converting Enzyme (ACE) gene, associations with obesity phenotypes have been reported for the Alu insertion/deletion (I/D) polymorphism in Italians and single-nucleotide polymorphisms (SNP)/clades in Swedes. We have also previously reported a linkage result in a genome scan of severely obese French Caucasians, at chromosome 17q23, which contains the ACE gene. Eight polymorphic ACE gene polymorphisms (seven SNPs and the I/D polymorphism) were genotyped in 1054 severely obese cases (548 adults (mean BMI = 45.4), 506 children (ZBMI > 97th percentile) specifically recruited for extreme obesity and 918 non-obese, non-diabetic controls. These SNPs include those proposed as being responsible for variation in ACE levels and also enabled the previously-described clades to be inferred. Statistical analysis of the frequencies of alleles, genotypes, haplotypes, clades and diploclades showed no significant difference at all ($p>0.05$) between cases and controls in total or when age and/or sex were taken into account, after Bonferroni correction. Quantitative analysis of the clades and diploclades for BMI, waist to hip ratio, or ZBMI in children, were not significant as well. These results demonstrate that functional sequence variation in the ACE gene, at whatever level, is not associated with either severe or morbid obesity phenotypes in French Caucasian subjects.

Characterization of the 2p dyslexia candidate region. *H. Anthoni[1], M. Zucchelli[1], J. Schumacher[2], G. Schulte-Körne[3], M. Nöthen[4], J. Kere[1,5], M. Peyrard-Janvid[1].* 1) Dept of Biosciences at Novum, Karolinska Institutet, Sweden; 2) Institute of Human Genetics, University of Bonn, Germany; 3) Dept of Child and Adolescent Psychiatry and Psychotherapy, University of Marburg, Germany; 4) Dept of Genomics, Life & Brain Center, University of Bonn, Germany; 5) Dept of Medical Genetics, Biomedicum, University of Helsinki, Finland.

Developmental dyslexia is a complex disorder characterized by unexpected difficulty in learning to read despite adequate intelligence, education, and normal senses. It is one of the most frequently diagnosed disorders in childhood, with a prevalence rate of 3-10%. Genetic loci have been mapped to at least seven different chromosomes by several independent studies. Candidate genes have so far been proposed for *DYX1* (*DYX1C1*) and *DYX2* (*VMP*, *DCDC2*, *KIAA0319*, *TTRAP*, *THEM2*). We have previously mapped a susceptibility gene for dyslexia to 2p11-p12 in eleven Finnish pedigrees using microsatellite markers. In order to refine this candidate region, we increased the marker density by successive rounds of fine mapping using microsatellites and SNPs in an extended Finnish sample set, including new families and case-controls. Initially, 29 new microsatellites narrowed the 40 cM candidate region down to 6 Mb. Three positional and functional candidate genes were screened by direct sequencing in affected individuals; *TACR1*, *CTNNA2* and *LRRTM4*. All of these have important roles in the central nervous system and are abundantly expressed in brain. However, no mutations could be detected in their coding regions. We further selected and genotyped 26 SNPs in the 6 Mb region. Association analysis using the HPM algorithm and the TDT gave significant p-values for a number of individual markers (p=0.003). We replicated these associations in an independent sample set of 253 trios of German origin, showing the same marker patterns and alleles as in the Finnish sample, with the best single marker p-value of 0.002. To refine this association and further narrow down the candidate gene(s), we are now genotyping SNPs in the region at a 10 kb density, characterizing the three positional candidate genes it contains, as well as identifying any unknown genes.

DOCK9, a candidate bipolar disorder susceptibility gene on chromosome 13q32.3. *S. Detera-Wadleigh[1], C. Liu[2], J. Badner[2], W. Corona[1], N. Akula[1], I. Cardona[1], M. Kundu[1], C.J.M. Steele[1], M. Maheshwari[3], T. Bonner[1], R. Gibbs[3], E. Gershon[2], F. McMahon[1].* 1) NIMH/NIH, Bethesda, MD; 2) University of Chicago, Chicago, IL; 3) Baylor College of Medicine, Houston, TX.

Overlapping linkage peaks for schizophrenia and bipolar affective disorder (BPAD) span a wide expanse of chromosome 13q. A preponderance of studies highlight 13q32-q33. The G72/G30 locus, associated with schizophrenia and BPAD, accounts for some of the linkage signal in the region. In order to detect additional susceptibility genes in the region, we undertook association mapping of a ~7 Mb interval on 13q32-33. Initially, 98 SNPs were genotyped in a sample of 285 families ascertained through probands with BPAD. Family-based association analysis detected nominally-significant signals at 8 SNPs. Some of these results could be spurious, but 3 of the associated SNPs reside in the DOCK9 gene, a Rho-GTPase activator involved in axonal guidance. These SNPs cover the 5flanking region, extending to the first intron of AK127329, and are part of a ~90 kb haplotype block. One of these SNPs significantly partitioned the linkage evidence in this sample. Replication testing in a second sample of 335 families also detected significant evidence of association with BPAD. Subsequently, 16.5 kb of the associated haplotype block were re-sequenced in 24 cases, half of which were derived from 13q-linked families. This detected several novel SNPs and a 5-bp intronic deletion. The deleted allele, initially found only in 13q-linked families, was transmitted in excess to affected offspring, but no SNPs so far appear to be functional. DOCK9 may be one of the genes on 13q that contributes to susceptibility to BPAD.

Epidemiological and genetic survey of hypertension in a Sardinian isolated population. *A. Angius[1,2], M. Fanciulli[2], M. Fattorini[2], V. Cabras[1], M. Adamo[2], D. Serra[2], D. Degli Esposti[3], G. Biino[1,2], M. Pirastu[1,2].* 1) Institute Population Genetics,National Research Council,CA,Italy; 2) SharDNA LifeScience,CA,Italy; 3) Department Internal Medicine,University Bologna,BO,Italy.

The aim of this study was estimate the prevalence of hypertension and to identify the underlying genetic factors in the general population of an isolated village of Sardinia: Talana (~1000 inhabitants). Several lines of evidence indicate that this village has clinical similarity to the European population, while it has more power for genetic analysis than outbred population. Voluntary participants (80%) of the entire population underwent blood tests and a standardized interview collecting demographic information, living habits, clinical and family history. Hypertension was defined as SBP 140 and DBP 90 mmHg or current treatment for hypertension. SBP and DBP were normally distributed with average of 13520 and 8010 mmHg respectively and 26%; of the adult population of Talana was affected by hypertension. The epidemiological survey highlighted the association of the same clinical and environmental factors which were found in different populations. Eight multigenerational pedigrees, that consisted of 332 total individuals of whom 67 were affected, were constructed. The majority of the extant Talana population was genotyped using 1054 markers, which comprehend 50% of the hypertension family members. We reconstructed a genetic map using the frequencies estimated on the entire population. GWS was performed by a non-parametric analysis using SIMWALK2. We confirmed the previously described locus on chr 2 (-log10(P):3.872) and identified 8 additional loci with suggestive significance on chr 3, 4, 10, 14, 18, 19, 20 and 22. Increasing the number of markers we confirmed the loci on chromosome 18 (-log10(P): 2,97), 20 (-log10(P):2,41) and 22 (-log10(P):4). We replicated some of results in a nearby isolated village with different founders and low genetic exchange with Talana, confirming loci on chr 18 and 20, which were previously described in different populations. We are currently investigating these loci with high density SNPs map taking advantage of the extended linkage disequilibrium in our population.

Differential liabilities of rare coding and common non-coding *RET* mutations explain the multifactorial genetics of Hirschsprung Disease. *E. Emison, A. Rea, A. Chakravarti.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Hirschsprung aganglionosis (HSCR) is a non-Mendelian birth defect that affects four times as many males as females; mutations are known in 8 genes (*ECE1*, *EDN3*, *EDNRB*, *GDNF*, *NRTN*, *RET*, *SOX10*, *ZFHX1B*). The pathognomonic hallmark of HSCR is the absence of neural-crest cell-derived enteric ganglia along variable segments of the gut. In the mouse, several genes encoding key proteins involved in neural crest development, including those with HSCR mutations, have peak expression in the developing gut at 13.5 dpc, coincident with the peak migration of neural crest-derived neuronal precursors in the hindgut. We utilized this biological feature to identify new genes with identical features within mapped human HSCR loci to assess whether they contribute to HSCR risk.

Our family-based linkage studies have revealed three contributory loci (3p21, 9q31 and 19q12) where the disease genes have yet to be elucidated. To identify HSCR genes at 3p21, we have interrogated expression of all known and predicted genes within the orthologous region on mouse chr14. A total of 62 known and predicted protein-encoding genes were identified in the relevant 10 Mb interval. Expression profiles for each of these transcripts were determined in RNA isolated from a panel of 42 gender-identified pre- and post-natal mouse tissues. Duplicate male and female samples were analyzed for a total of 168 tissue samples. In parallel, expression profiles of 17 transcripts which encode proteins known to be involved in the development of the neural crest were determined. Patterns of temporal and spatial expression of the chromosome 3 orthologs in comparison with patterns of expression for genes known to be involved in the development and establishment of the neural crest have been used for predicting candidate genes. Further, as HSCR is more prevalent in males than females, we are assessing whether genes known to be involved in neural crest development are differentially expressed in the developing male and female embryos.

A multi-pronged approach to association testing for body mass index in the 3q27 region, guided by prior probability. *H. Lyon[1], X. Zhu[2], R. Cooper[2], X. Wu[2], J. Drake[1,3], T. Bersaglieri[1], M. Egyud[1], J. Hirschhorn[1,3].* 1) Div of Genetics, Boston Children's Hosp, Boston, MA; 2) Dept of Prev Med and Epidemiology, Loyola Univ, Maywood, IL; 3) Broad Inst, Harvard and MIT, Cambridge, MA.

Obesity in African-Americans is increasing rapidly and is co-morbid with hypertension, diabetes and heart disease. Linkage analysis has identified the 3q27 region as an obesity QTL in African-Americans. We are using multiple approaches to test variants with the highest prior probability of being associated with BMI: SNPs in candidate genes, SNPs predicted to affect protein function, or SNPs in LD with many other SNPs in the region. Specifically, we are (1) selecting and genotyping tag SNPs in 11 candidate genes; (2) genotyping all known missense SNPs, and (3) using an LD-based approach to survey as much of the region as possible by genotyping ~1,000 of the most informative SNPs - those that are proxies for the largest number of other variants in the region. These three sets of SNPs are being tested for association by genotyping them in a cohort of 1007 African-Americans (572 women, 435 men). **For (1), candidate genes** were chosen based on involvement in a metabolic pathway: ACDC, GHSR, PLD1, TLOC1, PRKCI, SERPINI1, BCHE, SKIL, TNFSF10, GLUT2, CLDN11. To select tag SNPs for these genes, we genotyped a dense set of SNPs (1 SNP per 2 kb) in a random trio panel drawn from our African-American population. By also genotyping these SNPs in the Yoruba and CEPH HapMap samples, we found that HapMap data will be adequate to select tag SNPs that are informative in our African-American sample. **For (2), missense SNPs** were identified by applying custom annotation software to UCSC genome browser tables. **For (3), informative SNPs** for the LD approach were chosen based on LD patterns from the Yoruba cohort; we chose the SNPs that tagged the largest number of proxies based on a pairwise measure of LD (r^2). We estimate that this set of ~1,000 SNPs captures about a quarter of the estimated 50,000-100,000 common variants in the 30Mb region, and thus serves as an efficient first pass. This LD-based approach can be generally applied to complement candidate gene and missense SNP-based strategies in association studies.

Contribution of sequence variation within the ABCG1 gene to bipolar disorder and suicidal behaviour. *S. Deutsch[1], C. Buresi[2], M.L. Samolyk[2], C. Gehrig[1], E. Neidhart[2], M. Gagnebin[1], S.E. Antonarakis[1], A. Malafosse[2].* 1) Dept of Genetic Medecine and Development, University of Geneva, Geneva, Switzerland; 2) Dept of Psychiatry, University of Geneva, Geneva, Switzerland.

Independent studies have demonstrated the involvement of a locus on chromosome 21q22.3 in the etiology of bipolar affective disorder (BPAD). Here we investigate the contribution of the ABCG1 gene, an ATP-binding cassette (ABC) transporter located within the HSA21 candidate region, in conferring susceptibility to BPAD and other related mood disorders. Our cohort for case-control association studies consisted of 330 controls and 950 affected subjects, who were diagnosed on the basis of DSM-IV criteria and included individuals with unipolar and bipolar disorder, as well as subjects with a history of suicide attempts. Six SNPs distributed across the ABCG1 gene, which were selected on the basis of pairwise LD values, were screened in all subjects. No significant association was detected when comparing genotypic distributions of control subjects versus all affected patients, or versus bipolar patients for any of the SNPs studied. However, significant associations were observed for a SNP located in the 3UTR of the gene (rs1044317) when comparing genotype frequencies of controls to subjects with a history of violent suicide attempts (p=0.005). A second SNP (rs2234719) located in intron 6 of the gene was also marginally associated to violent suicidal behaviour (p=0.05). Since no coding SNP in ABCG1 was identified, we hypothesised that associated SNPs might act by modifying the levels of ABCG1 mRNA. To test this hypothesis, we measured ABCG1 expression levels in cDNAs from lymphoblastoid cell lines of 40 unrelated individuals by Taqman qPCR. Significant differences in gene expression were observed, and Kruskall-Wallis analysis showed that SNP (rs2234719) was associated with ABCG1 mRNA levels (p=0.003). We conclude that ABCG1 polymorphisms contribute to susceptibility to violent suicidal behaviour, and that at least some of this contribution is mediated by modifying the expression of ABCG1. Additional studies are in progress to further characterise the functional nature of the sequence variants studied.

Replicated association of a functional promoter variant at the serotonin 1A receptor locus with autism. *L. Jiang, R.J. Delahanty, J.S. Sutcliffe.* Center for Human Genetics Research, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Autism is a neurodevelopmental disorder exhibiting deficiencies in development and use of language and social interactions, in addition to patterns of repetitive, restricted and stereotyped behaviors and interests, and resistance to change in environment and daily routines. Abnormalities of serotonergic regulation have been long speculated as an etiological factor in autism given findings of a heritable elevation of circulating 5-HT in ~25% of subjects, efficacy of selective serotonin reuptake inhibitors (SSRIs) in treating repetitive, rigid and compulsive behaviors and anxiety, and increased symptom severity following tryptophan depletion. We recently showed that allelic heterogenetity at the serotonin transporter (SERT) locus (SLC6A4) suggests it represents an autism susceptibility gene. The 5-HT_{1A} receptor is another critical regulator of central serotonergic function, as it acts both postsynaptically and presynaptically as a somatodendritic autoregulatory receptor. To explore the potential for genetic risk alleles to exist at this locus, we identified and genotyped a series of single nucleotide polymorphisms (SNPs) in a dataset of 384 combined multiplex (327) and parent-child trio (57) families. Analysis of linkage disequilibrium (LD), consistent with data from the HapMap Project, revealed that this locus resides in an expansive ~500kb block of LD in 5q11.2. Tests of allelic association showed significant male-specific association at several SNPs when considering paternal transmissions. One marker represents a functional promoter polymorphism, and the associated allele ($P=0.01$) results in partial loss of transcriptional repression and has been linked to depression, suicide, poorer SSRI treatment response, and other phenotypes. An infrequent nonsynonymous variant was also associated. A replication analysis in a sample of 262 independent families revealed a more significant overall association ($P<0.005$) and a nominal parent-of-origin effect with the same markers. These results strongly suggest a role for HTR1A in genetic risk for autism spectrum disorders.

The integrin 3 locus (ITGB3) confers genetic risk for autism. *R.J. Delahanty, L. Jiang, J.S. Sutcliffe.* Center for Human Genetics Research, Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Autism is a neurobehavioral phenotype involving abnormalities in the development of language and social relationships, and repetitive, rigid and compulsive behaviors and resistance to change. Proximal chromosome 17q is implicated as harboring significant male-biased genetic effect(s) in autism, based on linkage studies by the Autism Genetics Resource Exchange (AGRE) Consortium, the International Molecular Genetic Study of Autism Consortium (IMGSAC), and our group. Evidence for association at the serotonin transporter (SERT) locus (SLC6A4) is mixed, although increasingly reports suggest involvement of the short allele at the insertion/deletion promoter variant (HTTLPR). We recently identified a number of rare coding and noncoding variants at SLC6A4 that suggesting it is a risk locus for autism under an allelic heterogeneity model. This may explain inconsistent reports of association in the presence of highly significant linkage in this region. Careful examination of the linkage data on 17q strongly suggests that SLC6A4 is not the only main effect locus in 17q. A candidate for the second locus is ITGB3, recently shown to represent a male quantitative trait locus (QTL) for circulating serotonin (5-HT). Because 5-HT is elevated in ~25% of subjects with autism, we examined ITGB3 for evidence of contribution to genetic risk for autism. Linkage disequilibrium across the locus was evaluated, and markers representing common alleles were selected. We included a nonsynonymous (Pro33Leu) SNP, shown to associate with 5-HT levels. Analysis in a dataset of 643 predominantly multiplex families from Vanderbilt, AGRE, and other groups in the NIMH Repository revealed significant overall association to the Pro33Leu SNP (P=0.0026), but not other common alleles tested. Surprisingly, no significant association was detected when solely examining transmissions to males, or transmissions in families with only affected males. These data support a role for ITGB3 in autism susceptibility, suggest that this coding variant may exhibit dysfunctional properties, and that ITGB3 is very likely to represent the second locus contributing to highly significant linkage in proximal 17q.

High-throughput candidate gene screening for dyslexia susceptibility genes on chromosome 18p11-q21. *T. Scerri[1], A. Morris[1], J. Stein[2], A.P. Monaco[1].* 1) Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, United Kingdom; 2) Department of Physiology, Oxford, OX1 3PT, United Kingdom.

Developmental dyslexia (DD) is a specific and significant impairment in reading ability despite adequate educational opportunity and intelligence, and is diagnosed in ~5% of school-aged children. We first reported linkage of a DD quantitative trait locus (QTL) at 18p11.2 in three large independent family samples from the UK and US, and have since identified a second DD QTL at 18q12.2. These 2 loci together cover ~40Mb of genetic material and contain over 200 genes. We have embarked on a gene-based, high-density SNP genotyping and association study to identify the DD susceptibility variants on chromosome 18.

We used genotype data of the CEPH families from the HapMap project to evaluate the distribution of linkage disequilibrium (LD) and haplotype blocks across the ~40Mb region. We selected haplotype-tagging SNPs using Haploview (with the Gabriel algorithm) from blocks overlapping all known genes and their putative regulatory elements, thereby reducing the amount of genotyping required and capturing the majority of common variation in ~80% of these gene regions. Following power calculations to maximize efficiency, we genotyped 1492 SNPs at 18p11-q21, and a further 44 unlinked SNPs for inheritance checking and stratification purposes, using the GoldenGate assay, on a sample of 960 individuals that includes 192 sex- and population-matched controls, and 188 nuclear UK families each containing a proband with severe dyslexia.

Preliminary bioinformatic analysis has been carried out on the LD block and gap sizes, and intragenic haplotype tagging efficiency. Sample and SNP genotyping success rates are both at least 97%. Analysis will be performed on haplotypes within each block using both family-based and case-control association tests, and the results presented.

Linkage and association of SLC11A1 and tuberculosis. *C.D. Hamilton, W.F. Hulme, L. Zhang, S.G. Patillo, C.A. Linton, R.M. Carney, A.W. Mosher, J.R. Gilbert, W.K. Scott.* Dept. of Medicine, Duke Univ. Medical Center, Durham, NC.

Tuberculosis (TB) is a significant cause of premature mortality worldwide. 10% of exposed individuals develop pulmonary TB, suggesting that host factors, partly under genetic control, determine development of active TB. SLC11A1 (formerly NRAMP1) was linked to TB in a Canadian aboriginal family and associated with TB in Africans, Asians, and North American whites. SLC11A1 is an ion transporter that influences the intracellular environment, potentially affecting *M. tuberculosis* replication. We examined nine markers in SLC11A1 for linkage and association with TB in a family-based study of 477 individuals from 229 families (143 African-American and 76 white). Individuals older than 14 years with culture-confirmed pulmonary TB and children younger than 14 years with culture- or clinically-confirmed TB reported to the NC or SC TB control programs from 1992-2005 were enrolled along with unaffected sibling or parental controls. FASTLINK was used to analyze 23 multiplex families for linkage. Suggestive linkage was obtained at G249G (lod=1.7,=0). Family-based tests of association were conducted in each ethnic group using APL. Of the four markers associated with TB in other studies, only rs3731865 (intron 4) was significantly associated with TB in the African-American sample (p=0.02). In whites, two 3' UTR markers were associated with TB: rs1059823 (p=0.007) and rs13062 (p=0.04). These results are novel to this sample. None of these three SNPs has a known function. Contrary to prior studies, no association was detected with the 5'(GT)n promoter polymorphism associated with lower expression of SLC11A1, the rare coding variant in exon 15 (D543N) or the 3' TGTG ins/del polymorphism. Consistent with previous studies, markers in the 5' and 3' ends of SLC11A1 are independently associated with TB. In this sample, association in African-Americans is restricted to intron 4, and association in whites is limited to the 3'UTR. The patterns of association in this study, compared to prior studies, suggest that the functional variants in SLC11A1 that increase susceptibility to pulmonary TB remain to be discovered and may differ by ethnicity.

Objective prioritization of positional candidate genes at a QTL for pre-eclampsia on 2q22. *E. Moses[1], E. Fitzpatrick[2], K. Freed[2], S. Forrest[3], T. Dyer[1], J. Blangero[1], S. Brennecke[2].* 1) Dept Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Dept Perinatal Medicine & University of Melbourne Dept of Obstetrics & Gynaecology, Royal Women's Hospital, Melbourne, Australia; 3) Australian Genome Research Facility, Melbourne, Australia.

Pre-eclampsia/eclampsia (PE/E) is the most common and serious disorder of human pregnancy. While the familial association of PE/E has been recognized for decades the genetics are complex and poorly understood. In an attempt to identify PE/E susceptibility genes we embarked on a positional cloning strategy using 34 Australian & New Zealand PE/E pedigrees in which the estimated heritability is 0.647 0.168. An initial 10 cM resolution genome scan revealed a putative susceptibility locus spanning a broad region on chromosome 2 that overlaps an independent linkage signal seen in Icelandic PE pedigrees. We have now genotyped an additional 25 STR markers in this region and used a variance components-based linkage approach to perform multipoint linkage analysis on this dataset. Under the strict diagnosis of PE, we obtained significant evidence of linkage on 2q with a peak LOD score of 3.43 near marker D2S151 at 155 cM. To prioritize positional candidate genes at this QTL for detailed analysis, we have applied an objective prioritization strategy that integrates quantitative bioinformatics, assessment of differential gene expression and SNP association/LD analyses. Our bioinformatics tool assigned the highest priority to the activin receptor gene ACVR2. This gene also showed greater than 10-fold differential gene expression in human decidual tissue from normotensive and PE individuals. We genotyped five known SNPs in this gene in our cohort of 34 PE/E pedigrees and performed tests for association and LD using the QTDT test. One SNP (rs1424954) showed strong preliminary evidence of association with PE ($p = 0.007$) while two others (rs1364658 and rs1895694) exhibited nominal evidence ($p < 0.05$). There was evidence of weak LD among these SNPs. The highest observed LD occurs amongst the three associated SNPs suggesting that the observed signals may be the signature of an observed functional variant.

Cluster Rank Analysis provides evidence for mitochondrial inheritance of presbycusis. *D.L. Newman[1], K.D. Raish[1], L.E. Edsall[1], C.M. Witkowski[1], D.R. Frisina[2], P.A. Shipman[1], M.V. Osier[1].* 1) Dept Bio Sci, Rochester Inst Tech, Rochester, NY; 2) Internatl Ctr for Hearing & Speech Research, Rochester, NY.

The genetic basis of human presbycusis (age-related hearing loss) is unknown. This common disorder is characterized by inability to understand speech, particularly in noisy backgrounds. Audiograms of presbycusics show sloping hearing loss, with greatest deficiencies at the highest frequencies, and over time an individuals hearing loss progresses into the lower frequencies that are more important for understanding speech. We hypothesized that the mitochondrial genome plays a role in presbycusis susceptibility, based on previous research that showed a greater correlation of presbycusis for mothers and their children than for fathers and their children (Gates et al. 1999; Marietta et al. 2004). We sequenced the hypervariable region (HVRI&II) of the mitochondrial genome for >200 subjects aged 58 and older who were extensively characterized for their hearing abilities. We used a novel method, Cluster Rank Analysis (CRA) to explore correlations between phenotypic and genotypic data. HVRI&II sequences for each individual were taken as the independent variable, and distances between the values were used to generate a UPGMA tree. Values from each of several dependent variables (quantitative measures of hearing ability) were then assigned to the appropriate node of the tree. Phenotypes included pure tone thresholds from 500 to 20,000 Hz, pure tone averages (PTA1-4), speech reception thresholds, and otoacoustic emissions (DPOAE, TEOAE) for each ear, as well as binaural speech comprehension. The identical tree was identified in which the ranks, from left to right, were ordered to maximize a rank statistic (e.g. Spearman Rank Correlation). The rank statistic for each dependent variable was determined and the list of variables sorted based on the rank statistic. We found that the high frequency thresholds were strongly correlated with position on the tree (Spearman correlation of 0.72-0.88). This result supports the hypothesis that a mitochondrial factor influences the development of presbycusis. Future studies will follow up on mitochondrial lineages to identify causative mutations.

Oxidative stress candidate genes and mitochondrial haplogroup analyses in multiple sclerosis. *J. Hart[1], J.M. van der Walt[1], J. DiPiero[1], J. Rimmler[1], S. Schmidt[1], S. Gregory[1], N. Schnetz-Boutaud[2], S.J. Kenealy[2], M.A. Pericak-Vance[1], J.L. Haines[2].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Reactive oxygen species (ROS)generated within brain tissue can lead to the damaging oxidation of lipids, proteins and DNA. Accumulation of this damage (oxidative stress) can lead to disease pathogenesis if cells are unable to eliminate ROS agents through the antioxidant defense system. Several lines of evidence have implicated oxidative stress and mitochondrial dysfunction in the etiology of multiple sclerosis (MS). We tested whether mtDNA SNPs or nuclear SNPs within oxidative response genes influence MS risk. We genotyped 10 SNPs that define the Caucasian haplogroups in cases (n=469) and age-matched Caucasian controls (n=463). We did not observe any significant difference of any mtDNA allele frequency or haplogroup between cases versus controls. We then selected a set of oxidative stress candidate genes to test for association with MS risk which included: solute carrier 11A1 (SLC11A1), heme oxygenase 1 (HMOX1), glutathione reductase 1&2 (GSTO1,GSTO2). In this preliminary analysis, 5-7 SNPs were genotyped in 842 families and 636 discordant sib-pairs. Family-based tests (PDT, APL) were used to test whether SNPs in these genes influence risk of MS overall or in subsets stratified by HLA-DR2pos or HLA-DR2neg. Both APL and PDT results demonstrated that one SNP(rs743811) within HMOX1 influences risk of MS in the DRpos; set (p=0.03). All other SNPs tested were not significant. However, a second SNP (rs73777) located in an adjacent gene (MCM5)also showed significant association with MS risk in the overall dataset (p=0.01). These two SNPs were in strong linkage disequilibrium (D=0.99). Our results indicate that Caucasian haplogroup defining SNPs do not influence risk of MS. However, two markers in strong LD located in HMOX1 and MCM5 genes influence risk of MS in our family-based study. Since HMOX1 is upregulated in brain tissue under oxidative stress, we intend to pursue this candidate gene for further study.

MTND1*LHON4216C, a secondary Lebers Hereditary Optic Neuropathy polymorphism, and age-related macular degeneration (AMD): A report of an age-matched case-control study. *J.A. Canter[1], M.A. Pericak-Vance[2], M.A. Hauser[2], S. Schmidt[2], W.K. Scott[2], P. Gallins[2], K.L. Spencer[1], S.Y. Kwan[2], M. Noureddine[2], J.R. Gilbert[2], N. Schnetz-Boutard[1], A. Agarwal[1], E.A. Postel[2], L.M. Olsen[1], J.L. Haines[1].* 1) Vanderbilt University Medical Center, Nashville, TN; 2) Duke University Medical Center, Durham, NC.

Age-related macular degeneration (AMD) is the leading cause of severe, irreversible vision loss in white persons over age 50. MTND1*LHON4216C alters a key subunit of Complex I in the mitochondrial electron transport chain and has been implicated in several neurodegenerative disorders, including an association with Leber's Hereditary Optic Neuropathy. We hypothesized that this variant is also risk factor for AMD. While age is a key risk factor in the development of AMD, the MTND1*LHON4216C polymorphism may also impact longevity either directly or via linkage with other mitochondrial polymorphisms. Due to the importance of age in predicting risk of AMD, we devised a matching strategy that matched on age at time of examination and optimized inclusion of cases and controls. Among 246 extensively evaluated cases (defined as stage 3, 4, or 5 AMD) and 116 controls, we age- and race-matched 103 pairs of subjects (exclusively white) for this analysis. Of these pairs, 74 (72%) were matched on the exact age at time of examination. The mean age at examination for the group was 67.9 years. Cases were on average 3 years older than controls. Fifteen of 103 (14.6%) had the MTND1*LHON4216C variant, while only 5/103 (4.9%) of controls had this variant (OR 3.34, 95% CI 1.09-12.17, p=0.02). Cases and controls were not statistically different with regard to age at examination, gender, or cigarette smoking. MTND1*LHON4216C remained an independent predictor of AMD after adjustment for both complement factor H (CFH) Y402H status and smoking status using logistic regression analysis (OR 3.02, 95% CI 1.04-8.73). No interaction was observed between MTND1*LHON4216C and the CFH Y402H variant. These results suggest a role for the MTND1*LHON4216C variant in susceptibility to AMD directly or by its association with other polymorphisms in the TJ mitochondrial cluster.

Endostatin T48 variant has an impaired affinity to basement membrane components. *O.T. Suzuki[1,2], H. Tu[3], T. Pihlajaniemi[3], P.H. Godoi[4], G. Oliva[4], B.R. Olsen[5], M.R. Passos-Bueno[1,2].* 1) Centro de Estudos do Genoma Humano; 2) Instituto de Biociências, Universidade de São Paulo, Brazil; 3) Collagen Research Unit, Biocenter and Department of Medical Biochemistry and Molecular Biology, University of Oulu; 4) Instituto de Física de São Carlos, USP, São Carlos; 5) Department of Cell Biology, Harvard Medical School, Boston.

Angiogenesis is a process involved in numerous diseases, such as cancer, rheumatoid arthritis and diabetic retinopathy. Endostatin (ES), a proteolytic cleavage product of the c-terminal domain of type XVIII collagen, is a potent angiogenesis inhibitor that influences endothelial cell proliferation, migration, apoptosis and tube formation. It is an adhesion molecule that binds to several extracellular matrix (ECM) components. Lack of type XVIII collagen causes Knobloch syndrome (KS), an autosomal recessive condition characterized by high myopia, macular abnormalities, vitreoretinal degeneration, retinal detachment and occipital encephalocele. We have suggested through molecular modeling that the polymorphic ES residue change D104N (D1437N) might alter its function and predispose to prostate cancer (2001, *Cancer Res*, 61:7375). Another rare residue change in the ES domain, A48T, was found in homozygosity in only two KS sib patients (Kliemann *et al*., 2003, *Am J Med Genet A*, 119:15) and its relation to the disease is still unknown. We produced recombinant human ES N104 and T48 to evaluated their binding properties to other ECM proteins using ELISA and surface plasmon resonance. Fibronectin, type IV collagen, nidogen, heparin-BSA, laminin-1-nidogen-1 complex, perlecan, and fibulin were tested as ligands. N104 ES did not show a great difference from the wild type protein in its binding to the tested molecules, while the T48 ES revealed a slightly lower but significant affinity to the laminin-1-nidogen-1 complex and fibulin ($P = 0.0017$ and $P = 0.0011$, respectively). Based on the protein interactions studied, the A48T change seems unlikely to result in KS, unless it alters the interaction with a still unknown protein. On the other hand, N104 ES does not seem to significantly impair the function of the protein. FAPESP/CEPID, CNPq.

Alternative Splicing and Sequence Variation in *NRG3*, a Positional Candidate for Schizophrenia. *N. Feng, S. Almashanu, D. Avramopoulos, C. Obie, K. Cheng, M.D. Fallin, A.E. Pulver, D. Valle.* Johns Hopkins School of Medicine, Baltimore, MD.

Neuregulin 1 (*NRG1*) located at 8p22-21 has been implicated in schizophrenia (SZ) in genome-wide scan studies and by studies of an *NRG1* knockout mouse model. NRG1 encodes a single membrane pass plasma membrane protein with an EGF motif in its extracellular N-terminus. Interestingly, an *NRG1* paralog, *NRG3*, maps to 10q22, a region suggested to harbor a SZ susceptibility gene by our linkage studies in Ashkenazi Jewish (AJ) families with SZ (Fallin et al Am J Hum Genet 73: 601, 2003). *NRG3* has structural similarity with *NRG1* with 12 exons distributed over 1.2 Mb of genomic DNA but unlike *NRG1*, its expression is limited to the CNS. To learn more about this positional candidate for SZ, we characterized splice forms of the human *NRG3* and performed molecular screening for sequence variants of *NRG3* in AJ SZ families. Using RT-PCR and subsequent sequencing as well as blast searches of the EST database, we found that *NRG3*, like *NRG1*, has at least 6 splice forms and multiple 5 transcriptional start sites that produce different N-terminal sequences. Interestingly, in both genes, a highly conserved micro exon 3 of two tandem acceptor splice sites in intron 3 encodes a segment of the protein that lies just on the extracellular side of the transmembrane domain, a location that may be important for release of the EGF domain by proteolytic cleavage. Additionally, we sequenced all 12 exons plus 5 conserved non-coding regions and 1000 bp of 5 UTR and proximal promoter of *NRG3* in 15 AJ SZ probands and 6 controls. We identified 6 single nucleotide substitutions including 5 known SNPs (rs478010, rs17101139, rs17101193, rs17101196 and rs2295933) and one novel SNP in the proximal promoter. Of the known *NRG3* SNPs, 2 are synonymous and one is nonsynonymous variant (rs17101193, N576K). We are proceeding to genotype these variants in our collection of approximately 600 AJ SZ patients and 600 AJ and to determine if there is developmental and/or region-specific expression of the *NRG3* splice form.

Mutations in the FGF/FGFR Pathway Play a Role in Nonsyndromic Cleft Lip and Palate. *B. Riley[1], M. Mansilla[1], B. Maher[2], B. Trump[1], E. Russo[1], A. Vieira[1], M. Marazita[2], J. Murray[1].* 1) University of Iowa; 2) University of Pittsburgh.

Isolated or nonsyndromic cleft lip and palate (NS CLP) is a complex multifactorial birth defect resulting from a combination of genetic and environmental factors. We are investigating the contribution of the fibroblast growth factors (FGF) and their receptors (FGFR) to craniofacial development in humans based on their known role in other vertebrate species and hypothesize that mutations in members of this pathway contribute to NS CLP. The following genes have been investigated: FGFR1, FGFR2, FGFR3, FGFRL-1, FGF2, FGF3, FGF4, FGF7, FGF8, FGF9, FGF10, and FGF18. We have used both direct sequencing of the coding regions of these genes in 180 NS CLP patients and linkage/association analysis using 230 multiplex Filipino families. Several likely disease-causing mutations were identified by sequencing, including a nonsense mutation, R609X, identified in a two-generation family from Iowa originally diagnosed with NS CLP. Further contact with this family revealed that the proband developed features of Kallmann syndrome but her father, who also has the R609X genotype, has NS CLP as his only phenotype. Two missense mutations in FGFR1, M369I and E467K, and one missense mutation in FGFR2, R84S, were found in five independent families but were absent in 1400 controls. A missense mutation, D62H, was identified in FGF8, which arose de novo in a child with NS CLP. Finally, in two families with confirmed parentage an obligate loss of an allele was observed for FGF4 suggesting the presence of microdeletions. Association methods have also been used to assess FGF involvement. Genotyping of single nucleotide polymorphisms (SNPs) in the FGF and FGFR candidate genes found significant P-value associations for FGF3, FGF10 and FGF18 with NS CLP. Statistical evidence also supports a gene x gene interaction between FGF10 and FGF18. In the aggregate these complementary methods, direct sequencing and statistical association, support the contribution of the FGF signaling pathway to NS CLP and support additional investigations looking at conserved regulatory regions and evidence for gene x gene interactions to fully establish their role in disease gene etiology.

Excess of structural variants in the neurexin 1b gene in patients with autism. *J. Yan[1], J. Feng[1], A. Bockholt[1], C. Yang[1], W. Song[1], E. Cook, Jr.[2], C. Skinner[3], R. Schroer[3], C. Schwartz[3], S. Sommer[1].* 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) Dept Psychiatry, University of Chicago, Chicago IL; 3) J.C. Self Research Institute, The Greenwood Genetic Center, Greenwood, SC.

Autism is a complex developmental disorder that is characterized by deficits in social interaction and communication and by restricted and stereotyped patterns of behavior. Neuroligins are postsynaptic membrane cell-adhesion molecules which bind to b-neurexins, a family of proteins that act as neuronal cell surface receptors. Recently, mutations in the neuroligin 3 (NLGN3) and neuroligin 4 gene (NLGN4) were identified in patients with autism or mental retardation. To explore the possibility that structural variants in the b-neurexin genes could predispose to autism, the coding regions and associated splice junctions of three b-neurexin genes were scanned with DOVAM-S (Detection of Virtually All Mutations-SSCP) in 24 Caucasian patients with autism. In addition, segments of the neurexin 1b gene were sequenced in 229 additional Caucasian patients with autism. Four putative structural variants (two missense variants and two in-frame insertions) were identified in the neurexin 1b gene in six Caucasian patients with autism and not in 291 healthy Caucasian controls (6/253 vs 0/291, P=0.01). Initial family data suggest that incomplete penetrance may occur. In addition, no structural variant was found in the neurexin 2b gene and one rare structural variant was found in the neurexin 3b gene. In the context of all available data, we conclude that mutations of the neurexin 1b gene may contribute to autism susceptibility.

Serotonin transporter polymorphism and SSRI-induced nausea. *E. Peet[1], S.B. Manuck[1], R.E. Ferrell[2], M.F. Muldoon[1], J.D. Flory[1].* 1) Psychology, Univ Pittsburgh, Pittsburgh, PA; 2) Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Background: Recent studies have examined possible associations between serotonin regulating polymorphisms, including common variation in the promoter region of the serotonin transporter gene (5-HTTLPR), and incidence of side effects in patients treated clinically with selective serotonin reuptake inhibitors (SSRIs). Here, we investigated the association between 5-HTTLPR genotypes and nausea induced by acute SSRI administration in a non-patient sample. Methods: 232 community volunteers (137 male, 95 female); ages 30-55 (msd: 45 6.5) were administered intravenously a weight-adjusted dose of the SSRI Citalopram (.33mg/kg lean body mass). Subjects reported presence or absence of nausea at t = +30, +60, +90, and +150 minutes post-infusion. Chi-square tests were used to compare nausea+/- groups by genotype of the 5-HTTLPR length polymorphism [(long/long + long/short) vs short/short alleles]. Plasma Citalopram levels were measured at t = +30, +45, and +90. Results: The highest incidence (n = 52) of nausea occurred at t = +60. Mean plasma Citalopram levels did not differ between nausea +/- groups at t = +30(p = .43), +45(p = .69), or +90(p = .83), nor did Citalopram levels vary significantly by genotype at t = +30(p = .72), +45(p = .34), or +90(p = .40). 5-HTTLPR genotypes did not differ in frequency by sex (p = .92). Nausea tended to be reported by a greater proportion of subjects carrying any long allele, relative to short/short homozygotes (25% any *l* vs. 14% *s/s*), (p = .08). Because more women reported nausea than men (p = .03), sex-specific analyses were also conducted. No effect of the 5-HTTLPR genotype was found in men, whereas nausea was reported in a significantly greater proportion of women carrying the *l* allele group (35% any *l* vs. 13% *s/s*), (p = .047). Conclusions: In women, but not men, nausea is more likely to occur in individuals carrying either one or two copies of the 5-HTTLPR *l* allele 60 minutes after administration of IV Citalopram. These findings may have implications for treatment adherence to commonly prescribed reuptake inhibitors. Supported by NIH Grants HL-40962 and HL-65137.

Genome-wide scan for genetic markers associated with severe cutaneous adverse reactions. *S.I. Hung[1], W.H. Chung[1, 2], W.H. Fan[1], C.H. Chen[1], C.S.J. Fann[1], J.Y. Wu[1], Y.T. Chen[1].* 1) Inst. Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Dermatology, Chang Gung Memorial Hospital, Taipei, Taiwan.

Carbamazepine (CBZ) and allopurinol are commonly prescribed medication for seizure and gout/hyperuricemia, respectively. They are also frequent causes of severe cutaneous adverse reactions (SCAR), which include the drug hypersensitivity syndrome (HSS), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). Despite the treatment, these adverse events still carry significant morbidity and mortality. Using candidate gene approach, we previously identified genetic markers strongly associated with CBZ-induced SJS/TEN and allopurinol-SCAR; specifically, HLA-B*1502 is associated with CBZ-SJS/TEN (Nature, 428:486, 2004) and HLA-B*5801 with allopurinol-SCAR (PNAS, 102:4134-9, 2005). In this study, we carried out a genome-wide scan using Affymetrix GeneChip Human Mapping 100K set in a case-control association study to identify additional markers/susceptibility genes other than HLA-B molecules which might predispose these individuals to the SCAR. Using 56 cases/54 controls for CBZ-SJS/TEN and 60 cases/89 controls for allopurinol-SCAR, we confirmed the previous observation that the most significant association was observed in the SNPs of the HLA-B regions on chromosome 6 (p value for allopurinol-SCAR: 9.28x10(-9); p value for CBZ-SJS/TEN: 6.91x10(-13)). In addition, we found clustering of SNPs located between cysteine and tyrosine-rich 1 (CYYR1) gene and a disintegrin and metalloprotease with thrombospondin motifs-1 (ADAMTS1) gene on chromosome 21 were strongly associated with allopurinol-SCAR (p value=9.87x10(-6)). These genetic markers provide a plausible basis for the development of such a test to identify individuals at risk for these life-threatening conditions induced by drugs, as well as point out the direction of research for an increased understanding of the pathogenesis of these clinical syndromes.

Investigation of serotonin related genes in antidepressant response. *E.J. Peters[1], J.B. Kraft[1], S.L. Slager[2], G.D. Jenkins[2], M.S. Reinalda[2], P.J. McGrath[3], S.P. Hamilton[1].* 1) Department of Psychiatry, University of California, San Francisco; 2) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) New York State Psychiatric Institute and Columbia University.

The large inter-individual variability seen in patient response to antidepressant medication is thought to be influenced at least in part by DNA variation. Selective Serotonin Reuptake Inhibitors (SSRIs) act by antagonizing the serotonin transporter, however, the delay in therapeutic response suggests other mechanisms or regulatory events are necessary for a response phenotype to occur. In a previous pilot study in a patient population with major depression (N=96) taking the Selective Serotonin Reuptake Inhibitor (SSRI) fluoxetine, we investigated 93 publicly available SNP markers in six serotonin pathway genes (HTR1A, HTR2A, HTR2C, TPH1, TPH2 and MAOA). Variants in the 5 region of TPH1 were associated with categorical response and variants in HTR2A and TPH2 were associated with response specificity (p=0.02-0.04, OR=2.3-2.9). In order to uncover unknown variants and select maximally informative tagging SNPs, we resequenced all exons, intron-exon boundaries, and 5 conserved non-coding sequence of these six genes in our pilot population. Based on the linkage disequilibrium patterns of these SNPs (N=188), we chose 46 tagging SNPs in these six genes, which are currently being genotyped in a larger study population (N=1,953) of patients with major depression taking the SSRI citalopram. This population is a subset of a larger study investigating treatment options for patients with major depression (STARD). Genotyping is being performed using a combination of single base extension with fluorescence polarization detection (FP-TDI) and multiplexed oligonucleotide ligation assay. Our initial results indicate that the His-Tyr variant in the HTR2A gene is not associated with categorical response to citalopram (p>0.1). Results from the other tagging SNPs in these six genes will be presented, as well as data from additional serotonin pathway genes utilizing tagging SNPs selected from HapMap data.

Preliminary Pharmacogenetic Analysis of Gene Expression in Major Depressives Treated with Citalopram. *F. Mamdani[1], A. Sequeira[1], J. ffrench-Mullen[2], B. Moltrecht[1], S. Wilder[1], G. Turecki[1].* 1) McGill Group for Suicide Studies, Douglas Hospital Research Centre, McGill University, Montréal, Quebec, Canada; 2) GeneLogic Inc., Gaithersburg, Maryland, USA.

Major depression (MD) is a psychiatric disorder that affects 5-10% of the population and is considered the second leading cause of disability by the World Health Organization. Several studies have indicated the involvement of genetic factors in MD, which may also play a role in a patients response to antidepressant treatment. In order to identify gene targets that may mediate response to Citalopram (CIT) treatment, a commonly used SSRI (selective serotonin reuptake inhibitor) antidepressant, we are conducting a large-scale gene expression study of patients being administered CIT for 8 weeks, with Affymetrix U-133 microarrays being performed pre- and post-treatment. We are presenting preliminary results on 13 cases. Outlier detection was performed using several quality control variables and principal component analysis. Differential expression analysis resulted in 297 genes having altered expression between pre and post-treatment samples. Interestingly, our preliminary analysis indicates the possibility of a gender effect, which is not surprising given gender differences in MD prevalence rates. Gene ontology analysis of differentially expressed genes revealed several biological processes being affected by treatment; these include genes involved in regulation, biosynthesis and metabolism of macromolecules and proteins, as well as, transcription and response to stress. Our results suggest that there appears to be differential expression following CIT treatment and these differences may be correlated to treatment response.

A retrospective pharmacogenetic analysis of polymorphisms in the OATP-C gene in XUO320 ALERT trial. *J.Z. Gu[1], E. Leroy[1], C. Hurwitz[1], G. Bermann[2], M. Bortolini[2], H. Holdaas[3], B. Fellström[3], A. Jardine[3], J. Meyer[1].* 1) Biomarker Development, Novartis Pharmaceuticals, Cambridge, MA; 2) Clinical Research, Novartis Pharmaceuticals, Basel, Switzerland; 3) Rikshospitalet, Oslo, Norway.

Statins are highly efficacious in lowering plasma levels of low-density lipoprotein cholesterol (LDL-C). Large scale clinical trials have demonstrated significant inter-individual variability in LDL-C reduction in response to statin treatment. Recently a pharmacogenetic effect has been demonstrated for variations in 3-hydroxy-3 methylglutaril coenzyme A reductase (HMGCR, Chasman et al., 2004), with an association between several SNPs in that gene and efficacy of pravastatin therapy. As the hepatic uptake of statins is at least partially dependent on a membrane transporter OATP-C, we postulated that genetic variation in OATP-C might impact statin bioavailability and therefore influence drug response. Fluvastatin is a synthetic competitive inhibitor of HMGCR for the treatment of hypercholesterolemia. A retrospective pharmacogenetic analysis was conducted in an attempt to evaluate and replicate observed associations between a genetic variation in the OATP-C gene (Slc21A6) and cholesterol parameters in response to fluvastatin in the XUO320 ALERT clinical trial. Specifically, we examined 6 polymorphisms in this gene. Significant associations were seen between A463C (Pro155Thr) in OATP-C and LDL cholesterol and total cholesterol reduction in response to fluvastatin treatment ($p=0.0034$), as reported from the FAME study by Dr. Carrie et al (manuscript in preparation). The LDL-C reduction for the three genotypes are 34% (AA), 23% (AC) and 28% (CC) respectively. To help explain the reason of the heterozygotes having the lowest LDL-C reduction, an analysis of interaction between the use of cyclosporine and LDL-C reduction was carried out. The results did not indicate any association between the use of cyclosporine defined either as dose, trough concentration, or the ratio of dose to trough concentration, and genotype. Moreover, the inclusion of use of cyclosporine as a variable in a model of LDL-C by genotype did not appear to be associated with the observed effect on LDL-C.

CYP2D6 genotype and phenotype determination in a Mexican Mestizo population. *M. Lopez[1], M.E. Alonso[2], J. Guerrero[2], H. Jung[2].* 1) Sistemas Biol, Univ Autonoma Metropolitana, Mexico DF, Mexico; 2) National Institute of Neurology and Neurosurgery Manuel Velasco Suarez, Mexico DF, Mexico.

Objective: Although CYP2D6 genetic polymorphism plays an important role in interindividual and interethnic variability in drug response, very few pharmacogenetic data are available from Hispanic populations, including Mexicans. For this purpose, this study was undertaken to determine CYP2D6 genotype and phenotype in a healthy Mexican Mestizo population. Methods: Two hundred and forty three healthy Mexican Mestizo individuals were genotyped for five CYP2D6 mutant alleles by PCR-RFLP, and duplicated CYP2D6 alleles by long-PCR. Of these, one hundred subjects were also phenotyped using dextromethorphan as the probe drug. Results: The frequency of CYP2D6*2, *3, *4, *10, *17 and duplicated CYP2D6 alleles among 243 genotyped subjects was 21.4%, 1.5%, 11.5%, 14.2%, 2.1% and 6.2%, respectively. Among the 100 phenotyped subjects, we identified ten (10%, 95% confidence interval of 4.12-15.9) individuals as poor metabolizers by using the published antimode for Caucasians. The mean log10 dextromethorphan/dextrorphan ratio of the total sample was -2.05. Of the ten poor metabolizers who were also genotyped, four were homozygous for nonfunctional alleles, and six were heterozygous for CYP2D6 normal and mutant alleles. Conclusions: The population frequency of the CYP2D6 poor metabolizer status in the Mexican Mestizo population studied was estimated to be 10%, which is very similar to Spanish Caucasians. The observed frequency of the CYP2D6 alleles tested was unique for the Mexican Mestizo sample analyzed, and in accordance to the Caucasian, Asian and African admixture in this population. A good correlation between phenotype and genotype was obtained only in poor metabolizers.

Association of the pro-melanin concentrating hormone (PMCH) gene with the body mass index as a side effect of the antipsychotic olanzapine. *Y.C. Chagnon, C. Mérette, J. Lamarche, R.H. Bouchard, M-A. Roy, M. Maziade.* Dept Molecular Psychiatry, Robert-Giffard Research Ctr, Beauport, PQ, Canada.

Introduction.We have reported a linkage at 12q24 with a chronic phenotype of obesity under antipsychotics close to the pro-melanin-concentrating hormone (PMCH) gene. We have tested PMCH for a possible association in humans with the body mass index (BMI; kg/m2) under antipsychotics. **Methods**. A search for single nucleotide polymorphisms (SNP) in the exons/introns of PMCH, and in the 5 and 3 regions has been done in the dbSNP database of the National Center for Biological Information. Two potential intronic SNPs (rs10860843, rs11558437) did not varied in our sample, while SNPs rs7973796 located 5 and rs11111201 at 3 of PMCH showed variation. These SNPs were genotyped in 300 chronically antipsychotic-treated schizophrenic (SZ) patients and 150 controls (CTL). Obese (OB; BMI30 kg/m2), overweight (OW; 25BMI30 kg/m2), and normal weight (NW; BMI25 kg/m2) SZ and CTL were compared for genotype and allele distributions of SNPs by a chi-square analysis, and for mean effect of genotypes on BMI by a variance analysis with age and sex as covariates. **Results**.No significant difference in genotype or allele frequencies were observed between SZ and CTL, or between OB, OW and NW in SZ, while rs7973796 showed a greater frequency (p=0.02) of the common allele in NW of CTL. In variance analysis, age and sex showed no effect on BMI in SZ (0.17p0.82) in contrast to CTL (0.0002p0.01). In SZ taking olanzapine, common homozygote genotype showed a higher BMI for rs7973796 (p=0.05 Duncan's Multiple Range Test) and rs11111201 (p=0.03), in contrast to SZ taking risperidone (p=0.51, 0.62, respectively), or CTL (p=0.35, 0.89, respectively). **Conclusion**.These results suggest that the common alleles of PMCH rs7973796 and rs11111201 SNPs are associated with a greater BMI in olanzapine-treated SZ, and with leanness for rs7973796 in CTL.

Male restricted genetic association of variant R620W in PTPN22 with psoriatic arthritis. *U. Huffmeier[1], H. Burkhardt[2], J. Lascorz[1], B. Bohm[2], J. Lohmann[3], J. Wendler[4], H. Traupe[5], W. Küster[6], A. Reis[1].* 1) Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany; 2) Inst. for Clinical Immunology and Rheumatology, Dept. of Internal Medicine III, University Erlangen-Nuremberg; 3) Psoriasis rehabilitation hospital, Bad Bentheim; 4) Rheumatologische Schwerpunktpraxis, Erlangen; 5) Dept. of Dermatology, University of Münster; 6) TOMESA Clinics, Bad Salzschlirf.

Protein tyrosine phosphatase N22 (PTPN22) is a key regulator of TCR signalling in memory/ effector T lymphocytes. A PTPN22 missense variant (R620W) has been associated with several autoimmune diseases including rheumatoid arthritis (RA). Psoriatic arthritis (PsA) is an inflammatory arthritis that can accompany the skin affection in the common inflammatory disease psoriasis. The observation of phenotypical overlap between RA and PsA and the understanding of psoriasis as a T cell mediated disease lead us to investigate this variant in PsA, as well. We performed a case control study with 375 PsA patients recruited by board certified rheumatologists and 376 healthy controls. When compared to controls no association with susceptibility to PsA was detected. Similarly, association was neither evident when stratifying PsA patients for HLA-Cw6 associated risk allele, nor for clinical criteria such as poly-/ oligoarthritis, erosive joint changes and spinal involvement. In contrast, the proportion of male PsA patients carrying *620W was significantly higher than those in the *620R wild-type group ($p = 0.001$). This difference remained significant even after Bonferroni correction for multiple testing (6 tests, $p = 0.006$). Recently, when using a similar stratification strategy in RA patients, Orozco et al. (2005) also detected a sex specific trend, with males being more prone to carry the risk allele. When we stratified a group of 375 psoriasis vulgaris patients without signs of arthritis we did not find a sex difference regarding association to *620W indicating specificity for joint manifestation in psoriasis. If verified these findings are suggestive of sex-specific effects of *620W on arthritic disease susceptibility.

High affinity nicotine receptor genes in schizophrenia and smoking. *S.H. Voineskos, V. De Luca, N. King, G. Wong, J.L. Kennedy.* Department of Psychiatry, CAMH, Clarke, Toronto, Ontario, Canada.

A number of studies have suggested that polymorphisms in nicotinic receptor genes (CHRNA7, CHRFAM7A, CHRNA4, CHRNB2) in particular the D15S1360 in CHRNA7, are associated with schizophrenia. Schizophrenic patients have a high rate of smoking, usually 75 to 85%. It has been suggested that smoking may be an attempt by schizophrenia patients to self-medicate (Adler et al, 1998), and various studies have explored the possible links between schizophrenia and smoking. The aim of this study is to investigate the role of CHRNA4 and CHRNB2 genes in conferring risk for smoking in schizophrenia. Our sample consisted of 177 DSM-IV patients affected by schizophrenia from the Toronto area. Current smoking status was assessed by medical history questionnaire, and there were 108 smokers and 69 non-smokers. There was no difference in age or ethnicity between the two groups. Our results do not demonstrate a significant association between the CHRNA4 ($p=0.142$) and CHRNB2 ($p=0.994$) genes and schizophrenia smoker versus non-smoker status. On the other hand, we found that male gender is a risk factor for smoking in schizophrenics (chi-sq=6.275; 1df $p=0.012$). Our negative results in genetic analysis might be confounded by the gender effect in our sample. Further study into the relationship between schizophrenia and smoking is warranted and additional markers in CHRNA4 and CHRNB2 genes will be typed to analyse these genes in detail as risk factors for smoking.

Variation in low-density lipoprotein receptor-related protein 5 (LRP5) gene is associated with bone mineral density in men and women. *Y.H. Hsu[1], T. Niu[2], H. Terwedow[1], X. Xu[1], Y. Feng[1], M. Bouxsein[3], X. Xu[1], C. Rosen[4], N. Laird[5], J. Brain[1].* 1) Prog Population Genetics, Harvard Sch Pub Hlth, Boston, MA; 2) Division of Preventive Medicine, Dept. of Medicine, Brigham and Women Hospital, Harvard Medical School, Boston, MA; 3) Beth Israel Deaconess Medical Center, Boston, MA; 4) Maine Center for Osteoporosis Research and Education, St. Joseph Hospital, Bangor, ME; 5) Dept.Biostatistics, Harvard Sch Pub Hlth, Boston, MA.

Objective: To determine the contribution of polymorphisms in the low density lipoprotein receptor-related protein 5 (LRP5) gene to bone mineral density (BMD), and to estimate the risk of osteoporosis. Design: A population-based cohort with 1120 extreme low hip BMD cases or extreme high hip BMD controls was genotyped for 10 SNPs. We further confirmed the results by genotyping 266 offspring and 309 available parents from 160 nuclear families. A family-based association test was used. Haplotype association analysis was performed in both study cohorts. Results: Subjects with the GG genotype of the Q89R polymorphism had a 4.4 times higher risk ($p = 0.009$) of having extreme low hip BMD, and an 18.9 times higher risk ($p<0.0001$) of developing osteoporosis. Significant associations were found in men, premenopausal and postmenopausal women. Subjects with the TT genotype of the A1330V polymorphism had a 3.8 times higher risk ($p = 0.002$) of developing osteoporosis. The association between the Q89R polymorphism and BMD was further confirmed by a family-based association study ($p<0.0001$) and cross-sectional study. Individuals with haplotype G-T-T-C (Q89R - N740N - A1330V - D1363D polymorphism) had a higher risk of extreme low hip BMD and osteoporosis. Conclusions: Using both population-based and family-based association designs, our study demonstrates that genetic variation in the LRP5 gene is significantly associated with BMD in adult men, premenopausal women and postmenopausal women. Polymorphisms in the LRP5 gene are potential risk factors for osteoporosis and also potentially contribute to the normal variance in BMD in healthy adults.

Adipokine gene variants associated with Type 2 Diabetes in the aboriginal Sakha (Yakut) population of Eastern Siberia. *N. Sambuughin[1], F. Platonov[2], P. Ignatiev[2], V. Osakovskiy[2], T. Sivtseva[2], A. de Bantel[1], A. Shatunov[1], V. Krivoshapkin[2], L. Goldfarb[1].* 1) NINDS/NIH, Bethesda, MD; 2) Institute of Health, Yakutsk, Russia.

Adipose tissue produces a variety of bioactive peptides collectively named adipokines; genetic variations in some of the adipokines profoundly affect insulin sensitivity, glucose and lipid metabolism. We studied the frequency of Type 2 Diabetes (T2D)-associated adipokine alleles in an aboriginal Sakha population of Russian Siberia, in which the T2D prevalence has increased 4-fold within the past ten years. The obtained allele frequencies were compared with published data on other Asian populations (Japanese, Chinese, Koreans), Caucasians (French, Dutch, Swedish, Finns), and Africans. The sequence variants within five adipokine genes were screened among 130 Sakha individuals. The H variant at the Y111H amino-acid-altering-polymorphism of Adiponectin was identified in 11.9% of the Sakha vs. 0 in other Asian populations and 0-1.6% in the Caucasians. The C allele of Interleukin 6 (IL6) at the minus 572 G>C polymorphic site of the promoter was detected in 42.5% of the Sakha, while it was present in 25% of the Koreans, 6.7% of Caucasians and 9.5% of the tested Africans. Tumor necrosis factor alpha (TNF) A variant at the minus 308 G>A site of the promoter was found in 16.7% of the Sakha, 1.1 to 7.1% of other Asians, but 18.0 to 22.1% of the studied Caucasians. The frequency of the T2D-associated T variant at position 156 of Resistin is less frequent in the Sakha (13.9%) than the Caucasians (21-23%). Similarly, the A allele at the minus 2549 A>C polymorphic site of the Leptin promoter was seen in 24% of the Sakha and 25.3% of the Chinese, while it was detected in 46.3% of the French population. These important differences in the spectrum of the diabetogenic alleles are likely to influence the genetic susceptibility to T2D and the effectiveness of the existing therapies.

Association of Polymorphisms and Haplotypes in the Glucocorticoid Receptor with Chronic Fatigue Syndrome.

M.S. Rajeevan, A.K. Smith, I. Dimulescu, S.D. Vernon, C. Heim, W.C. Reeves. Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA USA 30333.

Chronic Fatigue Syndrome (CFS) is a significant public health problem of unknown etiology with no identifiable lesions, diagnostic markers or risk factors. Some studies have indicated that deregulation of immune functions and hypothalamic pituitary adrenal (HPA) axis may be associated with CFS. Family, twin, and case-control studies support a genetic contribution to CFS. Based on these observations, we hypothesize that sequence variations in genes regulating immune functions and HPA axis are significant risk factors of CFS. Since glucocorticoid receptor is a major effector of HPA axis through cortisol signaling, we examined the association of sequence variations in glucocorticoid receptor gene (NR3C1) with CFS. Subjects came from an ongoing in-hospital study of clinical characteristics of CFS, and were identified from the general population of Wichita, Kansas. We evaluated 145 participants in the study (43 with CFS, 59 with non-syndromic unexplained chronic fatigue, and 43 non-fatigued controls). Multiple SNPs (cut off, minor allelic frequency >10%) were selected by the Applied Biosystems (ABI) SNPbrowser 2.0, and genotyping was done using the validated TaqMan genotyping assay kits from ABI. Genotyping assays used DNA amplified by the GenomiPhi DNA Amplification kit (Amersham Biosciences). Haplotype analysis was done using Haplo.stat software. We observed association ($p<0.05$) of multiple NR3C1 SNPs with CFS when compared to nonfatigued controls. These results were supported when quantitative measures of fatigue were analyzed in all subjects. Evaluation of common haplotypes for association with CFS and quantitative measures of fatigue identified associated haplotypes ($p<0.05$) consistent with the individual SNPs. These data implicate variations in the glucocorticoid receptor gene as a possible mechanism through which the alterations in immune function, HPA axis regulation, and behavior characteristic of CFS may manifest.

Cholinergic System Genes and Bipolar Disorder. *J. Shi[1], E. Hattori[2], H. Zou[1], J.A. Badner[1], S.L. Christian[1], E.S. Gershon[1], C. Liu[1].* 1) Department of Psychiatry, University of Chicago, Chicago, IL; 2) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute (BSI), Wako, Saitama, Japan.

Bipolar disorder (BP) is a serious mental illness with a life time prevalence of about 1% of the world population. Since the cholinergic dysfunction was proposed for the pathogenesis of BP, we have performed a systematic association study of cholinergic system genes in BP. We have genotyped 58 single nucleotide polymorphisms (SNPs) in 16 genes (CHAT, CHRM1, CHRM4, CHRM5, CHRNA1, CHRNA2, CHRNA3, CHRNA4, CHRNA5, CHRNA6, CHRNA7, CHRNA9, CHRNA10, CHRNB1, CHRNB2, CHRNB3) in two series of samples: the National Institute of Mental Health (NIMH) Genetics Initiative pedigrees with 474 samples from 152 families, and the Clinical Neurogenetics (CNG) pedigrees with 83 samples from 22 multiplex families. Sib-Transmission/Disequilibrium test (TDT) analysis showed nominally significant transmission bias for three SNPs (CHRNA2: rs7017417, p=0.023; CHRNA3: rs514743, p=0.035; rs1948, p=0.019), and Exhaustive Allelic Transmission Disequilibrium test (EATDT) analysis showed a few haplotypes nominally significant transmission in CHRNA7, CHRNA10, CHRNA3, CHRNA5 and CHRNB1, respectively. However, none of these reached gene-wide significance after correction by permutation. Thus, it is unlikely that these cholinergic genes play a major role in the development for bipolar disorder.

Glucocerebrosidase alterations E326K and T369M in subjects with and without parkinsonism. *M.J. Eblan, K. Hruska, J. Nguyen, J. Walker, E. Sidransky.* NIMH/NHGRI, National Institutes of Health, Bethesda, MD.

Mutations in the gene for glucocerebrosidase (GBA) result in the rare lysosomal storage disorder Gaucher disease. Clinical observations and neuropathologic data suggest an association between mutations in glucocerebrosidase and parkinsonian syndromes. Mutations in GBA have been identified at a greater than expected frequency in several cohorts with synucleinopathies, including Lewy Body Variant Alzheimer Disease (LBVAD), Diffuse Lewy Body Disease (DLB), and classic Parkinson disease (PD), suggesting that aberrant glucocerebrosidase may serve as a risk factor for the development of parkinsonian symptoms. Included among the alleles identified in the subjects with parkinsonism were E326K or T369M. These alterations have been considered polymorphisms, because they are found only in alleles in patients with Gaucher disease that harbor an additional mutation and are also encountered in normal controls. However, some studies suggest that these alterations reduce enzymatic activity. We sequenced GBA in samples from 254 subjects with parkinsonism, and found 5 with the T369M allele (2%) and 12 with E326K (4.7%). To determine if either allele might have a causative role in the development of parkinsonism, we screened for their presence using SNP analysis in 173 adult controls who lacked any signs of parkinsonism on clinical examination. The E326K allele was identified in 7 controls (4%), while the T369M allele was found in only 2 control subjects (1.2%). This frequency was similar to that seen in the subjects with parkinsonism. These results confirm that E326K and T369M are frequently encountered polymorphisms that, unlike other GBA missense mutations, are unlikely to serve as risk factors in the development of parkinsonism.

Association between the c.66A>G variant in the Methionine Synthase reductase and nonsyndromic cleft palate.

M. Rubini[1], S. Carturan[1], A. Cavallaro[1], S. Manca[1], A. Fabiano[1], P. Aguiari[1], M. Accordi[2], C. Magnani[3], F. Bianchi[4], F. Liviero[5], G. Garattini[5], R. Brusati[5], E. Calzolari[1]. 1) Medical Genetics U., University of Ferrara, Italy; 2) Phoniatric Center, Padova, Italy; 3) Dept. Obstetrics, University of Parma, Italy; 4) Inst. Clinical Physiology, CNR Pisa, Italy; 5) Dept. of Maxillo-facial Surgery, University of Milan, Italy.

Cleft palate (CP) is one of the most frequent congenital malformations in humans. It can occur as part of a syndrome, or, most commonly, be non-syndromic (CPO). There is evidence indicating that both genes and environmental factors are implicated in the etiology of CPO. So far very little is known about genetic susceptibility genes and the molecular mechanisms causing the failure of the secondary palate to close. We used a case-parent triad design to examine whether common variants in genes encoding folate metabolism enzymes are risk factors for CPO, and analyzed 64 complete CPO Italian triads. All individuals were genotyped for c.677C>T and c.1298A>C variants in the methylene tetrahydrofolate reductase (MTHFR), c.2756A>G variant in the methionine synthase (MTR) gene, and the c.66A>G methionine synthase reductase (MTRR) gene. Association was assessed using transmission disequilibrium test (TDT) and relative risks of variant alleles in mother or child were calculated by log-linear Poisson regression model. While no association was evident for variants in the MTHFR and MTR genes, a highly significant (p=0.0075) excess of transmission of c.66G allele from both parents was found for the MTRR gene variant. Estimated relative risks of CPO in children with one or two copies of c.66G allele was 3.01 (95%C.I. 1.52-5.95) and 3.54 (95% C.I. 1.26-9.94) respectively. Catalyzing the conversion of vitamin B12-dependent MTR enzyme into its active state, MTRR plays a role of paramount importance for the conversion of homocysteine (Hcy) to methionine. Our results for the first time indicate the c.66A>G variant, that is associated with altered levels of blood Hcy, as a possible genetic risk factor for CPO, and suggest that impairment of Hcy remethylation may be a crucial step in the etiology of cleft palate.

Genetic association study of ADAM-12 in late onset Alzheimers disease. *L. Jehu, D. Harold, A.R. Morgan, D. Turic, M. Owen, J. Williams.* Cardiff University Dept of Psychological Medicine, University Hospital of Wales, Cardiff CF14 4XN.

ADAM 12 is a member of a family of disintegrin-containing metalloproteases that have been implicated in a variety of diseases including arthritis, cancer and Alzheimer's disease. In this study we are testing the hypothesis that genetic variation within ADAM-12 is associated with late onset Alzheimers disease (LOAD). Polymorphic markers within ADAM-12 were identified both experimentally by DHPLC (20 SNPs, SNP#), and from dbSNP (25 SNPs, DB#). All SNPs were genotyped in DNA pools of 186 LOAD cases and 186 age- and sex-matched controls using a relaxed significance threshold of 0.1. Fourteen displayed a significant difference in allele frequencies between cases and controls at the p0.1 level. The significant SNPs were individually typed in a larger sample of 546 LOAD cases and 546 controls. A significant association with LOAD was detected with two SNPs: the intronic SNP: DB19 and the synonymous coding SNP: SNP8. There was no significant LD between these SNPs (r2=0.031), implying that these two signals are independent. Stratifying the cases based on the presence or absence of an APOE e4 allele had no effect on the data.

As DB19 was the most significant SNP, we used DHPLC on the sequence around this SNP and identified 12 SNPs (Frg#). We also picked out 13 database SNPs from this region (SAT#). These 25 SNPs were typed in our DNA pools, as before. 3 of the 25 were significant at the p0.05 level and have been typed individually in 546 LOAD cases and 546 controls. One SNP: SAT3 remained significant after individual genotyping. Another 5 SNPs were also significant at p0.05 in the DNA pools but are yet to be individually typed.

In conclusion, although this study is work in progress with individual genotyping for some SNPs yet to be done, and for other SNPs to be confirmed by individual genotyping in new samples (500 extra case + 500 extra controls), our results look promising as our data demonstrates an association of ADAM-12 genetic variations with LOAD.

Association between DJ-1 gene polymorphism and PD. *G. Annesi, P. Tarantino, F. Condino, P. Spadafora, S. Carrideo, F.E. Rocca, I.C. Cirò Candiano, D. Civitelli, F. Annesi.* Inst Neurological Sci, National Research Council, Cosenza, Italy.

Mutations in the DJ-1 gene have recently been shown to cause autosomal recessive Parkinsons disease. To assess whether an 18 bp insertion/deletion variant in the promoter gene of DJ-1 (g.168_185 del) gene is associated with Parkinsons disease (PD). We analysed 290 patients (180 men and 110 women) with sporadic PD and 283 (126 men and 157 women) unrelated healthy subjects from the same geographical area. The median age at the time of the study was 67 years (range 34-86) for PD patients .To type the g168_185del polymorphism, PCR was performed. The alleles were visualized on a 3% agarose gel stained with ethidium bromide. Statistical analysis of allele frequencies was performed by Chisquare test with P<0.05. The frequency of the DJ-1 deletion allele was found statistically different between the PD patients and control population (2=34.026;df=1; p-value <0.001). The frequency of the DJ-1 genotypes was also significantly different between patients and controls (2= 39.890;df=1; p-value<0.001). The presence of the DJ-1 deletion allele polymorphism increased the risk of developing PD (OR 3.07; 95%CI 2.08-4.54). Our findings indicate that the presence of the DJ-1 deletion polymorphism is associated with a higher risk of developing PD. This is in contrast with two previous European finding that did not show an association between this D-1 variant and PD. The contradictory results obtained in the previous studies between DJ-1 promoter polymorphism and PD could be owing to difference in population stratification, small sample size, poorly matched controls or statistical artefacts.

Apolipoprotein E and Parkinson disease: A case-control study. *M. Alonso[1], M. Lopez[2], J. Guerrero[1], P. Yescas[1], C. Boll[1], A. Rasmussen[1], I. Familiar[1].* 1) Genetics, National Institute Neurology and Neurosurgery, Mexico DF, Mexico DF, Mexico; 2) Sistemas Biologicos, Universidad Autonoma Metropolitana, Mexico DF, Mexico.

Parkinson disease (PD) is a common neurological disorder with an estimated prevalence of about 1% of the general population older than 60 years. There are a number of families in which PD segregates in an unambiguously Mendelian fashion. To date, nine genetic loci have been reported and four pathogenic genes have been identified: alpha-synuclein, parkin, DJ1 and PINK1 in very few patients. PD is a complex disease with combined genetic and environmental causes and many association studies have focused on the identification of genes that causes susceptibility to PD, among these candidate genes is Apolipoprotein E (APOE). The role of APOE in PD has been investigated by several association studies, but results are inconsistent. In the present study, we determined the differences in the APOE genotype and allele distribution among 233 unrelated Mexican PD patients and 388 controls matched by sex and age. In all cases DNA samples were genotyped for the common APOE polymorphisms epsilon 2, 3 and 4. The frequencies of the APOE alleles were compared by x2 test and Fisher's exact test if necessary. The relative risk was estimated through calculations of the odds ratio (OR) with 95% confidential interval (CI) and only values less than 0.05 were considered statistically significant. We found that genotype APOE 4/3 ($p = 0.01$) and APOE-4 allele ($p = 0.07$) increases disease risk. Stratified analysis revealed that APOE-4 allele increases PD risk only in men ($p = 0.032$). This sex difference may be related to environmental exposures that influence the expression of susceptibility genes.

Functional variants of the cysteinyl leukotriene 1 and 2 receptors are independently associated with atopy in the Tristan da Cunha population. *M.D. Thompson[1,2], V. Capra[3], J. Takasaki[4], A. Slutsky[5], C. Lilly[6], N. Zamel[7], K.A. Siminovitch[8].* 1) Lab Medicine, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) Department of Pharmacology, University of Toronto; 3) Lab. of Molecular Pharmacology Dept. Pharmacological Sciences University of Milan; 4) Astellas Pharma Inc., Drug Discovery Research, Molecular; 5) St. Michaels Hospital, Toronto, ON; 6) Harvard Medical School, Pulmonary and Critical Care Division Brigham and Women's Hospital, Boston, MA; 7) Department of Medicine, University of Toronto; 8) Departments of Medicine, Immunology and Medical Genetics and Microbiology, University of Toronto, Samuel Lunenfeld and Toronto General Hospital Research Institutes, Toronto, ON.

Atopy is a well-defined immune phenotype that is reported to be a risk factor for asthma. Among the many loci implicated in asthma, only the cysteinyl leukotrienes receptor genes will be discussed here. The cysteinyl leukotriene 1 (CysLT1 at Xq13.2) receptor gene is implicated in asthma because its product is targeted by anti-leukotrienes. The cysteinyl leukotriene 2 (CysLT2 at 13q14) receptor gene has been implicated in atopic asthma by association studies (Thompson et al. 2002; Pillai et al 2004; Fukai et al 2005; Park et al 2005). Our studies focussed on the highly asthmatic Tristan da Cunha population and a smaller cohort from Boston. General linear modeling suggested the independent association of single nucleotide polymorphisms (SNPs) of CysLT1 (p.G300S) and CysLT2 (p.M201V) with atopic asthma. As a result, we decided to compare the functional changes conferred by each SNP. By contrast with the CysLT2 M201V variant, which was less sensitive to leukotriene D4 (LTD4) (Thompson et al 2003), we show that LTD4 acts at the CysLT1 G300s variant with a significantly greater potency. The fact that all double heterozygotes were atopic, consistent with an additive model ($r=.50$; $p<.001$), suggests that functional CysLT1/2 SNPs modify atopy severity on Tristan da Cunha. Due to the founder effect present, we attempted to control for kinship in order to refine the relationship between CysLT1/2 genotypes and atopy/asthma phenotypes in this population.

Variants in GSTP1 and Emphysema Distribution in the National Emphysema Treatment Trial. *D. DeMeo[1], C. Hersh[1], E. Hoffman[2], R. Lazarus[1], J. Celedon[1], B. Raby[1], F. Sciurba[3], F. Martinez[5], J. Benditt[4], J. Utz[6], J. Reilly[1], E. Silverman[1].* 1) Dept of Medicine, Brigham & Women's Hospital, Boston, MA; 2) University of Iowa, Iowa City, Iowa; 3) University of Pittsburgh, Pittsburg,PA; 4) University of Washington, Seattle, WA; 5) University of Michigan, Ann Arbor, MI; 6) Mayo Clinic, Rochester, MN.

Genetic investigation in chronic obstructive pulmonary disease (COPD) has been plagued by frequent non-replication of genetic associations;phenotypic heterogeneity may be an important contributor. High-resolution CT scans of the chest allow for quantification of emphysema (a COPD subtype) and may enable definition of more precise phenotypes in genetic studies. We hypothesized that the apical and basal distributions of emphysema may be influenced by genetic factors. We evaluated CT scan emphysema phenotypes in 304 individuals enrolled in the genetics ancillary study of the National Emphysema Treatment Trial. The apical and basal percentages of emphysema were calculated using computer generated voxel measures divided by total voxels in the region. 78 single nucleotide polymorphisms(SNPs) in 20 biological and positional candidate genes for COPD were analyzed. In multivariate models adjusted for pack-years, lung function, age, and sex, different subsets of genetic variants were associated with apical versus basal distributions of emphysema. At -950 Hounsfield Units, SNPs in GSTP1(p=0.005), SERPINE2(2 snps,p=0.007,0.01), and TGFB1(3 snps, p=0.01-0.03) were associated with apical emphysema; SNPs in EPHX1(p=0.01) and LTBP4(p=0.02) were associated with basal emphysema. SNPs in GSTP1(p=0.0007),EPHX1(p=0.01-0.04), TGFB1(p=0.03-0.05), and MMP1(0.02) were associated with emphysema distribution (defined as apical minus basal percent emphysema). GSTP1 also demonstrated significant haplotype association. In the associated GSTP1 haplotypes, the functional SNP Ile105Val may contribute to a lower rate of detoxification of cigarette smoke and higher rates of apical emphysema. Thus, apical and basal emphysematous changes in the lung appear to be influenced by different genes. Funding: K08HL072918,R01HL71393,N01HR76102 ,ALA Career Investigator Award.

The Gln551Arg polymorphism of the *IL4RA* gene is associated with atopic dermatitis in a prospective study. *J. He[1], M. Chan-Yeung[2], AB. Becker[3], H. Dimich-Ward[2], AC. Ferguson[2], J. Manfreda[3], WT. Watson[3], PD. Par~{(&~}[1], AJ. Sandford[1].* 1) The James Hogg iCAPTURE Centre for Cardiovascular and Pulmonary Research, St. Paul~{!/~}s Hospital, University of British Columbia; 2) The Occupational and Environmental Lung Diseases Unit, Department of Medicine, UBC; 3) The Section of Allergy and Clinical Immunology, Department of Pediatrics, University of Manitoba.

Background: The interleukin (IL) 4 pathway is involved in the regulation of IgE production associated with atopic diseases. Many coding polymorphisms have been identified in the IL4 receptor alpha chain (IL4RA) and previous association studies have shown conflicting results. We have reported that the *IL4* -589C/T polymorphism was a risk factor for the development of atopy, asthma, and rhinitis at a group of high risk children.

Methods: This prospective study cohort contained 208 white children at high-risk of developing atopy and atopic disorders because at least one first-degree relative had asthma or two first-degree relatives had other allergic diseases. We investigated whether the Gln551Arg polymorphism of the *IL4RA* gene was associated with atopic dermatitis and other related phenotypes such as atopy, allergic rhinitis and asthma.

Results: In 208 white children, the prevalence of atopic dermatitis at 7 years of age was significantly increased in children with the 551Arg allele (16/95 = 16.8%) compared with children without the 551Arg allele (8/113 = 7.1%). The relative risk (RR) for atopic dermatitis for children with the 551Arg allele compared to children without 551Arg allele was 2.4 (95%CI 1.1 - 5.3, p = 0.028). After adjusting for confounding factors such as sex and intervention group, the RR was 2.7 (95%CI 1.1 - 7.1, p = 0.029). No association was found for the Gln551Arg polymorphism of the *IL4RA* gene with asthma and other allergic diseases at 7 years of age. Conclusion: Our data indicate that *IL4RA* polymorphism plays a role in genetic predisposition to the development of atopic dermatitis in children.

Genes Mediating Lipid Metabolism and Alzheimer Disease Susceptibility. *K.H. Miller[1], R.P. Friedland[2], G.J. Petot[3], H. Kuivaniemi[4], G. Tromp[4], K.A.B. Goddard[1].* 1) Div. Genetic Epidemiology, Case Western Reserve Univ, Cleveland, OH; 2) Laboratory of Neurogeriatrics, Case Western Reserve Univ, Cleveland, OH; 3) Department of Nutrition, Case Western Reserve Univ, Cleveland, OH; 4) Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, MI.

Genes mediating lipid metabolism are promising candidates in an investigation of Alzheimer Disease (AD) susceptibility as lipids are a critical neuronal structural component and pathways affecting circulating lipids are associated with neuronal health and disease. To test this hypothesis, 18 SNPs selected to maximize the potential for causality were genotyped in 427 cases and controls from the Case Western Reserve University Alzheimer Center for six genes related to neuronal health and/or lipid metabolism: brain-derived neurotrophic factor (BDNF), transthyretin (TTR), tumor necrosis factor alpha (TNF), low-density lipoprotein receptor-related protein (LRP1), apolipoprotein L-3 (APOL3), and sterol O-acyltransferase 1 (SOAT1). In this predominantly Caucasian population of slightly more (57%) women to men and median age of 75.5, AD status was defined using clinical criteria (specifically NINCDS-ADRDA). Data were compiled, inconsistencies and missing values assessed, and statistical tests executed using SAS software. Significant differences were found between cases and controls using a chi square test at markers in two genes: BDNF ($p=0.0261$) and LRP1 ($p=0.0021$). After correcting for multiple testing by the Bonferroni method, the result for LRP1 remained significant. No significant association with disease was found among SNPs genotyped in the remaining genes. Modification of gene effect by diet will be analyzed using food frequency/remote diet recall data from three life stages. Further analyses will explore haplotypic effects, gene-gene interaction, and the role of potential confounders using a generalized linear model. Results from the sub-analysis will demonstrate genetic involvement in AD pathology and if modifications in diet can alter genetic effects, enhancing our understanding of AD and further elucidating potential treatments.

Follow-up investigation of twelve proposed linkage regions in Multiple Sclerosis. *B.M. Herrera[1], M.Z. Cader[1], D.A. Dyment[1], J. Tzenova[2], M.R. Lincoln[1], S. Orton[1], S. Ramagopalan[1], G.C. Ebers[1].* 1) Multiple Sclerosis Group, WTCHG, Oxford University, Oxford, United Kingdom; 2) Cardiovascular Medicine, WTCHG, Oxford University, Oxford, United Kingdom.

Multiple Sclerosis (MS) is an autoimmune disease with good evidence for a strong genetic component, and a recently described maternal parent-of-origin. So far, the only replicated linkage and association is to the DRB1-15 allele of the HLA region on chromosome 6p21. As with other complex diseases, multiple suggestive linkage signals have been observed. We have recently reported a whole-genome scan in a sample of 552 affected sibling pairs from 442 families with MS; where several regions of suggestive linkage were found. We have now carried out high-density microsatellite genotyping for twelve of the most promising regions (on chromosomes 1p, 1q, 2q, 4q, 5p, 9q, 10p, 11p, 12q, 17q, 18p and 19p) in a novel dataset of 193 families containing affected aunt-uncle/niece-nephew (AUNN) pairs from the CCPGSMS cohort. These families permit examination of parent-of-origin effects when dividing them into likely maternal (n=103) and paternal (n= 93) trait transmission. The results did not confirm linkage in the overall dataset, in subsets defined by maternal or paternal transmission or in the HLA-DR15-positive subset. Additionally, we were able to establish exclusion for locus specific N greater than 1.3 for all the regions studied. These negative data unable to confirm any linkages for locations outside the MHC raise the possibility that the paradigm that has been used to justify genome searches may be incorrect at least in this disease.

Association analysis of NRXN1 and NRXN3 provides evidence for synaptic dysfunction in autism. *J.A. Duvall[1,2], N. Kono[1], J.L. Stone[1], S.F. Nelson[1], R.M. Cantor[1], D.H. Geschwind[2].* 1) Dept Human Genetics, Univ California at Los Angeles, Los Angeles, CA; 2) Dept Neurology, Univ California at Los Angeles, Los Angeles, CA.

Autism is a neurodevelopmental disorder that is characterized by language difficulties, social deficits, and repetitive, stereotyped behaviors, and which has a significant genetic component. Recently, evidence for involvement of neuroligin genes has been garnered from several sources. We chose to investigate whether genes that are known to interact with neuroligins at the synapse were also associated, to test the broader hypothesis that synaptogenesis is a key dysregulated biological pathway in autism. Here we investigated neurexin 1 (NRXN1) and neurexin 3 (NRXN3), since certain neurexins, a family of cell surface proteins expressed in neurons, interact with neuroligins to promote synaptic maturation. Neurexins 1 and 3 were densely genotyped with 315 and 357 SNPs, respectively, in 224 trios for an average density of 2-4kb. SNPs that were not in Hardy-Weinberg equilibrium ($p<0.01$), SNPs with more than two Mendelian errors, and SNPs in significant linkage disequilibrium with another SNP ($r2>0.9$) were removed from the analysis. The Transmission Disequilibrium Test (TDT) was performed and each gene was tested for an over-representation of SNPs from expected values. SNPs with $p<0.1$ were over-represented in both NRXN1 and NRXN3 ($p=0.0054$ and $p=0.0076$, respectively) and NRXN1 showed an over-representation of SNPs with $p<0.01$ ($p=0.027$). NRXN3 showed this same trend but did not reach a level of significance due to small numbers ($p=0.072$). Preliminary analysis revealed that the most highly associated SNPs within both NRXN1 and NRXN3 clustered within several small regions of each gene. The most significant p values obtained for neurexins 1 and 3 were $p=0.0001$ and $p=0.0016$, respectively. Haplotype analysis provided further support for these associations. While these findings are highly suggestive, confirmation of these disease-associated SNPs in NRXN1 and/or NRXN 3, and other pathway members would provide further evidence that synaptic maturation defects underlie susceptibility to autism.

Comprehensive analysis of sequence variation in the peptidyl arginine deiminase type IV gene (*PADI4*) suggests a novel intronic variant is associated with rheumatoid arthritis in the North American Caucasian population. *E. Remmers[1], R. Plenge[2], J. Le[1], A. Lee[3], I. Aksentijevich[1], D. Kastner[1], P. Gregersen[3].* 1) Genetics and Genomics Branch, NIAMS, Bethesda, MD; 2) The Broad Institute, Cambridge, MA; 3) The Robert S. Boas Center for Genomics and Human Genetics, North Shore LIJ Institute for Medical Research, Manhasset, NY.

Peptidyl arginine deiminase type IV (*PADI4*) produces citrullinated peptides by converting arginyl residues to citrullyl residues. Auto-antibodies directed against citrullinated peptides are relatively specific for rheumatoid arthritis (RA). Several *PADI4* gene variants are associated with RA in the Japanese population. We sought to determine whether these or other variants of the *PADI4* gene are associated with RA in Caucasians. A set of 22 SNPs that captures virtually all the *PADI4* variation found in a densely spaced set of 69 SNPs was identified by genotyping the 30 HapMap Project CEU trios and analyzing pair-wise LD among the 69 SNPs. The 22 selected SNPs, plus 3 additional *PADI4* SNPs that were associated with disease in Japanese RA patients, were genotyped in 571 independent Caucasian RA patients from the North American Rheumatoid Arthritis Consortium cohort and 750 controls. The SNP most strongly associated with RA in the Japanese study (rs2240340) was weakly associated with disease in this cohort (minor allele frequency (maf) = 0.45 in cases vs 0.40 in controls, p=0.03). However, a nearby SNP (rs2147333) with lower frequency, but in strong LD with rs2240340 (D'=0.99) was strongly associated with disease (maf = 0.11 in cases vs 0.06 in controls, p=0.00006). The association was not detected in rheumatoid factor negative patients (maf = 0.067, p=0.79) and was strongest in patients with a single copy of the HLA shared epitope (maf = 0.13, p=0.000003). This RA-associated SNP is located within the first intron of the *PADI4* gene and the disease-associated variant disrupts a predicted N-Oct3 transcription factor binding site. These data suggest that, similar to the Japanese population, variation of the *PADI4* gene contributes to RA susceptibility; however, a novel, non-coding variant was associated with RA in the Caucasian population.

Association of single nucleotide polymorphisms (SNPs) with rheumatoid arthritis (RA) in candidate genes at *IDDM5*. *L.J. Gibbons[1], A. Hinks[1], E. Zeggini[2], J. Worthington[1], A. Barton[1], S. Eyre[1], R. Donn[1], W. Thomson[1].* 1) arc Epidemiology Unit, University of Manchester, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom.

Background: Autoimmune diseases may share a common genetic aetiology, as evidenced by the clustering of these diseases in families, the overlap of susceptibility loci, and the consistent involvement of genes at the major histocompatibility locus (MHC). Two microsatellite markers, *D6S311* and *D6S440*, at the type 1 diabetes (T1D) locus, *IDDM5*, have previously been linked and associated with RA.

Aim: To assess association between RA and polymorphisms in candidate genes within the *IDDM5* locus. Selected genes were oestrogen receptor (*ESR1*), vasoactive intestinal peptide (*VIP*), and those encoding UL16-binding proteins (*ULBP1-3*).

Methods: 82 SNPs were selected and genotyped in 359 RA cases and 372 healthy controls by MassARRAY technology (Sequenom). Allele and genotype frequencies were compared between cases and controls by the ^{2} test. Linkage disequilibrium (LD) analysis and haplotype analysis were carried out using HelixTree (Golden Helix Inc.).

Results: Allele frequencies were out of Hardy-Weinberg equilibrium for 8 SNPs, which were excluded from the analysis. 12 *ESR1* SNPs showed association with RA at the 5% significance level, in comparison with 8 expected. Two *ULBP3* SNPs showed significant association with increased risk of RA: the minor allele of rs2009345 was increased in cases compared with controls (OR 1.37, 95% CI 1.09 - 1.73, p = 0.006), as was the minor allele of rs932744 (OR 1.40, 95% CI 1.12 - 1.75, p = 0.002). A 2-marker haplotype formed by these SNPs was associated with RA (p = 0.01). rs2009345 is in intron 1 of *ULBP3*, while rs932744 maps 461bp 5 of the transcription start site. No *VIP* or *ULBP1-2* SNPs were associated with RA.

Conclusion: All associations must be replicated in an independent data set in order to rule out false positives. Of interest is the association with *ULBP3*: ULBP1-3 bind to and activate natural killer cells, stimulating cytotoxicity and cytokine and chemokine secretion.

Severity of substance use disorder and interaction of dopamine system genes. *M.M. Vanyukov[1,2,3,5], B.S. Maher[1,2,4,5], B. Devlin[1,2,3,5], G.P. Kirillova[1,5], R.E. Tarter[1,3,5], R.E. Ferrell[1,2,5].* 1) Center for Education and Drug Abuse Research (CEDAR), Dept. of Pharmaceutical Sciences; 2) Dept. of Human Genetics; 3) Dept. of Psychiatry; 4) School of Dental Medicine; 5) University of Pittsburgh, Pittsburgh, PA.

The risk for substance use disorders (SUD) is significantly heritable. The dopaminergic system (DS) has been implicated in the etiology of SUD. The genes encoding components of the DS, including the five dopamine receptor genes (DRD1-DRD5), may contribute to the heritability of SUD liability. The dopamine receptors, comprising the D1- and D2-like families (respectively, D1 and D5; and D2, D3 and D4 receptors) are known to act through the opposite effects on adenylate cyclase. It is thus possible that interaction between the two receptor families (D1xD2) is important as a mechanism of SUD risk variation. To test this hypothesis, we conducted 2-way ANOVAs involving the D1- and D2-family genes in adolescent (12-18 years of age) European-American males, using a validated index of the severity of drug involvement (a scale of the Drug Use Screening Inventory-Revised [Tarter & Kirisci, 2001]) as a quantitative trait. All subjects had a DSM-IV diagnosis of substance dependence. The D1xD2 interactions were detected between DRD1 and DRD2, and DRD1 and DRD3 polymorphisms. These interactions may point at potential mechanisms involved in the development of drug dependence and warrant further investigation involving phenotypic mediators of SUD liability.

Interferon Regulatory Factor 6 (IRF6): a Modifier Gene Predisposing to Isolated Cleft Lip with or without Cleft Palate in the Belgian Population. *M. Ghassibe[1], B. Bayet[2], N. Revencu[1,3], Ch. Verellen-Dumoulin[3], Y. Gillerot[3], R. Vanwijck[2], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and University of Louvain Medical School, Brussels, Belgium; 2) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St Luc, Brussels, Belgium; 3) Center for Human Genetics, Cliniques universitaires St Luc and University of Louvain Medical School, Brussels, Belgium.

Cleft lip with or without cleft palate is the most frequent craniofacial malformation in humans (~ 1/700). Its etiology is multifactorial; some are a result of a genetic mutation, while others may be due to environmental factors, with genetic predisposition playing an important role. The prevalence varies widely between populations and the mode of inheritance remains controversial. The Interferon regulatory factor-6 (IRF6) gene has been shown to harbor mutations in patients with van der Woude syndrome, a dominant form of clefts associated with small pits of the lower lip (Kondo et al. 2002; Ghassibe et al. 2004). Moreover IRF6 has been associated with non-syndromic CL/P in two separate studies (Zucchero et al. 2004; Scapoli et al. 2005). We investigated the role of IRF6 in a set of 195 trios from Belgium. Cleft occurred as an isolated feature. We studied association of the IRF6 locus using two variants: one in the IRF6 gene and the other 100 Kb 3' of the gene. Our independent study group confirms that the IRF6 locus is associated with non-syndromic cleft lip with or without cleft palate. This result, with previous studies performed in the United States and Italy, shows the wide implication of IRF6 in isolated CL/P. It is likely that association to this locus can be identified in various populations and that the IRF6 locus thus represents an important genetic modifier for this multifactorial malformation.

Investigation of serotonin 1B receptor variants and impulsive aggressive measures in suicide completers. *H. Zouk, G. Csikos, M. Tousignant, M. Séguin, A. Lesage, G. Rouleau, C. Benkelfat, G. Turecki.* McGill Group for Suicide Studies, Douglas Hospital Research Center, Montreal, Canada.

Suicide is a major public health problem that ranks among the top ten causes of death for individuals of all age groups in several countries. Several studies suggest that the predisposition to suicide is the outcome of the interaction of environmental and biological factors. Evidence from family, twin and adoption studies suggests that there is a genetic susceptibility to suicide. Changes in the central serotonin neurotransmission have been described as possible mediators of suicide risk; hence, genes encoding for components of the serotonergic system are promising study targets. One such gene is the 5HT-1B receptor. 5HT-1B knockout mice show greater aggression, anxiety and impulsivity, behaviors that are believe to increase suicide risk. We carried out a study examining this intronless gene located on chromosome 6q14.1. Using SNaPshot multiplex assays, we investigated a total of 2 functional promoter SNPs, 1 SNP in the 3UTR and 2 SNPs in the coding region for their allelic and genotypic frequencies in a sample from the Québec general population consisting of 376 suicide completers and 443 normal controls. We found that the frequencies of the T alleles of the functional promoter 5HT1B -261 SNP (T to G change, $P = 0.016$) as well as that of the 5HT1B 129 SNP (C to T change, $P = 0.001$) are significantly increased among the suicides. Moreover, suicide completers having the T allele of the 129 SNP are significantly more impulsive than those carrying the C allele as determined by the Barratt Impulsivity Scale ($P = 0.039$) and the Novelty Seeking subscale of the Temperament and Character Inventory ($P = 0.007$). Our results suggest that the T allele of the 129 SNP may be associated to the suicide phenotype through the manifestation of higher levels of impulsivity traits.

The identification of haplotypes in radiosensitive genes associated with risk for adverse skin reactions following radiotherapy in breast cancer patients. *T. Imai[1], T. Suga[1], M. Kohda[1], S. Noda[1], S. Yamada[2], N. Yamamoto[3], A. Ishikawa[1], Y. Ohtsuka[1], H. Suzuki[1], K. Sugawara[1], S. Kawai[1], Y. Michikawa[1], M. Sagara[1], J. Mizoe[2], H. Tsujii[2], M. Iwakawa[1].* 1) Frontier Research Center, National Institute of Radiological Sciences, Chiba, Japan; 2) Research Center for Charged Particle Therapy, National Institute of Radiological Sciences, Chiba, Japan; 3) Chiba Cancer Center, Chiba, Japan.

The goal of radiation therapy in cancer treatment is to achieve a personalized, uncomplicated, loco-regional control. For this, it is of critical importance to have a precise knowledge of the tumoricidal dose for each target tumor and the tolerance doses of normal tissues for each patient. Single nucleotide polymorphisms (SNPs) and derived haplotypes within multiple genes may explain the genetic basis for variations in the adverse reactions after radiotherapy for cancer patients. Using DNA samples collected from 184 Japanese breast cancer patients who qualified for breast-conserving surgery and radiotherapy, we genotyped 905 SNPs from 127 candidate genes for radiation susceptibility. These genes were mainly selected from our gene expression analyses of cultured human cell lines and mouse strains that had exhibited variable radiosensitivities. The SNPs in the candidate genes were selected from jSNP and dbSNP databases and their allele frequencies were examined using 133 healthy controls. The adverse skin reactions were clinically graded according to the National Cancer Institute Common Toxicity Criteria scoring system. Of all 905 SNPs tested, approximately 64% were polymorphic in this cohort of patients. Significant differences were observed in genotype frequencies between the grade 0+1 (n=140) and the grade 2+3 (n=44) groups of skin reactions among the breast cancer patients within 3 months after starting radiotherapy for 24 SNPs in 12 candidate gene loci. Forty-four haplotypes were generated in 7 of the above loci and 4 of these haplotypes were associated with the risk of the adverse skin reactions. These data suggest that the tagged SNPs in the loci may be useful in predicting the risk of adverse reactions following radiation treatment.

Investigation of TPH2 genetic variants and clinical risk factors for suicide completion in major depression. *C. Lopez de Lara[1], G. Rouleau[1], A. Lesage[1], M. Dumont[1], N. Chawky[1], M. Alda[2], C. Benkelfat[1], G. Turecki[1].* 1) McGill Group for Suicide Studies, Douglas Hospital Research Center, Montreal, Canada; 2) Department of Psychiatry, Dalhousie University, Halifax, Canada.

Suicide is the most serious outcome of major depression, yet not all depressed patients will commit suicide. Several lines of evidence suggest that biological and genetic factors account for at least part of the variability in suicide risk among patients with major depressive disorder. Neurobiological studies have shown overlapping but different neurochemical alterations in suicide and depression, both involving a dysfunction of the central serotonergic neurotransmission characterized by a reduced serotonergic activity. In this context, the gene encoding a second isoform of the tryptophan hydroxylase (TPH2), which is a rate-limiting enzyme expressed predominantly in the brain and involved in the synthesis of serotonin, is an interesting candidate. Here we aimed to identify predisposing factors for suicide taking into account genetic variation at the TPH2 locus while controlling for depressive psychopathology. A total of 14 SNPs in the TPH2 gene and regulatory region, as well as their relationship to several behavioral and clinical risk factors for suicide, were investigated in a sample of 114 suicides that died during an episode of major depressive disorder and 154 depressed controls diagnosed by means of proxy-based interviews. Nine out of the 14 SNPs were intronic, 2 exonic and 3 were located in the regulatory region of this gene. We also carried out linkage disequilibrium and haplotype analyses for these SNPs. We found that three TPH2 SNPs had a significant effect on suicide completion. Moreover, two of these three SNPs, which were located in the regulatory region and in intron 8, had an effect on different TCI (Temperament and Character Inventory) personality dimensions. These results suggest a possible role of genetic variation at the TPH2 gene in suicide completion in major depression as well as a mediating effect through some behavioral traits.

Association of Y402H variant and clinical subtypes of AMD. *E.A. Postel[1], A. Agarwal[2], P. Gallins[1], S. Schmidt[1], W.K. Scott[1], M.A. Hauser[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Duke University Medical Center, Durham, NC; 2) Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is the leading cause of blindness in older Americans, manifested in its most severe forms by neovascular (grade 5) and atrophic (GA, grade 4) changes. Though neovascular disease is responsible for the majority of severe vision loss with AMD, geographic atrophy is also a significant cause of vision loss, and without effective treatment. Therefore, an attempt to clarify its pathogenesis is of utmost importance. Complement Factor H (CFH) is a major AMD risk gene. The Y402H (rs1061170) variant significantly increases the risk for AMD with odds ratios between 2.45 and 5.57, and a population attributable risk of 43%.

To determine if CFH had any effect on determining risk for development of GA in an independent case-control data set of 520 AMD cases and 163 controls, the rs1061170 SNP was tested for association separately by AMD grade. Odds ratios were calculated using standard logistic regression models (SAS version 8.2). There were 407 grade-5 individuals, 107 grade-4, 133 grade-3 (nonatrophic, dry AMD), 35 grade-2, and 128 grade-1 (control) individuals.

There was significant association with AMD when comparing grades 3, 4, and 5 versus the controls. The highest odds ratio was obtained when analyzing the grade-4 cases versus controls (OR = 3.217, P 0.0001). Comparing grade-5 cases versus controls (OR = 2.503, P 0.0001) and grade-3 cases versus controls (OR = 2.143, P = 0.0002) were also highly significant.

In summary, CFH increases the risk of developing GA as well as neovascular and milder AMD. It remains to be seen whether other genes or environmental risk factors such as smoking (Scott et al., this meeting) or diet play a role in determining whether a patient develops exudative or atrophic disease.

Misregulation of Circadian Clock in Fmr1/Fxr2 Knockout Mice. *J. Zhang[1], Z. Fang[1], K. Kaasik[2], C.C. Lee[2], B.A. Oostra[3], D.L. Nelson[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, USA; 2) Biochemistry and Molecular Biology, University of Texas-Houston Medical School, USA; 3) Clinical Genetics, Erasmus University, The Netherlands.

Fragile X syndrome, the most common heritable cause of mental retardation, is caused by loss-of-function mutations in the fragile X mental retardation (FMR1) gene resulting in the absence of the gene product (FMRP). FMRP belongs to a family of proteins that includes the Fragile X related proteins 1 and 2 (FXRP1 & FXRP2). FXRPs share high similarity in their functional domains with FMRP. It is likely that FXRPs play redundant roles with FMRP. Previous studies have indicated that sleep problems occur in young fragile X patients. Fruit fly *Drosophila* models carrying loss-of- function alleles of dfxr have shown defects in circadian activity. Circadian rhythm abnormalities observed in patients and in *Drosophila* led us to study circadian rhythm in mice with mutations in Fmr1 and Fxr2 gene. We observed abnormalities in circadian controlled locomotor activity in Fmr1, Fxr2 single knockout mice and Fmr1/Fxr2 double knockout mice, with double knockout mice exhibiting a profound defect, comprised of loss of circadian control and hyperactivity. Single knockout animals showed elongated period length in the absence of light cues. There are three possible mechanisms (central clock defect, output pathway defect or input defect) that may attribute to the circadian phenotype in Fmr1 family knockout mice. We examined whether the central clock pathway is intact in the Fxr2 single and the Fmr1/Fxr2 double knockout mice. We tested the expression of 6 central clock components: Clock, Bmal1, Per1, Per2, Cry1 and Npas2. We found that RNA levels of Per1, Cry1 and Npas2 were altered significantly in Fxr2 knockout mice and RNA levels of Per1, Npas2 and Clock were changed dramatically in Fmr1/Fxr2 double knockout mice. In addition, we found that levels of Fxr2 RNA fluctuated with time both *in vivo*(mouse liver) and *in vitro*(mouse embryo fibroblast cell line). These data suggest a role for the Fmr1 gene family in control of the central clock.

Animal models of Andersen-Tawil syndrome carrying mutations of KCNJ2 recapitulate the human phenotype. *Y. TONG[1], K. ZHANG[1], W. TINGLEY[2], Y.H. FU[1], L. PTACEK[1].* 1) Neurology, UCSF, SF, CA; 2) Gladstone Institute, SF, CA.

Andersen-Tawil syndrome (ATS) is an autosomal dominant disease characterized by cardiac arrhythmias, periodic paralysis and dysmorphic features. Mutations of the KCNJ2 gene, which encodes the inward rectifying potassium channel subunit Kir2.1, have been identified in affected patients. The D71V mutation has the strongest dominant negative effect on Kir2.1 channel function in vitro while R218W is the most frequent mutation found in ATS families. Based on these data, we generated three lines of transgenic mice, WT, D71V and R218W, by bacteriophage--mediated transgenesis. The coding region (including partial 5UTR/3UTR) of mouse KCNJ2 was amplified from a BAC clone (RP23-408D5), and ligated into the pIRES2-EGFP vector. The FRT-neo/kan-FRT fragment from pKD4 plasmid was fused to the C-terminal end of GFP and used as selection marker. Point mutation of D71V or R218W was introduced into the KCNJ2 coding region respectively. The cassette DNA consists of KCNJ2 genomic sequence (WT, D71V or R218W with flanking DNA), IRES-GFP, and FRT-neo/kan-FRT. This was co-transformed with the original BAC clone RP23-408D5 by electroporation. Positive recombinant BAC clones were selected using chloramphenicol-kanamycin. Then, MAMA PCR was performed to identify of WT, D71V and R218W BAC clones. Finally, the FRT-neo/kan-FRT DNA was removed by L-rarbinose in an EL250 bacterial strain. The final BAC constructs (WT, D71V and R218W) were verified by sequencing and injected into mouse oocytes to generate transgenic founders. Southern blot confirmed the transgenic lines. The expression of WT, D71V, and R218W mutations were proved by RT-PCR and sequencing. Preliminary experiments found cardiac arrhythmias and LQT among several mutant transgenic mice. WT-Kir2.1 transgenic mice were resistant to glucose-insulin-induced paralysis while non-transgenic littermate controls developed paralysis. Further work is ongoing to characterize these and other phenotypes in these mice.

If a virus causes diabetes, what are the implications for genetic predisposition? *W. Klitz[1], B. Niklasson[2].* 1) Sch Public Health, University of California, Berkeley, CA; 2) Apodemus A.B., Stockholm, Sweden.

A variety of evidence points to the role of Ljungan virus (LV), a recently discovered picornavirus, in diabetes and reproductive diseases. LV has been found in the native mammals of Sweden, and governs the population cycles of several native rodents of northern Sweden. LV is also present in North American rodents. In native voles and laboratory mice, LV causes a variety of symptoms mimicking T1D and T2D. Kochs postulates for pathogen transmission have been satisfied in laboratory mice. Antiviral therapy reduces the frequency of diabetes in laboratory mice. In humans the incidence of new cases of T1D, gestational diabetes, preeclampsia and intrauterine fetal death (IUFD) in northern Sweden is correlated with rodent population cycles, showing that the attributable risk due to the underlying factor must be substantial. These diseases are found concurrently in individuals far in excess of random expectations. Antisera and IHC (immunohistochemical) assays show an excess frequency of LV in T1D patients and LV in samples of IUFD from several organs and from placentas of women with preeclampsia. RT-PCR confirms the presence of LV in preeclampsia placenta. In a case control study using the IHC assay LV is positive only in preeclampsia cases. At last, an often posited environmental factor in autoimmunity may be at hand. If LV causes these diseases, then how can genetic predisposition? The diverse genetic associations of T1D, T2D and gestational diabetes suggest that physiological predisposition to specific metabolic processes of each disease must underlie these relationships, rather than reflecting response to a specific pathogen. The variability in response among individuals for disruption of metabolism and in various tissues by LV requires further exploration.

Large scale mutation analysis of the third glaucoma-causing gene, *WDR36*, at *GLC1G* in the French-Canadian population of Québec. *V. Raymond[1], S. Dubois[1], A. Marquis[1], R. Arseneault[1], J.-L. Anctil[2], A. Duchesne[1], M.-A. Rodrigue[1], The Québec Glaucoma Network.* 1) Ocular Genetics & Genomics, Molecular Endocrinology & Oncology, Laval University Hospital (CHUL) Research Ctr, Québec, PQ, Canada; 2) Ophthalmology Dept, St-Sacrement Hospital, Québec City, PQ.

Glaucoma is a leading cause of blindness worldwide. Of all the different forms, primary open-angle glaucoma (POAG) occurs most frequently and 9 loci have been localized for the disorder. *WDR36* was recently characterized as the third POAG gene mapping to *GLC1G* at 5q22.1 (*Hum Mol Gen* (2005)14:725). To assess the prevalence of *WDR36* mutations in the French-Canadian population, we screened its 23 coding exons for variations in 308 unrelated POAG patients recruited in the Province of Québec, Canada. 107 asymptomatic persons were used as controls. The 23 exons and their intron-exon junctions were screened by direct genomic sequencing. A minimum of 254 POAG subjects with ocular hypertension 21 mm Hg and 15 POAG patients with normal ocular tension were sequenced for each exon. Overall, 23 sequence alterations were detected. 18 of these encoded amino acid (AA) changes while the other 5 were SNPs that did not alter wild-type AA. Of these 18 AA variations, 12 were not identified in controls and were considered potential disease-causing mutations. The T65K (1 patient/306 POAG), D126N (1/298), K284T (1/300), I292T (1/300), N351T (1/303), H411R (1/300), N626T (1/301) and G851R (1/273) potential mutations were novel. The N355S (1/303), A449T (3/295), R529Q (1/295) and M671V (1/309) potential mutations have been described previously. The most common disease-susceptibility mutation observed, H212P (previously reported as Y216P), was detected in 13/296 (4.4%) glaucoma probands and only once (1/106) in controls. The L25P susceptibility mutation was observed in 8/306 POAG probands and 1/107 controls. The D658G alteration was found in 3/309 patients and 3/107 controls. Overall, the frequency of potential disease-causing and potential disease-susceptibility mutations was estimated at 10 % in our unrelated POAG patients. Our data thus demonstrate that *WDR36* mutations are a major cause of glaucoma in the French-Canadian population.

OPA1 DNA sequence variants in normal tension glaucoma patients. *J. Wiggs[1], S. Wagner[1], E. DelBono[1], J. Haines[2], L. Pasquale[1].* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Glaucoma is characterized by degeneration of the optic nerve. Although the disease is frequently associated with an elevation of intraocular pressure, in 20-30% of cases the intraocular pressure is normal. Identifying genes that contribute to normal tension glaucoma would be a first step toward defining the underlying pathologic mechanisms of optic nerve degeneration. The OPA1 gene codes for a dynamin-related GTPase that contributes to mitochondrial biogenesis and has been implicated in many cases of autosomal dominant optic atrophy, which is also characterized by a spontaneous degeneration of the optic nerve. To evaluate the role of the OPA1 gene in normal tension glaucoma, we screened a population of 80 normal tension glaucoma patients, 130 high tension glaucoma patients and 80 age and ethnically matched controls. Normal tension glaucoma was defined as optic nerve damage with corresponding visual field changes in at least one eye and intraocular pressure less than 22 mmHg. All of the 29 exons and flanking introns of the OPA1 gene were sequenced in normal tension glaucoma patients. Two novel missense changes (Thr95Met, Lys582Arg) and one previously identified missense change (Ser158Asn) were found. The Thr95Met and Lys582Arg variants were not present in the high tension glaucoma patients or controls. Eleven intronic DNA sequence variants were identified, and one of these, IVS 8+4C>T, was found more frequently in normal tension glaucoma patients than controls (28% compared with 9%, $p < .01$). These results indicate that OPA1 gene defects may contribute to normal tension glaucoma and that mitochondrial dysfunction may be one component of this disease.

Evaluation of MTHFR, MTR and MTRR polymorphisms in patients with glaucoma associated with hyperhomocysteinemia. *D. Figueiredo[1], J. Auguste[1], E. DelBono[1], J.L. Haines[2], J.L. Wiggs[1].* 1) Dept Ophthalmology, Harvard Medical School, MEEI, Boston, MA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Recent studies have indicated that plasma and aqueous humor levels of homocysteine are elevated in patients with a form of open angle glaucoma called pseudoexfoliation glaucoma. This form of glaucoma is associated with abnormalities of blood vessels and the blood aqueous barrier in the eye, as well as a systemic deposition of a characteristic fibrillar material in the stroma of visceral organs. These results suggest that moderate hyperhomocysteinemia may be associated with pseudoexfoliation glaucoma and may contribute to the vascular abnormalities seen in this syndrome. To determine if the elevation of homocysteine in pseudoexfoliation has a genetic etiology, we evaluated the distribution of alleles at two polymorphic sites in the gene for the enzyme methylenetetrahydrofolate reductase (MTHFR), which is a critical component of homocysteine metabolism, as well as polymorphisms in the methionine synthase (MTR), and methionine synthase reductase (MTRR) genes. 84 patients with pseudoexfoliation glaucoma (PXF), 201 patients affected with adult onset primary open angle glaucoma (POAG), and 107 control patients without either glaucoma or PXF were used for this study. POAG was defined as age of diagnosis greater than 35, intraocular pressure >22 mm Hg in both eyes, and glaucomatous optic nerve damage and visual field loss in at least one eye. PXF patients had evidence of characteristic pseudoexfoliative material on the lens capsule or pupillary margin. The distribution of genotypes for the MTHFR polymorphisms C677T, A1298C, the MTR polymorphisms D294N, D919G and MTRR polymorphism S202L did not differ significantly between PXF patients, POAG patients and controls. These results suggest that the allelic variants of the MTHFR, MTR and MTRR genes selected for analysis in this study do not significantly contribute to the disease in this patient population. Other genetic etiologies for hyperhomocysteinemia may be responsible for this phenotype.

The novel A4435G mutation in the mitochondrial tRNAMet may modulate the phenotypic expression of the LHON-associated ND4 G11778A mutation in a Chinese family. *J. Qu[1,4], R. Li[2], X. Zhou[1], Y. Tong[3], Y. Hu[4], Y. Qian[2], J.Q. Mo[5,6], F. Lu[1], M.X. Guan[2,4,6].* 1) Dept Ophthalmology/Optometry, Wenzhou Medical Col, Wenzhou, Zhejia, China; 2) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA; 3) Fujian Medical University, Fuzhou, China; 4) Zhejiang Provincial Key Laboratory of Medical Genetics, School of Life Sciences, Wenzhou Medical College, Wenzhou, Zhejiang , China; 5) Division of Pathology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA; 6) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45229.

We report here the characterization of a three-generation Chinese family with Lebers hereditary optic neuropathy (LHON). Strikingly, this Chinese family exhibits high penetrance and expressivity of visual impairment. In particular, the average age-of-onset was 13.9 years in this family. 86% of male and 29% female matrilineal relatives in this family developed visual loss with a wide range of severity, ranging from blindness to normal vision. Sequence analysis of the complete mitochondrial DNA in this pedigree revealed the presence of the ND4 G11778A mutation and 35 other variants, belonging to the Asian haplogroup D5. The G11778A mutation is present at near homoplasmy in matrilineal relatives of this Chinese family. Of other variants, the novel homoplasmic A4435G mutation absent in 164 Chinese controls is localized at 3 end adjacent to the anticodon, at conventional position 37 (A37), of tRNAMet. The adenine (A37) at this position of tRNAMet is extraordinarily conserved from bacteria to human mitochondria. Indeed, this modified A37 was shown to contribute to the high fidelity of codon-recognition, the structural formation and stabilization of functional tRNAs. Thus, the A4435G mutation may lead to a failure in mitochondrial tRNA metabolism, worsening the mitochondrial dysfunction associated with the primary G11778A mutation. These imply that the novel tRNAMet A4435G mutation has a potential modifier role in increasing the penetrance and expressivity of the primary LHON-associated G11778A mutation in this Chinese family.

Mitochondrial DNA Content and the *MTND4* Gene Expression in Leber's Hereditary Optic Neuropathy. *M.W. Seong[1], J.Y. Kim[2], H.Y. Ko[1], J.M. Hwang[3], S.S. Park[1].* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Central Blood Laboratory Center, Korean Red Cross, Seoul, Korea; 3) Department of Ophthalmology, Seoul National University Bundang Hospital, Seongnam, Korea.

Leber's hereditary optic neuropathy (LHON) is characterized by acute or subacute bilateral visual loss, primarily caused by mitochondrial DNA (mtDNA) point mutation. However the pathogenic mechanism of visual loss is not clearly unraveled. We investigated the pathogenetic mechanism of LHON by the analysis of mtDNA content and the *MTND4* expression. Absolute mtDNA contents were determined in 17 patients, 8 carriers and 47 normal subjects as the copy number ratio of the *MTCYB* gene to nuclear *RNase P* gene using real-time PCR. All patients and carriers had the 11778GA mutation of mtDNA. For real-time PCR assay of mtDNA content, the reference ranges were established by age groups and the reproducibility was assessed by intra-run and inter-run assay. We also quantified the mRNA expression of two mitochondrial genes (*MTND4* harboring 11778GA and *MTCYB*) relative to a nuclear gene (*GAPDH*) in three subject groups. The mean mtDNA contents in patients, carriers and normal subjects were 894.9 (186.9), 848.5 (221.7) and 1148.6 (406.9) copies/cell, respectively. Patients and carriers had significantly lower mtDNA contents than normal subjects (P=0.001 and P=0.048, respectively). The mRNA expression of both *MTND4* and *MTCYB* tended to be lower in patients and carriers than in normal subjects (statistically insignificant), but *MTND4/MTCYB* ratios were similar among three groups. In conclusion, mtDNA content and the *MTND4* expression are decreased in LHON patients and carriers, and it may be caused by mitochondrial depletion. Mitochondrial depletion may be an additional cause of respiratory defect.

X-Chromosome Inactivation patterns in Females with Non syndromic Cleft Lip and/or Palate. *J.W. Kimani[1], M. Shi[1], L.L. Field[2], M.L. Marazita[3], J.C. Murray[1].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Univ British Columbia, Vancouver, Canada; 3) Center for Craniofacial and Dental Genetics, Univ Pittsburgh, Pittsburgh, PA.

Clefts of the lip and/or palate (CLP) and cleft palate only (CPO) are common congenital anomalies with a complex etiology. Epidemiological studies have found that CLP is more frequent in males than females with a ratio of 2:1 respectively, but approximately 1:1 in CPO. This altered gender ratio for CLP may be explained by sex differences in timing during craniofacial development, but underlying genetic mechanisms remain unidentified. We hypothesized that differences in X chromosome inactivation (XCI) patterns may provide insight into the etiology of CLP and perhaps explain the excess of males affected with CLP. We collected 149 sister pairs (one affected and one unaffected) from various geographic origins (Philippines, India, Spain, Guatemala, USA and China) and extracted DNA from peripheral blood lymphocytes. The samples were classified into 3 phenotypic groups: CL&P-76(13), CLO-60(15) and CPO-13(2); Bracketed numbers indicate pairs that were uninformative for the marker tested, which utilized a trinucleotide repeat in the androgen receptor gene. The XCI ratio was obtained as an average of three experiments, and differences between sister pairs were calculated using the paired t-test. The observed P values were 0.05, 0.65 and 0.99 for CL&P, CLO and CPO respectively. These results indicate an impact of non-random XCI patterns on CL&P. The P values for the CLO and CPO groups were not significant, although this could be attributed to lack of power due to small sample sizes. It is therefore likely that non-random XCI patterns may explain some of the male tendency towards CL&P: X-linked gene expression in males is limited to one X chromosome, whereas females are generally a mosaic of cells expressing genes from either X chromosome. Phenotypic effects that are linked to the X chromosome may therefore manifest readily in males, but are obscured in females due to non-random XCI patterns. Supported by NIH grants R37-DE-08559, R01-DE-09886, R01-DE016148, P50-DE016215.

Patients with defects in -adrenergic signaling manifest abnormal CFTR activation in the absence of clinical CF.
S.C. Hsu, J. Groman, C. Merlo, K. Naughton, E. Germain-Lee, M. Boyle, G.R. Cutting. Johns Hopkins Univ, Baltimore, MD.

Activation of the cystic fibrosis transmembrane conductance regulator (CFTR) by the -adrenergic signaling pathway is thought to play a central role in the development of cystic fibrosis (CF). To test this hypothesis, we have studied CFTR activity in Albrights Hereditary Osteodystrophy (AHO) patients who have a defect in G_s, a key component of the -adrenergic pathway. To examine this pathway in a tissue where CFTR is present, nasal epithelial cells were harvested from 5 AHO patients and 20 normal controls and tested for cyclic AMP (cAMP) levels in response to isoproterenol (ISO), a -agonist. The response to forskolin, a direct stimulator of adenylyl cyclase, was used to normalize among patients and controls. Beta-adrenergic stimulated cAMP production (mean % ISO/forskolin s.d.) was significantly reduced in the AHO patients compared to normal controls (4013 vs. 6014, $p<0.05$). Activation of CFTR by the -adrenergic pathway was examined *in vivo* using two different assays: nasal potential difference measurement (NPD) of respiratory epithelia and sweat rates in the skin. The means of the NPD and the sweat rate for AHO patients were lower than for normals, but both groups displayed wide variance for each test and their ranges partially overlapped. Two AHO patients with CFTR responses outside of the normal range fell within the CF range for both NPD (-5.5, -5.5mV) and sweat rate (0.3, 0.9mg/20min). Yet constitutive CFTR function was normal in both patients based on normal chloride reabsorption following cholinergic stimulation of the sweat glands. Neither patient has clinical features of CF lung disease such as chronic cough or sputum production, and both have normal pulmonary function tests (FEV_1 100% and 102% predicted). Neither patient has evidence of pancreatic disease (normal serum amylase, trypsin and fecal elastase). Thus, identification of AHO patients with reduced CFTR activation due to a defect in the -adrenergic pathway questions the role of this signaling pathway in the pathogenesis of CF.

Progress toward the generation of a transgenic ovine model for Huntington's Disease (HD). *J.C. Kitchen[1,2], H.J. Waldvogel[2], S.J. Reid[3], C.S. Bawden[4], R.L.M. Faull[2], R.G. Snell[3], M.I. Rees[1,5].* 1) Department of Molecular Medicine and pathology, University of Auckland Medical School, Auckland, New Zealand; 2) Department of Anatomy with Radiology, University of Auckland Medical School, Auckland, New Zealand; 3) The Neurogenetics group, School of Biological Sciences, University of Auckland, Auckland, New Zealand; 4) Molecular Biology Laboratory, Meat and Wool Division, South Australian Research and Development Institute, South Australia; 5) Molecular Neuroscience Group, School of Medicine, University of Wales Swansea, UK.

Huntingtons Disease (HD) is a dominant neurodegenerative disorder caused by an expanded trinucleotide (CAG) repeat in the IT15 gene for huntingtin. We are developing an ovine transgenic model of HD. Our aim is to develop a relatively late onset model of the disease in an organism with a brain structure more closely resembling humans.

We have isolated the ovine HD homologue using a combination of degenerate RT-PCR, 5/3 RACE, and long-range genomic PCR. The ovine cDNA revealed a 9,378bp reading frame creating a 3,126aa protein and exhibiting an 88% peptide homology to human huntingtin. The ovine *HD* gene contains a CAG motif ranging from 10-12 copies, similar to the primate gene and in contrast to the length in rodents.

Two regions divergent in human and ovine huntingtin have been selected for monoclonal antibody generation in order to assess transgene and wild type expression.

Sequence comparison and immunohistochemical distribution of htt, calbindin, substance P and enkephalin in wild type ovine brain tissue will be reported at this meeting. The transgene microinjections will be completed by the time of this presentation and we will be able to report on the progress of the pregnancies. This project will provide an opportunity to trial intervention strategies *in vitro* and *in vivo*.

Use of real-time quantitative PCR to detect exonic deletions/duplications of *BMPR2* in familial primary pulmonary hypertension. *M.W. Pauciulo, A.P. Batchman, W.C. Nichols.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Familial primary pulmonary hypertension (FPPH) is an autosomal dominant disorder characterized by occlusion and remodeling of the pulmonary arteries which leads to sustained elevation of pulmonary vascular resistance and progressive right heart failure. Using direct sequencing, previous studies have shown that approximately 50% of FPPH patients have coding sequence mutations in the gene for bone morphogenetic protein receptor type II (*BMPR2*). While effective, direct sequencing of a genes coding sequence does not detect other types of heterozygous mutations such as gross gene deletions or duplications. To date, studies using either Southern blot analysis or RT-PCR of *BMPR2* message to identify exonic deletions/duplications have been limited due to cumbersome methodology and inadequate availability of patient RNA samples. The aim of our study was to validate the use of real-time quantitative PCR in identifying *BMPR2* gross gene deletions/duplications in FPPH patients. We examined patients from 2 unrelated PPH families (A and B) recently reported to carry either a heterozygous deletion of exons 4 and 5 (Family A) or a heterozygous duplication of exon 10 (Family B). Following determination of patient DNA concentration using PicoGreen, gene dosage assays were performed on each patient for all 13 exons of *BMPR2*. Absolute quantitation values for each *BMPR2* exon of the FPPH patients were determined using a standard curve and compared to those of control subjects to look for the presence of exonic deletions or duplications. Our results showed both a heterozygous deletion of exons 4 and 5 in Family A and a heterozygous duplication of exon 10 in Family B, thereby replicating the recent report of these two families. This study demonstrates that real-time quantitative PCR is a viable alternative to either Southern blot analysis or RT-PCR for the detection of *BMPR2* exonic deletions/duplications in FPPH. Moreover, this method is significantly less time consuming than Southern blot analysis and obviates the need for patient RNA samples which can be difficult to obtain.

Novel Splice-site Mutation in the Pre-mRNA Splicing Gene PRPF31 in a Large Chinese Family with Autosomal Dominant Retinitis Pigmentosa. *c. zhao[1,2], S.S. Lu[1,2], A. Alimov[2], X.L. Zhou[2], F.Q. Xiang[2], N.D. Li[1], K.X. Zhao[1], C. Larsson[2].* 1) Molecular Genetics Lab, TianJin Eye Hospital, TianJin, TianJin, China; 2) Department of Molecular Medicine, Karolinska University Hospital, CMM, Stockholm, Sweden.

Purpose: To identify mutations in a four-generation Chinese family with autosomal dominant retinitis pigmentosa (adRP) and to characterize its clinical phenotype. Methods: Ophthalmologic and electrophysiological examinations of 11 patients with RP were performed. A genome-wide linkage screening was conducted in the family. Direct genomic sequencing was used to evaluate all the exons and flanking intron sequences of the candidate gene PRPF31. A restriction assay was used to confirm the mutation status in the family, and to exclude it as a polymorphism in a reference population. Results: The clinical findings were consistent with a relatively severe and diffuse type of RP. By linkage analysis we mapped the disease gene close to RP11 in chromosomal region 19q13.4. A novel single heterozygous base substitution (G>C) was detected at the beginning of intron 8 in the PRPF31 gene whereby the consensus GT dinucleotide of the intron 8 splice donor site was changed to CT. The mutation co-segregated completely with the disease phenotype, but was absent in the unaffected relatives and 100 reference subjects, thus supporting its pathogenic nature in the family. Conclusions: A novel splice site mutation (IVS8+1G>C) in the PRPF31 gene caused retinitis pigmentosa in the four-generation Chinese adRP family studied. The relatively severe clinical findings in the RP patients and the high penetrance observed support the severity of the mutation detected in this family.

Spectrum of WFS1 mutations in low frequency sensorineural hearing loss and Wolfram syndrome. *M. Lesperance[1], E.D. Snyder[1], C. Nishimura[2], T.A. Sivakumaran[1], J. Toung[1], R.J.H. Smith[2].* 1) Otolaryngology/Head/Neck Surg, Univ Michigan, Ann Arbor, MI; 2) Dept Otolaryngology, Univ Iowa Hosps and Clinics, Iowa City, IA.

Non-syndromic low frequency sensorineural hearing loss (LFSNHL) affects frequencies at or below 2000 Hz. It is typically delayed-onset and progressive without leading to profound deafness. LFSNHL may result from mutations in DIAPH1 (DFNA1) or WFS1 (DFNA6/14/38), the Wolfram syndrome 1 gene. Mutations causing Wolfram syndrome (WS) are recessive and typically inactivating, whereas LFSNHL mutations are dominant and non-inactivating, usually affecting the C-terminal domain. We screened WFS1 in DNA samples from 61 probands with LFSNHL (15 multiplex, 46 simplex) and 9 probands meeting diagnostic criteria for WS. Sequencing results were compared to those reported in the literature and from 110 control DNA samples. 2/9 WS subjects had biallelic WFS1 mutations (1230-1233 delCTCT/W540X or W613X/D211N), and 3/9 had heterozygous variants (R868G, H323R, or A684V). In 4/9, no WFS1 mutations were found. In multiplex LFNSHL families, 6/15 segregated heterozygous deafness alleles. 4 mutations were previously reported and 2 were novel (2203G>T, W678L and 2575G>T, I802S), both affecting residues conserved in rat and mouse. Known LFSNHL mutations L829P and A716T were found in 2 families each. One A716T haplotype shared common SNPs with Dutch Family W. In simplex families, 6/46 had heterozygous WFS1 variants, 3 of which were novel (V624A, R457S and L557F). The 3 others were A602V, found in controls and in psychiatric disease; M518I, reported in psychiatric disease, and K193Q, reported in sporadic LFSNHL.1 simplex case had biallelic GJB2 mutations (235delC/V37I). Subjects with clinical evidence of WS but without WFS1 mutations may have undetected mutations in non-coding regions; or, mutations in WFS2, which has been mapped but not cloned, may be responsible. Our results demonstrate that LFSNHL inherited as a fully penetrant, dominant, nonsyndromic trait is highly predictive of a WFS1 mutation.WFS1 mutations are much less likely when LFSNHL is sporadic, unilateral, or associated with craniofacial malformations.

Is autosomal recessive deafness associated to oculocutaneous albinism a coincidence syndrome? *K. Lezirovitz[1], F.S. Nicastro[2], E. Pardono[1], R.S. Abreu-Silva[1], A.C. Batissoco[1], I. Neustein[3], M. Spinelli[2], R.C. Mingroni-Netto[1].* 1) Centro de Estudos do Genoma Humano, Genética e Biologia Evolutiva, IB-Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) Divisão de Educação e Reabilitação de Distúrbios da Comunicação, Pontifícia Universidade Católica, São Paulo, Brazil; 3) Depto de Oftalmologia, Hospital Servidor Público Estadual SP, São Paulo, Brazil.

Ziprkowski and Adam (Arch Dermatol. 1964; 89:151-5) reported deafness associated to oculocutaneous albinism (OCA) in two sibships in the same inbred pedigree. A syndrome associating deafness and OCA was suggested [OMIM # 220900]. Deafness and oculocutaenous albinism were also observed by us in a non-consanguineous family: the proband was affected by both diseases, one of his sisters had only OCA and another sister only deafness. Both the proband and his deaf sister were found to be homozygous for the c.35delG mutation in the *GJB2* gene, the most frequent cause of hereditary deafness. Linkage analysis with markers close to the four OCA *loci* excluded linkage to OCA1, OCA2 and OCA3, but homozygosis in markers for OCA4 *locus* (chromosome 5) was observed. Sequencing of the corresponding gene *MATP* revealed the c.1121delT mutation in exon 5, which leads to a stop codon in position 397 (L374*fs*X397). Deafness and albinism in this pedigree were independent autosomal recessive conditions due to mutations in two different genes. It is noteworthy that parents were not consanguineous. We speculate that the putative syndrome reported by Ziprkowski and Adam might have resulted from the co-occurrence of autosomal recessive deafness and albinism in the same pedigree. Financially supported by CEPID/FAPESP and CNPq/PRONEX.

Novel mutations in the gene encoding otoferlin (OTOF) in Spanish subjects with non-syndromic profound hearing impairment. *I. del Castillo, M. Rodriguez-Ballesteros, M.A. Moreno-Pelayo, M. Villamar, F. Moreno.* Unidad de Genetica Molecular, Hospital Ramon y Cajal, Madrid, Spain.

Inherited hearing impairment (HI) affects about 1 in 2,000 newborns. Mutations in the gene encoding otoferlin (OTOF, on 2p23) are responsible for a subtype of AR prelingual HI (DFNB9), characterized by a profound hearing deficit and features of auditory neuropathy (AN), i.e. absence of auditory brainstem responses but preserved otoacoustic emissions (OAEs). To date, 15 different mutations have been reported in OTOF. Among them, Q829X is highly prevalent among Spanish subjects with prelingual HI. After getting informed consent, we enrolled 443 Spanish unrelated subjects with AR non-syndromic HI (191 multiplex cases and 252 simplex cases, including 6 simplex cases with a diagnosis of AN). DNA was extracted from blood samples, and a specific test for the Q829X mutation was performed. In subjects heterozygous for Q829X, OTOF exons and exon/intron boundaries were sequenced. In patients with AN not carrying Q829X, OTOF mutations were investigated by sequencing. We found 15 cases biallelic for mutations in OTOF. Nine cases (including 2 with previous diagnosis of AN) were homozygous for Q829X. Five cases (including 3 with AN) were compound heterozygotes for Q829X and a novel OTOF mutation. One subject with AN was a compound heterozygote for two novel OTOF mutations. The novel mutant alleles included one insertion (1180-1181insG), three deletions (1236delC, 1601delC, 2684-2685delGG), one indel mutation (2905-2923del19ins11), one nonsense mutation (C883X), and one splice site mutation (IVS35+1G>T). All subjects biallelic for OTOF mutations had a prelingual profound HI. All subjects in our cohort with a previous diagnosis of AN and profound HI were biallelic for OTOF mutations. DFNB9 hearing impairment accounts for at least 3.4 % of cases in our cohort. Our results further support that genetic diagnosis of subjects with AN and profound HI should be directed to the OTOF gene. Our data are of concern to universal screening programmes which use transient-evoked OAEs as the first detection test for HI in newborns, since this technique may overlook a non-negligible proportion of cases.

Genotype-Phenotype correlations of GJB2 mutations. *K. Kahrizi[1], M. Malekpour[1], C. Nishimura[2], Y. Riazalhosseini[1], A. Daneshi[3], P. Majidpour[3], M. Avenarius[2], R.J.H Smith[2], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 3) Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran.

In this study, we analyzed the genotype-phenotype correlations in the Iranian GJB2-related deaf population. Included in this study were 154 patients who met the defining criteria for autosomal recessive non-syndromic hearing impairment. Hearing loss was non-progressive in all of study patients. Of these, 95 patients (65%) were homozygous for the 35delG mutation and 25 patients (17%) carried the 35delG mutation *in trans* with another GJB2 mutation. The next two most prevalent mutations were W24X, present on 17 chromosomes (5.8%) and -3170G>A, present on 14 chromosomes (4.8%). In the entire group, severe-to-profound deafness was seen in 83.8% of the cases, including 92% of those homozygous for the 35delG mutation. All persons segregating missense mutations, whether homo- or heterozygous, had severe-to-profound hearing loss.

A *Coch* knock-in mouse model for DFNA9 deafness. *N.G. Robertson[1], T.A. Sivakumaran[1,2], S.A. Hamaker[1], C.C. Morton[1,2].* 1) Depts. Ob/Gyn & Pathology, Brigham & Women's Hospital; 2) Harvard Medical School, Boston, MA.

COCH, encoding cochlin, is expressed at high levels in the inner ear. Five missense mutations in the FCH/LCCL domain of *COCH* have been found in the autosomal dominant late-onset deafness and vestibular disorder, DFNA9, showing abnormal eosinophilic deposits in the cochlear and vestibular labyrinths. To create a mouse model for DFNA9, we generated a mouse knock-in by introducing one of the *COCH* mutations (G88E). A recent *Coch* knock-out mouse does not show any hearing or vestibular defects (Makishima *et al.*, Hum. Genet., in press) supporting a hypothesis of a dominant negative effect of the mutations.

The targeting construct consists of ~5.6kb of 129/SvJae mouse *Coch* genomic sequence spanning introns 3 to 8. Positive and negative selection were performed through neomycin (*neo*) flanked by *loxP* sites in *Coch* intron 5, and thymidine kinase upstream of the *Coch* sequence, respectively. J1 embryonic stem (ES) cells were transfected with the *Coch* mutant construct and 240 ES cell clone were screened. Integrity of the recombination, *loxP* sites, the mutation, and exons were confirmed by PCR, Southern blots, and sequencing. A homologous recombinant ES cell clone was microinjected into C57BL/6 blastocysts for implantation into pseudopregnant mice, yielding several chimera which showed germline transmission of mutant *Coch*.

F1 mice heterozygous for the mutant allele were mated with EIIa-*cre* "deletor" mice for *neo* excision. Prior to *neo* excision, RT/PCR in heterozygotes showed only the wild-type transcript, indicating that the presence of *neo* in the intron disrupts transcription or splicing of mutant *Coch*. These mice are being mated together to generate a *Coch* functional knock-out. After *neo* excision, RT/PCR of knock-in heterozygotes showed presence of the mutant *Coch* transcript. Heterozygotes are being bred for homozygosity. Studies of these mice will include auditory brainstem response (ABR) analysis, vestibular testing, histopathology and immunohistochemistry of all major organs including the inner ear, and cochlear cDNA microarray and proteomic analyses.

Analysis of *TRPA1* as a Candidate Gene for Bilateral Sensorineural Hearing Loss. *J. McCallum, D. Yaeger, I.D. Krantz.* Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Non-syndromic bilateral sensorineural hearing loss (NSBLSNHL) is genetically heterogeneous with over 80 loci and 30 genes implicated. Approximately 50% of recessive NSBLSNHL is due to mutations in the *GJB2* gene. A recent and growing body of evidence (biophysical, immunochemical, and molecular) suggests that TRPA1 (transient receptor potential ion channel A1; aka ANKTM1) may play a significant role in the signal transduction pathway in hair cells acting as the gated spring on sterocilia tip links in mechanotransduction which results in the perception of sound. *TRPA1* is a 27 exon gene that is defined in its N-terminal region by a series of ankyrin repeats. To assess the contribution that mutations in this gene make towards the etiology of NSBLSNHL we have performed mutational analysis of *TRPA1* in a cohort of 70 probands with NSBLSNHL from a pediatric population. All individuals were evaluated by a clinical geneticist to rule out syndromic etiologies. The cohort did not carry biallelic mutations in *GJB2* and were negative for the A1555G mitochondrial mutation and the *GJB6* deletion. A panel of 80 normal controls (160 chromosomes) was also screened. All exons and intron/exon boundaries of *TRPA1* were amplified by PCR followed by CSGE. All identified shifts were sequenced. Sixteen exonic changes were identified, of which 7 lead to an amino acid change. Two missense changes (each seen heterozygously in a single proband) were not identified amongst the controls: D306N and I469V both of which are found within ankyrin repeat regions. The isoleucine at position 469 is conserved in human and mouse, whereas the aspartic acid at position 306 is conserved in human, mouse, zebra fish and drosophila. The proband with the I469V change has severe to profound hearing loss and no history of affected family members. The proband with the D306N change also has a heterozygous V37I *GJB2* change with mild to moderate hearing loss (this proband is adopted and no parental samples are available). Additional work is underway to characterize these mutations and to better understand the contribution that changes in *TRPA1* make towards the etiology of NSBLSNHL.

A mutation spectrum of *MYO7A* associated with Usher syndrome type 1 and evidence for the existence of *DFNB2*. *S. Riazuddin[1], S. Nazli[2], R.S. Sheikh[2], S.N. Khan[2], F. Sabir[2], F.T. Javid[2], E.R. Wilcox[1,3], Z.A. Ahmed[1], S. Riazuddin[2], T.B. Friedman[1].* 1) LMG, NIDCD, National Institutes of Health, Rockville, MD; 2) National Center of Excellence in Molecular Biology, Punjab University, Lahore, Pakistan; 3) DNA Sequencing Center, Brigham Young University, Provo, UT, USA.

Defects of myosin VIIa are responsible for splayed and disorganized stereocilia of hair cells of the inner ear of the deaf shaker 1 mouse, the circler phenotype of mariner zebrafish and Usher syndrome type 1 (*USH1B*) and dominantly inherited, progressive hearing loss (*DFNA11*) in humans. We screened for linkage to *MYO7A* markers in a cohort of 557 consanguineous families segregating severe to profound hearing loss as a recessive trait. In 24 of these families, hearing loss was linked to markers for *MYO7A* and affected members of these families had mutations in this gene. Twenty-three of these families have USH1 associated with 14 novel recessive alleles of *MYO7A*. Based on opthalmological and audiological examinations, affected members of just one of the 24 families segregated only profound, congenital hearing loss and affected individuals were found to be homozygous for an in-frame deletion of a single amino acid in the tail of *MYO7A*. This one family is arguably the first convincing clinical case for the existence of *DFNB2*, which is a very rare phenotype associated with recessive alleles of *MYO7A*. In this study we also describe 14 novel recessive mutant alleles of *MYO7A* associated with USH1.

Molecular basis of deafness in Portuguese familes exhibiting monoallelic or null mutations in exon 2 of GJB2. *H. Teixeira[1], T. Matos[1], C. Correia[1], O. Dias[3], M. Andreia[3], H. Caria[1,2], G. Fialho[1].* 1) Center of Genetics and Molecular Biology, Faculty of Sciences, University of Lisbon, Lisbon, Portugal; 2) College of Health Care, Politechnic Institute of Setúbal, Setúbal, Portugal; 3) Center of ORL, Faculty of Medicine, University of Lisbon, Lisbon, Portugal.

A first characterization of the Portuguese population led us to the conclusion that mutations in GJB2 gene, encoding connexin 26, are a major cause of sensorineural pre-lingual deafness, as described for other populations. Mutation screening of GJB2 coding sequence has however revealed a high proportion of affected individuals carrying only a single mutant allele or no mutation in GJB2. This study aims at contributing for the elucidation of the molecular basis of deafness in those Portuguese families with sensorineural nonsyndromic deafness and exhibiting monoallelic or null disease-causing mutations in exon 2 of GJB2. Exclusion analysis with polymorphic microsatellite markers corresponding to DFNB1 locus was first performed in order to exclude the cases not linked to this locus. Families in which DFNB1-related deafness was confirmed through this analysis were then screened for the two common non-coding, non-complementary DFNB1-causing mutations, the intron 1 splice donor mutation IVS1+1G-A in GJB2 and del(GJB6-D13S1830) in GJB6, before attempting other strategies. The relevance of refining GJB2 screening in order to unequivocally diagnose non-elucidated cases of nonsyndromic deafness will be discussed together with the analysis of the results obtained.

Linkage mapping of a major familial Ménière disease locus to human chromosome 14. *M.E.S. Bailey[1], Y. Lowe[1], S. Bevan[2], S.A. Carter[1], J. Brooking[2], K.J. Johnson[3], G.A.J. Morrison[4], A.W. Morrison[5].* 1) Division of Molecular Genetics, IBLS, University of Glasgow, Glasgow, U.K; 2) MRC geneservice, Wellcome Trust Genome Campus, Hinxton, Cambridge, U.K; 3) Pharmacogenomics Division, Pfizer Inc., Ann Arbor, Michigan, U.S.A; 4) Dept. of Otolaryngology, Guys and St Thomas Hospitals, London, U.K; 5) Dept. of Otolaryngology, Royal London Hospital, London, U.K. (retired).

Ménière disease (MD) is a relatively common disorder (approx. 1/2000 of the population) of hearing and balance characterised by episodic hearing loss, tinnitus, and rotatory vertigo with nausea and vomiting. MD has mid-life onset and leads to a significant reduction in quality of life. The pathology results from endolymphatic hydrops leading to increased pressure in the sensory compartments of the inner ear and vestibular system. There is strong evidence that the causes of MD are partly genetic and partly environmental. Although mostly sporadic, approx. 7% of cases are familial, a sibling relative risk of 9 has been estimated, and the worldwide distribution is consistent with a founder effect. HLA associations have been reported.

We have used a set of 19 MD families families consistent with autosomal dominant inheritance in a genome scan to map predisposing loci. We have strongly suggestive evidence for linkage of half the families (HLOD 3.4, = 53% of families linked, 95% penetrance) to a single locus in chromosome 14q21-q22. There were no other strongly supported loci. Meiotic recombination analysis of linked families suggests a critical region of 11.6Mbp. Fine mapping of this region is ongoing, but a preliminary analysis indicates that additional informative markers exist and potentially narrow the critical region to <4cM, with a concomitant increase in the HLOD score to 5.0. Analysis of current and former positional candidate genes has ruled out several, including COCH. We hope that identification of the causative gene in the linked families will suggest candidates for the remaining families and illuminate pathways contributing to susceptibility to the more common, sporadic cases of MD.

V37I is a GJB2 pathogenic mutation with reduced penetrance leading to non-syndromic sensorineural hearing loss. *H. Bruyere[1], C. Huculak[2], T. Nelson[1], B. Casey[1], M. Van Allen[2], F. Kozak[3], S. Langlois[2].* 1) Department of Pathology and Laboratory Medicine, UBC, Canada; 2) Department of Medical Genetics, UBC, Canada; 3) Division of Pediatric Otolaryngology, UBC, Canada.

BACKGROUND More than a hundred GJB2 mutations have been identified in patients with non-syndromic sensorineural hearing loss (SNHL), but the status of some of them is unclear, as they have been reported as both polymorphisms and pathogenic mutations. One such alteration is c.109G>A (V37I), frequently reported in Asian patients and controls. In the culturally diverse SNHL population tested in our lab, the V37I allele is more frequent than the 35delG, 235delC and 167delT alleles, reportedly the most common GJB2 mutations in Caucasian, Asian and Jewish Ashkenazi SNHL patients. Further studies of V37I frequencies in Asian versus Caucasian and patients versus normal hearing controls were deemed necessary for the accurate interpretation of our patients' results. METHODS We reviewed the clinical charts and molecular results of 80 SNHL patients of Chinese and Caucasian descent and compared the results to the frequency of V37I in 200 ethnically matched controls. We compiled the audiograms of individuals with SNHL to determine whether V37I homozygosity was associated with a specific audiologic profile. RESULTS 12 patients of Chinese descent were found to be V37I homozygous and 10 were V37I heterozygotes. In one family, normal hearing parents were also V37I homozygotes. In the 100 Chinese controls, 1 V37I homozygote and 21 heterozygotes were found. The V37I allele was not found in either the 40 Caucasian patients or the Caucasian controls. The difference in V37I homozygote and heterozygote distribution among Chinese patients and controls is statistically significant (Pearson chi squared test: $p<0.00001$). Audiological reports from V37I homozygote patients showed that they present with mild to moderate, high frequency SNHL, in contrast to the mild to severe SNHL observed in the Chinese patients. CONCLUSION V37I is a common allele in the Chinese population with a carrier frequency of 1 in 5, and plays a role in SNHL as an allele responsible for mild to moderate hearing loss with reduced penetrance.

Predominance of W24X and absence of 35delG mutations in the Baloochi and Sistani deaf population of Iran: a different population. *A. Naghavi[1, 2], C. Nishimura[3], K. Kahrizi[1], Y. Riazalhosseini[1], S. Rigi[4], N. Mahdieh[1], R.J.H. Smith[3], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Molecular-Cellular Biology Department, Khatam University, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 4) Zahedan Welfare Organization, Zahedan, Iran.

Hereditary hearing impairment is a heterogeneous disability showing different patterns of inheritance and involving a multitude of different genes. Mutations in the GJB2 gene, especially the 35delG mutation, have been established as a major cause of inherited and sporadic non-syndromic deafness in various ethnic groups. Because population-specific differences are relatively common, in this study we sought to determine the prevalence and spectrum of GJB2 mutations in two isolated ethnic groups: the Baloochi and the Sistani populations of southeastern Iran. Consanguinity and assortative mating are very common in these populations. We analyzed one hundred Baloochi and Sistani families suffering from autosomal recessive non-syndromic hearing impairment. We performed mutation screening of GJB2 using an allele-specific PCR assay to detect the 35delG mutation. The negative or heterozygous cases for the 35delG mutation were screened by denaturing high performance liquid chromatography (DHPLC) and sequencing analysis. Surprisingly, we did not find the 35delG mutation, the most common GJB2 mutation in the white population and in other parts of Iran, in any of the Baloochi or Sistani patients. We identified GJB2 mutant alleles in 18 chromosomes (9%) including R127H, K122I, W24X, 167delT and M93I. Among them, W24X had the highest frequency (10 chromosomes). Based on these data, the hot-spot mutations in the GJB2 gene in the Baloochi and Sistani population with non-syndromic hearing loss may be different from other ethnic groups in Iran. In addition, these results further indicate the existence of an ethnic bias in the distribution of GJB2 mutations in western Asia.

Contribution of GJB6 large deletion to the hereditary deafness genetic load in the Iranian population. *P. Imanirad[1, 2], M. Avenarius[3], Y. Riazalhosseini[1], C. Nishimura[3], M. Mohseni[1], N. Bazazzadegan[1], K. Kahrizi[1], R.J.H. Smith[3], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Molecular-Cellular Biology Department, Khatam University, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA.

Mutations in the gene that encodes the gap-junction protein connexin 26 (GJB2) at the DFNB1 locus on chromosome 13q12 are the major cause of autosomal recessive non-syndromic sensorineural deafness (ARNSD) in many different populations. A second gap-junction gene, GJB6, also localizes to the DFNB1 interval. Interestingly, the encoded protein connexin 30 is expressed in the same inner-ear structures as connexin 26 and both connexins are functionally related. The importance of GJB6 to normal hearing has been confirmed by the identification of a large deletion (()(GJB6-D13S1830)) involving the first two exons and a part of the third exon of GJB6 and a large region of the upstream sequence in persons with ARNSD. Homozygotes for this deletion and compound heterozygotes carrying (GJB6-D13S1830) and a deafness-causing allele variant of GJB2 have severe-to-profound congenital deafness. The aim of this study was to evaluate the contribution made by this deletion to the ARNSD genetic load in the Iranian population. One hundred and fifty four probands with ARNSD from various regions of the country were screened for this mutation using polymerase chain reaction (PCR) primers that amplified the breakpoint junctions of the deletion. Among them, one hundred and sixteen patients were deaf probands with normal GJB2 alleles and the remaining 38 were heterozygote for only one GJB2 mutation. None of patients screened for (GJB6-D13S1830) was shown to carry this deletion, suggesting that this mutation is not a common cause of deafness in Iran.

Autosomal dominant optic atrophy and sensorineural deafness due to OPA1 R445H mutation. *P. Amati-Bonneau[1], A. Guichet[2], A. Olichon[3], A. Chevrollier[1], F. Viala[4], C. Ayuso[5], S. Odent[6], C. Verny[7], P. Belenguer[3], J.P. Puel[8], C. Hamel[8], Y. Malthièry[1], G. Lenaers[8], P. Reynier[1], D. Bonneau[2].* 1) Service de Biochimie et Biologie Moléculaire,CHU;INSERM U694,Angers, France; 2) Service de Génétique Médicale, CHU Angers, France; 3) Laboratoire de Biologie Cellulaire UMR CNRS 5088, Université Paul Sabatier, Toulouse, France; 4) Service d'ORL, CHU Toulouse, France; 5) Servicio de Genetica, Fundacion Jimenez Diaz, Madrid, Spain; 6) Service de Génétique Médicale, CHU Rennes, France; 7) Département de Neurologie, CHU Angers, France; 8) INSERM U583, Hôpital Saint-Eloi, Montpellier, France.

Autosomal dominant optic atrophy (ADOA, OMIM 165500) generally starts in childhood and is characterized by a progressive decrease in visual acuity, color vision defect in the blue-yellow hues and optic nerve pallor. In most cases, optic atrophy appears as an isolated disorder but ADOA has been reported to be associated with deafness. Mutations in the Optic Atrophy 1 (OPA1) gene, located on chromosome 3q28-q29, have been found in about 47% of patients affected with ADOA. The OPA1 gene encodes a dynamin-related GTPase, located in the mitochondrial inter-membrane space, which plays a key role in controlling the balance of mitochondrial fusion and fission. We report 5 patients from 4 unrelated families affected with optic atrophy associated with sensorineural deafness. The same heterozygous R445H mutation in OPA1 was discovered in all 5 patients. In 3 of the 5 patients, audiological investigations indicated that the deafness was probably due to auditory neuropathy. Hyperfragmentation of the mitochondrial network and decreased mitochondrial membrane potential were observed in the skin fibroblasts of 3 patients. In a complementary study, we investigated the expression profile of OPA1 in the guinea pig cochlear cells. These findings suggest that the occurrence of sensorineural deafness associated with optic atrophy in patients with the R445H mutation could be the consequence of abnormalities of mitochondrial network dynamics and show the importance of a careful examination of auditory performance in ADOA patients.

Expression of *GJB2* and *GJB6* is reduced in a novel DFNB1 allele. *E. Wilch[1], M. Zhu[2], K. Burkhart[2], M. Regier[3], J. Elfenbein[4], R. Fisher[5], K. Friderici[1,2,5].* 1) Genetics Program; 2) Department of Microbiology & Molecular Genetics; 3) Department of Epidemiology; 4) Department of Audiology & Speech Sciences; 5) Department of Pediatrics & Human Development, Michigan State Univ, East Lansing, MI.

Mutations in *GJB2*, the gene encoding gap junction protein connexin 26 (Cx26), are the most common cause of prelingual-onset, recessively inherited, non-syndromic, sensorineural hearing loss (SNHL) in humans. *GJB2* and *GJB6*, the gene encoding connexin 30 (Cx30), together comprise the DFNB1/A3 locus at 13q12. Although more than 70 mutations of *GJB2* are known or suspected to cause recessive nonsyndromic SNHL, *GJB2/GJB6* mutation screening consistently yields a significant proportion of deaf subjects bearing only one identified mutation, leading to the speculation that unidentified mutations exist at the DFNB1 locus, beyond the proximal promoter region of *GJB2* that is most commonly screened, in *cis*-regulatory elements that control expression of the Cx26 message. We have identified four such *GJB2* heterozygotes in a large kindred of German descent. Each of these profoundly deaf individuals bears a single 35delG mutation, and all share a common haplotype across >250kb on their non-35delG chromosome. We sequenced the entire coding regions and 5 and 3 UTRs of both *GJB2* and *GJB6* in our affected probands, including splice sites, alternative exons and promoter regions, the entire single intron of *GJB2* and >5kb upstream of *GJB2*, and found no sequence variants unique to the novel haplotype. Heterozygosities found in sequencing also showed that both genes are intact on both chromosomes and that affected individuals do not bear the >300kb deletion del(*GJB6*-D13S1830) that segregates with deafness when present in trans with a *GJB2* mutation. Southern blotting indicated no rearrangements or unusual methylation around *GJB2*. However, PCR-based allele-specific expression assays showed that expression of both *GJB2* and *GJB6* from the novel allele is significantly reduced. This is the first evidence of a deafness-associated regulatory mutation of *GJB2*, and the first genetic evidence of potential coregulation of *GJB2* and *GJB6*.

Knock-in mouse model of Usher type IC and cloning of the Zebrafish *USH1C* ortholog. *J. Lentz[1], S. Sampath[1], S. Ng[1], A. Flynn[1], P. Deininger[2], B. Keats[1].* 1) LSU Health Sciences Center, New Orleans, LA; 2) Tulane University Health Sciences Center, New Orleans, LA.

Usher syndrome type I is characterized by deafness at birth, vestibular dysfunction and progressive retinitis pigmentosa beginning in early adolescence. A cryptic splice site mutation (216GA) in exon 3 of the *USH1C* gene on 11p, which encodes a PDZ-domain protein, harmonin, was found in Acadian Usher type IC families in south Louisiana. In vitro analysis using constructs containing the mutant 216A and subsequent analysis of patient cells lines revealed a 35 base deletion. In order to analyze the impact of this frame-shift mutation, we are creating a knock-in mouse model containing the human 216GA mutation. The targeting construct contains two 4-kb homology arms cloned from mouse DNA, a human fragment with the 216GA mutation cloned from a patient, and the neomycin resistance gene (neo) flanked by loxP sites. Sequence analysis confirmed orientation. Linearized construct was electroporated into embryonic stem (ES) cells and drug (neo) selected for ten days. ES cell clones were analyzed for targeted homologous recombination by polymerase chain reaction (PCR) and Southern blot. Of 485 clones screened by PCR, 50 were positive for homologous recombination (10.3%). Clones confirmed by Southern blot are being microinjected into blastocysts and implanted into pseudo-pregnant mice. Following confirmation of germline transmission of the mutation, breeding will continue to obtain heterozygous and homozygous 216GA offspring. Characterization of hearing and vision defects, as well as expression and developmental studies will be performed. In parallel, we are isolating a full length zebrafish *USH1C* cDNA using sequence information from the zebrafish genome and EST databases, together with RACE experiments. Our transcript has 76% identity with the N-terminus of human and maps to LG25, which shares significant synteny with human chromosome 11p. We will characterize this gene and encoded protein, and determine developmental expression patterns by in situ hybridization analysis. Extending our work on Usher type IC to zebrafish will complement and enhance our ongoing mouse and human studies.

Molecular characteristics of the *GJB2* gene in Korean patients with nonsyndromic hearing loss. *S.I. Cho[1], M.W. Seong[1], B.Y. Choi[2], S.H. Oh[2], E.Y. Ra[1], S.S. Park[1].* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Department of Otolaryngology-Head and Neck Surgery, Seoul National University Hospital, Seoul, Korea.

Mutations of the *GJB2* gene are the most common cause of nonsyndromic hearing loss of autosomal recessive inheritance in the world. The spectrum of mutation is different to ethnicity and the most frequent mutation is 35delG in Caucasian, 167delT in Ashkenazi Jews, and 235delC in some Asian populations. In this study, we analyzed the *GJB2* gene for mutations in forty-three unrelated Korean patients with nonsyndromic hearing loss and forty-eight normal subjects. Direct sequencing was done for two exons and their flanking regions of the *GJB2* gene and gap PCR for large deletion including the *GJB6* gene [del(GJB6-D13S1830)]. Results showed that two patients were 235delC/427CT compound heterozygote and three patients were heterozygous for 109GA, 235delC, or 427CT without other mutations identified. Any of three mutations was not identified in normal subjects. The allele frequency of 235delC, 427CT, 109GA was 3.5%, 3.5 %, and 1.2% in patients. The large deletion including *GJB6* was not identified. We found a haplotype of two linked polymorphisms frequently: [V27I (79GA) + E114G (341AG)]. In patients, five cases (8.5%) were homozygous and twelve (27.9%) were heterozygous for the haplotype. In normal subjects, two (4.2%) were homozygous, and fourteen (29.2%) were heterozygous. This haplotype has a common origin. Previously the haplotype of these two polymorphisms was suggested as a pathogenic mutation in some reports, but the significance is still unclear. In conclusion, *GJB2* gene is obviously an important cause of the Korean patients with nonsyndromic hearing loss, but its mutation frequency is lower than that of Caucasian and similar with those of Chinese and Japanese.

Genetic studies of the Iranian deaf population. *H. Najmabadi[1], C. Nishimura[2], K. Kahrizi[1], Y. Riazalhosseini[1], M. Malekpour[1], A. Daneshi[3], M. Farhadi[3], M. Mohseni[1], N. Bazazzadegan[1], A. Naghavi[1], M. Avenarius[2], E. Taherzadeh[1], S. Arzhangi[1], Kh. Javan[1], R.J.H Smith[2].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 3) Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran.

During last six years, probands from 1259 families with hearing loss have been referred to our center for genetic testing. In 13 persons, the following syndromic phenotypes were recognized: Usher, Familial Expansile Osteolysis, Meniere, Bilateral Enlarged Vestibular Aqueduct, Waardenburg, Oto-Palato-Digital, Gorlin, Pendred, Stickler and Kallmann. In the remaining 1245 probands, the diagnosis of non-syndromic deafness was made. Pedigrees were consistent with autosomal recessive inheritance in 1167 probands and autosomal dominant inheritance in ten persons. Three families segregated X-linked deafness. In 65 probands, no other affected relative could be identified - we classified these as simplex cases. So far, GJB2 mutation screening has been completed in 1103 patients with autosomal recessive deafness, initially by completing an allele specific polymerase chain reaction (ASPCR) to detect the 35delG mutation. Persons either negative or heterozygous for this mutation were analyzed by denaturing high performance liquid chromatography (DHPLC) and direct sequencing. We found GJB2-related deafness in 172 of 1103 familial cases (15.6%) and in 4 of 65 simplex cases (6.1%). Identified deafness-causing allele variants included: delE120, 167delT, R184P, 310del14, R32H, 314del14, 35delG, IVS1+1G>A, -3170G>A, R127H, W24X, R143W, E129K, 312del14, M93I, W77R, 8insT, 512insAACG, 510insCGAA, 507insAACG, 329delA, 363delC, Q80L. The last four are novel mutations, which have not been reported in other populations. Selected probands and families negative for deafness at the DFNB1 locus are beginning used to complete a genome-wide linkage analysis. In four of these families, the deafness-causing gene has been localized to specific chromosomal regions.

Oim Mice: A Model to Assess Thoracic Aortic Integrity, Collagen Content and Collagen Crosslinking During Aging. *B.J. Pfeiffer[1], D.A. Wirth[1], C.L. Franklin[2], F.H. Hsieh[3], R.A. Bank[5], C.L. Phillips[1,4].* 1) Biochemistry; 2) Veterinary Pathobiology; 3) Biological Engineering; 4) Child Health, University of Missouri, Columbia, MO; 5) University of Amsterdam, The Netherlands.

Our initial interest in the *oim* mouse focused on the possible extraskeletal vascular complications associated with aging, which is increasingly important as treatments improve and patients live longer. Recent reports demonstrated increased risk of cardiovascular complications in EDS patients that fail to synthesize pro2(I) chains, the result of COL1A2 gene defects. This and a prior study of an OI patient with a similar gene defect as the *oim* mouse highlight a unique molecular mechanism that may alter cardiovascular properties. Type I collagen, normally a heterotrimer of two 1(I) and one 2(I) collagen chains, is hypothesized to be the major contributor to aortic strength (F_{max}) and stiffness (IEM). To assess the role of 2(I) chains in aortic integrity we used the *oim* mouse, which synthesize only homotrimeric type I collagen, $1(I)_3$. We evaluated thoracic aortas from 3, 8, and 18-month old oim, heterozygote, and wildtype mice for circumferential F_{max}/IEM, histology, 1(I)/2(I)/lysyl oxidase mRNA, collagen content and collagen crosslinking. Circumferential biomechanics of *oim* thoracic aortas exhibited reduced F_{max} and IEM in all age classes. Histological analyses of *oim* descending aortas show reduced collagen staining at each age class, confirmed by hydroxyproline analyses. RT-PCR analysis did not show genotypic differences in 1(I) and 2(I) mRNA expression suggesting that the decreased collagen content is not due to pretranslational mechanisms. Together, these findings suggest the reduced *oim* thoracic aortic integrity correlates with the absence of the 2(I) collagen chains and in part with reduced collagen content. In addition, increased pyridinoline crosslinks per collagen molecule were observed in *oim* aortas for all age classes relative to wildtype with lysyl oxidase mRNA significantly increased in 3-month *oim* aortas relative to age matched wildtype aortas. The role of increased collagen crosslinks is uncertain, but may represent a compensatory mechanism for decreased aortic integrity.

The carboxy terminus of CFTR interacts with glycolytic enzymes. *M. Lisi, R. Amanchy, A. Pandey, J. Mickle.*
Institute of Genetic Medicine , Johns Hopkins University School of Medicine, Baltimore, MD.

Cystic fibrosis is a life-limiting lung disease caused by the absence or dysfunction of the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel of the ATP-binding cassette (ABC) transporter family of proteins. To discover accessory proteins that bind CFTR and affect function we created Glutathione-S-Transferase (GST) CFTR fusion constructs for the isolation of interacting proteins from native epithelia. Because CFTR is expressed at relatively low levels in human epithelia, and airway epithelia are not readily accessible, we used opercular epithelia from killifish (*Fundulus heteroclitus*) where CFTR is abundantly expressed and easily accessible. Accordingly, epithelia were isolated, homogenized and the lysate was incubated with GST-kfCFTR C-ter (amino acids 1388-1503). Proteins that bound the C-terminus of CFTR were subsequently eluted and resolved by SDS-PAGE. The gel was silver stained and protein bands that were observed specifically with GST-kfCFTR C-ter, but not GST alone, were excised and subjected to in-gel tryptic digestion; the resulting tryptic digested peptides were analyzed by tandem mass spectrometry using a quadrupole time-of-flight mass spectrometer. As a result, we identified aldolase and enolase as interacting partners of CFTR C-ter. Both of these enzymes are cytosolic components of the glycolytic pathway, a multi-step process that converts glucose to pyruvate with a net yield of ATP. Multi-enzyme complexes facilitate metabolic reactions by allowing reaction intermediates to pass directly from one enzyme to the next without needless diffusion through the cytoplasm. The synergy with CFTR would link this enzyme complex to the plasma membrane where glucose import occurs. Moreover, an association of the glycolytic complex with the carboxy terminus of CFTR would bring ATP in close proximity to the nucleotide binding folds for the immediate binding and hydrolysis needed to gate the CFTR chloride channel.

A new look of disease genes revealed by a comparison with housekeeping genes. *Z. Tu, L. Wang, M. Xu, X. Zhou, T. Chen, F. Sun.* Molecular and Computational Biology Program, Department of Biological Sciences, University of Southern California, Los Angeles, CA.

The Online Mendelian Inheritance in Man (OMIM) has collected more than 2,000 genes that contribute to hereditary diseases. Previous studies compared them with all other human genes to find the common features of disease genes. However, this approach ignores the fact that the human genome also contains a large number of essential genes (genes that are essential for survival and producing progeny). The relationship among essential genes, disease genes and all other genes haven't been systematically studied yet. We hypothesize that human genes form a continuum. In one extreme are those functionally most important genes, the mutations of which at certain residues will severely affect human health and lead to early death. In the middle are those genes when mutated will cause diseases but patients with such diseases can still survive long enough to have progenies. In the other extreme are genes whose mutations generally will not cause detectable pathological phenotypes. In the absence of a set of well defined human essential genes, we choose 1,789 ubiquitously expressed human genes (UEHGs), also known as housekeeping genes, as category I genes and the disease genes in OMIM as category II genes. All other human genes are referred as category III genes. We show by several means that the category I genes are most likely to be essential genes. For example, a mapping of human genes to *C.elegans* genome reveals that category I genes have significantly more homologs which are essential genes in *C.elegans* (41%) than category II genes do (22%, p-value is 1.8e-11). We also show that the three classes of genes have distinct features such as evolutionary conservation, DNA coding length, gene function, etc. Our findings indicate that disease genes have an intermediate essentiality between category I and category III genes. We believe it is more reasonable to divide human genome into the above three classes in the systematic studies on disease genes. These findings and the features we studied show a new picture of disease genes and thus will help people better identify new disease genes.

A novel locus for primary ciliary dyskinesia (PCD) with inner and outer dynein arm defects in the Pakistani population. *H. Mitchison[1], V.H. Castleman[1], C. OCallaghan[2], E. Moya[3], J.E. Dankert-Roelse[4], G. Pals[5], R.M. Gardiner[1], E.M.K. Chung[1], R. Chodhari[1].* 1) Paediatrics and Child Health, Royal Free and University College Medical School, Rayne Building, London, UK; 2) Division of Child Health, Department of Infection, Immunity, and Inflammation, University of Leicester, UK; 3) Department of Paediatrics, Bradford Royal Infirmary Hospital, Bradford, UK; 4) Department of Pediatrics, University Hospital, Academisch Ziekenhuis van de Vrije Universiteit, Amsterdam, Netherlands; 5) Department of Human Genetics, VU Medical Center, Amsterdam, The Netherlands.

PCD is a genetically heterogeneous autosomal recessive disorder affecting 1:20,000 live births which is characterised by respiratory tract infections, sinusitis, bronchiectasis and subfertility. This arises from cilia dysmotility, associated with various ultrastructural abnormalities. Half of patients exhibit laterality defects (Kartagener syndrome), thought to result from embryonic nodal cilia defects. We have studied 5 consanguineous families with a ciliary defect of absent inner and outer dynein arms from the N. Pakistan Mirpur region. There are 9 affected and 29 unaffected individuals and a 400 marker microsatellite genome wide scan using GENEHUNTER identified a region of statistically significant linkage in 3/5 families, on chromosome 17q21-22. Haplotypes showed a shared region of excess homozygosity across a 9 Mb region between D17S951 and D17S1865. To isolate the PCD gene at this new locus, additional genotyping is in progress to refine the critical region and identify allelic association. We detect 107 gene-coding elements in the region (NCBI Build 35) which vary in their degree of biological confirmation. Vertebrate cilia are highly evolutionarily conserved for structure/function, so using a comparative bioinformatic approach incorporating ciliated and non-ciliated organism genomic and proteomic data, we have prioritised positional candidate genes for mutational analysis according to putative function, expression pattern and conservation in ciliates. This has highlighted appropriately expressed genes in the region for further analysis, including a well studied sperm-associated protein, SPAG9.

Ehlers-Danlos syndrome classic type: COL5A1 haploinsufficiency disrupts multiple steps in collagen fibril assembly. *R. Wenstrup[1], J. Florer[1], J. Davidson[2], C. Phillips[3], B. Pfeiffer[3], D. Menezes[4], I. Chervoneva[5], D. Birk[4].* 1) Div of Human Genetics, Children's Hosp Research Fndn, Cincinnati, OH; 2) Department of Laboratory Medicine, Vanderbilt University School of Medicine, Nashville TN; 3) Dept of Biochemistry, University of Missouri-Columbia, Columbia MO; 4) Department of Pathology, Anatomy, and Cell Biology, Thomas Jefferson University, Philidelphia PA; 5) Department of Medicine, Thomas Jefferson University, Philidelphia PA.

The most commonly identified mutations causing Ehlers-Danlos syndrome (EDS) classic type result in haploinsufficiency of COL5A1 which encodes pro 1(V) chains of type V collagen, a quantitatively minor collagen that co-assembles with type I collagen as heterotypic fibrils. Mice heterozygous for a targeted inactivating mutation in col5a1 that caused 50% reduction in col5a1 mRNA and collagen V had, comparable to EDS patients, decreased aortic tensile strength and hyperextensible skin with decreased tensile strength of both normal and wounded skin. In dermis of col5a1 +/- animals, 50% fewer fibrils were assembled with two subpopulations: normal fibrils with periodic immuno-reactivity for collagen V for which type I/V interactions regulate nucleation of fibril assembly; and highly irregular fibrils lacking collagen V, generated by unregulated sequestration of type I collagen. Fusions of normal and aberrant fibril subpopulations disrupt the normal linear and lateral growth mediated by fibril fusion. Therefore, reduced fibril nucleation and dysfunctional fibril growth with potential disruption of cell directed fibril organization leads to the connective tissue dysfunction associated with EDS.

Consortium for Osteogenesis Imperfecta Mutations: Lethal Regions in the Helical Portion of Type I Collagen Chains Align with Collagen Binding Sites for Integrin and Proteoglycans. *J. Marini[1], A. Forlino[1], W. Cabral[1], A. Barnes[1], J. San Antonio[2], S. Milgrom[1], J. Hyland[3], J. Korkko[3], D. Prockop[3], A. DePaepe[4], P. Coucke[4], F. Glorieux[5], P. Roughley[5], A. Lund[6], K. Kuurila[7], D. Cohn[8], D. Krakow[8], M. Mottes[1], R. Dalgleish[1], P. Byers[9].* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Thomas Jefferson Univ, Phila, PA; 3) Tulane Univ, New Orleans, LA; 4) Univ Ghent, Belgium; 5) Shriners Hospital, Montreal, Canada; 6) Rigshospitalet, Copenhagen, Denmark; 7) Vaasa Hosp, Finland; 8) Cedars-Sinai, Los Angeles, CA; 9) Univ of Washington, Seattle, WA.

To explore genotype-phenotype relationships between mutations in type I collagen genes (COL1A1 and COL1A2, encoding 1(I) and 2(I) chains, respectively) and Osteogenesis Imperfecta, we identified 832 independent mutations, of which 682 result in substitution for glycine residues in the helical domain and 150 alter splice sites. Distinct genotype-phenotype relationships emerge for each chain. One-third of 1(I) glycine substitutions are lethal, especially residues with a charged or branched side chain. Substitutions in the first 200 residues are non-lethal and have variable effect thereafter, unrelated to folding or helix stability domains. Two exclusively lethal regions (691-823 and 910-964) align with Major Ligand Binding Regions, suggesting crucial interactions of collagen monomers or fibrils with integrins, MMPs, fibronectin and COMP. Mutations in COL1A2 are predominantly non-lethal (80%). Lethal substitutions are located in 8 regularly spaced clusters along the chain, supporting a regional model. The lethal regions align with proteoglycan binding sites along the fibril, suggesting a role in fibril-matrix interactions. Unlike 1(I), recurrences at the same site in 2(I) are generally concordant for outcome. Splice site mutations in COL1A1 are rarely lethal; they often lead to frameshifts and the mild OI type I phenotype. In 2(I), lethal exon skipping events are located in the carboxyl half of the chain. These genotype-phenotype relationships indicate that the two collagen chains play very different roles in matrix integrity and that phenotype depends on intracellular and extracellular effects.

A new locus for an autosomal recessive congenital mucular dystrophy with hyperlaxity. *M. Tetreault[1,2], A. Duquette[1], I. Thiffault[1,2], J. Jarry[1,2], L. Loisel[1], M. Vanasse[3], Y. Robitaille[3], B. Brais[1,2].* 1) Laboratoire Neurogenetique, Hopital Notre-Dame-CHUM, Montreal, Canada; 2) Centre for the Study of Brain Disease, Montreal, Canada; 3) Hopital Ste-Justine, Montreal, Canada.

Joint hyperlaxity and concomitant joint contractures are often observed in different congenital muscular dystrophies (CMD). We have recruited a group of 16 French-Canadian patients from Southwestern Quebec belonging to 13 different families displaying a recessive congenital muscular dystrophy with joint hyperlaxity (CMDH). We have excluded by linkage and sequencing analyses that this new form of CMD is caused by mutations in one of the three subunits of collagen VI mutated in Ullrich CMD, which has an overlapping phenotype with CMDH. We have carried out a genome wide scan (GWS) by genotyping 500 markers at 8cM intervals for 2 families. The GWS results combined to fine mapping analyses demonstrated linkage of all our families to a 10cM chromosomal region not previously known to be linked to a recessive congenital muscular dystrophy (multipoint LOD score 5.3). Haplotypes for markers in the region suggested that the two more common mutations present in the French-Canadian population explain 81% of carrier chromosomes in this population. The identification of the mutated gene in CMDH should shed light on the biological basis of joint hyperlaxity and congenital muscular dystrophy.

Ocular manifestation of collagen V mutations. *E. Heon[1,3], F. Segev[1,2], W.G. Cole[3,4], R.J. Wenstrup[5], F. Young[3], A.R. Slomovic[2], D.S. Rootman[1,2], D. Whitaker Menezes[6], I. Chervoneva[6], D.E. Birk[6].* 1) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Ophthalmology, Toronto Western Hospital, Toronto, ON, Canada; 3) The Genetics and Genomic Biology Program, The Hospital for Sick Children Research Institute; 4) Division of Orthopedic Surgery, Dept of Surgery, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 5) Division of Human Genetics, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH; 6) Department of Pathology, Anatomy & Cell Biology, Thomas Jefferson University, Philadelphia, PA.

Type V collagen forms heterotypic fibrils with type I collagen. This study aimed to define the ocular phenotype of mutations in type V collagen genes, COL5A1 and COL5A2, and to study the phenotype in a col5a1 deficient mouse.Seven patients with classical Ehlers Danlos syndrome (EDS) due to COL5A1 haploinsufficiency and one with an exon skipping mutation in COL5A2 underwent an ocular examination, corneal topography, pachymetry and specular microscopy. A col5a1 haploinsufficient mouse model of classical EDS was used for biochemical and immunochemical analyses of corneas. Light and electron microscopy were utilized to quantify stromal thickness as well as diameter, density and collagen fibril shape. Five males and three females (mean age: 2613.57yrs; range: 11-52yrs) were studied. All patients had floppy eyelids. Cornea were thinner when compared with controls. In the heterozygous col5a1 mouse, corneal type V collagen content was reduced by 40-60percent, while corneal stroma thickness was reduced by ~26percent. Throughout the corneal stroma, collagen fibril diameters were increased, while fibril density at all developmental stages was decreased. In the eye, COL5A1 and COL5A2 mutations manifest as abnormally thin and steep corneas with floppy eyelids. Mechanisms involved here likely involve heterotypic type I/V collagen fibrillogenesis abnormalities similar to those observed in the col5a1 haploinsufficient mouse cornea. This abnormal corneal thickness likely affects interpretation of intraocular pressure measurements.

Mutations responsible for Larsen syndrome cluster in the FLNB protein. *D. Zhang[1], J.A. Herring[2], S.S. Swaney[1], T.B. McClendon[1], X. Gao[1], R.H. Browne[1], K. Rathjen[2], C.E. Johnston[2], S. Harris[3], N.M. Cain[1], C.A. Wise[1].* 1) Seay Center for Musculoskeletal Research, TX Scottish Rite Hosp, Dallas, TX; 2) Orthopaedics Dept., TX Scottish Rite Hosp, Dallas, TX; 3) Clinical Laboratory, TX Scottish Rite Hosp, Dallas, TX.

Larsen syndrome is a rare disorder of craniofacial and musculoskeletal systems. Distinct facial features include hypertelorism, prominent forehead, and depressed nasal bridge. Clinical management can be difficult due to extensive skeletal involvement including joints, feet, and spine. Both sporadic and dominantly inherited cases have been described. Mutations in the gene encoding filamin B were recently described in Larsen syndrome. Filamin B is a member of the filamin family of cytoskeletal proteins that induce non-muscle actin polymerization and participate in signal transduction pathways. Filamin B contains 2,602 amino acids that are organized into an N-terminal actin-binding domain (ABD) followed by twenty-four repeating units. It is expressed in chondrocytes throughout the epiphyseal growth plate and may function in chondrogenesis. To further characterize the spectrum of mutations causing Larsen syndrome, and to test genetic heterogeneity, we screened coding exons of the filamin B gene (FLNB) in our collection of sporadic and inherited cases. A single heterozygous missense mutation was found in each case. These mutations affect amino acids that are orthologously conserved in filamin B protein of vertebrate species, and homologously conserved in other filamin family members. All were apparently private, except for a dominantly inherited 679G-A change that was previously reported in a sporadic case. Compilation of our results and other reported mutations in Larsen syndrome revealed a clustered pattern in exons encoding either the ABD or repeat domains 14 or 15 of the filamin B protein. These results suggest that Larsen syndrome is genetically homogeneous and may be entirely explained by mutations in FLNB. Clustered mutations highlight filamin B domains that mediate cellular functions important in early skeletal development. This mutation pattern also may simplify diagnostic and genetic testing for the disorder.

Skeletal dysplasia and infertility mutations on mouse Chr 4 and 9. *S.M. Faust[1], I.J. Karolyi[1], A. Bartke[2], K.B. Cha[1], A. Hunt[1], K.D. Hankensen[3], J. Moran[4], D.R Beier[4], S.A. Camper[1].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Physiology, Southern Illinois University, Springfield, IL; 3) Department of Orthopaedic Surgery, University of Michigan, Ann Arbor, MI; 4) Genetics Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Skeletal dysplasias are characterized by abnormal growth of cartilage and bone, and occur in approximately 3.2 per 10,000 births. The gravity of the defects range from asymptomatic minor skeletal abnormalities to major, fatal defects. We report genetic mapping and characterization of two spontaneously arising, recessive mouse mutants with skeletal defects and infertility. Peewee (*pwe*) mutants exhibit disproportionate dwarfism, apparently due to disorganized chondrocytes and ossification without vascularization. Females are infertile, and males are subfertile. *Pwe* maps on mouse Chr 4 near *Mmp16*, a member of the membrane-bound matrix metalloproteinase gene family. *MMP16* maps to human chromosome 8, while neighboring genes of *MMP16* on mouse Chr4 map to a region homologous to chromosome 9 in humans. *MMP14* deficiency causes decreased chondrocyte proliferation, defective vascular invasion of cartilage, and dwarfism, suggesting that *Mmp16* is an excellent candidate gene. Identification of the molecular defect in *pwe* mice could uncover the molecular basis for a human skeletal defect. Chagun (*cha*) mutants are chondrocyte deficient, and males are hypogonadal and infertile. We report refinement of the Chagun (*cha*) locus on mouse Chr 9 in a high-resolution intercross, suggesting that *AK079355* is the responsible gene; virtually nothing is known about its function. This gene corresponds to a region homologous to human chromosome 3. Numerous human skeletal dysplasias have been described but not mapped. Identification of the responsible mutations in *cha* and *pwe* mice may identify unmapped human skeletal dysplasia genes.

Skeletal Dysplasia in Trps1 mutant mice demonstrates Trps1 repression of Runx2 in the pathogenesis of Tricho-Rhino-Phalangeal Syndrome. *D. Napierala[1], K. Sam[2], Q. Zheng[2], G. Zhou[2], T. Bertin[2], R. Shivdasani[3], B. Lee[1,2].* 1) Howard Hughes Medical Institute; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA.

Tricho-rhino-phalangeal syndrome (TRPS) is a dominantly inherited craniofacial and skeletal dysplasia characterized by short stature, hip abnormalities, cone-shaped epiphyses, premature closure of growth plates and distinctive craniofacial appearance. TRPS is caused by mutations of the TRPS1 gene located at 8q23-24 and coding for the transcriptional repressor TRPS1. To elucidate the role of Trps1 in skeletogenesis, we analyzed Trps1 mutant mice deleted for the GATA-type DNA-binding domain. Heterozygous mutant mice have normal appearance except of the craniofacial abnormalities. Homozygous Trps1 mutant mice die shortly after birth. Skeletal preparations of newborn homozygous mutant mice demonstrated delayed ossification of vertebrae and sternum, and significantly reduced maxilla and mandible. Histological analysis of growth plates showed the elongation of prehypertrophic and hypertrophic chondrocytes zone and delay in endochondral ossification. The quantitative real-time PCR on mRNA isolated from humerus of 4 week old mice showed dramatic increase of expression of chondrogenic markers - col10a1 and col2a1 as well as elevated expression of Runx2 in heterozygous mice. Runx2 is a key transcription factor involved in osteoblast differentiation and chondrocyte maturation. To test the potential interaction of Trps1 and Runx2, we performed cotransfection studies. In COS7 cells, Trps1 strongly represses Runx2 transactivation of the target 6xOSE reporter, which responds only to Runx2 transactivation. Moreover, the bone-related promoter of Runx2 contains several potential GATA consensus sequences. In vitro analyses showed that Trps1 forms complexes with each of these elements in COS7 but not in ROS17 cell lines. Our data suggest that Trps1 regulates the cartilage to bone transition during endochondral ossification in part by inhibition of Runx2 transcription as well as Runx2 protein function.

FISH analysis in the molecular diagnosis of Cleidocranial Dysplasia in patients without mutations of *RUNX2*. *K. Sam[1], R. Mendoza-Londono[1], S.A. Yatsenko[1], D. Napierala[2], P. Stankiewicz[1], B. Lee[1,2].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Baylor College of Medicine.

Cleidocranial dysplasia (CCD) is an autosomal dominant skeletal dysplasia with high penetrance and variable expressivity. Clinically, CCD manifests with short stature, delayed fontanel closure, hypoplastic clavicles, and dental anomalies. Most cases of CCD are caused by haploinsufficiency of *RUNX2*, which encodes for a transcription factor essential for osteoblast differentiation and chondrocyte maturation. The majority of mutations described to date are missense mutations located in the conserved RUNT domain, which disrupt RUNX2 binding to the target OSE2 element in osteoblast-specific genes. Sequencing of the coding region of *RUNX2* identifies mutations only in a fraction of individuals with clinical diagnosis of CCD. Microdeletions involving *RUNX2* may account for some of the additional cases. In order to optimize the detection in these individuals we established a combined approach of gene sequencing and fluorescent in situ hybridization (FISH). We studied 40 samples from individuals with clinical diagnosis of classic CCD or CCD-like phenotype. Mutations were identified in 18 (45%) patients, and sequence variants in the *RUNX2* promoter in five(12%) patients. In vitro analyses suggest that some of these promoter variants may affect transcriptional activity of RUNX2 and therefore modify the CCD phenotype. FISH analysis with BAC probes spanning *RUNX2* was performed on 14 of the 22 samples that were negative for mutation. We detected a deletion of one copy of *RUNX2* in three(8%) patients, which corresponds to 14% of the mutation-negative samples. In addition, FISH analysis allowed us to fine-map the breakpoints of a complex translocation, involving 6p21, in a patient with CCD-plus phenotype. Interestingly this patient has a breakpoint 34 Kb upstream of *RUNX2* that may affect a regulatory region, or result in positional dysregulation of the gene. Our results indicate that patients with CCD or CCD-like phenotypes with no mutation in *RUNX2* should undergo FISH analysis.

High-Throughput Analysis of Candidate Extracellular Matrix Genes in Connective Tissue Disorders. *B. Tinkle[1], W. Cole[2], R. Wenstrup[1].* 1) Div Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Hospital for Sick Children, Dept of Genetics, Toronto, Ontario, Canada.

We have developed a microarray based genetic screening method designed to discover new genetic causation(s) for heritable connective tissue disorders (CTDs) that does not depend on family studies or linkage analysis. For several CTDs, linkage studies have not proved successful because of genetic heterogeneity, small pedigree size, decreased penetrance, variable expressivity, or high prevalence of singleton cases. Our approach takes advantage of prior observations that many CTDs are due to mutations that, through a variety of molecular mechanisms, result in the functional loss of one allele (i.e. haploinsufficiency). Specifically, we have developed an automated Illumina^{TM}-based platform that compares allelic representation of single-nucleotide polymorphisms (SNPs) within exons in genomic DNA with allelic representation in cDNAs generated from total cellular RNA of fibroblasts. A minimum of 3 SNPs per gene with a cumulative frequency >50% are used to optimize informativeness and reduce false positives. Computational algorithms determine if the alleles are expressed approximately equal or below a threshold established to be consistent with haploinsufficiency. A second, parallel set of cDNAs are made from fibroblasts incubated under conditions that block nonsense-mediated decay to restore equimolar expression of the two alleles as a confirmatory step. As proof of principle, we analyzed 14 cell lines across a SNP microarray containing 384 loci in 63 extracellular matrix genes. Eight cell lines from patients with Ehlers-Danlos syndrome were analyzed, 5 of which had been previously shown to have haploinsufficiency of COL5A1 and the remaining 3 were informative but not haploinsufficient. Differential allelic expression was conclusively shown in all 5 lines while no COL5A1 haploinsufficiency could be detected in any of the others. This methodology will be useful for determining disease candidate genes for some CTDs not approachable through traditional genetic methods and may speed the discovery of disease-causing mutations for improvements in diagnostics and therapeutics.

Genetic Background in Determining Phenotypic Severity in the Osteogenesis Imperfecta Mouse Model. *SM. Carleton[1], DJ. McBride[2], WL. Carson[1], CT. Winkelmann[1], CE. Buff[1], JS. Morris[1], CL. Phillips[1].* 1) University of Missouri, Columbia, MO; 2) University of Maryland, Baltimore, MD.

Osteogenesis imperfecta (OI) is a clinically and genetically heterogeneous disease characterized by impaired biomechanical properties of bone. More than 800 type I collagen mutations have been shown to cause OI, with most limited to single individuals or families. Patients with identical mutations may exhibit significant inter- and intra-familial variation in phenotypic severity making genotype-phenotype correlations difficult. The oim mutation results in deposition of only homotrimeric collagen, $1(I)_3$, leading to an OI type III-like phenotype (short stature and deformation of long bones). To study the impact of genetic background on clinical outcome, we evaluated the *oim* defect on two genetic backgrounds, C57BL/6J (B6) and B6C3Fe a/a. B6 mice are an inbred strain with inherently low bone mineral density and B6C3Fe a/a are an outbred strain used by Jackson Laboratory to propagate *oim* mice. To evaluate geometry and biomechanics, femurs from wildtype (WT) and homozygous (*oim*) animals from each strain were subjected to qCT analyses and torsional loading to failure. Several geometric and biomechanical properties exhibited significant strain and genotype interactions. B6 WT marrow cavity diameter was significantly larger than WT outbred (18% increase), while cortical bone width was significantly decreased in B6 WT as compared to outbred WT (14% decrease). An 18% increase in marrow cavity diameter with a corresponding 9% decrease in cortical bone width was also seen for B6 *oim* as compared to outbred *oim*, though not significant. For each strain, torsional ultimate strength was significantly reduced in *oim* by more than 50% relative to WT. Tensile strength in B6 *oim* was 57% of B6 WT. OH-proline assay showed a 22% decrease in collagen content in outbred *oim* tibias relative to WT, while B6 *oim* tibia collagen was reduced 40% relative to WT. Neutron activation analysis demonstrated significant strain and genotype interactions including alterations in the Ca/P ratios. Taken together, these data indicate a role for genetic background in determination of phenotypic severity for OI.

Mutation in the *MATN3* gene is common in patients with osteoarthritis. *M. Czarny-Ratajczak[1, 2], A. Kolczewska[3], A. Wozniak[2], A. Latos-Bielenska[2], I. Zimmermann-Gorska[3], D.J. Prockop[1].* 1) Center for Gene Therapy, Tulane University, New Orleans; 2) Department of Medical Genetics, Poznan University of Medical Sciences, Poznan, Poland; 3) Department of Rheumatology, Rehabilitation and Internal Medicine, Poznan University of Medical Sciences, Poznan, Poland.

Matrilin 3, one of a group of extracellular matrix proteins, is expressed in the cartilage. Mutations in the *MATN3* gene (2p24-p23), encoding matrilin 3 cause a spectrum of disorders: osteoarthritis, multiple epiphyseal dysplasia and a severe form of spondyloepimetaphyseal dysplasia. Osteoarthritis (OA) is a common debilitating disease involving degeneration of the articular cartilage of joints, particularly hips, knees, lumbar and cervical spine, as well as the distal interphalangeal, the first carpometacarpal and proximal interphalangeal joints of hands.

Fifty consecutive unrelated patients from the Polish population with idiopathic OA were studied. Analysis of the *MATN3* gene revealed that four patients were heterozygous for C to T transition in the codon 303 (T303M), located in the exon 3, that corresponds to the first EGF repeat on the protein level. Two of these patients belong to families with an autosomal dominant form of OA. The T303M substitution was previously detected in patients with hand OA in the Icelandic population and it has been considered as a rare cause (2%) for hand OA. Based on our results, this mutation can account for 8% of all idiopathic OA cases in the Polish population. Analysis of the phenotype of our patients revealed that this mutation causes not only hand OA but also other forms like generalized OA. Currently, we are performing genome-wide screening in four large families with the excluded *MATN3* gene.

This work was supported by grants from: HCA - The Healthcare Company; The Louisiana Gene Therapy Research Consortium (grants to D. J. Prockop); and The Polish State Committee for Scientific Research (grant 3P05E00722 to M.C-R.).

Characterization of craniofacial phenotype in different SMS mouse models. *J. Yan, W. Bi, V.W. Keener, M.J. Justice, J.R. Lupski.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Craniofacial abnormality, by midface hypoplasia, broad nasal bridge, frontal bossing and prognathia, is one of the major clinical manifestations of the Smith-Magenis syndrome (SMS). The majority of the SMS patients have a common 3.7 Mb deletion of 17p11.2, while some with smaller deletions have enabled the refinement of the critical region (SMCR) to an ~1 Mb interval. Recently, mutations have been identified in *RAI1* in patients without FISH detectable deletions. To further investigate the genetic basis of the SMS phenotype, our lab created several mouse models with different deletion sizes including *Df(11)17*, a 2 Mb deletion covering the majority of the mouse region syntenic to the SMS common deletion, *Df(11)17-4* covering the region corresponding to the entire SMCR, and *Df(11)17-1* covering half of the SMCR, as well as *Rai1* knock out mice. Craniofacial abnormalities, including hypertelorism and shorter and curved snouts, have been observed in all of these mouse models, but the penetrance and severity are reduced with the reduced deletion sizes (from 70-80% in *Df(11)17*, to 54% in *Df(11)17-4*, to 46% in *Df(11)17-1*, and 18% in *Rai1*+/- at the N2 generation). Genetic background influences the penetrance as well, with increased penetrance in C57BL/6 background. Skeleton preparations provided quantitative confirmation of visual observations and revealed that the most striking change is the underdeveloped nasal bone. Soft-tissue three-dimensional surface scans of mice is a recently created technique to quantitatively assess the craniofacial changes without sacrificing the mice and provides some measurements which are not possible with skeleton preparation and also enables overall pattern comparison with cluster analysis. With this technique, we confirmed the severity difference in different SMS mouse models and we are now analyzing them in a pure C57 background to see if that will reveal more changes than in the mixed background. To investigate the gene(s) or factors contributing to the variability of craniofacial phenotype in different SMS mouse models will greatly enrich our knowledge of craniofacial development.

Widely variable phenotype associated with intronic mutation in the NF1 gene. *S. Plotkin[1], M. MacCollin[1], H. Feit[2], J. Gusella[1], T. Callens[3], L. Messiaen[3].* 1) Neurology, Mass General Hospital, Boston, MA; 2) Henry Ford Hospital, Detroit, MI; 3) Dept of Genetics, University of Alabama at Birmingham.

Neurofibromatosis 1 (NF1) is a tumor suppressor gene syndrome associated with a well defined, developmentally expressed phenotype including skin pigmentation changes, nerve sheath tumors, and a range of other manifestations. Over 80% of mutations in the NF1 gene in typical NF1 patients are predicted to grossly truncate or completely eliminate the protein product. A number of recent reports have suggested that a variant or spinal form of NF1 exists and is associated with a different spectrum of mutation including over-representation of missense mutations and C terminal truncating mutations. We report a 24 year old man who presented with massive subcutaneous and deep involvement by neurofibromas at age 16. Most prominently, the entire pelvic contents was replaced by multilobulated tumor growth causing chronic malnutrition and pain. His 25 year old first cousin was identically affected, however both the obligate carrier father and paternal aunt had only painless subcutaneous masses. None of these four individuals had cafe au lait spots, skin fold freckling, typical cutaneous tumors, abnormalities of growth or learning disabilities. Comprehensive RNA- and DNA-based mutational analysis of the NF1 gene revealed an insertion of 47 basepairs between exons 39 and 40 at the cDNA level. Subsequent genomic analysis of this region revealed a substitution at c.7127-770 G>T, creating a strong cryptic splice donor sequence which was present in both cousins and a sibling with several small subcutaneous tumors that had not previously been appreciated. Subtle changes in the NF1 gene appear to result in highly unusual and variably manifesting phenotypes and may hold key insights into the tumor suppressor roles of NF1.

Mutant glucocerebrosidase provides a link between neurodegenerative disorders. *O. Goker-Alpan[1, 2], D. Urban[1, 2], B.K. Stubblefield[1, 2], E. Sidransky[1, 2].* 1) NSB/NIMH, NIH, Bethesda, MD; 2) MGB/NHGRI, NIH, Bethesda, MD.

Gaucher disease (GD), the deficiency of lysosomal glucocerebrosidase, may provide insights into neurodegenerative disorders characterized by protein misfolding and aggregation. Immunofluorescence studies showed that both mutant glucocerebrosidase and alpha-synuclein were present in Lewy bodies and neuronal inclusions in brain samples from patients with GD and parkinsonism. Moreover, glucocerebrosidase mutations have been identified in subjects with a spectrum of synucleinopathies. In these disorders, mutant glucocerebrosidase may serve as a risk factor, leading to aggregate formation either by impairing proteosome function or by interfering with synuclein clearance. To test the first hypothesis, ubiquitination of glucocerebrosidase-reactive inclusions were studied in brain tissues from subjects with GD and parkinsonism. Mutant glucocerebrosidase was identified in both ubiquitinated and non-ubiquitinated aggregates. The non-ubiquitinated aggregates stained with antibodies against the lysosomal markers, suggesting the role of both ubiquitin-dependent proteolysis and lysosomal degradation in inclusion formation. Additional evidence that mutant glucocerebrosidase might cause proteosomal dysfunction was provided by examining molecular chaperones in fibroblast cell lines. Levels of HSP90, the primary chaperone preventing aggregation of misfolded proteins and maintaining proteosome integrity, were decreased in cell lines carrying missense mutations. In the HSP90-deficient fibroblasts, levels of another chaperone, Hsc-70, and its receptor, LAMP2, were also reduced. Hsc-70 and LAMP2 levels are rate-limiting for chaperone mediated autophagy (CMA) in the lysosomes. As alpha-synuclein is degraded by the CMA pathway, this finding suggests that mutant glucocerebrosidase may interfere with synuclein degradation as well. Thus, mutations in glucocerebrosidase may impact different pathways implicated in the synucleinopathies. Further studies of the relationship between alpha-synuclein and mutant glucocerebrosidase may advance our understanding of the pathogenesis of common neurodegenerative disorders.

Compound heterozygosity of *LHX3* in a patient with septo-optic dysplasia. *A. Campos-Barros, L. Soriano-Guillen, K.E. Heath, J. Argente.* Endocrinology, Hospital Infantil Universitario Niño Jesús, Madrid, SPAIN.

Septo-optic dysplasia (SOD) is a clinically heterogeneous disorder defined by any combination of optic nerve hypoplasia, pituitary gland hypoplasia and midline abnormalities of the brain, including absence of the corpus callosum and septum pellucidum. SOD is often associated with combined pituitary hormone deficiency (CPHD). Mutations in *HESX1* have been found in homozygosity in severe SOD and in heterozygosity in mild SOD. However, incomplete penetrance has been observed, and in many SOD cases the molecular bases remains unknown.

We present the case of a short stature (P3) female proband (4 years and 11 months old at diagnosis) born by caesarean delivery after a 38 weeks pregnancy. As a newborn she was transferred to an ICU because of severe transient neonatal hypoglycaemia and shock. Cranial MRI studies revealed the absence of the septum pellucidum together with optic nerves and chiasma atrophy. Hormonal tests revealed hypothyroidism and TSH deficiency at the age of 6 months, GH deficiency with low growth velocity (P3) at age 5, and undetectable ACTH at 8 years, respectively, compatible with a diagnosis of CPHD associated to SOD. Molecular studies excluded the presence of mutations in the coding sequences and intron/exon boundaries of *HESX1*, *PROP1*, *POU1F1* and *LHX4*, by dHPLC and DNA sequencing. Screening of *LHX3* detected two previously undescribed mutations in the proband: a missense mutation in exon 6 at a phylogenetically conserved residue, R309P, and a c1494CA conversion in the 3'-UTR of the *LHX3* transcript, inherited from the unaffected father and mother, respectively. None of the new variants was observed in 100 chromosomes from healthy controls, nor in a group of 35 CPHD patients.

To our knowledge this is the first case of SOD which is associated with *LHX3* mutations. Two recessive mutations in *LHX3*, which encodes a LIM class homeodomain protein member, have been previously linked to rare cases of CPHD presenting with GH, TSH, PRL, LH and TSH deficiency and a rigid cervical spine. Functional analysis will characterize the compound pathogenicity of these two novel mutations. (acamposbarros@yahoo.es).

Clearance of tau oligomers by the proteasome is critically dependent on the Tau phosphorylation state in Drosophila. *O. Blard[1], A. Boutajangout[2], J-P. Brion[2], D. Campion[1], T. Frebourg[1], M. Lecourtois[1].* 1) Inserm U614, Faculty of Medicine, 22 boulevard Gambetta, 76183 Rouen, France; 2) Laboratory of Histology, Neuropathology and Neuroanatomy, Universite Libre de Bruxelles, School of Medicine, 808 route de Lennik, B-1070 Brussels, Belgium.

In tauopathies, including Alzheimers disease (AD) and fronto-temporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), microtubule associated protein Tau is abnormally hyperphosphorylated and is accumulated as intraneuronal tangles of paired helical filaments (PHF). In AD brains, it has been shown that the level of Tau is higher than in age-matched control brains, and this increase concerns abnormally hyperphosphorylated Tau. Using Drosophila as a model of tauopathies, we studied the relationship between Tau phosphorylation and degradation. We showed that genetic inactivation of the proteasome specifically induces an accumulation of oligomeric forms of highly phosphorylated Tau. The clearance of these Tau oligomers by the proteasomal system is critically dependent on the Tau phosphorylation state. Finally, we found that impairment of proteasome activity or deregulation of Tau phosphorylation leads, concomitantly to the accumulation of oligomeric forms of highly phosphorylated Tau, to the formation of filaments.

A new locus for a progressive autosomal recessive spastic ataxia in the French-canadian population: clinical description and genome-wide scan analysis. *I. Thiffault[1,2], M.F Rioux[1], M. Tetreault[1,2], J. Jarry[1,2], J. Poirier[2], L. Loiselle[2], J. Mathieu[3], J.P. Bouchard[4], G.A. Rouleau[2], B. Brais[1,2].* 1) Neurogenetics,CHUM-Notre Dame Hospital, Montreal, QC, Canada; 2) Centre for the Study of Brain Diseases, Notre-Dame Hospital, CRCHUM, Montreal, QC, Canada; 3) Department of Neurology, Sagamie, Saguenay, QC, Canada; 4) Department of Neurology, CHUL, Quebec, QC, Canada.

Recessive spastic ataxias are a heterogeneous group of neurodegenerative diseases. Relying on a network of Ataxia and Neuromuscular clinics we were able to identify familial cases of an original form of autosomal recessive spastic ataxia. We identified a group of 25 cases belonging to 19 families that share clinical similarities. More than 50% of families have a genealogical relationship with the Portneuf County south of Quebec City. The major clinical features are the presence of spasticity, hyperreflexia, ataxia and dysarthria. The age of diagnosis is variable (mean 15.2 years, range 2-59). The more severe cases have severe spasticity from birth, scoliosis, dystonia and cognitive impairment and are often considered cases of cerebral palsy. There is a great intrafamilial and interfamilial variability in the severity of the phenotype. All MRI show cerebellar atrophy. In the more severe cases cortical atrophy, leukodystrophy and corpus callosum thinning are also observed. A genome scan uncovered linkage of three informative families to a candidate region of 15cM (multipoint LOD score of 2.08). Linkage analysis confirmed that at least 15 families are linked to the same region (multipoint LOD score of 5.76). Haplotype analysis suggests that the two most common mutations would account for approximately 85% carrier chromosomes. The identification of the mutated gene in will help the genetic counseling for this disease in French-Canadian population. The identification of the mutated gene will likely also shed light on key pathways underlining cerebellar and other central nervous system development and degeneration because of the significant clinical overlap between this form of ataxia and paraparesis, cerebral palsy and leukodystrophies.

Identification of the SCA28 locus for a novel form of autosomal dominant spinocerebellar ataxia. *D. Di Bella[1], C. Cagnoli[2], C. Gellera[1], C. Mariotti[1], M. Seri[3], P. Pappi[2], M. Plumari[1], R. Fancellu[1], A. Brussino[2], N. Migone[2], S. DiDonato[1], F. Taroni[1], A. Brusco[2].* 1) Div Biochemistry & Genetics, Istituto Neurologico C Besta, Milan, Italy; 2) Dept Genet Biol Biochem, University of Torino, Italy; 3) Dept Internal Med, University of Bologna, Italy.

The spinocerebellar ataxias (SCAs) are a clinically and genetically heterogeneous group of autosomal dominant neurodegenerative disorders characterized by progressive cerebellar ataxia associated with other neurological features. Molecular studies in SCAs indicate a large genetic heterogeneity and, at present, 26 distinct loci have been mapped, while the disease genes have been identified for only 12 forms. In 6 SCA subtypes and DRPLA the molecular mutation is characterized by CAG/CTG repeat expansion; however, known SCA genes appear to be responsible for only 40-60% of familial cases. We have identified a 4-generation family (29 subjects, including 11 affected members) with a novel form of autosomal dominant cerebellar ataxia, characterized by juvenile onset, slowly progressive ataxia, and oculomotor abnormalities including nystagmus and ophthalmoparesis. Genetic analyses excluded known SCA genes and loci (SCA1-8, 10-23, 25-27, and DRPLA). RED analysis did not reveal CAG/CTG expansions larger than 40 repeats (Brusco et al, Arch Neurol 2004). A genome wide study suggested linkage to a new locus on chromosome 18. Pairwise and multipoint linkage analyses obtained a maximal LOD score of Z=4.77. Haplotype reconstruction showed that a single haplotype segregated with the disease in the family and defined the minimal region in linkage as a 7.9 Mb region which encompasses approx. 70 genes. This new locus has been assigned the SCA28 symbol by the HGNC (www.gene.ucl.ac.uk/hugo). A number of interesting candidate genes have been selected and sequence analysis of the coding exons is currently underway. This disorder represents a novel form of autosomal dominant spinocerebellar ataxia mapped to chromosome 18 and identification of the responsible gene will provide further insight into mechanisms of neurodegeneration. (Supported by grants: Telethon GGP04254 to AB, EuroSCA to SDD, RF2002/160 to FT).

BI-1, an mBattenin/Battenin-interactive partner protein, is exclusively mislocalized at nuclei in Batten disease. *N. Zhong, W. Ju, J. Shen, W.T. Brown.* Dept Human Genetics, New York State Inst Basic Res, Staten Island, NY.

We have earlier identified Bax inhibitor-1 (BI-1) protein as an mBattenin/Battenin-interactive partner protein. We have found that the mutant Battenin (mBattenin) has an increased binding affinity with BI-1 compared to Battenin. To investigate whether BI-1 is affected by the differential binding activity in Batten disease, we undertook studies with immunostaining of BI-1 in both wild type and mutant fibroblasts. Our data showed that in wild type fibroiblasts, BI-1 predominantly distributes in the endoplasmic reticulum (ER). However, it is exclusively localized at nuclei in the mutant fibroblasts derived from Batten disease. To investigate if the mislocalization of BI-1 seen in the mutant fibroblasts is also seen in neuronal cells, immunostaining of endogenous BI-1 was conducted in human neuron precursor NT2 cells that stably express mBattenin, compared to control cells. Our results confirmed that normal BI-1 is localized at ER in control NT2 cells. However, in mBattenin-expressing NT2 cells, there was no detectable BI-1 at the ER, rather the anti-BI-1Ab strongly stained the nuclei. To further investigate if the mislocalization of BI-1 at the nuclei results from a gain-of-function due to the expression of truncated exogenous mBattenin or to the loss-of-function of endogenous normal Battenin, we undertook knock down experiments with siRNA approach. Our studies showed that the siRNA specific targeting of endogenous Battenin in NT2 cells resulted in the same outcome, that BI-1 is exclusively mislocalized at nuclei. To further quantitatively analyze the distribution of BI-1 in NCL3 cells, total protein from nuclei, ER, and cytosol was extracted from NCL3 and control fibroblasts. The BI-1 signal in the fraction of nuclei isolated from NCL3 patient fibroblasts is much stronger than in normal controls, while it is weaker in the ER of mutant cells and not significantly different in the cytosol comparing normal and mutant cells. Our results indicated that the anti-apoptotic agent BI-1 is affected in the Batten disease.

The genetically dystonic rat harbors a novel *Atcay* insertional mutation. *J. Xiao, M.S LeDoux.* Departments of Neurology and Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN.

The genetically dystonic rat (SD-dt:JFL), an autosomal recessive animal model of primary generalized dystonia discovered in the Sprague-Dawley strain, develops a dystonic motor syndrome by P12. Dystonic rats exhibit axial and appendicular dystonia that progresses in severity with increasing postnatal age. Dystonia is reduced when the animals are at rest and disappears during sleep. Without surgical intervention, dt rats die prior to P40 despite gavage feedings and other supportive measures. The mutation is fully penetrant and there is negligible variability to its expressivity. Mutations in the coding region of the gene (*DYT1*) associated with Oppenheims dystonia have been excluded in the dt rat. A constellation of morphological, pharmacological, neurochemical, and neurophysiological studies have identified olivocerebellar pathways as a site of functional abnormality in the dt rat. To find the mutant gene, a post-cerebellectomy male dt rat was crossed with a female of an inbred strain (SHR) to create F1 heterozygotes. Next, F1 rats were crossbred to yield 875 F2 offspring. After the first round of genotyping, three microsatellite markers on Chr 7 (D7Rat36, D7Rat35, and D7Rat32) showed strong linkage to the dystonia phenotype. Relative distances from the telomeric end of Chr 7 (0.04 cM, 6.8 cM, and 11.6 cM, respectively) and recombination rates (0%, 2.9%, and 8.7%, respectively) indicated that microsatellite marker D7Rat36 was nearest the causal mutation. Additional microsatellite markers near D7Rat36 were selected from a genetic linkage map based on the SHRSP x BN cross. Refined mapping was performed with these additional markers in 875 F2 rats. The dt locus was mapped to a 4.2 Mb region on Chr 7q11 (between D7Rat188 and D7Rat113) and candidate genes were screened with semi-quantitative RT-PCR. Then, Southern blotting and genomic DNA sequencing identified the 3-long terminal repeat portion of an intracisternal A particle element inserted into Intron 1 of *Atcay*, the gene which encodes caytaxin. Northern and Western blotting and quantitative real-time RT-PCR defined the Atcay allele in dt rats ($Atcay^{dt}$) as hypomorphic.

The elucidation of cell compartmentalization and spatial expression pattern of the paroxysmal non-kinesigenic dyskinesia gene. *H.-Y. Lee[1], Y. Xu[1], J. Nakayama[1], R. Tu[1], Y.-H. Fu[1], L.J. Ptacek[1,2].* 1) Department of Neurology, University of California, San Francisco, CA; 2) Howard Hughes Medical Institute, University of California, San Francisco, CA.

Paroxysmal non-kinesigenic dyskinesia (PNKD) is an autosomal-dominant disorder that belongs to a group of hyperkinetic movement disorders called the paroxysmal dyskinesias. We have identified two missense mutations in a novel gene called Myofibrillogenesis Regulator 1 (MR-1) located on chromosome 2q, which caused PNKD in 50 affected individuals from eight kindreds. There are three isoforms of MR-1, named long (L), medium (M), and short (S). These mutations caused alanine-to-valine changes in the N-terminus of MR-1L and MR-1S isoforms. Two antibodies for MR-1 were made by using two synthesized oligopeptides which corresponded to the predicted amino-terminus of MR-1L and S, and the predicted carboxy-terminus of MR-1L and M. These antibodies can also recognize the ortholog of MR-1 in mouse (mMR-1). Western blot analysis shows that mMR-1L is expressed exclusively in brain, and the mMR-1M is widely expressed in different tissues. Immunohistochemistry using anti-MR-1 antibodies indicates that mMR-1 is widely expressed in neuronal cells throughout the mouse central nervous system (CNS). The expression of mMR-1 in the motor cortex, cerebellum, spinal cord, and basal ganglia, implies that MR-1 plays an important role in maintaining the excitability of these essential parts of the motor system. Based on the sequence homology, we predict that MR-1 belongs to the glyoxalase family. Transfection of EGFP fusion protein construct of MR-1L in HEK293 cells shows that the MR-1L is localized to membrane in this heterologous system and this membrane localization feature is unique from any known glyoxalase. By transfecting EGFP constructs of MR-1L followed by an immunohistochemistry study of permeable or non-permeable HEK293 cells; we find that both the N-terminus and C-terminus of MR-1L are located inside the cell. Further experiments are underway to examine possible differences in mMR-1 expression in the CNS between wild-type mice and a transgenic mouse model of PNKD.

A Phosphorylation Cascade Regulating Circadian Period in Mammals. *Y. Xu[1], C.R. Jones[2], K.L. Toh[1], Q.S. Padiath[1], L.J Ptacek[1,3], Y.--H Fu[1].* 1) Neurology, University of California, san francisco, CA; 2) Department of Neurology, University of Utah, Salt Lake City, Utah 84132-2450; 3) 3Howard Hughes Medical Institute, University of California, San FranciscoŸŸŸ.

The behavior and physiology of most organisms is subject to circadian (24 hr) rhythmicity. Negative-feedback loops in clock genes are though to control circadian period. Familial advanced sleep phase syndrome (FASPS) in humans manifests with extreme early sleep onset times and early morning awakening. We previously reported a missense mutation (S662G) in the Period 2 (PER2) protein causing FASPS in one family and resulting in hypophosphorylation in vitro. Here we engineered mice containing a human Per2 S662 transgene. Mice transgenic for S662G recapitulate the short period FASPS phenotype seen in humans. Mice with a transgene encoding an acidic residue at position 662 showed period elongation. These and additional biochemical experiments demonstrate the charge on residue S662 regulates a phosphorylation cascade of downstream serines that critical for determination of circadian period. This represents direct in vivo demonstration that phosphorylation of PER2 regulates circadian period in mammals and defines a critical role for PER2 in circadian period length determination. Further analysis of these human animal models will provide us with a unique opportunity to understand the regulation of the circadian clock and its effect on various behavioral phenotypes.

Spastic paraplegia type 2 associated with axonal neuropathy and apparent *PLP1* position effect. *K. Inoue[1,2], J.A. Lee[2], R.E. Madrid[3], K. Sperle[4], C. Ritterson[5], G.M. Hobson[4,6], J. Garbern[7], J.R. Lupski[2,8,9].* 1) Dept Mental Retardation & Birth Defect Research, National Institute Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 3) NYS Institute for Basic Research in Developmental Disabilities, George A. Jervis Clinic, Staten Island, New York; 4) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Nemours Children's Clinic, Wilmington, Delaware; 5) Department of Biology, Boston University, Boston, Massachusetts; 6) Department of Pediatrics, Jefferson Medical College, Philadelphia, Pennsylvania; 7) Department of Neurology and Center of Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, Michigan; 8) Department of Pediatrics, Baylor College of Medicine, Houston, Texas; 9) Texas Childrens Hospital, Houston, Texas.

Pelizaeus-Merzbacher disease (PMD) and spastic paraplegia type 2 (SPG2) are clinically distinct allelic disorders, yet represent a wide spectrum of central nervous system dysmyelination associated with mutations in the Xq22.2 proteolipid protein gene (*PLP1*). Approximately 80-90% of PMD/SPG2 patients have *PLP1* mutations, including duplication, deletion, and point mutations in exons or splice junctions. Interestingly, although *PLP1* deletion mutations are very rare, they cause a more extended nervous system clinical phenotype that includes peripheral neuropathy. We report an association between SPG2 with axonal peripheral neuropathy and apparent *PLP1* gene silencing in a family. Electrodiagnostic studies and a sural nerve biopsy revealed features of a chronic axonal neuropathy. Pulsed-field gel electrophoresis, custom array comparative genomic hybridization, and semi-quantitative multiplex PCR analyses identified a small duplication downstream of *PLP1*, which we propose to result in *PLP1* gene silencing by virtue of a position effect. Our observations further suggest that genomic rearrangements that do not include *PLP1* coding sequences should be considered as yet another mutational mechanism underlying *PLP1*-related dysmyelinating disorders.

SIX3 and ZIC2 mutations in a series of holoprosencephaly patients. *J. Herbergs[1], S. Spierts[1], D. Tserpelis[1], A. Van Haeringen[2], M. Kerstjens-Frederikse[3], G. Mancini[4], M. Kwee[5], J. Hoogeboom[4], I. Stolte-Dijkstra[3], H. Smeets[1].* 1) Dept Clinical Genetics, Academic Hosp Maastricht, Maastricht, Netherlands; 2) Leiden University Medical Centre, Leiden, The Netherlands; 3) University Medical Center Groningen, The Netherlands,; 4) Erasmus Medical Center, Rotterdam, The Netherlands; 5) VU University Medical Center, Amsterdam, The Netherlands.

Holoprosencephaly (HPE) is a common severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. The prevalence is 1:250 during early embryogenesis, but the live born prevalence is only 1:16000. The etiology of HPE is extremely heterogeneous and can include both a teratogenic and/or genetic basis. We studied four genes known to be involved in HPE, namely SHH, ZIC2, SIX3 and TGIF by sequence analysis. A series of in total 31 sporadic and familial HPE cases with a variable clinical spectrum has been analysed. We detected 7 pathogenic mutations (23%), 5 out of 28 sporadic cases (18%) and 2 out of 3 familial cases (67%). Three mutations were detected in the SIX3 gene and four mutations in the ZIC2 gene. A ZIC2 mutation in a sporadic case appeared not to be a de novo mutation, but was also found in a healthy mother with no clinical features of the HPE spectrum. This was also seen in a carrier of the mutation in a familial case. In this study the genetic heterogeneity of the disease and the extremely variable phenotypes in HPE families have been confirmed.

Proteasome function in tauopathies. *A. Lecrux[1], D. Campion[1], J. Bou[1], J-B. Latouche[1], T. Frébourg[1,2], C. Dumanchin[1].* 1) Inserm U614, IFRMP, Faculty of Medicine, Rouen; 2) Department of Genetics, Rouen University Hospital, Rouen, France.

Tauopathies are neurodegenerative diseases caracterized by intraneuronal accumulation of hyperphosphorylated Tau protein (MAPT), into paired helical filaments (PHF) or straight filaments, leading to neuronal death by an unknown mechanism. Frontotemporal Dementia and Parkinsonism linked to chromosome 17 (FTDP-17) are primary tauopathies resulting from Tau gene mutations. These mutations have different consequences on Tau function: an increase of its aggregability, a decrease of its affinity to microtubules and of its ability to induce their polymerization. Secondary tauopathies, like Alzheimers Disease, result from an alteration of Tau phosphorylation. In several neurodegenerative diseases, like familial Parkinsons Disease and polyglutamine diseases like Huntington disease, it has been suggested that neuronal death can result in part from a dysfunction of the Ubiquitin Proteasome System (UPS), leading to a decrease of proapoptotic protein degradation. When the proteasome is overflowed, proteins are targeted to the centrosome where they form a structure: the agresome. However, the implication of the UPS in neurodegenerative diseases remains controversial. We hypothesized that the neuronal death observed in tauopathies could also result from an alteration of UPS function and therefore investigated the effect of Tau accumulation on UPS function. We studied two mutations: P301L and V337M, which induce an increase of Tau aggregation in FTDP-17, and determined the effect of the overexpression on UPS function using retroviral infection. To study UPS function, we established a clonal line of neuronal cells (SH-5YSY) stably expressing EGFP-degron, a reporter developed by Ron Kopito, consisting of a short degron fused to the COOH terminus of EGFP. We have expressed Tau protein during 12 days and the proteasome was not impaired in basal conditions. To determine the effect of Tau hyperphosphorylation in this system, wild type and mutant tau proteins and the kinases GSK3 and Cdk5 are being coexpressed, using the same reporter.

CKN1 gene analysis in Cockayne syndrome: novel mutations in eight typical patients. *D. Bertola[1], H. Cao[2], L.M.J. Albano[1], D.P. Oliveira[3], F. Kok[3], M.J. Marques-Dias[3], C.A. Kim[1], R.A. Hegele[2].* 1) Genetics Unit, Instituto da Crianca, Sao Paulo, Brazil; 2) Robarts Research Institute, Ontario, Canada; 3) Neurology, University of Sao Paulo, Sao Paulo, Brazil.

Cockayne syndrome is a rare autosomal recessive neurodegenerative disorder. It is considered to be a heterogeneous condition based on complementation in cell-fusion studies, with three major forms, namely CS-A, CS-B and CS-C. CKN1 is the gene responsible for CS-A, whose mutations disrupt the transcription-coupled repair system of the actively transcribed DNA. Mutation analysis of the CKN1 gene in eight typical CS-A Brazilian patients from six families showed a gene alteration in all of them. Six novel different unreported mutations were found and only one pair of siblings was a compound heterozygote. While the findings extend the range of mutations in CS-A, there is no obvious genotype-phenotype correlation across the mutational spectrum.

Apparent transgenerational stability of CTG trinucleotide repeats in 2 families of women with myotonic dystrophy. *D. Genevieve[1], M. Jambou[1], G. Gourdon[2], J. Martinovic[1], S. Loizeau[3], M. Vekemans[1], A. Benachi[3], Y. Dumez[3], M. Masri[4], A. Munnich[1], J.P. Bonnefont[1].* 1) Dept de Genetique, Hosp Necker-Enfants Malades, Paris, France; 2) Unite INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 3) Service de Gynecologie Obstetrique, Hopital Necker-Enfants Malades, Paris, France; 4) Service de Gynecologie Obstetrique, Hopital François Mitterrand, Pau, France.

Myotonic dystrophy (MD) is a frequent neuromuscular disease due to instability of CTG trinucleotide repeats in the 3 untranslated region of the dystrophia myotonica protein kinase (DMPK) on chromosome 19q13.3. Normal individuals have 5 to 37 CTG repeats which remain stable across generations while affected individuals have over 50 CTG repeats. In the majority of DM patients, the number of repeats is highly unstable and increases following transmissions of the mutant allele, providing molecular bases to the anticipation phenomenon. Here, we report on apparent intergenerational CTG repeat stability in two families of MD females. The number of the CTG repeats in blood cells was estimated at 143, 133, 121 and 109 for the great-grand mother, grandmother, mother and daughter, respectively in the first family and 350, 300 and 200 for the grand mother, mother and fetus respectively in the second family.Interestingly, the absence of intergenerational CTG expansion correlated with the absence of clinical anticiption We have had the opportunity to analyse the number of CTG repeats in several fetal tissues after termination of pregnancy in an affected fetus in each family at 15 weeks of gestation. The size of the CTG repeats was strictly identical in muscle, brain, liver, heart and chorion villi in both fetuses. These data suggest the existence of a dominantly inherited factor preventing the instability of the expanded CTG stretch during female gametogenesis in these families. Based on data from a MD murine model suggesting that DNA mismatch repair genes could account for CTG repeats contraction (Savouret et al,. Mol Cell Biol. 2004 24:629-37), molecular and protein studies of MSH2 and MSH3 genes are in progress in these families.

Decreased expression of Hsp27 and Hsp70 in transformed lymphoblastoid cells from patients with Spinocerebellar Ataxia Type 7. *S.Y. Li[1], M. Hsieh[2], S.J. Lin[3], C. Li[4], H.F. Tsai[5].* 1) Genetics Lab, Dept Life Sci, Chung Shan Medical Univ, Taichung, Taiwan; 2) Dept Life Sci, Tunghai Univ, Taichung, Taiwan; 3) Dept of Medicine, College of Medicine, National Cheng Kung Univ, Tainan, Taiwan; 4) Dept Life Sci, Chung Shan Medical Univ, Taichung, Taiwan; 5) School of Medical Technology, Chung Shan Medical Univ, Taichung, Taiwan.

Spinocerebellar ataxia type 7 (SCA7) is caused by an expansion of unstable CAG repeats within the coding region of the novel gene, ataxin-7, on chromosome 3. This disease is also associated with an accumulation of abnormal proteins, including expanded polyglutamine-containing proteins, molecular chaperones, and the ubiquitin-proteasome system. In this study, two SCA7 lymphoblastoid cell lines (LCLs) with 100 and 41 polyglutamine repeats were utilized to examine the effects of polyglutamine expansion on heat shock proteins. Interestingly, under basal conditions, Western blot and immunocytochemical analysis showed a significant decrease of Hsp27 and Hsp70 protein expression in cells containing expanded ataxin-7, as compared with that of the normal LCL. On the other hand, the protein levels of Hsp60 and Hsp90 were not significantly altered in the mutant LCLs. Results from semi-quantitative RT-PCR indicated that the differences in Hsp70 protein levels were due to transcriptional defects while the reduction of Hsp27 in the mutant cells was not caused by transcriptional defects. Our results further demonstrated that despite of defective protein expression of Hsp27 and Hsp70, a normal heat shock response was observed in lymphoblastoid cells expressing mutant ataxin-7. Taken together, our results indicated that expanded ataxin-7 that leads to neurodegeneration significantly impaired the expression of Hsp27 and Hsp70 protein, which may be, at least in part, responsible for the toxicity of mutant ataxin-7 proteins and ultimately resulted in an increase of stress-induced cell death.

***E. coli ssb* stabilizes GAA triplet-repeat sequences.** *L. Pollard, S. Bidichandani.* Dept Biochem & Molec Biol, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK.

Friedreich ataxia is caused by the expansion of a GAA triplet-repeat (GAA-TR) sequence in intron 1 of the *FRDA* gene. This expanded GAA-TR is unstable in somatic cells, with a predilection for contractions, but the mechansim for this instability is poorly understood. Using *E. coli* as a model system, we have previously found that the GAA-TR is more unstable, with a marked contraction bias, when "GAA" is the template for lagging strand synthesis and that replication is impeded in this orientation. We propose that the mechanism for the observed contraction bias is related to the known ability of single-stranded GAA sequence to form secondary structures, thus being bypassed during lagging strand replication. We found that interruptions in the GAA-TR tract, which prevent the sequence from forming secondary structures, stabilize the repeat. Since replication protein A (RPA), which stabilizes the single-stranded lagging strand template during replication, binds to purine-rich sequences with 50-fold lower affinity than pyrimidine-rich sequences, we propose that contractions of the GAA-TR in somatic cells occur when "GAA" is the lagging strand template, due in part to an increased capacity for stable secondary structure formation. To test this hypothesis, we replicated GAA-TR sequences in an *E. coli* strain harboring a temperature-sensitive mutation in single-stranded binding (*ssb*) protein (RPA homolog). By comparing the level of GAA-TR instability in this strain to that in the isogenic wild-type strain at the non-permissive temperature, we observed a dramatic length-dependent increase in instability when *ssb* is mutated. Instability was also orientation-dependent; when *ssb* is inactive, the GAA-TR is significantly more unstable when "GAA" is the lagging strand template. However, this difference in instability did not appear to coincide with a disparity in the replication rate between the two orientations. These results indicate that although mutating *ssb* may not affect the replication rate of GAA-TR sequences, *ssb* does play an important role in reducing instability during replication, especially when "GAA" is the template for lagging strand synthesis.

Alteration of the Microtubule-Associated Proteins mRNA levels by CTG repeats effect. *P. Velazquez-Bernardino[1,2], M. Bermudez[2], F. Garcia-Sierra[1], B. Cisneros[2].* 1) Dept Cell Biology; 2) Dept Genetics & Mol Biol, CINVESTAV-IPN, Mexico, D.F., Mexico.

Myotonic dystrophy (DM) is a dominant neuromuscular disorder caused by expansion of the CTG trinucleotide repeat tract localized in the 3'-untranslated region (3'-UTR) of the DMPK gene. To address the effect of the DM gene mutation on neuronal function, we isolated cell clones derived from PC12 neuronal cell line, which express the 3'-UTR DMPK region with 90 CTG repeats (CTG90 clone). Previously, we found that 90 CTG repeats expression provokes an inhibition of the NGF-induced PC12 cell neuronal differentiation. In order to identify neuronal genes that could be altered by the DM mutation, we have analyzed the gene expression of the CTG90 clone using the cDNA microarray technology. We found altered expression of several microtubule-associated proteins (MAP1A, MAP1B, MAP2, MAP6, Tau and Doublecortin). We confirmed by real time PCR that MAP2 mRNA expression is decreased in the CTG90 clone, as compared with the wild type cell line. At the present stage of this investigation, it is difficult to identify what level of the MAP2 gene expression is altered by the CTG repeat expansion. Recently, it was found that mutant DM transcripts sequestered Sp1 and Sp3 transcription factors. At this respect, it is important to mention that the MAP2 promoter sequence revealed two Sp1 binding sites. Therefore, it is tempting to speculate that the CTG repeat expansion affects MAP2 expression at promoter level by interfering with the action of Sp1. As a first step to test this hypothesis, we decided to evaluate the effect of Sp1 over-expression on MAP2 mRNA levels in the wild type PC12 cells. We found an increased MAP2 mRNA expression, which suggests that Sp1 indeed regulates positively the MAP2 promoter activity. Given the importance of MAP2 as structural components of neurites, it is likely that mutant CTG repeats inhibits PC12 neuronal differentiation by affecting its expression. This work is supported by the Muscular Dystrophy Association, Inc. Grant No. MDA-3693.

A new locus for autosomal dominant hereditary spastic paraplegia (SPG29) maps to chromosome 2p12. *A. Ashley-Koch[1], M.E. Kail[1], M.A. Nance[2], P.C. Gaskell[1], I.K. Svenson[3], D.A. Marchuk[3], M.A. Pericak-Vance[1], S. Züchner[1].* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Park Nicollet Clinic, Minneapolis, MN 55415, USA; 3) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC.

The hereditary spastic paraplegias (SPG) are a group of neurodegenerative diseases clinically characterized by progressive lower limb spasticity and paresis of varying severity. Clinical heterogeneity in the form of additional neurological symptoms and varying degrees of severity as well as varying age of onset is supported by an impressive genetic heterogeneity. To date, 10 chromosomal loci have been reported causing autosomal dominant forms of SPG and five of the underlying genes have been identified. However, additional genetic heterogeneity has been suggested. We conducted a whole genome linkage screen on two independent families and identified a new SPG locus on chromosome 2p12. The combined two-point LOD score was 4.7 at marker D2S2951. Fine mapping with additional microsatellite markers narrowed the region to about 9 Mb between D2S139 and D2S2181. Within that region we identified several candidate genes that share domains or pathways with known SPG genes. Thus far, we have excluded causative mutations in the genes vesicle-associated membrane protein 5 (VAMP5), VAMP8, vacuolar protein sorting 24 (VPS24), and the trans-Golgi network protein (TGOLN2).

A single nucleotide substitution in the 5'f-UTR in the gene encoding spectrin repeat and Rho guanine nucleotide exchange factor domains is strongly associated with autosomal dominant cerebellar ataxia linked to chromosome 16q22.1. *K. Ishikawa[1], S. Toru[1], T. Tsunemi[1], T. Amino[1], K. Kobayashi[2], I. Kondo[3], T. Toda[2], H. Mizusawa[1].* 1) Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept Clinical Genetics, Osaka Univ., Suita, Japan; 3) Dept Medical Genetics, Ehime Univ, Ehime, Japan.

Autosomal dominant cerebellar ataxia (ADCA) is a group of heterogeneous neurodegenerative diseases showing progressive cerebellar ataxia as a cardinal clinical feature. We mapped families with 'gpure'h cerebellar ataxia to a 3 cM region in the chromosome 16q22.1 (Nagaoka et al.,2000). This region was the locus for another ADCA, spinocerebellar ataxia type 4 (SCA4)(Flanigan et al., 1996), which shows prominent peripheral neuropathy. Unlike SCA4, our families showed progressive ataxia confined to cerebellar nature, although some patients show hearing impairment. To identify the gene for our families with ADCA linked to chromosome 16q22.1, we constructed a physical map of the locus and analyzed haplotypes for newly discovered polymorphic DNA markers in our 50 families recruited all over Japan. This approach allowed us to identify the critical interval into <600 kb region with a common haplotype determined with 4 polymorphic markers in 16q22.1. Within this region we found a C-to-T single-nucleotide change in the 5'f-UTR in the gene, puratrophin-1. This genetic change, resided 16 nucleotides upstream of the tranlation initiation codon, was seen in all affected individuals from all 50 families, but was not seen in 1000 control Japanese chromosome. The in vitro luciferase assay showed that this C-to-T change results in significantly reduced transcription efficacy. Supporting this observation, a tendency for reduction of puratrophin-1 mRNA expression was seen in patients'f frozen cerebellar samples. Interestingly, immunohistochemistry for puratrophin-1 demonstrated formation of microscopic aggregation in Purkinje cells of patients'f cerebelli. Golgi apparatus associated protein and spectrins were also aggregated. These observations may suggest that the C-to-T change in the 5'f-UTR is strongly associated with ADCA linked to 16q22.1.

Development of a DNA microarray-based high-throughput gene analysis system for Parkinson disease. *N. Seki, Y. Takahashi, J. Goto, S. Tsuji.* Department of Neurology, The University of Tokyo, Tokyo.

[Introduction] Parkinson disease (PD) is a common neurodegenerative disorder characterized by extrapyramidal symptoms caused by neuronal loss in substantia nigra. The causative genes for hereditary PD thus far identified are *SNCA*, *PARK2*, *UCHL1*, *DJ1*, *NR4A2*, *LRRK2*, and *PINK1*. Occasionally, the mutations of these genes are also identified in apparently sporadic cases. In addition, accumulating evidences suggest that sporadic PD is a polygenic disease, where multiple genes play essential roles in the pathogenesis.With this background, comprehensive screening of these causative and candidate genes is mandatory not only for hereditary PD but also to explore genetic components involved in the pathogenesis of sporadic PD. The purpose of this study is to develop a high-throughput system that allows mutational analysis of causative and related genes for Parkinson disease employing a DNA microarray-based resequencing platform. [Method] DNA microarrays TKYPD01 and TKYPD02 were designed based on a microarray-based resequencing system(Affymetrix). These microarrays contain all the causative genes for PD as described above and for related disorders (*GCH1* and *DYT1*), as well as PD-related genes (*TH*, *SNCAIP*, *GPR37*, *APOE*, *CHT1*, *GBA* and *MTX1*). The promoter sequence and intronic sequences of *SNCA* were also included. To validate the accuracy of nucleotide sequence analysis, genomic DNA samples from a normal control and 6 patients with PD were subjected to specific PCR amplification and processed. In order to handle the numerous PCR products, a robotic system was employed. [Result]All the causative and PD-related genes for PD could be analyzed simultaneously, and the accuracy of base calls was 99.94% (18897 bases out of 18908). 7 known SNPs and 7 novel SNPs(1 nonsynonymous, 2 synonymous, and 4 non-coding) were identified in these samples. [Conclusion]The microarray-based resequencing system is a highly efficacious and reliable system for mutational analysis and identification of SNPs of the causative genes as well as the PD-related genes.

Development of microarray-based rapid gene analysis system for X-linked adrenoleukodystrophy. -application for genotype-phenotype correlation analysis and search for genes modifying clinical presentations of ALD-. *T. Matsukawa[1], Y. Takahashi[1], O. Onodera[2], N. Shimozawa[3], Y. Suzuki[3], M. Nishizawa[2], J. Goto[1], S. Tsuji[1].* 1) Department of neurology, The University of Tokyo, Tokyo, Japan; 2) Department of neurology, Brain Research Institute, Niigata University, Niigata, Japan; 3) Department of Pediatrics, Gifu University School of Medicine, Gifu, Japan.

Background & Purpose: Adrenoleukodystrophy (ALD) is an X-linked disorder affecting the white matter of the central nervous system occasionally accompanied with adrenal insufficiency. Despite the discovery of the causative gene, *ABCD1*, clear genotype-phenotype correlations have not been established. To investigate the molecular basis for the broad clinical spectrum of ALD, comprehensive gene analyses of not only *ABCD1* but also other candidate genes that modify the clinical presentations would be necessary. To accomplish this aim, we have developed a microarray-based high throughput gene analysis system on *ABCD1* (TKYPD01) and its related gene, *ABCD2* (TKYAD01). The purpose of this study is to validate this system and to explore the possibility of *ABCD2* as the disease modifying gene. Methods: Primers were designed using BLAST search and Smith-Waterman method to avoid amplification of the homologous genes. We applied this PCR system to analyze genomic DNAs from 16 ALD patients with 12 known *ABCD1* mutations and 4 patients with unidentified mutations. All the PCR products were hybridized to DNA microarrays and subjected to scan and analyses. Result: All the known mutations of *ABCD1* were identified by this system. Moreover, four mutations (P84S, H657N, G277R, and W595X) in the patients with adrenomyeloneuropathy. Mutation G277R was found in the patients with adult cerebral form previously reported. A novel SNP was identified in the 5'fUTR of *ABCD2* in a patient with adult cerebral form. Conclusion: Our microarray-based high throughput gene analysis system should be highly useful for mutational analysis of *ABCD1* for patients with ALD, and identifying novel SNPs of related genes to explore SNPs of related genes as the candidates modifying clinical presentations of ALD.

Importance of open skin biopsy for the diagnosis of CADASIL. *M. Morbin[1], S. Baratta[2], D. Testa[3], D. Pareyson[2], L. Chiapparini[4], O. Bugiani[1], F. Taroni[2].* 1) Div Neuropathology, Istituto Neurologico C Besta, Milan, Italy; 2) Div Biochem & Genet, Istituto Neurologico C Besta, Milan, Italy; 3) Dept Clin Neurosci, Istituto Neurologico C Besta, Milan, Italy; 4) Div Neuroradiol, Istituto Neurologico C Besta, Milan, Italy.

The most appropriate procedure for the diagnosis of CADASIL is still debated. CADASIL is a hereditary cerebrovascular disease that segregates with mutations in the NOTCH3 gene and is characterized by mid-adult onset multiinfarct encephalopathy with headache, multiple stroke and dementia. Deposits of granular osmiophilic material (GOM) in the basal lamina of arterioles are the ultrastructural hallmark of the disease. Although GOM can be identified by skin biopsy, the false-negative rate of this finding is still unknown. Therefore, ultimate diagnosis is based on DNA analysis. Evidence from our and other laboratories indicate that approx. 75% of mutations cluster in exons 3 and 4, which are sequenced routinely to assess the clinical suspect. Negative results raise the problem of mutations elsewhere. Since molecular analysis of the full 33-exon gene can hardly be given as a routine service, complementary methods, such as skin biopsy, should be considered to justify extended DNA analysis. In spite of 100% specificity, sensitivity of skin biopsy in CADASIL has been reported to be as low as 50%, possibly due to the bioptic procedure employed (punch vs. open biopsy). We have carried out open skin biopsies in 9 out of 21 index patients with clinical and MRI findings consistent with the diagnosis of CADASIL. GOM was detected by electron microscopy (EM) in all such patients, who had distinct mutations involving an Arg-to-Cys substitution (2 in ex 3, 3 in ex 4, 1 in ex 2, 1 in ex 8, 1 in ex 11, 1 in ex 19). These results justify to proceed in additional patients as follows. The clinical suspect of CADASIL should be first screened for mutations in NOTCH3 exons 3 and 4; if negative, an open skin biopsy with EM analysis for GOM should be carried out; if this is positive, sequencing of the remaining NOTCH3 exons is strongly recommended. (Partly supported by grant RF2002/160 from the Italian Ministry of Health to FT).

Mutational Analysis of the *LRRK2* Gene in a Clinic-Based Sample of Patients with Parkinson's Disease. *C.P. Zabetian[1,2], A. Samii[2,3], A.D. Mosley[4], J.W. Roberts[5], B.C. Leis[4], D. Yearout[1,2], W.H. Raskind[6,7,8], A. Griffith[4].* 1) Geriatric Research Education & Clinical Center, VA Puget Sound Health Care System, Seattle, WA; 2) Department of Neurology, University of Washington, Seattle, WA; 3) Parkinsons Disease Research, Education & Clinical Center, VA Puget Sound Health Care System, Seattle, WA; 4) Booth Gardner Parkinson's Care Center, Evergreen Hospital, Kirkland, WA; 5) Virginia Mason Medical Center, Seattle, WA; 6) Department of Medicine, University of Washington, Seattle, WA; 7) Department of Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA; 8) Mental Illness Research Education & Clinical Center, VA Puget Sound Health Care System, Seattle, WA.

BACKGROUND: Recent studies of referral-based samples indicate that a single mutation (G2019S) in exon 41 of the *LRRK2* gene accounts for an unexpectedly large proportion of both familial and sporadic cases of Parkinson's disease (PD). If these data are representative of PD in the general population, then genetic testing for *LRRK2* mutations might be useful in clinical settings. METHODS: We resequenced exons 31, 35, and 41 of the *LRRK2* gene in 371 PD patients consecutively recruited through five movement disorder clinics, and in 281 controls. RESULTS: We found mutations in six (1.6%) PD patients, including two heterozygous for new putative pathogenic variants (R1441H, IVS31+3AG). None of these mutations were observed in the control group. R1441H replaces a highly conserved amino acid, while IVS31+3AG is predicted to disrupt splicing. We also found evidence of substantially reduced penetrance in a family with a previously reported pathogenic mutation (R1441C). CONCLUSIONS: Our findings in a clinic-based PD sample suggest that *LRRK2* mutations are sufficiently common to justify testing in neurological practice. However, more data are needed on the spectrum, frequency, and penetrance of pathogenic variants in the gene. We have now begun to screen the entire *LRRK2* coding region (51 exons) in large numbers of PD patients to address these issues.

Identification in Drosophila of genetic modifiers of the Tau-induced neurodegeneration. *M. Lecourtois, J. Bou, B. Chaumette, O. Blard, D. Campion, T. Frebourg.* Inserm U614, IFRMP, Faculty of Medicine, 22 boulevard Gambetta, 76183 Rouen, France.

Tauopathies, including Alzheimers disease (AD) and fronto-temporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), are a group of neurodegenerative disorders characterized by the presence of intraneuronal filamentous inclusions of aberrantly phosphorylated tau. Tau is a neuronal microtubule-associated protein involved in microtubule assembly and stabilization. To investigate the molecular mechanisms responsible for Tau-induced neurodegeneration, we used Drosophila as model of tauopathies. Expression of human Tau in the Drosophila brain recapitulates several features of human tauopathies, including age-dependent neurodegeneration, early death, abnormally phosphorylated and folded Tau. We have performed a deregulation screen to identify genetic modifiers of Tau-induced neurodegeneration. Based on the GAL4-UAS expression system, Tau expression was targeted to the fly eye using the GMR-GAL4 driver line. We have screened 1400 insertion lines containing the P[UAS] transposon elements. This genetic screening allowed us to detect numerous interactors which function is in agreement with the potential biological role of Tau.

Analysis of ARX gene in X-linked Lissencephaly in an extended pedigree with multiple affected and consanguinity. *A.J. Parsian[1], M. Karim[1], D. Fair[1], M. Elsayed[2], E. Elsobky[2], A. Parsian[1].* 1) Dept Pediatrics, Univ Arkansas Medical Sci, Little Rock, AR; 2) Medical Genetic Center, Cairo, Egypt.

Lissencephaly is a human neuronal migration disorder associated with abnormal cortical layering leading to a thickened neocortex with mixed agyria and pachygyria or pachygyria alone. X-linked Lissencephaly gene cause classic Lissencephaly in hemizygous males and a milder phenotype known as subcortical band heterotopia in females, sometimes exist in the same family. There are several X-linked loci that affect neuronal migration. Reported mutations in Aristaless-related homeobox gene ARX (Xp21.3) in X-linked Lissencephaly with abnormal genitalia (XLAG) and the phenotype in Arx null mice supported us to screen this gene first in our extended pedigree from Egypt. The pedigree includes two nuclear families with affected children and consanguinity. The male proband (from consanguine parents) has the diagnosis of Lissencephaly, mental retardation and abnormal genitalia. We excluded initially the two known reported mutations in ARX exon 2 by PCR assay and AflIII and HpyCH4V restriction enzyme digestion. We then sequenced the entire ARX coding regions and flanking introns including the splice sites using genomic DNA from affected, carrier, and unaffected pedigree members. We did not detect any mutation in ARX gene in our pedigree, suggesting genetic heterogeneity. We will investigate other X-linked loci for abnormal neuronal migratory disorder such as doublecortin (DCX).

Chromosome 18qter region is excluded in an extended pedigree with Marinesco-Sjögren syndrome. *J.W. Bracey[1], A.J. Parsian[1], M. Elsayed[2], E. Elsobky[2], A. Parsian[1].* 1) Dept Pediatrics, Univ Arkansas Medical Sci, Little Rock, AR; 2) Medical Genetic Center, Cairo, Egypt.

Marinesco-Sjögren syndrome (MSS) is a rare, autosomal recessive disorder with several distinguished symptoms. The syndrome is usually characterized by cerebellar ataxia, congenital cataracts, hypotonia, and mild to moderate mental retardation. Other observed symptoms include short stature, dysarthia, additional skeletal deformities, and occasionally hypergonadotrophic hypogonadism. Previous studies in a gypsy family linked a subtype of MSS to the chromosome 18qter along with congenital cataracts-facial dysmorphism-neuropathy (CCFDN) syndrome, indicating these as two overlapping disorders (Merlini et al., 2002). However, more recent genetic linkage mapping found MSS in consanguineous families of Turkish and Norwegian origin to be linked to chromosome 5q31, lacking overlap with CCFDN and indicating the two as genetically distinct disorders (Lagier-Tourenne et al., 2003). In this study, a consanguineous Egyptian pedigree with typical MSS symptoms in affected members in two generations is reported. We screened 12 family members, in three generations, with four microsatellite markers (D18S1122, D18S1141, and D18S1390, D18S70) on chromosome 18qter to determine the linkage to this region. Using homozygosity mapping, none of the four affected pedigree members were homozygous for haplotypes in the region of 18qter. The result of linkage analysis using a recessive model with full penetrance was also negative. Therefore, we excluded the region of chromosome 18qter as a candidate for MSS in our pedigree. Our result also supports the previous linkage finding by Lagier-Tourenne et al., (2003).

***AHI1* mutations cause both retinal dystrophy and renal cystic disease in Joubert syndrome.** *M.A. Parisi[1], D. Doherty[1], M.L. Eckert[1], D.W. Shaw[2], H. Ozyurek[3], O. Giray[4], A. Al Swaid[5], S. Al Shahwan[5], N. Dohayan[5], E. Bakhsh[6], O.S. Indridason[7], W.B. Dobyns[8], C.L. Bennett[1], P.F. Chance[1], I.A. Glass[1].* 1) Dept Ped/Div Gen & Develop, Children's Hosp & Reg Med Ctr, Seattle, WA; 2) Dept Radiol, Children's Hosp & Reg Med Ctr, Seattle, WA; 3) Dept Ped, Hacettepe Univ, Ankara, Turkey; 4) Dept Ped Gen, Dokuz Eylul Univ, Izmir, Turkey; 5) Dept Paed, Riyadh Armed Forces Hosp, Riyadh, Saudi Arabia; 6) Dept Radiol, Riyadh Armed Forces Hosp, Riyadh, Saudi Arabia; 7) Dept Med, Landspitali-Univ Hosp, Reykjavik, Iceland; 8) Dept Hum Gen, Univ Chicago, Chicago, IL.

Joubert syndrome (JS) is an autosomal recessive disorder characterized by hypotonia, ataxia, mental retardation, altered breathing pattern, abnormal eye movements, and a brain malformation known as the "molar tooth sign" (MTS) on cranial MRI. Four genetic loci have been mapped, with two genes identified (*AHI1* and *NPHP1*). We performed a combination of haplotype analysis and sequencing of *AHI1* in a cohort of 117 JS subjects, and found 15 mutations in 13 families, representing 11% of the group. We identified a variety of novel *AHI1* mutations, including nonsense, missense, splice-site, and insertion mutations, with clustering in the WD40 domains. Eight families with *AHI1* mutations were consanguineous, but no single founder mutation was found. In addition to the MTS, retinal dystrophy was present in 10 of 12 informative families; however, no subjects exhibited other variable features of JS such as polydactyly, colobomas, or liver fibrosis. In contrast to previous studies of *AHI1* mutations, we report two families with siblings who developed renal disease compatible with nephronophthisis (NPH) in their 20s. The same cohort was tested for deletions in *NPHP1*, and two individuals with classic NPH were found to have a homozygous *NPHP1* deletion, representing ~2% of the group. Overall, the contribution of *NPHP1* and *AHI1* mutations is less than 15% in our cohort. Preliminary genotype-phenotype correlations suggest the association of renal impairment, specifically NPH, in those with *NPHP1* deletions. Those with *AHI1* mutations appear to be at risk of developing both retinal dystrophy and progressive kidney disease.

Homozygous T118M substitution in *PMP22* is associated with severe neuropathy whereas heterozygous mutation can be associated with an HNPP phenotype. *G.M. Saifi[1], M.T. Scavina[2], A. Clark[2], K.M. Krajewski[3], J. Kamholz[3], E. Kolodny[4], K. Szigeti[1], J.R. Lupski[1,5], M.E. Shy[3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Neurology, duPont Hospital for Children, Wilmington, Delaware; 3) Department of Neurology and Center for Molecular Medicine and Genetics, Wayne State University, Detroit, Michigan; 4) Division of Neurogenetics, NYU School of Medicine, New York; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

PMP22 encodes a tetraspan myelin membrane protein expressed in Schwann cells of the peripheral nervous system. Altered dosage of, and point mutations in, *PMP22* cause the inherited peripheral neuropathies Charcot-Marie-Tooth disease type 1A (CMT1A) and Hereditary Neuropathy with Liability to Pressure Palsies (HNPP). Both conditions are characterized by length dependent limb weakness and sensory loss. The clinical consequences of the amino acid substitution of threonine to methionine at amino 118 in *PMP22* (T118M), however, has been the subject of controversy. Whereas the initial evidence suggested T118M represented a recessive disease causing allele, subsequent findings interpreted this mutation as a benign polymorphism. We identified homozygous T118M mutation in an 11 year old girl with severe progressive distal weakness, diminished temperature and pinprick sensation in a stocking/glove distribution with preserved vibration and proprioception and gait abnormalities whose nerve conduction and needle EMG studies demonstrated progressive length dependent axonal degeneration without demyelination. Her heterozygous T118M parents are both clinically and electrophysiologically normal. Furthermore, we identified three patients heterozygous for the T118M mutation each of whom manifested a clinical neuropathy consistent with HNPP. Our findings support the contention that T118M is a pathogenic partial loss-of-function mutation, but that its clinical expression may depend on the genetic context or background.

A potential *RAI1* point mutation hotspot in a heptameric C-tract associated with nondeletion Smith-Magenis syndrome. *H. Firth[1], W. Bi[2], G.M. Saifi[2], J.R. Lupski[2,3,4].* 1) Department of Medical Genetics, Addenbrooke's Hospital, University of Cambridge, Cambridge, United Kingdom; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Texas Children's Hospital, Houston, TX.

Smith-Magenis syndrome (SMS, MIM182290) is a mental retardation disorder characterized by craniofacial features and neurobehavioral abnormalities. The majority (75-80%) of SMS patients have a heterozygous ~ 4 Mb common deletion in 17p11.2 mediated by non-allelic homologous recombination (NAHR) between SMS-REPs, low-copy repeats flanking the deletion. About 20-25% patients harbor unusual-sized deletions (smaller or larger). Up-to-date, a heterozygous point mutation in the retinoic acid induced 1 gene (*RAI1*) encoding a PHD zinc finger containing transcriptional regulator has been reported in nine phenotypic SMS patients without deletion detectable by FISH. All the mutations are unique, located within exon 3, and de novo, associated with sporadic disease. We report here a novel *RAI1* frameshift mutation in a nondeletion SMS patient. This individual has many SMS features: characteristic craniofacial dysmorphology (midface hypoplasia and broad face), brachydactyly, obesity, and neurobehavioral anomalies including learning disability, speech delay, skin picking, increased pain threshold, and marked sleep disturbance (night time waking, day time sleeping). The mutation is 3102delC, a deletion of a single cytosine in a heptameric C-tract (CCCCCCC), the longest single nucleotide repeat in the *RAI1* coding region. Interestingly, we previously identified a frameshift mutation 3103insC, an insertion of a single cytosine, in the same region. Thus, the heptameric C-tract in *RAI1* is a potential hotspot (2 out of 10 individuals) for the point mutation, likely because of DNA polymerase slippage, in nondeletion SMS patients.

Mutations in the GABRA1 and EFHC1 genes are rare in autosomal dominant juvenile myoclonic epilepsy. *S. Ma[1], B. Abou-Khalil[1], M.A. Blair[1], A.H. Lagrange[1], J.L. Haines[2,3], P. Hedera[1,2].* 1) Department of Neurology, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Juvenile myoclonic epilepsy, accounting for approximately 25% of idiopathic generalized epilepsies, is genetically heterogeneous. The first genes causing autosomal dominant (AD) JME have been only recently identified. A mutation in the alpha-1 subunit of the GABAA receptor has been reported in a single family and 5 mutations have been reported in 6 families in the EFHC1 gene, encoding a protein with an EF-hand, a calcium-binding motif. We have investigated the contribution of these 2 genes to familial JME in our cohort of 35 families. Syndromic classification of JME was based on previously published criteria. We considered kindreds with at least one affected first-degree relative and the evidence of a vertical transmission as definite ADJME, and families with at least one affected second-degree relative as probable ADJME. We included 16 families meeting criteria for definitive ADJME and 19 classified as probable ADJME. None of these families were considered informative enough to analyze candidate loci for JME using linkage analysis. We have systematically screened coding exons of these 2 genes using temperature gradient capillary electrophoresis. Every heteroduplex with an abnormal mobility was sequenced. We did not identify any disease-causing mutations in the GABRA1 and EFHC1 genes. Several coding polymorphisms have been found but the allelic frequency did not differ between controls and affected individuals. Our preliminary data suggests that the majority of familial ADJME is not caused by mutations in the GABRA1 and EFHC1 genes.

Analysing the function of ALF proteins in the CNS. *K. Davies, E. Bitoun, P.L. Oliver, J. Clark, O. Osborn.* MRC Functional Genetics, Unit, Dept Human Anatomy & Genetics, Univ Oxford, Oxford, United Kingdom.

We have established that AF4 plays a vital role in neuronal survival which would not have been predicted from its known function or from knockout studies. AF4, AF5Q31 and LAF4 are translocated in acute leukaemias and with FMR2, mutated in FRAXE mental handicap, these proteins make up the ALF family of transcription factors. Af4 is mutated in the dominant robotic mouse mutant characterised by ataxia and Purkinje cell loss. The E3 ubiquitin ligase Siah-1a was identified as an interacting protein in the brain and binding assays revealed a significant reduction in the affinity of Siah-1a with robotic Af4 compared to wild-type. This correlates with an almost complete abolition of mutant Af4 degradation by Siah-1a, leading to an accumulation of the mutant protein in the robotic mouse. Fmr2 binds Siah proteins in a similar manner, suggesting that this common regulatory mechanism regulates the levels of ALF proteins. We have also investigated the influence of the mutation on the transcriptional activation properties of these proteins and analysed its functional significance in neuronal cell cultures. The robotic mouse therefore provides a unique opportunity to understand how ALF proteins play a role in disorders as diverse as leukaemia, mental retardation and neurodegeneration.

A mutation in the cathepsin D gene (*CTSD*) in American Bulldogs with neuronal ceroid lipofuscinosis. *G.S. Johnson[1], T. Awano[1], J.F. Taylor[2], D.P. O'Brien[3], S. Khan[1], J. Evans[4], I. Sohar[5], P. Lobel[5], M.L. Katz[1,6].* 1) Veterinary Pathobiology, University of Missouri, Columbia; 2) Animal Sciences, University of Missouri, Columbia; 3) Veterinary Medicine and Surgery, University of Missouri, Columbia; 4) Veterinary Neurological Center, Las Vegas, NV; 5) Center for Advanced Biotechnology and Medicine, University of Medicine and Dentistry of New Jersey, Piscataway; 6) Mason Eye Institute, University of Missouri, Columbia.

We examined DNA, brains and eyes from American Bulldogs with signs of neurodegeneration that appeared before two years of age and progressed slowly leading to death by 4 to 6 years of age. Autofluorescent cytoplasmic inclusions were observed throughout the brains, in retinal ganglion cells and along the outer limiting membrane (OLM) of the retinas, establishing a diagnosis of neuronal ceroid lipofuscinosis (NCL). Electron microscopy revealed that the inclusions consisted of coarsely granular matrices surrounding well-delineated spherical structures and that the inclusions along the OLM were within photoreceptor cells, primarily cones. Affected American Bulldogs were homozygous for the A allele of a G to A missense mutation in *CTSD* which predicts the conversion of methionine-199 to isoleucine. Only the G allele was detected in DNA samples from 131 randomly selected dogs of 108 other breeds; however, the A allele had a frequency of 0.26 among the 123 genotyped American Bulldogs. Pedigree analysis indicated a probability of less than 10^{-12} that another locus unlinked to *CTSD* was the true NCL-causing mutation. Enzyme activity measurements on brain extracts revealed that cathepsin D activity in affected dogs was 34% of that found in unaffected controls while 15 other lysosomal enzyme activities were either unchanged or increased. Previously described *CTSD* knockout mice exhibited NCL with viseral complications and sheep lacking cathepsin D enzyme activity were born with a grossly underdeveloped CNS. In comparison, the clinical course of NCL in the American Bulldogs was less severe with a later onset, thus, more closely resembling that of many of the human NCLs. This suggests that *CTSD* should be considered a candidate locus for human NCLs of unknown cause.

A novel homozygous recessive mutation in PINK1 gene associated with Early-Onset Parkinsons Disease in a Saudi family. *M.A. Chishti[1], P. Carroll[2], M. Ahmed[1], A. Loualich[1], E. Rogaeva[3], S. Bohlega[4].* 1) Transgenic Laboratory, CMD, KFSH&RC, Riyadh,Saudi Arabia; 2) Aragene, KFSH&RC, Riyadh, Saudi Arabia; 3) CRND, Department of Medicine, UofT, Toronto, ON, Canada; 4) Department of Neurosciences, KFSH&RC, Riyadh, Saudi Arabia.

Parkinsons Disease (PD) is a neurodegenerative disorder that is characterized by progressive dysfunction of movement due to the predominant degeneration of dopaminergic neurons in the basal ganglia. Although familial PD represents less than 10% of all cases, parkinsonism-causing mutations have been defined in at least five different genes: SNCA, Parkin, DJ-1, LRRK2 and PINK1. Mutations in the PINK1 gene have been associated with the hereditary early-onset form of PD. PINK1 encodes a 581 amino acid protein with two predicted domains: a mitochondrial targeting motif and a highly conserved protein kinase domain (residues 156 to 509) that shows a high degree of homology to the serine/threonine kinases of the Ca2+/calmodulin family. In a study recently commenced, the entire coding region of the PINK1 gene (8 exons with intron/exon boundaries) has been screened in a total of 5 consanguineous Saudi families with a clinical diagnosis of early onset PD (less than 50 years of age). In one of five families screened, a novel missense homozygous mutation was found in exon 4, nucleotide 1032 CT (GenBankAB053323) resulting in an amino acid change from threonine to methionine at residue 313 (T313M). This family consists of eleven siblings resulting from a first cousin marriage. To date three of the eleven siblings demonstrate clinical manifestations of early-onset PD. The one affected female sibling began to experience tremulous movements of her hands at age 29 years, the two affected male siblings both report onset of symptoms at the age of 32 years. The T313M amino acid change occurs in a region of the protein kinase domain that is conserved across six species surveyed. It is reported that wild type PINK1 may protect neurons from stress-induced mitochondrial dysfunction and stress-induced apoptosis and it may be this effect that is abrogated by the T313M mutation reported here, resulting in early-onset PD.

A mutation in carbonic anhydrase related protein 8 causes ataxia in the mouse waddles mutant. *A. Nystuen.*
Department of Genetics, Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE.

The waddles (*wdl*) mutant is a mouse model for human ataxia. *Wdl* is a recessive, non-lethal mutant characterized by a non-progressive, ataxic gait. The mutation was mapped to a 6 megabase region on chromosome 4. Rather than further genetic fine mapping, I used a comprehensive informatics approach to identify functionally relevant candidate genes. Mutational analysis identified a 19bp deletion in exon 8 of the carbonic anhydrase related protein 8 (*Car8*) gene. This deletion was not detected in a survey of common and wild mouse strains including the strain of origin. *Car8* functions in the inositol pathway by interacting with 1,4,5-trisphophate receptor type I (IP3R1) to regulate intracellular Ca^{2+} in Purkinje cells. The mutation results in a frame shift causing a nonsense codon 21 amino acids downstream and removes part of the protein necessary for interaction with IP3R1. The *wdl* mutant further demonstrates the central importance of the inositol second messenger system in the Purkinje cell. Phenotypic and histological analysis showed that *wdl* has a relatively mild phenotype when compared to other mutants in this pathway. Thus, *wdl* becomes an important model for pure ataxic disorders. In fact, an ataxic patient with circulating antibodies to CAR8 has been described. Additionally, *Car8* is over-expressed at tumor invasion fronts of certain cancers, suggesting that this mutant may be a useful model to study the process of invasion.

Role of CSTB in neuronal survival: Implications to disease mechanisms in progressive myoclonus epilepsy. *S. Tegelberg[1], T. Joensuu[1], K. Alakurtti[1], E. Weber[2], O. Kopra[3], A.-E. Lehesjoki[1].* 1) Folkhälsan Institute of Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland; 2) Institute of Physiological Chemistry, Martin Luther University Halle-Wittenberg, Halle, Germany; 3) Deptartment of Molecular Medicine, National Public Health Institute and Neuroscience Center, University of Helsinki, Finland.

Loss-of-function mutations in the gene encoding cystatin B (CSTB), a cysteine protease inhibitor, underlie progressive myoclonus epilepsy of Unverricht-Lundborg type (EPM1), an autosomal recessive disorder. EPM1 is characterized by onset at 6-15 years of age, stimulus-sensitive myoclonus, tonic-clonic seizures, characteristic EEG-findings, ataxia and a progressive course. *Cstb*-deficient mice develop a phenotype resembling that of human EPM1 patients including progressive ataxia and myoclonic seizures. The mice show severe cerebellar granule cell apoptosis as well as neuronal atrophy, apoptosis and gliosis in the cerebrum, suggesting that CSTB has a role in preventing neuronal apoptosis in specific cell types and in maintaining normal neuronal structure. In order to understand the neuronal function of CSTB, we have initiated studies on its neuronal localization, as well as on its role in neuronal survival, utilizing primary neuronal cultures and tissues of *Cstb*-deficient and wild-type mice. As the cerebellar granule cells in *Cstb*-deficient mice die apoptotically, we aim to investigate the oxidative and non-oxidative conditions under which CSTB is required for neuronal survival by using brain tissue and neurons derived from *Cstb*-deficient mice. Towards the neuronal localization of CSTB, we have produced novel monoclonal antibodies for mouse CSTB that we are currently characterizing. Initial results from experiments using embryonic cortical neurons revealed no differences in oxidative or non-oxidative stress responses between wild-type and *Cstb*-deficient mice. Further experiments in cerebellar granule cells are ongoing. We are also investigating the apoptotic cell death and the possible neuronal re-entry to cell cycle in *Cstb*-/- neurons on tissue level in order to monitor the spatial and temporal pathology in the early stages of the disease.

Functional analysis of the Cacna2d2 calcium channel gene using transcriptional profiling in the ducky mouse mutant: a model of epilepsy and ataxia.*Cacna2d2*. *M. Rees[1], T. Wilkinson[1], A.C. Dolphin[2].* 1) Pediatrics, UCL Medical Sch, London, United Kingdom; 2) Pharmacology, UCL, London, United Kingdom.

The mouse mutant ducky (du)is characterised by spike-wave seizures and cerebellar ataxia. Loss of function mutations in the Cacna2d2 gene were found to underlie the phenotype in du strain and its allele, du2J. Cacna2d2 encodes the 2-2 voltage-dependent calcium channel auxiliary subunit, which is highly glycosylated and largely extracellular, and is strongly expressed in cerebellar Purkinje cells. We have shown that homozygous du/du mice have abnormalities in their Purkinje cell dendritic tree and electrophysiological recordings from dissociated Purkinje cells showed a 40% reduction in whole cell calcium current. In addition, co-expression of the truncated 2-2 protein predicted by the original du mutation, with the Cav2.1/4 channel combination in vitro leads to a reduction in current density To aid elucidation of additional function(s) of 2-2 we have performed Affymetrix microarray analysis to analyse transcriptional differences between du2J/du2J and wild type cerebellum at three different stages of development (perinatal [P0], postnatal day 10 [P10] and around weaning [P21]). We have focused on the cerebellum as this is the region showing highest expression of 2-2. We expect that those transcripts identified as up- or down-regulated, will act up- or downstream of 2-2, either via the calcium channel as a whole, or directly though the 2-2 subunit and may provide further insight into the function of the 2-2 subunit. Results showed a marked reduction in Cacna2d2 message at all ages, implying nonsense mediated decay. The other genes identified as having altered expression at P0 have no overlap with those identified at P21, implying a dual role for 2-2 in development. To support this, no differences were seen at P10. At P0, genes showing changes in expression are largely uncharacterised ESTs, suggesting a novel pathway. At P21, there was reduced expression of a number of genes including an extracellular matrix protein and an angiotensin receptor 1-like transcript. All gene expression changes were confirmed by quantitative PCR.

VCP mutations in two kindreds with prominent frontotemporal dementia: clinical features and neuropathological examination. *L. Marechal[1], A. Laquerrière[2], C. Dumanchin[1], C. Duyckaerts[3], J. Bou[1], D. Hannequin[1], T. Frébourg[1], D. Campion[1].* 1) Inserm U614, IFRMP, Faculty of Medicine, Rouen, France; 2) Department of Pathology, Rouen University Hospital, France; 3) Laboratory of Neuropathology Escourolle, La Salpétrière Hospital, Paris, France.

Inclusion body myopathy with Paget disease of bone and frontotemporal dementia (IBMPFD) is a unique autosomal dominant disorder (OMIM 167320). The gene was mapped to chromosome 9p13.3-p12 and missense mutations within the gene encoding valosin-containing protein (VCP) have recently been identified. VCP/P97, an abundant homohexameric intracellular protein, is an AAA class ATPase able to bind directly to polyubiquinated proteins. It can exert a variety of cellular functions through interaction with specific adaptators, e.g. p47, UFD1 and Np14. VCP is strongly involved in the ubiquitin-proteasome dependent degradation of cytosolic proteins and in the retrotranslocation of missfolded proteins through the ER associated degradation pathway. We describe the clinical features of two large kindreds in which VCP R93C and R155C missense mutations segregate. We show that dementia concerned 100 % of affected subjects in family I and 55% in family II (as compared with 30% in average in previously described families). Dementia was the initial symptom in 50% of affected cases in family I and 11% in family II. By contrast, muscle weakness and PBD were much inconstant clinical features. We also report detailed neuropathological data from three cases provisionally diagnosed as "dementia lacking distinct histopathological features" after routine examination. Further examination revealed additional features, consistent with the hypothesis that the VCP R155C mutation disrupts normal VCP function, leading to diffuse accumulation of ubiquinated proteins within the cells. Ubiquinated proteins did not form aggresomes and the proteasomal function by itself remained intact. In past years, impairment of Ubiquitin-dependant proteolysis in neurons has emerged as the prime suspect in causing neurodegenerative diseases. Thus, IBMPFD linked VCP mutations define a novel class of alteration of the Ubiquitin-proteasome system.

Low frequency of PDCD10 mutations in a panel of CCM3 probands: potential implications for a fourth CCM locus. *C.L. Liquori[1], M.J. Berg[2], F. Squitieri[3], M. Ottenbacher[1], M. Sorlie[4], T.P. Leedom[1], M. Cannella[3], V. Maglione[3], L. Ptacek[5], E.J. Johnson[4], D.A. Marchuk[1].* 1) Dept of Molecular Genetics and Microbiology, Duke Univ Medical Center, Durham, NC; 2) Strong Epilepsy Center, Dept of Neurology, Univ of Rochester Medical Center, Rochester, NY; 3) Neurogenetics Unit, Istituto di Ricovero e Cura a Carattere Scientifico, Neuromed, Pozzilli, Italy; 4) Molecular Diagnostics and Biobanking, Prevention Genetics, Marchfield, WI; 5) Dept of Neurology, Univ of California San Francisco, San Francisco, CA.

Cerebral cavernous malformations (CCMs) are vascular abnormalities of the brain that can result in a variety of neurological disabilities, including stroke and seizures. Linkage analyses using autosomal dominant families manifesting CCMs have identified three different causative loci on chromosomes 7q21.2 (*CCM1*), 7p13 (*CCM2*), and 3q25.2-q27 (*CCM3*). Multipoint linkage data from a large number of families suggests that CCM1 accounts for 40% of all familial CCM cases, CCM2 accounts for 20%, and CCM3 accounts for 40%. Mutations in the gene *Krit1* are responsible for CCM1, mutations in the gene *MGC4607* are responsible for CCM2, and mutations in the gene *PDCD10* were recently reported to be responsible for CCM3. We report here that sequence analysis of *PDCD10* in a panel of 28 probands lacking *Krit1* and *MGC4607* mutations revealed only three mutations. The frequency of identified mutations in the *PDCD10* gene was surprisingly low at only 11%, especially given that this panel was heavily biased towards non-CCM1, non-CCM2 probands. These data are in stark contrast with the linkage data, which suggested that 40% of inherited cases would be due to mutations in this gene. Interestingly, when examining the haplotypes of previously published CCM3 families, we found a distinct recombination event in one of the largest CCM3 families that excludes the *PDCD10* gene. Although there are many potential explanations for this observation, when combined with the apparent under-representation of causative CCM mutations in *PDCD10*, this recombination event in a CCM3-linked family suggests that there may be an additional CCM gene in the same chromosomal region.

Analysis of IL-4, MxA, and IRF-1 Genes in Filipino Patients with Subacute Sclerosing Panencephalitis. *C.L.T. Silao[1,2], J.R. Pipo-Deveza[2], K. Kusuhara[3], A.M. Salonga[2], M.B. Lukban[2], B.C. Sanchez[2], R. Kira[3], H. Torisu[3], T. Hara[3].* 1) Institute of Human Genetics, National Institutes of Health Philippines, University of the Philippines Manila; 2) Department of Pediatrics, University of the Philippines - Philippine General Hospital; 3) Department of Pediatrics, Graduate School of Medical Sciences, Kyushu University, Kyushu, Japan.

Subacute Sclerosing Panencephalitis (SSPE) is a chronic and debilitating disease of the central nervous system caused by a latent measles infection. Although reported to be rare globally, this may not be so in a country like the Philippines were the prevalence of measles remains high. Three candidate genes, IL-4, MxA, and IRF-1 were shown to be associated among Japanese patients with SSPE. These genes have been suggested to play a role in the establishment of persistent viral infection in the central nervous system. To determine if there is an association of the IL-4, MxA, and IRF-1 promoter genes to SSPE susceptibility, a total of 180 samples (60 Filipino SSPE patients and 120 healthy control subjects) were included in the study. Demographic characteristics of the patients were recorded using an SSPE registry form. Single nucleotide polymorphisms at -590C/T IL-4 and -88G/T MxA promoter regions were screened using the PCR-RFLP method. Genotyping was done for the IRF-1 gene and association studies were performed between genotypes and SSPE. Our data showed that there is male predominance among the SSPE patients with a mean age at the time of diagnosis of 11.3 years old and an age range of 3-24 years old. Fifty-two percent had measles before one year of age. The TT genotype of MxA as well as the CT genotype of IL-4 were more frequently seen in SSPE patients as compared to the control subjects. The values though, did not reach statistical significance. IRF-1 gene analysis did not differ among the two groups. Our study demonstrated that there is no significant association of IL-4, MxA and IRF-1 genes among Filipino SSPE patients. Further studies are presently being conducted by our group by way of screening other candidate genes that may confer genetic susceptibility to SSPE.

Mechanisms of intranuclear rod formation in human disease. *K.N. North[1,2], A. Domazetovska[1,2], B. Ilkovski[2], M. Ghodoussi[3], E.C. Hardeman[3], S.T. Cooper[1,2].* 1) University of Sydney, Australia; 2) Institute for Neuromuscular Research, The Childrens Hospital at Westmead, Sydney, Australia; 3) Childrens Medical Research Institute, Sydney, Australia.

The -actinins are actin-binding proteins involved in establishing and maintaining cell structure. Abnormal accumulation of -actinin inside the nucleus is a recognized pathologic feature of some inherited myopathies. Accumulation of actin also occurs in the nucleus due to oxidative stress and is a feature of some neurodegenerative disorders. The mechanisms underlying intranuclear rod formation and their effects on cell function are unknown. Mutation at Val163 in -skeletal actin (*ACTA1*) result in muscle weakness and the formation of rods exclusively within the nuclei of muscle cells. These rods are abundant in -actinin-2 and filamentous actin, providing us with a model in which to study the development of abnormal intranuclear inclusions as part of a disease process.

Here we demonstrate for the first time that -actinin is normally found in the nucleus of a variety of cells and its export from the nucleus is sensitive to the nuclear export inhibitor leptomycin B. By live-cell imaging, we show that intranuclear aggregates due to mutations at Val163 in *ACTA1* form inside the nucleus and are dynamic structures. In the presence of mutant actin, the intranuclear inclusions form in muscle and non-muscle cells and contain both muscle and non-muscle -actinins. We then induced the formation of intranuclear inclusions rods by exposing both muscle and non-muscle cells to cytochalasin D. These intranuclear rods contain both wild type actin and -actinin, suggesting that a common mechanism is involved in their formation. We also demonstrate that the trapping of -actinin into intranuclear aggregates has an adverse effect on cell viability and division. These findings provide insight into the pathogenesis of myopathies and neurodegenerative disorders associated with abnormal intranuclear structures.

ER Quality Control as a Check Point for the Fate of Peripheral Myelin Protein 22. *T. Yang, W. Orfali, X. Chen, R.N. Sifers, G.J. Snipes.* Department of Pathology, Baylor College of Medicine, Houston, TX.

Missense mutations in Peripheral Myelin Protein 22 are responsible for a subset of Charcot-Marie-Tooth disease patients. The majority of PMP22 missense mutations are dominant gain of function mutations associated with retention of the mutant protein and degradation from the endoplasmic reticulum (ER). We previously demonstrated the dominantly inherited Pmp22L16P mutation, which causes hereditary nerve disease in humans and is modeled in the TremblerJ (Tr-J) mouse, is retained in the ER in association with the ER chaperone, calnexin (CNX). We have extended our study of Pmp22L16P to additional mechanisms associated with glycoprotein ER associated degradation (GERAD). Pulse-chase studies of Pmp22wt and Pmp22L16P in HEK293 cells immunoprecipitated with anti-CNX confirm the prolonged association of CNX with the mutant Pmp22 protein as compared to wild-type. Treatment with lactacysin, a proteasome inhibitor, almost completely abolished the degradation of newly-synthesized Pmp22L16P, but had not significant effect on the degradation of Pmp22wt. Both EDEM and ER manI have been shown to affect the degradation of several GERAD substrates. We found that overexpression of EDEM attenuated the association of Pmp22L16P with CNX, but had little effect on the overall rate of degradation of newly-synthesized Pmp22L16P. Inhibition of ER ManI with the alkaloid kifunensin, on the other hand, attenuated the degradation of Pmp22wt and Pmp22Tr-J, whereas overexpression of ER ManI accelerated the degradation of both wild-type and mutant Pmp22. Interestingly, we found that addition of a myc epitope tag to Pmp22 prolonged their half-lives relative to their untagged counterparts, suggesting the need for caution when interpreting the GERAD mechanisms in the degradation of myc-tagged Pmp22. In summary, the findings from untagged Pmp22 confirm that Pmp22wt and Pmp22L16P are substrates for GERAD with markedly different rates of degradation. Pmp22L16P is degraded predominantly via the proteasome, but the primary disposal mechanism for newly-synthesized Pmp22 (85% of which is rapidly degraded) is unknown. *This research is supported by the Muscular Dystrophy Association.

Interaction of huntingtin associated protein-1 with kinesin light chain: implication for vesicular transport in neurons. *J.R. McGuire, S.H. Li, X.J. Li.* Department of Human Genetics, Emory University, Atlanta, GA.

Huntingtin associated protein 1 (HAP1) was first identified in a yeast-2-hybrid screen using huntingtin (htt) as bait. Unlike htt that is ubiquitously expressed in the body and brain, HAP1 is enriched in brain and is abundantly expressed in the hypothalamus. Consistent with the critical role of HAP1 in neuronal function, HAP1 knockout mice show a postnatal lethality due to a possible feeding defect and neuronal dysfunction in the hypothalamus. HAP1 has been shown to interact with dynactin P150, a subunit of the dynein complex that drives microtubule-dependent retrograde transport in axons. Using the yeast-2-hybrid screen, we found that HAP1 also interacts with the light chain subunit of the kinesin complex, an anterograde motor. This interaction has been confirmed by in vitro binding assays, immunocytochemical colocalization, and immunoprecipitation from PC12 cell and mouse brain lysates. The interaction also appears to increase in strength upon NGF stimulation of PC12 cells. To understand the functional consequence of this interaction, microtubule binding assays and vesicular transport assays have been performed. These experiments suggest that HAP1 binding to microtubules is mediated by the kinesin complex and that HAP1 is involved in kinesin-mediated vesicular transport.

Haplotype analysis in German SCA17 families. *P. Bauer[1], J. Tomiuk[1], C. Bauer[1], A. Rolfs[2], L. Schoels[3], O. Riess[1].* 1) Dept Medical Genetics, Univ Tuebingen, Tuebingen, Germany; 2) Dept Neurology, Univ Rostock, Rostock, Germany; 3) Dept Neurology & Hertie-Institute of Brain Research, Univ Tuebingen, Tuebingen, Germany.

SCA17 is a progressive neurodegenerative disease leading to cerebellar ataxia and dementia. Several accessorial symptoms such as Parkinsonism, dystonia, and psychiatric disturbances commonly aggravate to disease course. Genetically, a CAG/CAA expansion in the TATA binding protein (TBP) is expanded in SCA17 patients, leading to an expanded polyglutamine chain in this ubiquitously expressed transcription factor. SCA17 is rare among the dominant spinocerebellar ataxias (ADCA). Overall less than 1% of all ADCA families do account for SCA17 mutations. In Germany, several SCA17 families have been identified. In order to assess possible founder effects, we performed a haplotype analysis with markers telomeric of the SCA17/TBP gene on chromosome 6q27 (D6S1585, D6S281, D6S446, D6S1590) and sequenced the repeat structure in all patients. Overall, five German SCA17 families have been investigated. In four families SCA17 haplotype phases could be determined unanimously. In two families from Mecklenburg-Vorpommern (MV) with rather cerebellar pronounced phenotypes the closest markers (D6S1590 and D6S446, haplotype for the pathological chromosome 1-3) displayed an identical haplotype. A large third family from MV with Huntingtons disease-like phenotypes had a different haplotype (1-1). A fourth family from MV could not be assigned unanimously, while the fifth family originating from western Germany showed to have an independent haplotype (1-2). To conclude, haplotype analysis in German SCA17 families does argue for at least three different possible founder mutations. Even those four families clustering within the county MV did show at least two different haplotypes. Additional epidemiological studies are needed in order to clarify dynamics in the TBP CAG/CAA repeat expansion.

Function of a Neuron-specific Isoform of the *TAF1* Gene. *S. Ando, S. Makino, G. Tamiya.* Department of Neurology, Tokushima Univ Sch Medicine, tokushima, Japan.

We previously found a neuron-specific isoform of the *TAF1* (TATA-binding protein-associated factor 1) gene, which is the disease causative gene of X-linked recessive dystonia-parkinsonism (XDP; OMIM#314250). The *TAF1* gene encodes the largest component of the TFIID complex involved in RNA polymerase II-mediated expression of genes. The neuron-specific isoform of the *TAF1* gene may have an essential role in neuronal survival in the striatum through transcriptional regulation of many neuron-specific genes. To investigate the detailed function of the neuron-specific isoform of the *TAF1* gene, we performed knockdown of the neuron-specific isoform using a specific siRNA in the human dopaminergic neuroblastoma cell line SH-SY5Y. The siRNA significantly reduced mRNA of the neuron-specific isoform to approximately 1/6 of that in the negative control siRNA with no induction of the interferon response. We subsequently performed microarray analysis for the knockdown cells using an Affymetrix Human Genome Focus Array representing 8,793 annotated genes. By these in vitro experiments, we demonstrated that the *TAF1* gene regulates the neuron-specific transcriptions of genes by the neuron-specific isoform.

Mutational Mapping of the *NF2* Gene: A Meta-Analysis of Published Data and Diagnostic Laboratory Findings.

I. Ahronowitz[1], W. Xin[2], R. Kiely[2], K. Sims[2], M. MacCollin[1], F. Nunes[1]. 1) Molecular Neurofibromatosis Lab, Massachusetts General Hospital, Charlestown, MA; 2) Neurogenetics DNA Diagnostic Lab, Massachusetts General Hospital, Charlestown, MA.

A number of single- and multiple-tumor phenotypes have been linked to the inactivation of the *NF2* tumor suppressor gene. To facilitate structural understanding of this gene across phenotypes, we compiled all published alterations since 1993 (N = 689) from 64 publications along with 49 unpublished alterations from our lab into a set of databases encompassing constitutional and somatic events. Somatic data were subdivided into the more common single sporadic tumor phenotype (N=336 including meningiomas and schwannomas among others) and multiple tumor syndromes. We conducted a meta-analysis of these alterations to assess the overall mutational spectrum and compare spectra across phenotypic subgroups. Alongside this dataset we also studied *NF2* alterations (N=125) found since 1994 by the Massachusetts General Hospital Neurogenetics DNA Diagnostic Lab to determine whether this clinical facility processes a representative cross-section of the mutational spectrum. Within the published dataset, we found a dramatic difference in alteration type between constitutional events and somatic events from single tumors, with somatic heavily skewed towards frameshift changes, and constitutional tending towards nonsense and splice-site ($P<0.001$). We also found a statistically significant difference in both mutation type and exon distribution in somatic events from sporadic schwannomas (N=155) and meningiomas (N=150), with the former overrepresented in frameshift mutations and the latter favoring nonsense changes ($P<0.01$). We did not observe a statistically significant difference in mutation type or exon distribution between published constitutional events and those found by the DNA Diagnostic Lab, suggesting a representative sample of tissue submitted for testing. Overall, this meta-analysis provides evidence for a fundamentally different genetic profile between constitutional and somatic events in the *NF2* gene, and among somatic events causing sporadic schwannomas versus those associated with sporadic meningiomas.

Deficient Glomulin Expression Disrupts Vascular Smooth Muscle Cell Differentiation and Causes Glomuvenous Malformations. *B.A.S. McIntyre[1], L.M. Boon[1,2], V.S. Vassilev[3], P.B. Brouillard[1], J.B. Mulliken[4], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute & University of Louvian Medical School, Brussels, Belgium; 2) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St Luc, Brussels, Belgium; 3) Cell Biology Unit, Christian de Duve Institute of Cellular Pathology & University of Louvain Medical School, Brussels, Belgium; 4) Vascular Anomalies Center, Division of Plastic Surgery, Childrens Hospital and Harvard Medical School, Boston, MA, USA.

Glomulin (GLMN) was recently identified in our laboratory as the gene mutated in glomuvenous malformation (GVM). These localized cutaneous anomalies are characterized histologically by enlarged venous channels with a variable number of normal-to-polygonal mural cells termed "glomus" cells (Boon et al. 2004).

Most GLMN mutations cause premature stop codons, probably resulting in non-sense mediated mRNA decay. Demonstration of a second-hit mutation in one GVM lesion suggested paradominant inheritance (Brouillard et al. 2002). GLMN is specifically expressed in vascular smooth muscle cells (vSMC) during murine development (McIntyre et al. 2004). We hypothesize that GLMN mutations alter differentiation of vSMCs due to a complete, localized lack of GLMN expression. Thus, we tested GVMs for the presence of GLMN mRNA using RNA ISH and examined the profile of other vSMC differentiation markers.

We demonstrate that during murine development, GLMN expression begins in vSMCs after desmin, h-caldesmon (h-CD) and smooth muscle myosin heavy chain (SMMHC), but before expression of smoothelin-b (SMTN-B). We also show that glomus cells in GVM do not express GLMN or SMTN-B (2 late vSMC markers), although earlier markers, SMMHC and h-CD, are detected. Expression of all of these markers was observed in vSMCs of venous malformations. We conclude that glomus cells have been halted in their differentiation due to a complete lack of GLMN giving further evidence for paradominant inheritance of GVM. Defining the clinical phenotype of deletion and duplication 1q21.1 syndromes. *M.J. Somerville, M. Lilley, O.J. Lehmann, M. Hicks, J. Christiansen, R. Tomaszewski, K.A. Sprysak, B.G. Elyas, S.M. Haase, N.J. Leonard, L.M. Vicen-Wyhony.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

A chromosome 1q21.1 multigene deletion syndrome has recently been identified in association with cardiac defects. This condition results in hemizygosity for several genes including GJA5 (connexin40) that is predicted to lead to the congenital heart disease (CHD) observed in these cases. Another gap junction protein (GJA8; connexin50) also deleted in these cases, is primarily expressed in the lens. Missense mutations in GJA8 have been shown to cause pulverulent zonular cataracts. We screened 731 unrelated CHD cases for deletions or duplications of the 1q21.1 region. Dosage was determined by real-time quantitative PCR amplification of ACPL1, GJA5, and GJA8 genes. Deletion breakpoints and parent of origin were determined using microsatellites spanning 1q21.1. In total, 4 cases (4/731) carried deletions and 1 case (1/731) a duplication of the 1q21.1 critical region, which were absent from 520 control cases. All deletion carriers were males with obstruction of the aortic arch. The duplication case was a female with tetralogy of Fallot. Two of the deletions were maternally derived the other one tested was de novo and of paternal origin. The duplication was paternally derived. Although the two mothers with 1q21.1 deletions and the father with a 1q21.1 duplication had no detectable heart defects, all three had lens opacities upon ophthalmic examination. The deletion carriers exhibited congenital opacities of the embryonic lens nucleus while the duplication carrier had small peripheral punctate lens opacities. All the opacities were sub-clinical with no appreciable effect on vision. In summary, we observed altered dosage of chromosome 1q21.1 in 5 out of 731 (0.7%) CHD cases. We hypothesize that altered dosage of the 1q21.1 region is associated with aortic arch defects and lens opacities, that penetrance of the heart defects is sex-dependent, but that sub-clinical lens defects are fully penetrant. Since there are no other consistent phenotypic features of these syndromes, screening individuals for lens opacities may provide a useful phenotypic marker to guide molecular testing.

ANKRD3, a candidate gene for involvement in Down syndrome heart defects. *R. Lyle[1,2], C. Burgi[1], S. Gagos[1], C. Gehrig[1], S. Nef[1], S. Dahoun[1], S.E. Antonarakis[1].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Institute of Public Health, Oslo, Norway.

Human autosomal aneuploides are very common but only trisomy for human chromosome 21 (Down syndrome, DS) normally survives beyond the early postnatal period. In addition to the mental retardation and facial characteristics, there are many other phenotypes associated with DS. Notably, 40-45% of DS individuals have congenital heart disease (CHD), generally atrioventricular septal defects (AVSD) or ventricular septal defects (VSD). Since the genes on the triplicated chromosome 21 (Hsa21) are normal, DS is considered to be a problem of gene-dosage. However it is not known which genes, or groups of genes, lead to the specific DS phenotypes. In previous work using the Ts65Dn mouse model of DS, we showed that the gene Ankrd3 was overexpressed ~4-fold in adult mouse heart but only ~1.5-fold in five other tissues. This large overexpression, and the fact that ANKRD3 maps within the putative DS heart critical region, suggests that it may be involved in DS heart defects. To study this possibilty we considered the following questions. Is ANKRD3 overexpressed in human DS fetal heart? Is ANKRD3 expressed at the appropriate time and place in heart development? First we examined the expression of ANKRD3 by qPCR in monozygotic twins discordant for DS and found that it is expressed 4.2-fold higher in the DS compared to euploid heart. This result was confirmed in other fetal hearts (3 DS, 3 normal), with DS/N ratio of 3-5 fold. We next studied the expression pattern of Ankrd3 in E11.5 and E13.5 mouse embryos by in situ hybridization. Ankrd3 is expressed in the developing mouse heart, and most strikingly there is strong expression in the developing heart atrioventricular septum at E11.5. ANKRD3 is therefore a good candidate for involvement in the heart defects most commonly seen in DS. We have also used Affymetrix arrays to study transcriptome changes in both mouse Ts65Dn and human DS heart, and have identified alterations in expression of several genes known to be important for correct heart function.

Phenotypic spectrum and pathogenesis of Loeys-Dietz aortic aneurysm syndrome. *B. Loeys[1], J. Chen[1], U. Schwarze[2], J. De Backer[4], A. Braverman[3], N. Mc Donnell[5], P. Coucke[4], T. Holm[1], G. Thomas[1], C. Francomano[5], P. Byers[2], A. De Paepe[4], H. Dietz[1,6].* 1) Johns Hopkins Univ, Baltimore; 2) Univ of Washington, Seattle; 3) Wash Univ, St. Louis; 4) Ghent Univ, Ghent; 5) NIH/NIA, Baltimore; 6) HHMI.

A novel autosomal dominant syndrome characterized by the triad of hypertelorism, bifid uvula/cleft palate, and arterial tortuosity with aortic aneurysm/dissection was previously described (Loeys-Dietz syndrome (LDS) MIM#609192). While some individuals show overlap with Marfan syndrome (MFS), none satisfied diagnostic criteria. So far, we have identified 27 mutations in either the type I or type II transforming growth factor beta receptor(TGFBR1/2) in typical LDS patients. In view of some phenotypic overlap between LDS and the vascular form of Ehlers-Danlos syndrome (EDS), we screened an additional cohort of vascular EDS patients with normal type III collagen studies. Their phenotype was characterized by typical skin findings, uterine rupture and arterial aneursym/dissections within the cerebral, thoracic and abdominal circulations. We identified heterozygous TGFBR mutations in 12 families, thus extending the clinical continuum of LDS. A clustering of mutations in TGFBR2-exon 5 (encoding the middle part of the kinase domain) was found in EDS-like patients, whereas typical LDS patients had mutations at both ends of the kinase domain. Despite evidence that receptors derived from mutant alleles cannot support TGF signaling, we have shown that heterozygous patient-derived fibroblasts retain appropriate responsiveness to TGF-ligand. Furthermore, tissues derived from affected individuals show increased output from TGF-responsive genes (eg CTGF) and increased pSmad2, indicative of increased TGF signaling. The study of VSMCs derived from patient aortas demonstrates inappropriate overactivation of the p38 and ERK1/2 cascades, both at baseline and in responses to TGF. In parallel, the production of CTGF by VSMCs is upregulated, thus correlating in vitro with in vivo observations. A pathogenetic model is proposed in which activation of these cascades is both a consequence of and a contributor to dysregulated TGF signaling.

Mutation Analysis of TBX5 in Families with Holt-Oram Syndrome: Viability of Composite Heterozygous Mutation in TBX5. *T. Huang[1,2], A. Boyadjian[1], X. Xie[1], J.G. Seidman[3], C.E. Seidman[3].* 1) Department of Pediatrics, Div Human Genetics, , CA; 2) Department of Developmental and Cell Biology Univ California, Irvine, Irvine; 3) Department of Genetics, Harvard Medical School and Howard Hughes Medical Institute, Boston, Massachusetts.

ABSTRACT Holt-Oram syndrome (HOS; OMIM#142900) is an autosomal-dominant condition characterized by cardiac malformations and radial ray skeletal abnormalities. Cardiac defects range from atrial or ventricular septal defects to complex cardiac defects; skeletal anomalies include thumb abnormalities such as triphalangeal thumbs to severe radial or ulnar defects. Mutations in TBX5 cause this condition. TBX5 is a member of the T-box transcription factor family. To understand pathogenesis of TBX5 mutations in HOS, we sequenced the coding regions and the intron/exon boundaries in familial and sporadic cases with HOS. We identified four novel mutations including one composite heterozygous mutation. This represents the first case of HOS with composite heterozygous mutation in live birth. Furthermore, we found no mutations in TBX5 in two families with evidence for linkage to 12q. These studies demonstrate that composite heterozygous mutation is viable in HOS and that mutation may harbor outside of the TBX5 coding region. Further analysis is needed to study the pathogenesis of composite heterozygous mutation and to search for mutation in other regions of the TBX5 gene.

R849W-TIE2 mutation is frequently observed in cutaneomucosal venous malformation (VMCM). *V. Wouters[1], A. Irrthum[1], L.M. Boon[1, 2], J. Murphy[3], P. Rieu[4], L. Kangesu[5], A. Pennington[6], J.B. Mulliken[7], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and University of Louvain Medical School, Brussels, Belgium; 2) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, University of Louvain Medical School, Brussels, Belgium; 3) Hospital for Sick Children, Toronto, Canada; 4) Kinderchirugie, UMC, St-Rabdoud, University of Nijmegen, Holland; 5) The St-Andrews Centre for Plastic Surgery and Burns, Essex Hospital, UK; 6) Department of Surgery, St-Vincents Hospital, University of Melbourne, Australia; 7) Division of Plastic Surgery, Childrens Hospital and Harvard Medical School, Boston, MA, USA.

Venous malformations (VM) are low-flow vascular lesions consisting of disorganized thin-walled vascular channels. They usually occur sporadically, but sometimes as an autosomal dominant condition termed cutaneomucosal venous malformation (VMCM; OMIM 600195). TIE2 gene, localized in 9p21, encodes an endothelial cell-specific receptor tyrosine kinase. TIE2 is required for blood vessel formation and maintenance. Two activating mutations, R849W and Y897S, in the kinase domain of TIE2 co-segregate with VMCM in four families (Vikkula et al., 1996; Calvert et al., 1999). We have identified a TIE2 mutation in four novel families with VMCM. In each of them, the identified mutation was the same R849W substitution previously reported (Vikkula et al., 1996). Thus, altogether 8 families with VMCM present a TIE2 mutation, 7 of which the R849W substitution. In 3 out of 5 of the VMCM families tested with polymorphic markers, we identified haplotype sharing in a 1.4 Mb region, suggesting that the R849W mutation in these families is an ancestral mutation. However, in the other two families the haplotype was different. Thus, the R849W mutation may represent one of few changes in TIE2 that can give rise to a signalling defect that results in VMCM, or the mutation site is a hot spot for mutations in TIE2. It remains to be established if TIE2 has any role in sporadic VM, via e.g. somatic mutations (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.ac.be/vikkula).

The Myosin Binding protein C R943X and 2864delCT founder mutations may confer relatively severe hypertrophic cardiomyopathy. *Y.M. Hoedemaekers[1,2], E. Biagini[2], W. Deelen[1], H.J. Meijers-Heijboer[1], M.J.M. Kofflard[2], D.J.J. Halley[1], F.J. ten Cate[2], D. Dooijes[1].* 1) Dept. of Clinical Genetics, Erasmus MC, the Netherlands; 2) Thoraxcenter, Erasmus MC, Rotterdam, the Netherlands.

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant monogenic disease, with incomplete penetrance and a variable phenotypic expression. It is the most common cause of sudden death (SD) in the young. Mutations in more than 11 genes, mostly encoding sarcomere proteins, have been shown to cause HCM. Many of these mutations arise independently and founder effects are rarely observed. Earlier studies associated mutations in the sarcomere Myosin Binding Protein C gene (MYBPC3) with late onset HCM and a relatively benign clinical expression. We performed sequence analysis of the MYBPC3 gene in 189 unrelated HCM index patients. A pathogenic mutation was identified in 52% of the patients. In addition to the previously identified 2373insG founder mutation, which was found in 17% of the patients, we identified the R943X and 2864delCT mutations in 6% and 7% of the analysed HCM population respectively. Subsequent extended haplotype analysis demonstrated these mutations to be additional HCM founder mutations in the Dutch population. Relevant clinical parameters were analysed in 19 carriers of the R943X mutation and 16 carriers of 2864delCT. HCM associated SD was observed in 50% of the families analysed. Mean age at diagnosis was 3912 years for the R943X mutation and 4515 years for the 2864delCT mutation. Validation was NYHA class II or higher at presentation in 42% and 63% of the respective mutation carriers. Conclusions: In addition to the 2373insG mutation, the R943X and 2864delCT mutations are MYBPC3 founder mutations, together accounting for one third of all HCM patients in the Netherlands. Variability of age at onset and clinical symptoms were observed in the R943X and 2864delCT mutation carriers and a surprisingly high percentage of sudden death was seen in the affected families. In contrast to earlier studies reporting MYBPC3 mutations to be relatively benign, both HCM mutations are associated with the development of heart failure symptoms and possible malignant course of the disease.

Mutation study on BMPR2 and ALK1 genes in Japanese patients with primary pulmonary hypertension. *H. Morisaki[1], N. Nakanishi[2], S. Kyotani[2], H. Tomoike[2], T. Morisaki[1,3].* 1) Dept Bioscience, NCVC Research Inst, Suita, Osaka, Japan; 2) Dept Cardiovascular Medicine, NCVC, Suita, Osaka, Japan; 3) Dept Molecular Pathophysiology, Osaka U Graduate Sch Pharmaceutical Sciences, Suita, Osaka, Japan.

Primary pulmonary hypertension (PPH) is a potentially lethal disorder, in which heterozygous mutations within the bone morphogenetic protein type II receptor (BMPR-II) gene (BMPR2) have been identified. We performed the molecular study of ALK1 gene as well as BMPR2 gene in 59 Japanese patients with PPH, including 7 familial PPH cases. We also performed the molecular study in 61 cases with secondary pulmonary hypertension (SPH). We identified mutations of BMPR2 gene in 23 cases'i39%'j of patients with PPH, while only one patient was found to have BMPR2 mutation. Regarding ALK1 gene, three cases (5%) of patients with PPH was found to have mutations, while only one patient with SPH was found to have a mutation. Those mutations are predicted to result in a premature termination codon or substitution of an amino acid residue. Furthermore, we identified functional relevance of those mutations by using cellular model for TGFb/BMP signaling. Based on these results, there is considerable genetic heterogeneity of PPH, and further functional study will be needed to identify pathophysiological mechanism of pulmonary hypertension.

BMPR2 gene rearrangements account for a significant proportion of mutations in familial and idiopathic pulmonary arterial hypertension. *M.A. Aldred[1], J. Vijayakrishnan[1], V. James[1], M.A. Gomez-Sanchez[2], G. Martensson[3], N.W. Morrell[4], R.C. Trembath[1].* 1) Div. of Medical Genetics, University of Leicester, UK; 2) Hospital Universitario 12 de Octubre, Madrid, Spain; 3) Sahlgrenska University Hospital, Gothenburg, Sweden; 4) Div. of Respiratory Medicine, University of Cambridge School of Medicine, Cambridge, UK.

Mutations of the *BMPR2* gene predispose to pulmonary arterial hypertension (PAH), a serious, progressive disease of the pulmonary vascular system. However, despite the fact that most PAH families are consistent with linkage to the *BMPR2* locus, sequencing only identifies mutations in some 55% of familial cases and approximately 26% of cases without a family history (idiopathic or IPAH). We therefore conducted a systematic analysis for larger gene rearrangements in panels of both familial and idiopathic PAH cases that were negative on sequencing of coding regions. Analysis of exon dosage across the entire gene using multiplex ligation-dependent probe amplification (MLPA)identified six novel deletions and enabled full characterization at the exon level of three previously reported deletions. Overall, *BMPR2* deletions were identified in 6 of 21 mutation-negative families (28.6%) and 4 of 87 IPAH cases (4.6%), suggesting that gross rearrangements underlie around 12% of all FPAH cases and 3% of IPAH. Deletions occurred at multiple different sites throughout the gene and while breakpoints for five deletions fell within intron-1, further analysis showed them to be distinct. Thus there was no evidence for breakpoint clustering. Notably, one deletion encompassed all functional protein domains and is predicted to result to in a null mutation, providing the strongest support yet that the predominant molecular mechanism for disease predisposition is haploinsufficiency. Dosage analysis of *BMPR2* should now be considered an integral of part of the molecular work-up of PAH patients, particularly those with a previous family history.

IDENTIFICATION OF NOVEL PKP2 MUTATIONS IN DUTCH ARVC PATIENTS. *M.R. Nelen[1], M. Entius[1], J.J. van der Smagt[1], R.N.A. Hauer[2], J.K. Ploos van Amstel[1], P.A. Doevendans[2], R.J. Sinke[1].* 1) Dept. of Medical Genetics,UMC Utrecht, Utrecht, The Netherlands; 2) Dept. of Cardiology,UMC Utrecht, Utrecht, The Netherlands.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a complex disorder and is associated with sudden unexpected death in young individuals. Patients with ARVC present with a gradual loss of myocytes that are replaced by fatty and fibrous tissue. In about 50% of ARVC-cases affected family members can be identified, usually consistent with an autosomal dominant mode of inheritance with reduced penetrance. The exact incidence of ARVC is unknown. A variety of chromosomal locations have been identified leading to the recognition of eight ARVC subtypes. Recently, the plakophilin 2 (PKP2) gene, an essential armadillo-repeat protein of the cardiac desmosome, was shown to be mutated in 27% of patients with ARVC (Gerull et al. 2004). Our goal was to assess the prevalence of PKP2 mutations in 22 Dutch patients that fulfilled the criteria for ARVC. The entire coding sequence and exon flanking sequences of the plakophilin 2 gene were screened for mutations using direct sequencing. In 6 unrelated probands 6 different disease releated mutations were identified (27%). These included 2 missense, 3 nonsense, and 1 frameshift mutation. One proband revealed 2 mutations: in addition to a causative intron 12 splice-site mutation (IVS12+1G>A) we also identified an amino acid substitution (Gln62Lys). Five of the mutations have not yet been reported. In conclusion, PKP2 mutations can be identified in up to 30% of Dutch patients fulfilling the ARVC criteria. These results will facilitate early recognition of persons at risk and future studies of potential genotype-phenotype relationships.

A 12-gene DNA resequencing chip for molecular diagnosis of hypertrophic cardiomyopathy. *J.L. Blouin[1], R. Lyle[2], U. Sigwart[3], A. Munoz[2], C. Gehrig[2], R. Lerch[2], M. Beghetti[4], J. Sztajzel[3], S.E. Antonarakis[1,2], S. Fokstuen[1].* 1) Medical Genetics, Univ. Hospitals of Geneva, Switzerland; 2) Genetic Medicine and Development, University of Geneva-School of Medicine, Switzerland; 3) Cardiology, Univ. Hospitals of Geneva, Switzerland; 4) Pediatric Cardiology, Univ Hospitals of Geneva, Switzerland.

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant disorder (prevalence 1/500) with a wide range of clinical features from a life-long asymptomatic course to chronic heart failure or sudden cardiac death. To date mutations associated with HCM have been identified in 14 genes, the majority of which (88%) are single nucleotide substitutions within exons, splice sites, or promoter regions. In clinical practice, molecular diagnosis of HCM is of considerable benefit for diagnosis, prognosis or predictive testing. However, the genetic heterogeneity of HCM means that mutation detection by classical methods is time-consuming and difficult to realise in a routine diagnostic molecular laboratory. The recent development of DNA resequencing microarrays allows the simultaneous analysis of multiple genes in a single experiment. We have developed such an array for fast (few days) and high-throughput molecular diagnosis of HCM. Our array comprises all coding exons (160), splice-site, and promoter regions of 12 genes mutated in HCM. We report the results of a first series of 25 unrelated patients with HCM. Mean Left-Ventricular-Wall-Thickness (LVWT) was 20 mm (14-29). We successfully assigned base calls at 95% of 26000 base positions. So far we confirmed at least 15 functional variants. One amino acid change (T1377M) in exon 30 of MYH7 is a known mutation. All the other variants are novel (12 amino acid changes in the genes MYBPC3, MYH7, MYL3, and TNNT2, 1 splice site variant -IVS25+1G>T- in MYBPC3, and 1 variant in the promoter region of PLN). Furthermore we detected at least 15 known silent SNPs. These first findings prove the utility and the performance of the HCM array as a high-throughput tool for the detection of nucleotide substitutions in clinical practice. The evaluation of further variants as well as of further samples is in progress.

Large phenotypic variability in 24 novel families with CM-AVM caused by a mutation in RASA1 gene. *N. Revencu[1,2], L. Boon[1,3], O. Enjolras[4], J.B. Mulliken[5], M. Vikkula[1], and the CM-AVM study group.* 1) Lab of Human Molecular Genetics, Christian de Duve Inst of Cellular Pathology, Université catholique de Louvain, Brussels, Belgium; 2) Centre for Human Genetics, Clin Univ St. Luc, Brussels, Belgium; 3) Centre for Vascular Anomalies, Clin Univ St. Luc, Brussels, Belgium; 4) Consultation des Angiomes, Lariboisière Hospital, Paris, France; 5) Vascular Anomalies Center, Div of Plastic Surgery, Childrens Hospital, Harvard Medical School, Boston, Ma 02115, USA.

Capillary Malformation-Arteriovenous Malformation (CM-AVM) (MIM 608354) is a recently identified phenotype characterised by atypical capillary malformations (CM) associated with either arteriovenous malformation, arteriovenous fistula, or Parkes Weber syndrome (PWS) (Eerola et al., 2003). The most prominent feature is the presence of atypical CMs, which are small, round-to-oval in shape and pinkish-red in color. We showed that the CM-AVM phenotype is caused by mutations in the RASA1 gene and reported 6 different mutations. We report here 23 distinct mutations in 24 novel families with CM-AVM. The mutations were spread throughout the gene and 22 of them caused a premature stop codon: 9 nonsense, 7 frameshift and 6 splicing mutations, suggesting a loss of function as the most likely mechanism. In one family, a missense mutation was identified (Y426C). Interestingly, 8 mutations were clustered in 2 exons, part of the RasGap domain: 3 in the exon 17 and 5 in the exon 19. Fifty-two individuals carrying a RASA1 mutation were identified in these 24 families: 37 had CMs and 15 had, in addition, a high-flow lesion (5 AVM, 1 AVF and 9 PWS). In conclusion, 28 different RASA1 mutations have been identified so far, clearly delineating the CM-AVM phenotype. A considerable proportion of patients (27%) had, besides the atypical CMs, a high-flow lesion. Its specific clinical, radiological and genetic characteristics should avoid the confusion with other vascular anomalies, such as hereditary benign telangiectasia or Klippel-Trenaunay syndrome. Our data also suggests that the CM-AVM phenotype could be a relatively frequent genetic disorder. (vikkula@bchm.ucl.ac.be).

Irish wolfhound Cardiomyopathy with Atrial Fibrillation maps to CFA23. *P.M. Jakobs[1], M. Bestwick[1], S. Nelson[1], M. Winther[1], E. Ostrander[2], R.E. Hershberger[1], M. Litt[3].* 1) Medicine, Cardiology, Oregon Health & Science Univ, Portland, OR; 2) NHGRI, NIH, Bethesda, MD; 3) Molecular & Medical Genetics, Oregon Health & Science Univ, Portland, OR.

In collaboration with dog owners and breeders we obtained clinical data and blood for DNA from a large Irish Wolfhound (IW) pedigree in which atrial fibrillation (AF) with dilated cardiomyopathy (DCM) is inherited. The disease, occurring naturally in IWs, offers a valuable opportunity to study a large animal model that closely resembles human genetic cardiomyopathy. Our working pedigree includes 142 IWs of which 45 dogs have AF and/or DCM. Overlapping 3-point linkage analysis using linkmap and assuming 1Mb = 1cM, was applied to data from 452 microsatellite markers. Assuming autosomal dominant inheritance with affecteds only, we excluded approximately 75% of the genome. A region with positive lodscores was identified on CFA23. Multipoint linkage analysis using an affected only model revealed a region with a multipoint lodscore exceeding 3. The critical region is between markers AHTK253 and 23_12.71 with a maximum multipoint LOD score of 3.44 at FH3671. We have yet to identify the causative gene in this 1.43 Mb chromosomal region, and our first approach will focus on the sequencing of SCN5A, a positional candidate gene, mutations in which have been shown to cause human dilated cardiomyopathy and conduction system disease.

Interaction between *Pkd1* and *Fbn1* in the pathogenesis of aortic aneurysm. *J. Moslehi[1], C. Wang[1], D. Judge[1], K. Piontek[1], J. Deng[1], G. Germino[1], T. Watnick[1], H.C. Dietz[1,2].* 1) Johns Hopkins Univ, Baltimore, MD; 2) HHMI, Bethesda, MD.

Marfan syndrome (MFS) is a systemic disorder of connective tissue caused by mutations in the gene encoding fibrillin-1 (*FBN1*), with cardinal manifestations including proximal aortic aneurysm and dissection. Autosomal dominant polycystic kidney disease (ADPKD) is also associated with vascular disease including aortic and intracranial aneurysm. The majority of cases are caused by mutations in the gene encoding polycystin-1 (*PKD1*). The precise function of polycystins in the vasculature has not been defined. We bred mice harboring mutant alleles of *Pkd1* and *Fbn1*, and the offspring were sacrificed at 6 months of age. *Pkd1*+/- mice had a mild increase in aortic wall thickness compared to controls (41.5 M vs 27.6 M for WT). *Fbn1*+/- mice had greater aortic wall thickness (50.3 M) and aneurysm. Compound heterozygous mice had even greater aortic wall thickness (60.8 M) and aneurysm compared to either isolated het. In addition, the compound het mice had prominent inflammation at the site of aortic aneurysm not seen in either isolated het. Based on our prior recognition of increased TGF activity in fibrillin-1 deficient mice, we speculated that an interaction between *Pkd1* and *Fbn1* might manifest further up-regulation of this pathway by *Pkd1* mutation. We found that aortic sections from these mice demonstrated increased active TGF and increased TGF signaling, as evidenced by nuclear enrichment of pSmad2/3 and increased expression of PAI-1 and CTGF when compared with either single het. In order to test whether polycystin-1 was capable of regulating TGF activity, we induced recombinant expression of either wild-type or C-truncated (P89) polycystin-1 in NIH3T3 cells, and stimulated with TGF1 (4ng/ml). In order to quantify activation of TGF signaling, western blots were probed with antibodies to Smad4 and pSmad2/3. We found that *PKD1*-transfected cells had a significantly blunted response to TGF stimulation when compared with either vector or P89-transfected cells, despite similar levels of expression. Our results suggest that polycystin-1 modulates activity of the TGF signaling pathway, and may thus contribute to the pathogenesis of aortic aneurysm.

Locus heterogeneity in ASD associated with AV-block. *L. De Roy[2], I. Gutierrez-Roelens[1], C. Ovaert[2], Th. Sluysmans[2], K. Devriendt[3], H.G Brunner[4], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular and Pathology, Brussels, Belgium; 2) Division of Pediatric Cardiology and Cardiology, Cliniques universitaires St Luc, University of Louvain Medical School, Brussels, Belgium; 3) Center for Human Genetics, University of Leuven, Leuven, Belgium; 4) Department of Human Genetics, University Medical Center St Radboud, Nijmegen, The Netherlands.

The prevalence of congenital heart defects is approximately 1% of all live births. Identifying the genes responsible for cardiac malformation is the first step to understand pathogenesis. Heterozygous mutations in the CSX/NKX2-5 gene have been identified to cause atrial septal defect (ASD) and/or atrioventricular conduction disturbance in some families. There is great variability in expressivity between the patients with a CSX/NKX2-5 mutation. We screened 4 sporadic patients and 5 index cases of families with ASD and/or conduction defects. In one of them, a CSX/NKX2-5 mutation was identified. This novel mutation was inherited in a 3-generation family causing 5 individuals to present cardiac symptoms ranging from ASD to arrhythmias. In the 4 other families affected with left ventricular non-compaction cardiomyopathy, hypoplastic left heart syndrome and ASD with AV-block, no CSX/NKX2-5 mutation was found. Two of the 4 families presented a phenotype characteristic of CSX/NKX2-5 mutated individuals. Deletion of the whole gene was also excluded. These two families have also been screened for mutations in CRELD1, FOG2 and BMP4, candidate genes for septation. As no mutation was identified in these genes either, the data strongly suggests genetic heterogeneity in ASD with conduction defects. (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.ac.be/vikkula/).

No evidence for mutations in five candidate genes, GATA4, FOG2, CRELD1, HEY2 and BMP4 as a common cause of structural cardiac defects. *Th. Sluysmans[2], C. Ovaert[2], I. Gutierrez-Roelens[1], K. Devriendt[3], H.G Brunner[4], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology; 2) Division of Pediatric Cardiology, Cliniques universitaires St Luc, University of Louvain Medical School, Brussels, Belgium; 3) Center for Human Genetics, University of Leuven, Leuven, Belgium; 4) University Medical Center St Radboud, Department of Human Genetics, Nijmegen, The Netherlands.

Cardiac septation involves the closure of direct communications between left and right atria, ventricles and subarterial channels, and the development of the atrioventricular junction and the ventriculoarterial junction. Disruption of these processes gives rise to cardiac septal defects. Several transcription factors including CSX/NKX2-5, TBX5, TBX1, JAG1, SALL4, EVC1 and EVC2 regulate septal formation. Yet, in non-syndromic septal defects it has been very difficult to identify predisposing genetic factors, and in man clear mutations have so far only been identified in the CSX/NKX2-5 gene, usually in association with conduction defects. Recently, three other genes (GATA4, FOG2, CRELD1), on the basis of certain non-synonymous amino-acid changes, were suggested to be responsible of isolated septal defects in man. In mouse, inactivation or modification of two other genes results in septal defects (HEY2, BMP4). In this study, we screened these five genes (GATA4, FOG2, CRELD1, HEY2 and BMP4) in a series of 66 patients affected with a structural, congenital cardiac malformation, mostly a septal defect. Twenty-nine nucleotide changes were identified, resulting in 12 synonymous and 10 non-synonymous amino acid changes. None of these nucleotide variations was considered a mutation, as they were either identified in dbSNP, dbEST, or the amino acid change did not occur in a conserved region. For some of them we cannot exclude an effect on RNA stability or abnormal splicing. We conclude that none of these five genes is a major cause of structural cardiac defects in man. (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.ac.be/vikkula).

Novel glycogen synthase kinase 3 (GSK3) and ubiquitination pathways in progressive myoclonus epilepsy. *H.T. Lohi[1], L. Ianzano[1], X.C. Zhao[1], E.M. Chan[1], J. Turnbull[1], S.W. Scherer[1], C.A. Ackerley[3], B.A. Minassian[1,2].* 1) Genetic and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Paediatrics (Neurology), The Hospital for Sick Children,Toronto,ON, Canada; 3) Department of Pathology and Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.

Lafora progressive myoclonus epilepsy, caused by defective laforin or malin, presents insidiously in normal teenagers with cognitive decline, followed by rapidly intractable epilepsy, dementia and death. Pathology reveals neurodegeneration with neurofibrillary tangle formation and Lafora bodies (LB). LB are deposits of starch-like polyglucosans, insufficiently branched and hence insoluble glycogen molecules resulting from glycogen synthase (GS) overactivity relative to glycogen branching enzyme activity. We previously made the unexpected observation that laforin, in the absence of which polyglucosans accumulate, specifically binds polyglucosans. This suggested that laforins role is to detect polyglucosan appearances during glycogen synthesis and initiate mechanisms to downregulate GS. Glycogen synthase kinase 3 (GSK3) is the principal inhibitor of GS. Dephosphorylation of GSK3 at Ser 9 activates GSK3 to inhibit GS through phosphorylation at multiple sites. Glucose 6-phosphate is a potent allosteric activator of GS. At times of glucose plenty, its levels are high, and its activation of GS overrides any phospho-inhibition. Here we show that laforin is a GSK3 Ser 9 phosphatase, and therefore capable of inactivating GS through GSK3. We also show that laforin interacts with malin, and that malin is an E3 ubiquitin ligase that binds GS. We propose that laforin, in response to appearance of polyglucosans, directs two negative feedback pathways, one, polyglucosan-laforin-GSK3-GS, to inhibit GS activity, and the other, polyglucosan-laforin-malin-GS to remove GS through proteasomal degradation.

Genetic and evolutionary analysis of the *ABCC6* gene and pseudoxanthoma elasticum (PXE). *H. Lou[1], J. Bergeron[2], L. Thomas[1], S.F. Terry[3], P.F. Terry[3], M. Dean[1].* 1) Lab Genomic Diversity, NCI-FCRDC, Frederick, MD; 2) SAIC-Frederick, Frederick, MD; 3) PXE International, Washington, DC.

The *ABCC6* gene is a member of the ATP-binding cassette (ABC) transporter superfamily and encoding multidrug resistance protein 6 (MRP6). Although the function of ABCC6 is unknown, mutations in the human *ABCC6* gene result in a heritable disorder principally affecting the skin and eyes, pseudoxanthoma elasticum (PXE). To explore the inheritance of PXE and the penetrance of *ABCC6* mutations, we typed several polymorphisms in and flanking the *ABCC6* gene in 16 PXE pedigrees. We identified two potential non-penetrant cases that one male and one female that require followup. An overrepresentation of affected females was found both in the probands and in the siblings of probands. This was not quite statistically significant in this sample.
To develop an animal model for PXE, the full-length zebrafish *Abcc6* cDNA was successfully cloned and sequenced. We quantitated the mRNA expression from a variety of zebrafish tissues including skin, head, eyes, bone, organs, eggs, muscle, and embryos using real-time RT-PCR. The highest levels of *Abcc6* mRNA were found in the skin, followed by head, eyes and embryo. Furthermore, we measured *Abcc6* mRNA in embryos 6 days post-fertilization (dpf). The level of *Abcc6* mRNA in embryos was shown to be intermediate between that of the eyes and bone. In situ hybridization revealed expression of the Abcc6 in discrete areas of the skin, consistent with the RT-PCR data. Our results demonstrate the presence of Abcc6 in a variety of tissues, including those tissues affected in PXE patients, suggesting a possible role for ABCC6 in the normal assembly of extracellular matrix components. The sequencing data contribute to the development of an animal model for PXE and identification of the function of ABCC6.

Detection of a heterozygous SALL1 deletion proves the contribution of a SALL1 dosage effect in the pathogenesis of Townes-Brocks syndrome. *W. Borozdin[1], K. Steinmann[1], B. Albrecht[2], J. Kohlhase[1].* 1) Institute for Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany; 2) Institute for Human Genetics, Duisburg-Essen University, Essen, Germany.

Townes-Brocks syndrome (TBS, OMIM #107480) is an autosomal dominantly inherited malformation syndrome characterized by anal, renal, limb, and ear anomalies caused by mutations in the putative zinc finger transcription factor gene SALL1. The mapping of the TBS gene locus to chromosome 16q12.1 was achieved by identification of two cytogenetic abnormalities, both involving a breakpoint at 16q12.1. Based on the sole observation of truncating mutations in the SALL1 gene in TBS patients and the association of TBS with chromosomal anomalies, haploinsufficiency was assumed as the pathogenic mechanism leading to TBS. However, Sall1 knock-out mice did not show any phenotype in the heterozygous situation and solely severe kidney defects in the homozygous mutants. Instead, another mouse model mimicking the human mutations revealed a TBS-like phenotype in the heterozygous mutants. Furthermore, biochemical evidence suggested that truncated SALL1 proteins do exist and possibly lead to the phenotype by a dominant-negative action as well as by interfering with other SALL proteins. This hypothesis could not integrate the observation of cytogenetic anomalies in TBS patients. Here we show the first patient with a heterozygous deletion of the SALL1 gene. The deletion was not visible on cytogenetic analysis and involves all coding exons of SALL1 as well as several kb of downstream sequence, as detected by quantitative real time PCR. The patient presented with a mild TBS-like phenotype, consisting of a small ear, bilateral triphalangeal thumbs and an anteriorly positioned anus. While further patients with deletions are needed to clarify if the severe TBS phenotype could also be associated with a SALL1 deletion, our data prove that a SALL1 dosage contributes significantly to human TBS and indicate that truncated proteins might lead to a more severe TBS phenotype by interacting with other SALL proteins.

No evidence for association between the serotonin transporter promoter polymorphism and pulmonary arterial hypertension. *R.D. Machado[1], E. Gruenig[2], B. Janssen[3], R. Koehler[3], C.G. Elliott[4], M. Humbert[5], F. Soubrier[6], N.W. Morrell[7], R.C. Trembath[1].* 1) Division of Medical Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom; 2) Department of Cardiology and Pneumology, University Hospital Heidelberg, Germany; 3) Institute of Human Genetics, University of Heidelberg, Germany; 4) LDS Hospital and the University of Utah, Salt Lake City, USA; 5) Service de Pneumologie, UPRES EA2705, Hopital Antoine Beclere, France; 6) Laboratoire dOncogénétique et dAngiogénétique Moléculaire, GH Pitié-Salpêtrière, 47 bd de lhôpital, France; 7) Respiratory Medicine Unit, University of Cambridge, UK.

Pulmonary arterial hypertension (PAH) is a severe disorder characterised by a sustained elevation of pulmonary arterial resistance leading to cardiac failure. PAH may segregate within families (FPAH), develop spontaneously (IPAH) or be observed in the setting of associated complications (APAH). Mutation of the BMPR2 gene, encoding a type II TGF-beta receptor, has been established as the major genetic factor underlying the condition. However, mutant alleles exhibit reduced age- and sex-dependent penetrance indicating the requirement for additional environmental and/or genetic modifiers in disease pathogenesis. Recently, a putative association between the mitogen serotonin, and, specifically, its transporter (5-HTT) with the pathogenesis of PAH has generated the important hypothesis that 5-HTT might act as a genetic modifier of disease. To comprehensively investigate the presence of a genetic association we compared the distribution of a functional INDEL polymorphism in the promoter of the 5-HTT gene between FPAH (n=145), IPAH (n=282) and APAH (n=136) cohorts, to ethnically matched controls (n=353). The analysis was extended to examine the possible contribution of 5HTT variation to age of onset of clinical disease. We obtained no evidence for association either with the three clinical classes of PAH (P>0.5)or with age of disease onset. The absence of association in these large case groups provides compelling evidence against a role for the 5HTT gene in PAH susceptibility or as a significant modifier of disease progression.

The Role of the GNRH1 gene in patients with Idiopathic Hypogonadotropic Hypogonadism. *B.S. Villarreal, L. Chorich, L. Layman.* Section of Reproductive Endocrinology, Infertility, & Genetics, Dept. OB/GYN, Developmental Neurobiology Program, Institute of Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA.

Idiopathic hypogonadotropic hypogonadism (IHH) is a rare disorder characterized by an irreversible delay of puberty (age 17 for females and 18 for males) and accompanying low levels of the serum gonadotropins follicle stimulating hormone (FSH) and luteinizing hormone (LH). Other pituitary hormone levels are typically normal, and pituitary tumors are absent. Because of its role in regulating gonadotropins, the GNRH1 (gonadotropin releasing hormone-1) gene represents the ideal candidate gene for mutations that may cause IHH. GNRH1 encodes for a signal peptide, the decapeptide GnRH, and GAP (GnRH-associated peptide), both of which increase gonadotropin secretion. Although there have been some studies of IHH families for mutations in the GNRH1 gene, to date, all of these were performed upon a relatively small sample size and failed to reveal any mutations in IHH patients. Because of the important orchestrating role of GnRH in the synthesis and secretion of gonadotropins and the identification of a Gnrh1 deletion in the hypogonadal mouse, we proposed to study a large sample of unrelated IHH probands for mutations. Total RNA extracted from lymphoblastoid cells from 80 unrelated IHH probands was subjected to reverse transcriptase PCR (RT-PCR) using a single primer set. The amplified region contained the entire coding region for GnRH and GAP, as well as part of the signal peptide. PCR products were electrophoresed on agarose gels to confirm the presence of an appropriately sized band, and sequenced. No sequence variation was present in any patient, including the previously identified polymorphism in the signal peptide at codon 16. We conclude that mutations in the coding region of the GNRH1 gene are extremely uncommon in IHH patients, as are mutations that affect splicing. These findings corroborate the observation that no human hypothalamic releasing factor to date possesses mutations in human genetic disease.

Characterizing the effect of *Tcof1* on cell proliferation using a neuroblastoma cell line. *L. Li, R. Shiang.* Human Genetics, Virgina Commonwealth University, Richmond, VA.

Treacher collins syndrome (TCS) is an autosomal dominant craniofacial development disorder. Previously, we identified candidate *Tcof1* downstream genes using microarray analysis by manipulating *Tcof1* level in a murine neuroblastoma (NB) cell line. Candidate downstream genes include cell cycle genes as well as transcription factors *Cnbp* and *Tbx2*, which are known to affect cell cycle through c-myc and p19-Mdm2/p21 pathway respectively. To further characterize the effects of *Tcof1* level changes on NB cell proliferation, growth curves were generated by counting cell numbers, BrdU incorporation was used to determine rate of DNA replication and analyzed with flow cytometry, and TUNEL assay was used to determine apoptosis levels. Western blot analysis was used to detect protein level changes of candidate downstream pathway genes. Both overexpress and knockdown of *Tcof1* caused decreased proliferation of NB cells. Overexpression of Tcof1 caused an increased apoptosis level as well as DNA replication level, which indicate the cells are likely entering apoptosis from the G2 stage of the cell cycle. Inconsistent with mouse model results, knockdown of Tcof1 caused a slightly decreased apoptosis level and no apparent difference in DNA replication level compared to wild type. Heterozygous *Tcof1* knock out mice showed an increased apoptosis level at highest *Tcof1* expression sites. This may be caused by the difference between neural crest cells *in vivo* and the NB cell line we used. Western blot analysis showed c-myc level changed coordinately with Tcof1. There are no apparent changes on p21 (Cdkn1a) and Mdm2 levels. Our results suggested an optimal Tcof1 level is required for cell proliferation and survival. Results indicated that *Tcof1* may affect cell proliferation through the c-myc pathway. We are investigating if *Cnbp* and *Tbx2* are involved in the effects of *Tcof1* on cell proliferation and survival.

Molecular studies of candidate genes involved in defects of human spermatogenesis. *W. Lissens[1], K. Stouffs[1], A. Willems[1], H. Tournaye[2], A. Van Steirteghem[2], I. Liebaers[1].* 1) Center for Medical Genetics; 2) Center for Reproductive Medicine, Univ Hosp of the Vrije Universiteit Brussel, Brussels, Belgium.

In an attempt to identify genetic causes of human male infertility due to severely defective spermatogenesis, we have studied several candidate genes. We focused on genes that are only expressed in testicular tissue and that are located on the X chromosome. Infertile patients for these studies were selected based on the expression pattern of the corresponding genes in mice and their likely consequence on spermatogenesis in case of deficiency. Genes studied were TEX13A, TEX13B and TAF7L. Testis-specific expression of genes was studied by PCR using gene-specific primers and commercially available or homemade cDNAs prepared from human testicular tissue. If appropriate, intronic primers were designed for PCR amplification and for sequencing of the genes. PCR amplification of cDNA failed to show expression of the human TEX13A and TEX13B genes. Published data on these genes possibly refer to DNA contamination of the cDNA preparations because primers were designed in intron-less regions. No further studies of these genes were performed. In contrast, TAF7L cDNA was specifically found in testicular tissue. Mutation analysis of the gene was performed in 27 patients with a maturation arrest of spermatogenesis. Four changes in comparison to the normal sequence were found, and three of them proved to be polymorphisms by studying 60-120 normal fertile males as controls. One change, c.1373G>A predicting Arg458Cys, was found in 2 patients but not in 103 male controls. From mouse studies, it is known that TAF proteins have an important function in the regulation of transcription. TAF7L is expressed from the stage of spermatogonia until the stage of round spermatids, and during meiosis, a shift of the protein from the cytoplasm to the nucleus is observed. If the expression of the gene is similar to that in mouse, defects in the gene are likely to cause maturation arrest at the level of meiosis or early spermatid differentiation. It will be important to prove the role of the TAF7L protein in the human, and to verify the possible effect of the Arg458Cys change on its function.

The role of Biogenesis of Lysosome-Related Organelles Complexes (BLOCs) in human genetic disease. *A. Helip Wooley[1], H. Dorward[1], W. Westbroek[1], R. Boissy[2], M. Huizing[1], W.A. Gahl[1].* 1) NHGRI, NIH, Bethesda, MD; 2) Univ. of Cin., OH.

Hermansky-Pudlak syndrome (HPS) is a disorder of impaired lysosome-related organelle (LRO) biogenesis. Defects in melanosomes in melanocytes and dense bodies in platelets are hallmarks of the disease and manifest clinically with oculocutaneous albinism and a bleeding diathesis. There are seven subtypes of human HPS described, with great variability in severity, irrespective of mutation. HPS-3, HPS-5 and HPS-6 generally have mild hypopigmentation with little or no bleeding, while HPS-1 and HPS-4 have severe albinism, bleeding and early death from pulmonary fibrosis. The correlation between disease subtype and severity is becoming more apparent as we learn how HPS proteins interact and function in Biogenesis of Lysosome-Related Organelles Complexes or BLOCs. HPS3, HPS5 and HPS6 proteins are found in BLOC-2. EM of melanocytes from patients with these subtypes reveals fewer mature melanosomes and an abundance of small tyrosinase (tyr)-positive vesicles mislocalized throughout the cell. We have found that HPS3 has a functional clathrin-binding domain and that HPS3 co-localizes with clathrin on small vesicles. We hypothesize that BLOC-2 binds the small, tyr-positive vesicles and escorts them to early stage melanosomes for delivery of their cargo. HPS1 and HPS4 are members of BLOC-3. The small mis-localized vesicles seen in BLOC-2 deficient cells are absent from BLOC-3 deficient melanocytes, but large, tyr-containing multilamellar compartments are present. Immunofluorescence studies reveal that some melanosomal and lysosomal proteins remain in the trans-Golgi region. It appears that BLOC-3 deficient cells fail to form the small vesicles that serve as transport intermediates for melanosomal proteins. In contrast, BLOC-2 deficient cells form these vesicles, but they do not properly traffic to and/or fuse with maturing melanosomes. Thus, BLOC-3 acts at an earlier stage of LRO biogenesis, so HPS-1 and HPS-4 result in clinically more severe disease compared with BLOC-2 defects (HPS-3, -5 and -6). HPS illustrates a new paradigm of using cell biology to understand human genetic disease.

Altered membrane trafficking in genetically accurate mouse and cerebellar cell culture models of juvenile neuronal ceroid lipofuscinosis. *S.L. Cotman[1], Y. Cao[1], E. Fossale[1], P. Wolf[1], J.A. Espinola[1], J.M. Weimer[2], D.A. Pearce[2], M.E. MacDonald[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Charlestown, MA; 2) Center for Aging and Developmental Biology, University of Rochester Medical Center, Rochester, NY.

Juvenile neuronal ceroid lipofuscinosis (JNCL) is the most common inherited neurodegenerative disease in children, causing blindness, seizures, cognitive and motor decline, and premature death. We previously generated *Cln3*$^{ex7/8}$ knock-in mice, harboring the common ~1kb deletion mutation that gives rise to most cases of JNCL. Because JNCL specifically impacts neuronal function and survival, we have also established a neuron-derived cell culture model of JNCL, by conditional immortalization of cerebellar granule neurons from perinatal *Cln3*$^{ex7/8}$ knock-in mice (Cb*Cln3*$^{ex7/8}$ cerebellar cells). Utilizing these two genetically accurate systems, our studies reveal that general disruptions in membrane trafficking are a prevalent feature associated with the common JNCL mutation. In homozygous Cb*Cln3*$^{ex7/8}$ cerebellar neuronal precursors, we show altered endocytosis, altered lysosomal distribution, altered autophagic membrane trafficking, and mitochondrial dysfunction. Furthermore, our studies provide evidence that these disruptions occur early in the disease process, preceding accumulation of the mitochondrial ATPase, subunit c, a hallmark feature of JNCL. Genechip array analysis of 10-week homozygous *Cln3*$^{ex7/8}$ knock-in cerebellum versus wild-type littermate cerebellum complements these observations, revealing that a substantial number of genes whose protein products are involved in membrane trafficking and protein transport are differentially expressed. Other major categories of differentially expressed genes in 10-week homozygous *Cln3*$^{ex7/8}$ knock-in cerebellum are those involved in transcription, mitochondrial function, immune response, the ubiquitin pathway and cell signaling. Collectively, these studies in Cb*Cln3*$^{ex7/8}$ cerebellar precursor cells and *Cln3*$^{ex7/8}$ knock-in mice highlight pathways that merit further investigation to unravel the JNCL pathogenic process.

Genotype/Phenotype Correlations in Pseudoxanthoma Elasticum (PXE). *P.F. Terry[1], S. Hariri[2], C. Moore[2], C.M. Vocke[1], L.G. Bercovitch[3,1], S.F. Terry[1], PXE International Genotype Consortium.* 1) PXE International, Washington, DC; 2) Centers for Disease Control and Prevention, Atlanta, GA; 3) Brown University, Providence, RI.

Purpose: To evaluate associations, if any, between PXE-related gene variants and phenotypes.

Materials and Methods: Using samples from 254 participants in the PXE International Blood and Tissue Bank/Genetic Alliance BioBank, PXE-related genotypes were detected in three independent laboratories with Transgenomics Wave technology utilizing DHPLC. Phenotypes, classified according the Phenodex indexing system criteria, were described for all study participants. Descriptive analysis was performed, and univariate and multivariate analysis were attempted on original data and after phenotypes were dichotomized. Additionally a subanalysis was performed on individuals over 40 years of age who are most likely to express all phenotypes of interest.

Results: Due to the high numbers of genetic variants and phenotype categories relative to the sample size, there was insufficient power to detect intended associations in this study.

Conclusions: Further analysis is needed to examine associations, not only between gene variants and clinical outcomes, but also to assess how these associations may be modified by environmental factors. In addition, analysis of correlations between mutations and cellular phenotype should be undertaken to identify effective treatment modalities.

Late X-chromosome inactivation skewing of a NEMO mutation causes Incontinentia Pigmenti in a female patient with immunodeficiency: a new mutation in NEMO gene. *A. SMAHI[1], N. MARTINEZ[2], I. MUNOZ-SAA[2], D. HEINE-SUNER[3], A. MARTIN[4], A. MUNNICH[1], N. MATAMOROS[2].* 1) Département de Genetique INSERM U393, Hopital Necker, Paris, France; 2) Immunology Service, Hospital Universitario Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 3) Genetic Service, Hospital Universitario Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 4) Dermatology Service. Hospital Universitario Son Dureta, Palma de Mallorca, Balearic Islands, Spain.

Incontinentia pigmenti (IP) is an X-linked genodermatosis, lethal in males. Affected females survive because of X-chromosome dizygosity and the negative selection of cells carrying the mutant X-chromosome, which results in a skewed X-inactivation pattern. The most frequent mutation is a deletion of part of the NEMO gene (NEMO4-10), although others have been reported. Mutations of NEMO which do not totally abolish NF-B activity are consistent with male survival, and cause an allelic variant of IP called hypohidrotic ectodermal dysplasia and immunodeficiency (HED-ID). We present a de novo insA790 NEMO mutation in a female patient with non classical IP who also suffered from immunodeficiency because of a late and progressive selection against peripheral blood cells carrying mutated X-chromosome. At the age of three years and six months all immunodeficiency signs had disappeared, and the X-chromosome inactivation pattern was completely skewed. The low T cell proliferation and CD40L expression emphasize the important role of NEMO/ NF-B pathway in T cell homeostasis. The decreased amount of NEMO protein and the impaired IkB degradation suggest that this new mutation, may result in RNA or protein instability. This is, to our knowledge the first example of an in vivo selection against the mutated X-chromosome in a X-linked disease in human.

Large deletion encompassing D4F104S1 in an extended pedigree with facioscapulohumeral muscular dystrophy.

K.L. Bastress[1], S.M. van der Maarel[2], R.J.L.F. Lemmers[2], J.M. Staijch[1], M.C. Speer[1], J.R. Gilbert[1]. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is a disease of skeletal muscle, with symptoms including both facial and shoulder girdle weakness. In the majority of FSHD cases, the molecular basis is a contraction of the D4Z4 repeat on the end of the long arm of chromosome 4. In a small number of cases, there is an apparent absence of the contracted D4Z4 repeat that is associated with FSHD. This is due to the presence of a deletion in the region proximal to the D4Z4 repeat array, which encompasses the p13E-11 (D4F104S1) probe-binding site. The frequency of such extended deletions is unknown, due to the difficulties in the molecular identification of such cases. To date, only a few patients with an extended deletion have been described, with no more than 2 members of the same family. Here we describe a family (DUK 2531) with 20 sampled individuals, where 10 affected individuals that segregate a contracted D4Z4 allele in addition to large proximal deletion of approximately 70 kb. This is the largest deletion to be described and the first extended pedigree showing such a deletion. This family was originally characterized as being unlinked to the 4q35 region (FSHD1B) and was thought to have normal D4Z4 fragment size. Because such deletions can lead to misinterpretation in the diagnostic setting, this suggests the need for the use of additional diagnostic tests in FSHD such as the 4qA probe. *Mse*I digestion and probing with the D4Z4 specific probe 9B6A reveals the presence of ten D4Z4 repeat units (33 kb), and the 4qA probe also reveals a fragment of this length. Subsequent *Mse*I/*Bln*I digestion confirms that the deletion allele is of chromosome 4 origin and *Not*I fragment analysis for chromosome assignment suggests that the allele resides on chromosome 4. It appears that the extended deletion includes the p13E-11 binding site, the B31 probe site, the inverted repeat D4S2463, and several genes including *FRG2* and *TUBB4Q*. Mapping of the exact breakpoint is currently underway.

Pathogenesis of Cartilage Hair Hypoplasia. *P. Hermanns[1,4], A.A. Betruch[6], J.G. Leroy[1,2], T. Bertin[1], B. Dawson[1,5], A. Tran[1], E. Munivez[1,5], M. Schmitt[3], B.U. Zabel[4], B. Lee[1,5].* 1) Molecular & Human Genetics, Baylor Colllege of Medicine, Houston, TX, USA; 2) Ghent University Medical School, Ghent Belgium; 3) Biochemistry and Molecular Biology, Upstate Medical University Syracuse, NY, USA; 4) Children's Hospital, University of Mainz, Mainz, Germany; 5) Howard Hughes Medical Institute, Houston, TX, USA; 6) Pediatrics-Hematology & Oncology, Texas Childrens Feigin Centre, Houston, TX, USA.

CHH is an autosomal recessive disease characterized by dwarfism, fine & sparse hair, deficient cellular immunity and predisposition to malignancy. CHH is one of the few Mendelian diseases caused by mutation in a non-coding RNA gene, RMRP. It is the RNA component of a ribonucleoprotein complex. Yeast studies suggest its involvement in processing of pre-rRNA in the nucleolus, cleavage of mitochondrial RNA priming mitochondrial DNA replication, and cell cycle progression. Mutation analysis was performed in 34 patients, referred with the diagnosis of probable CHH. RMRP mutations were found in 26 subjects. The combination of reduced birth length, severe growth failure and deficient hair growth appeared to be highly correlated with the detection of mutations in the RMRP gene. So far no modifiers have been identified that could explain the pleitropic presentation of CHH. In vitro studies show that promoter duplications found in CHH patients cause a hypomorphic allele affecting RMRP transcription. Quantitative RT-PCR analysis of patient lymphoblasts revealed a 7-fold decrease in RMRP RNA level irrespective of the nature of mutations tested. RMRP mutations introduced into the yeast ortholog NME1 neither altered mitochondrial function nor, affected mitochondrial content in a CHH patient fibroblast cell line. The 70A>G causes an alteration in rRNA processing and microarray studies performed with two patients suggest that RMRP mutation is associated with significant up-regulation of several cytokines and cell cycle regulatory genes. These data suggest that alteration of ribosomal processing leads to altered cytokine signaling and cell cycle progression in terminally differentiated cell types involved in CHH pathogenesis, i.e., lymphocytic and chondrocytic lineages.

Defective Protein Interactions as a Molecular Basis for Axenfeld-Rieger Syndrome (ARS). *B.A. Amendt[1], H.M. Espinoza[2], E.V. Semina[3], B.P. Brooks[4].* 1) Environmental and Genetic Medi, Texas A&M HSC, Houston, TX; 2) Department of Biological Sciences, University of Tulsa, Tulsa, OK; 3) Department of Medical Genetics, Medical College of Wisconsin, Milwaukee, WI; 4) National Eye Institute, National Institutes of Health, Bethesda, MD.

The PITX2 and Lymphoid Enhancer Factor (LEF-1) transcription factors are required for the inductive formation of several epithelial-derived organs including teeth. Individuals with Axenfeld-Rieger Syndrome present clinically with eye, dental and umbilical abnormalities as the hallmark of this genetic disorder. We are studying the transcriptional mechanisms of PITX2 and have identified several new PITX2 interacting factors, which regulate its transcriptional activity. PITX2 directly interacts with LEF-1 and -catenin to modulate gene expression. These interactions result in a synergistic activation of several gene promoters including LEF-1. A new C-terminal PITX2 mutation associated with ARS results in a deletion of a T nucleotide at position 1261 and changes the reading frame. Thus, this mutant protein (PITX2 T1261) is only 237 amino acids compared to 271 for wild type PITX2A. This mutation disrupts the distal C-terminal tail and OAR domain of PITX2. This mutant protein binds DNA normally, however it is unable to interact with several proteins including LEF-1. The inability of PITX2 T1261 to interact with LEF-1 severely decreases the transcriptional activation of this mutant protein compared to wild type PITX2. This mutation provides a functional analysis of PITX2 protein interactions in regulating normal human development. Protein interactions are required for the temporal and spatial regulation of transcription factors during embryogenesis and our data demonstrate a specific requirement for protein interactions in regulating PITX2 transcriptional activity. Thus, we have demonstrated a molecular basis for a genetic defect involving protein interactions.

New mutations on FGFR 3 and FGFR2 genes responsible for classical Hypochondroplasia and Crouzon syndrome phenotypes. *S. Carlo[1], J. Acevedo[2], V. Franceschini[1], M. Lopez[2], A. Quintero-Del-Rio[1], N. Arciniegas[1], A.S. Cornier[1].* 1) Genetic Division, Ponce Sch Medicine, Ponce, PR; 2) Department of Nursing, Univ. of Puerto Rico, Arecibo, PR.

Mutations within the FGFR genes have been described as responsible for a wide variety of phenotypes. The FGFRs are a family of tyrosine kinase receptors with three immunoglobulin-like regions in the extracellular domain, a transmembrane domain, and a split intracellular tyrosine kinase domain. We are presenting a series of two patients with hypochondroplasia with a n unusual mutation in the FGFR 3 gene indicating the presence on a G>A transition in intron 11 responsible for hypochondroplasia phenotype that has not been reported in the literature before. A third patient with Crouzon syndrome classical phenotype and an Nt 1204 G>A mutation is described. None of these mutations /variations has been associated to complete phenotype in the literature before. Given that mutations responsible for genetic disorders in Puerto Rican (Hispanic) population is so limited we believe is of both clinical and molecular importance to recognize pathological molecular changes to provide the appropriate genetic counseling.

Identification and functional characterization of a novel mutation in casein kinase I causing Familial Advanced Sleep Phase Syndrome. *Q.S. Padiath[1], Y. Xu[1], R.E. Shapiro[2], C.R. Jones[3], S.C. Wu[1], N. Saigoh[1], K. Saigoh[1], A. Shenoy[1], L.J. Ptacek[1,4], Y.H. Fu[1].* 1) Dept. of Neurology, UCSF, San Francisco, CA; 2) Dept. of Neurology, College of Medicine, University of Vermont, Burlington, VA; 3) Dept. of Neurology, University of Utah, Salt Lake City, UT; 4) HowardHughes Medical Institute, UCSF, San Francisco, CA.

Familial advanced sleep phase syndrome (FASPS) is a human behavioural phenotype characterized by early sleep times and early-morning awakening. It was the first human, mendelian circadian rhythm variant to be well-characterized, and was shown to result from a mutation in a phosphorylation site within the (CKI)-binding domain of the human PER2 gene. The identification of more FASPS families that did not carry the hPer2 mutation suggested the involvement of other genes producing this phenotype. We therefore set out to identify other mutations in human subjects leading to FASPS. We report here the identification of a missense mutation (T44A) in the human CKI gene, which results in FASPS. The mutation was not present in 250 normal controls and individuals with the mutation showed significantly earlier sleep and early-morning awakening times. This mutant kinase has decreased enzymatic activity in vitro. Transgenic *Drosophila* carrying the human CKI-T44A gene showed a phenotype with lengthened circadian period. In contrast, transgenic mice carrying the same mutation have a shorter circadian period. As some individuals with the mutation also presented with a history of depression behavioral analysis of the transgenic mice was also carried out.These results show that CKI is a central component in the mammalian clock, and suggest that mammalian and fly clocks might have different regulatory mechanisms despite the highly conserved nature of their individual components.

Mutations of Connexin 43 (Cx43) Reveal a Range of Clinical Phenotypes and Functional Channel Effects. *W. Paznekas[1], H. Musa[2], A. Lai[3], J. Shibayama[2], D-N. Le[3], M. Delmar[2], A. Charles[3], E.W. Jabs[1].* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Depts Pharmacology & Microbiology/Immunology, SUNY, Syracuse, NY; 3) Dept Neurology, UCLA, Los Angeles, CA.

Cx43 mutations are found in patients with oculodentodigital dysplasia (ODDD), an autosomal dominant disorder characterized by craniofacial and limb anomalies and also affecting central nervous system, eye, skin, heart and hearing. Connexins form a hexameric cell membrane complex known as a connexon or hemichannel. Coupling of connexons from adjacent cells forms a gap junction (GJ), an intercellular channel of low resistance between cytoplasmic compartments. Known Cx43 mutations total 37 (5 recurrent), occur in most regions of the protein, and result in phenotype ranging from syndactyly type III alone to an autosomal recessive case with features of both ODDD and Hallermann-Streiff syndromes. For channel studies we selected ODDD mutations Y17S, G21R, A40V, F52dup, L90V, I130T, K134E, & R202H for their associated phenotypic features and affected protein domain. Transfection studies of mutant Cx43 in GJ communication deficient HeLa showed reduced GJ plaque formation for all mutants compared to Cx43WT, with F52dup & R202H failing to form plaques. In transfected mouse N2A neuroblastoma electrical conductance of mutant homotypic channels relative to WT is reduced or lacking. Heterologous channels were formed by co-expression of Cx43WT with mutants F52dup or R202H, which were unable to form homotypic GJ plaques. Junctional conductance of cells co-expressing mutant to WT (1:1) showed a dominant negative effect for L90V but with F52dup or R202H conductance was not altered until higher ratio of mutant to WT. Mutants Y17S, L90V, I130T associated with neurological dysfunction and G21R, A40V, F52dup without neurological findings were tested in rat C6 glioma (low expressers of Cx43). All mutants could be detected on the C6 cell surface though GJ clusters for F52dup were fewer. Hemichannel function (indicated by propidium iodide uptake) and GJ dye transfer (by scrape-loading assay) were examined for mutants compared to WT. Thus, both hemichannel and gap junction function were impaired for all ODDD mutants tested.

Custom array comparative genomic hybridization applications in Pelizaeus-Merzbacher Disease. *J.A. Lee[1], K. Inoue[2], J.R. Lupski[1,3,4].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, Texas; 2) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan; 3) Department of Pediatrics, Baylor College of Medicine, Houston, Texas; 4) Texas Childrens Hospital, Houston, Texas.

Pelizaeus-Merzbacher Disease (PMD) is a rare X-linked genomic disorder characterized by dysmyelination in the central nervous system. A majority of cases are caused by dosage alterations of the proteolipid protein 1 gene *PLP1* on chromosome Xq22, including *PLP1* duplication in 60-70% of cases, and also rare cases of *PLP1* gene deletion. The remaining 10-20% of PMD cases are associated with point mutations. We developed a custom array comparative genomic hybridization (aCGH) assay, including 68 overlapping large-insert bacterial and P1 artificial chromosome clones tiling an approximate 10 Megabase region including and surrounding the *PLP1* gene. Therefore, our custom assay will detect dosage alterations within the region tested, a region which encompasses the causative genomic rearrangement in nearly all PMD duplication and deletion cases examined. Importantly, our aCGH assay can be applied to perform rearrangement breakpoint analysis, to determine the actual sizes of the duplications and deletions, and also for prenatal diagnosis of PMD caused by *PLP1* dosage alteration.

Complex rearrangements in Pelizaeus-Merzbacher disease. *G.M. Hobson[1,2], K. McLean[1], K. Sperle[1].* 1) Nemours Biomedical Research, A I duPont Hosp Children, Wilmington, DE; 2) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

Duplication of a genomic region that includes the proteolipid protein gene (*PLP1*) is the most common mutation causing Pelizaeus-Merzbacher disease (PMD), a dysmyelinating disorder of the central nervous system. Although families have been reported in which the additional *PLP1* genomic region has integrated into a location that is distant from the normal *PLP1* locus at Xq22, most duplications arise by intrachromosomal recombination and have a tandem head-to-tail orientation. Our studies using quantitative multiplex PCR map the extent of duplication in PMD patients with respect to the reference genomic sequence available at www.ensembl.org. In 4 of 36 patients examined, we have found a second duplicated genomic region in addition to the PLP1-containing duplication. In 2 of these patients, duplicated regions of at least 37 and 436 kb map proximal of the *PLP1*-containing duplications. The proximal end of one of these duplicated regions and the distal end of the other map within the same 26 kb interval. In the other two patients, duplicated regions of at least 15 and 20 kb map distal of the *PLP1*-containing duplications in the low copy repeat (LCR) region. Our data support the notion that genomic structure in the area of the *PLP1* gene can lead to complex rearrangements.

Gr/gr deletions within the AZFc region of the human Y chromosome may not be associated with spermatogenic failure. *S. Chantot-Bastaraud[1, 2], C. Ravel[1, 2], B. El Houate[2], G. Vinci[2], J. Mandelbaum[1], J.P. Siffroi[1], K. McElreavey[2].*
1) Service dHistologie-Biologie de la Reproduction-Cytogénétique, Hôpital Tenon APHP UMPC EA1533, PARIS, France; 2) Reproduction, Fertility and Populations, Institut Pasteur, Paris, France.

Three regions of the long arm of the Y chromosome, termed AZFa, AZFb and AZFc (AZF: azoospermia factor) are associated with spermatogenic failure. AZFc is the most commonly deleted interval in men with azoospermia or severe oligozoospermia (<1x106/ml)and it is in a region of the Y chromosome that is made up almost entirely of long direct and inverted repeats. Recently a 1,6 Mb deletion termed gr/gr was identified in infertile men with no other known cause of male infertility. This deletion removes the proximal portion of AZFc. The gr/gr deletion is therefore considered a significant risk factor for reduced sperm counts leading to male infertility. Here, we performed a case/control study to determine if the gr/gr deletion is associated with reduced sperm counts in a population consisting of men attending an infertility clinical with idiopathic infertility. In the infertile population we found that 4/192 individuals carried a gr/gr deletion. In the control population we found that 6/181 men carried a gr/gr deletion. For each gr/gr deleted chromosome, the Y haplotype was determined using binary markers. The results indicated that gr/gr deletion has arisen independently on several Y chromosome lineages. A trend is indicated by the distribution of the Y haplogroups between the control group and individuals with spermatogenic failure. All normospermic individuals belong to either the Y chromosome lineage E3b2 or P(xR1a), whereas the patients with spermatogenic failure fall within other Y chromosome lineages. This suggests that some Y chromosome lineages may protect against the effects of the gr/gr deletion, or that the type of gr/gr deletion may differ between lineages and have variable effects on spermatogenesis. We recommend that screening for gr/gr deletions in a clinical setting should be used with caution until larger studies are conducted on men from different ethnic groups and geographical regions.

Copy number alterations of TEKT3 in Charcot-Marie-Tooth disease. *F. Baas[1], M.A.J. Weterman[1], F. van Ruissen[1], M. de Wissel[1], L. Bordewijk[1], J.P.A. Samijn[2], J. Hoogendijk[3], F. Meggouh[1].* 1) Neurogenetics Lab, Academic Medical Center, Amsterdam, Netherlands; 2) Medisch Centrum Rijnmond Zuid 3075 EA Rotterdam, Netherlands; 3) Dept of Neurology, Rudolf Magnus Institute of Neuroscience, UMCU, Utrecht, Netherlands.

Charcot-Marie-Tooth disease is a genetically heterogeneous disorder. To date, more then 20 genes have been implicated in the disease process, and many other CMT loci have not yet been linked to a disease gene. Nerve conduction velocities are used to distinguish between diseases with demyelinating or axonal features. In demyelinating CMT the primary defect is in the formation or maintenance of a normal myelin sheet around the axon. The most frequent form of demyelinating CMT (CMT1a) is linked to chromosome 17 (17p11.2). Duplications and mutations of the PMP22 gene are found in the majority of CMT1a patients. Here we describe several apparently unrelated individuals with CMT1 who carry a copy number polymorphism (CNP) centromeric of PMP22. These CNPs do not include PMP22 itself. We propose that the CNP is responsible for a rare form of CMT1a, since this CNP is thus far only found in CMT patients in whom alterations of PMP22 were excluded. Most diagnostic tests for CMT1a will not detect this CNP.

Duchenne muscular dystrophy in a phenotypic female with androgen insensitivity: A case report. *J. Sullivan, C. Nichter, T. Marini, H. Allen, S. Pflueger.* Baystate Medical Center and Children's Hospital and Tufts University School of Medicine, Springfield, MA.

We report an unusual case of Duchenne muscular dystrophy (DMD) in a phenotypic female. At delivery the infant presented with clitoromegaly and failure to thrive. Female gender was assigned. Subsequent cytogenetic evaluation revealed a 46,XY karyotype. Endocrinology evaluation was consistent with a diagnosis of partial androgen insensitivity (PAIS). At age 5 the child was referred to neurology for proximal muscle weakness. Reported maternal family history raised the question of a male relative with some form of muscular dystrophy. Molecular testing revealed a deletion of exons 50-52 of the dystrophin gene, consistent with a clinical diagnosis of Duchenne muscular dystrophy. Molecular testing for AIS identified a hemizygous G623A missense mutation in exon 3. Although this mutation has not been previously reported, this is the likely explanation for the female phenotype in a karyotypic male. The male karyotype explains the expression of the X-linked disorder in this female child. Patients with Turner syndrome (monosomy X) may present with unexpected X-linked traits, however in the absence of stigmata of Turner syndrome the possibility of androgen insensitivity should be considered in the differential diagnosis of an X-linked condition in a phenotypic female.

Early transposable element intron insertion results in aberrant transcription of the *Hsf4* gene and cataracts in *lop11* mice. *D. Sidjanin[1], E. Talamas[1], L. Jackson[1], M. Koeberl[1], M. Jablonski[2], B. Chang[3].* 1) Dept Ophthalmology, Medical Col Wisconsin, Milwaukee, WI; 2) Dept Ophthalmology, University of Tennessee Memphis, TN; 3) Jackson Laboratories, Ben Harbor, ME.

Lens opacity 11 (*lop11*) is an autosomal recessive mouse cataract mutation that arose spontaneously in RIIIS/J strain. At weaning, mice exhibit total cataracts with vacuoles. In order to map this locus, *lop11* mice were outcrossed to CAST/Ei and F1 mice were backcrossed to *lop11* to generate 195 backcross progeny. The progeny were evaluated at weaning with a slit lamp following mydriasis with atropine, euthanized and tissues were collected. Genomic DNA was isolated from collected spleens. Polymorphic microsatellite markers were selected to evenly cover the mouse genome. Linkage was detected between *lop11* locus and microsatellite markers on chromosome 8. No recombinants were detected with *D8Mit198*. Evaluation of a mouse map of the *lop11* critical region identified *Hsf4* as a candidate gene. In humans, mutations in *HSF4* lead to development of cataracts. Exon scanning of all 13 *Hsf4* exons did not reveal any sequence difference between *lop11* and wild type. Further analysis identified a 5.5 kb insertion of an early transposable element in intron 9 about 60 bp upstream from intron/exon junction. Northern blot from *lop11* eye tissues hybridized with an *Hsf4* probe from exons 10-13 did not identify any *Hsf4* transcripts in *lop11*. The same blots when hybridized with an *Hsf4* probe from exons 1-6 revealed at least 100 fold up-regulated *Hsf4* transcript in *lop11*. These results suggest that in *lop11* mice an early transposable element insertion in intron 9 alters splicing and expression of the *Hsf4* gene. The *lop11* mouse is an excellent animal model for cataractogenesis in patients with mutations in human *HSF4* gene.

A *VCAM1* Promoter Mutation That Affects Transcription Factor Binding is Observed with Increased Prevalence in Adults with Sickle Cell Anemia. *J.G. Taylor[1], R.A. Chen[2], C. Haudenschild[1], N. Ragavachari[1], T. Bernig[2], D. Garcia-Rossi[3,4], A. Hutchinson[3,4], C. Hoppe[5], M.T. Gladwin[1], S.J. Chanock[2,4].* 1) Vascular Therapeutics Section, NHLBI, NIH, Bethesda, MD; 2) Section on Genomic Variation, NCI, NIH, Gaithersburg, MD; 3) SAIC, NCI-FCRDC, Frederick, MD; 4) NCI Core Genotyping Facility, Gaithersburg, MD; 5) Children's Hospital, Oakland, CA.

Sickle cell anemia (SCA) is characterized by a wide phenotypic spectrum of complications that are hypothesized to be partly attributable to inter-individual variation in modifier genes. Common *VCAM1* promoter SNPs have been associated with susceptibility to SCA complications including strokes. To refine these associations, we identified variants in healthy controls and then used phylogenetic analysis to prioritize promoter haplotypes for further study. Using comparative genomic alignments, a singleton promoter haplotype defined by 2 SNPs within phylogenetically conserved regions including a site at -540 was selected for functional analysis. In vitro, this promoter haplotype has higher reporter gene transcription in response to cytokine stimulation relative to wild type (3.4 fold and 1.8 fold, respectively, P = 0.01). Real time PCR in a cell line with the -540 genotype correlates with the in vitro data. Putative transcription factor (TF) binding sites are present at both SNP sites, although electromobility shift assays only demonstrate allele specific binding of c/EBP TF family members at -540 based upon preliminary study. In humans, the -540 genotype is carried by 3.7% of 81 adults with homozygous SCA while it is present as a mutation in only 1 of 255 African American controls (0.4%; P = 0.045), suggesting that this variant could be associated with a functional role in SCA. Studies are underway in larger populations to confirm this observation, and to determine the incidence of this variant in newborns with SCA. Finally, this variant represents a true mutation as only 1 additional heterozygote was identified in a survey of 2234 chromosomes from worldwide populations. Taken together, these detailed studies suggest that analysis of both common and rare variants will be required to identify genetic modifiers of monogenic diseases like SCA.

Townes-Brocks syndrome: 25 novel mutations in sporadic and familial cases and update on the mutational spectrum. *E.M. Botzenhart, B. Roesler, J. Kohlhase, Institute for Human Genetics and Anthropology, University of Freiburg.* Institute for Human Genetics and Anthropology, Freiburg University, Freiburg, Germany.

Townes-Brocks syndrome (TBS; OMIM#104780) is a rare autosomal dominantly inherited malformation syndrome due to mutations in SALL1, a human gene related to the developmental regulator SAL of Drosophila melanogaster. The clinical presentation of TBS is highly variable. It is predominantly characterized by renal, anal, ear and limb anomalies. Different types of hearing loss, urogenital malformations cardiac malformations, and mental retardation may additionally occur. The SALL1 gene is coding for a zinc finger protein thought to act as a transcriptional repressor. It is composed of four highly conserved evenly distributed double zinc finger domains and a C2HC motif at the amino terminus. A single C2H2 motif is attached to the second double zinc finger domain. Initially SALL1 mutations have been postulated to cause TBS by haploinsufficiency. A null allele of mouse SALL1 however does not mimick the human syndrome. Another mouse model, mimicking a typical TBS causing mutation showed that TBS mutations lead to the formation of truncated proteins with dominant negative effect in mice thereby causing the disease. Further research into the molecular mechanisms of these mutations will however be necessary to demonstrate the functional consequences of SALL1 mutations in humans. To date 23 SALL1 mutations leading to TBS have been described. Nearly all of these with the exception of R276X occur only in single patients or families thereby preventing phenotype-genotype correlations. Here we present 25 novel mutations associated with TBS in 26 unrelated families increasing the number of SALL1 mutations to 48.

Novel Mutations of the NIPBL gene in Cornelia de Lange Syndrome. *M. ZARHRATE[1], L. COLLEAUX[1], A. david[2], A. MUNNICH[1], V. CORMIER DAIRE[1], J. BONNEFONT[1].* 1) INSERM U393 and Department of Genetics, Hospital Necker Enfants Malades, Paris, France; 2) Genetics unit Hopital Mere-Enfant, Nantes, France.

Cornelia de Lange syndrome (CdLS) is characterised by facial dysmorphism, microcephaly, growth and mental retardation, and congenital anomalies including limb defects. Mutations in the gene NIPBL, the human homolog of Drosophila Nipped-B, have recently been found in approximately 50% of CdLS cases. We present here the molecular analysis in a series of thirteen children with CdLS. All children presented with typical features of CdLS but none of them had major limb anomalies. Fifty-one primer pairs were designed to cover all 46 NIPBL coding exons and the corresponding exon-intron boundaries. Direct sequencing enabled to identify three heterozygous de novo NIPBL mutations including two missense [c.7189T>C (p.S2397P), c.6166C>T (p.P2056S) and one splice site (64+5G>A) mutations. These mutations were not found in 100 control chromosomes. Additionally, analysing segregation of 3 poly (AC) intragenic markers ruled out large deletions in the remaining patients. Thus, NIPBL mutations account for only 1/4 of CdLS cases in our series. The absence of NIPBL mutation in more than 50% of CdLS individuals in the few series reported so far may suggest either the limitation of the screening methodology or the genetic heterogeneity of the disorder.

Residual splicing of the major Shwachman-Diamond syndrome allele with a non-canonical splice donor-acceptor pair. *L.L. Chen[1,2], G.R.B. Boocock[1,2], J.M. Rommens[1,2].* 1) Department of Molecular & Medical Genetics, University of Toronto; 2) Program in Genetics & Genomic Biology, The Hospital for Sick Children, 555 University Ave, Toronto, ON CANADA M5G 1X8.

Shwachman-Diamond Syndrome (SDS) is an autosomal recessive disorder characterized by exocrine pancreatic insufficiency, skeletal abnormalities, bone marrow failure and predisposition to hematologic malignancies. SDS is caused by mutations in the SBDS gene, which is a member of a highly conserved protein family thought to be involved in RNA processing and/or ribosome biogenesis. One of the two common mutations found in SDS patients involves a donor splice site, 258+2TC, leading to a non-canonical GC-AG donor-acceptor pair for intron 2. The non-canonical donor-acceptor pair has been observed in less than 0.7% of all human exons. RT-PCR analysis of patient RNA indicated that the mutant allele uses an upstream cryptic donor splice site in exon 2 that leads to frameshift and a truncated SBDS protein. The second common mutation, 183-184TACT, also predicts a stop codon and truncated protein. The frequent occurrence of patients that are compound heterozygotes for the common mutations (102/257 families) and the absence of homozygotes with the 183-184TACT mutation (0/257 families), together with the essential nature of SBDS in mice, indicate that the 258+2TC allele is hypomorphic and should lead to residual SBDS activity. To examine the associated mechanism, an expression vector containing a complete and tagged SBDS gene has been constructed. Transfection of human cell lines indicated that very low levels of SBDS are expressed from the mutated allele. The level of residual protein varied by cell type and could be increased by removal of the upstream cryptic donor splice site in exon 2. Since the majority of unrelated SDS patients (174/257) possess at least one allele with this mutation, therapeutic benefit may be realized by determining which factors and cell conditions contribute to the use of the non-canonical splice donor-acceptor GC-AG pair.

Nonsense-mediated decay (NMD) might be involved in phenotypic heterogeneity of *ROR2* mutations. *J. Lupski[1, 2, 3], S. Ben-Shachar[1], M. Khajavi[1], U. Cheema[1], N. Zamani[1], H. van Bokhoven[4].* 1) Department of Molecular & Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Childrens Hospital, Houston, Texas; 4) Department of Human Genetics, Radboud University Nijmegen Medical Centre The Netherlands.

Mutations in *ROR2*, encoding a receptor tyrosine kinase, can cause the autosomal recessive form of Robinow syndrome (RRS, OMIM# 268310), a severe skeletal dysplasia with shortening of the limbs, segmental defects of the spine, brachydactyly, and a dysmorphic facial appearance. Various nonsense and frameshift mutations in ROR2 result in both RRS and a dominant form of Brachydactyly type B (BDB, OMIM #113000), but no functional mechanisms have been delineated to effectively explain the association between mutation and different mode of inheritance causing different phenotypes (i.e. genotype/phenotype correlations). Interestingly, most mutations in ROR2 that results in premature termination codons (PTCs) in downstream exons appear to result in BDB segregating as an autosomal dominant trait whereas PTCs in upstream exons result in RRS. Previous studies have revealed decreased *ROR2* mRNA levels in fibroblast cell lines of patients with PTCs causing the autosomal recessive RRS. Considering the location of truncation in the gene, here we are investigating whether mutations that could possibly trigger the nonsense mediated decay (NMD) pathway and therefore decrease mRNA levels can cause a different phenotype with a distinct mode of inheritance. Although in theory all nonsense and frameshift mutations resulting in PTC are natural targets of NMD RNA surveillance system, it is not certain if NMD is the only pathway actually responsible for modulating disease severity by altered mRNA stability. To address this hypothesis, we have selected cell lines from patients carrying PTC mutations and are studying the potential role for NMD in the abrogation of aberrant effects of selected mutant alleles.

Nephrogenic Diabetes Insipidus in Mice Caused by Deleting C-terminal Tail of Aqp2. *B. Yang, P. Shi, E. Sweezer, S. Guo, T. Kinney, A. Assad, K. Huffman, X. Cao.* Dept OB/GYN, Univ Iowa, Iowa City, IA.

In mammals, the tight hormonal regulation of water homeostasis is mediated by the aquaporin-2 water channel (AQP2) of the collecting duct (CD). Vasopressin induces redistribution of AQP2 from intracellular vesicles to the apical membrane of CD principal cells, accompanied by increased water permeability. Mutations of *AQP2* gene cause recessive and dominant nephrogenic diabetes insipidus (NDI), a disease in which the kidney is unable to concentrate urine in response to vasopressin. In mouse complete inactivation of this gene resulted in neonatal lethality due to fluid loss. In this study, we generated a line of mice with the distal C-terminal tail of the Aqp2 deleted ($Aqp2^{231}$), including the protein kinase A phosphorylation site (Ser-256), while still retaining the putative apical targeting signal (221-230) at the C-terminus. Mice heterozygous for the truncation appear normal. Homozygotes are viable to adulthood, with reduced urine concentrating ability: increased urine output (5-10 times more than control mice) and decreased urine osmolality (193 17 in $Aqp2^{231/231}$ vs 1,173 130 mOsm/kg in control mice), and increased daily water consumption. While desmopressin can increase urine osmolality in wild type mice, it has no effect on $Aqp2^{231/231}$ mice, confirming that Aqp2 is regulated by hormone-activated protein kinase A phosphorylation of Ser-256 in the C-terminal cytoplasmic domain of the protein. Kidneys from affected mice showed CD and pelvis dilatation and papillary atrophy due to polyuria. Immunohistolological analyses using antibody against the C-terminal region of the protein could not detect any channels in the affected kidney, while antibody against the N-terminal region of the protein showed CD-specific staining, confirming the deletion of the C-terminal tail of Aqp2. CD-specific staining was obtained in wild type kidney using both antibodies. Thus we have generated a mouse model of NDI and it should be useful in studying the physiology and potential therapy of this disease.

Association of dystrophin Dp71 with the nuclear matrix of PC12 cells. *R. Rodriguez-Munoz[1], M. Villarreal-Silva[1], F. Garcia-Sierra[2], B. Cisneros[1].* 1) Dept Genetics & Molec Biol,; 2) Dept Cell Biol, CINVESTAV-IPN, Mexico.

Duchenne muscular dystrophy (DMD) is an X-linked recessive disorder caused by mutations in the dystrophin gene. Dystrophin Dp71 is the major product of this gene in the brain, but its function is poorly understood. Interestingly, C-terminal mutations of the DMD gene that would adversely affect the expression of Dp71 are associated with mental retardation. To study the function of Dp71 in neuronal cells, we previously adopted the PC12 neuronal cell line as a model. Recently, our group determined that alternative splicing regulates the cytoplasmic or nuclear localization of Dp71. We believe that the nuclear localization of Dp71 is a new and interesting clue for understanding its cellular function. It is thought that the nuclear matrix constitutes the nucleoskeleton structure that supports and modulates the main nuclear functions, such as DNA replication, transcription, and RNA splicing. Therefore, in this study we analyzed the possible association of Dp71 with the nuclear matrix of PC12 cells. By Western blot analysis of nuclear matrix preparations, we determined that Dp71 is a component of the PC12 nuclear matrix. By immunofluorescence analysis of in situ nuclear matrix preparation we observed that Dp71 localizes in the periphery and inner part of the nuclear matrix of undifferentiated PC12 cells. Interestingly, in the NGF-induced differentiated PC12 cells, the immunostaining of Dp71 accumulates mainly in the nuclear matrix periphery; additionally, we noted a labeling in a nucleoli-like structure. To analyze the nature of the association of Dp71 with the nuclear matrix, we withdrawn the internal nuclear matrix components with RNase A (300 g/ml) treatment followed by 650 mM (NH4)2SO4 and 20 mM DTT; such treatment resulted in a dramatic Dp71 immunostaining decrease in the internal nuclear matrix, but the Dp71 located in the nuclear matrix periphery remained unaltered. These results constitute the first evidence implicating Dp71 in the organization of the nuclear matrix.

Functional analysis of PTPN11/SHP-2 mutants identified in Noonan syndrome and childhood leukemia. *T. Niihori[1], Y. Aoki[1], H. Ohashi[2], K. Kurosawa[3], T. Kondoh[4], Y. Narum[1], Y. Suzuki[1], S. Kure[1], K. Fujii[5], M. Imaizumi[6], Y. Matsubara[1].* 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Miyagi, Japan; 2) Division of Medical Genetics, Saitama Children's Medical Center, Saitama, Japan; 3) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Department of Pediatrics, Nagasaki University of Medicine, Nagasaki, Japan; 5) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan; 6) Department of Hematology and Oncology, Miyagi Children's Hospital, Sendai, Japan.

Noonan syndrome (NS) is characterized by short stature, characteristic facial appearance, and'@heart defects. Recently, missense mutations of tyrosine phosphatase SHP-2 were identified in patients with NS and childhood leukemia. It remains unknown whether functional differences existed between the mutations identified in NS and leukemia.'@In this study, we identified ten mutations including a novel F71I mutation in 17 of 41 NS patients, and two mutations in 3 of 29 patients with leukemia. Immune complex phosphatase assays of individual mutants transfected in COS7 cells showed that ten mutants identified in NS and four mutants in leukemia showed 1.4-fold to 12.7-fold increased activation compared with wild-type SHP-2. These results suggest that the pathogenesis of NS and leukemia is associated with enhanced phosphatase activity of mutant SHP-2. A comparison of the phosphatase activity in each mutant and a review of previously reported cases showed that high phosphatase activity observed in mutations at codons 61, 71, 72, and 76 was significantly associated with leukemogenesis. Furthermore, we directly examined the phosphatase activity of SHP-2 in the lymphoblastoid cell lines from NS patients. This assay would provide an alternative method for diagnosing NS.

A TNNI2 mutation in a family with Distal Arthrogryposis type 2B. *J. Hoo[1], A. Shrimpton[1, 2].* 1) Dept Pediatrics, SUNY Upstate Med Univ, Syracuse, NY; 2) Dept Pathology, SUNY Upstate Med Univ, Syracuse, NY.

Linkage mapping in a three-generation family with a distal arthrogryposis (DA) phenotype intermediate between DA1 and DA2A indicated linkage to 11p15.5 (sites of TNNI2 and TNNT3 genes) but not 9p13 (site of TPM2 gene). Follow up DNA sequencing of the TNNI2 gene (troponin subunit I [inhibitory] of fast-twitching skeletal muscle isoform) detected a three base pair deletion that would be predicted to result in the deletion of a glutamic acid at codon position 167 (delE167). This mutation, like the two previously described TNNI2 mutations, is located in the carboxy-terminal domain and thus supports the existence of a TNNI2 critical region sensitive to alteration that will give rise to distal arthrogryposis. Physical examination of family members confirms the high degree of variability in expression amongst mutation carriers.

Mutations of the CYP21 gene among Filipino patients with Congenital Adrenal Hyperplasia. *E. Cutiongco[1], K. Goji[2], M. Matsuo[3].* 1) Inst Human Genetics, National Inst Health Philipine, Metro Manila, Philippines; 2) Department of Endocrinology and Metabolism, Kobe Children's Hospital, Japan; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Japan.

Congenital Adrenal Hyperplasia (CAH), an autosomal recessive disorder, is due to defective enzymes involved in adrenal steroidogenesis. Phenotypic manifestations are variable depending on the effects produced by the deficient hormones and by the excess production of steroids unaffected by the enzymatic block. The worldwide incidence of CAH is 1 in 15,000 with ethnic and racial variability. The incidence in France, Italy, Scotland, New Zealand and Japan ranges from 1 in 10,000 to 1 in 23,000. Among Filipinos, the crude incidence of CAH is 1 in 6,023 (Philippine Newborn Screening), which is higher than what is reported in most populations. More than 90 percent of cases result from a 21-hydroxylase (cytochrome p450c21) deficiency involving two 21-hydroxylase genes CYP21, the active gene, and CYP21P, a pseudogene. Studies have shown that mutations result from unequal crossover during meiosis, which leads to complete deletion of the gene, gene conversion events or to point mutations. Majority of these studies have demonstrated differences in the frequency of several gene mutations. Direct DNA sequencing of the CYP21 gene was performed among Filipino CAH patients and their families. In this study, the majority of cases, 11/13 or 85 percent; had a detectable mutation in the CYP21 gene. The mutation most frequently found in these families was the nucleotide 656 intron 2, a premature splicing error. However, in 2/13 or 15 percent; of the cases, a mutation could not be found. The determination of the most frequent alleles in our population will facilitate rapid screening for detection of mutations in the 21-hydroxylase gene. Establishment of a definitive diagnosis can also be made available which are important in the management and counseling of Filipino CAH cases.

Unregulated insulin secretion by pancreatic beta-cells in hyperinsulinism/hyperammonemia syndrome: Role of glutamate dehydrogenase, ATP-sensitive potassium channel, and nonselective cation channel. *Y. Okano[1], M. Kawajiri[1], M. Kuno[2], D. Tokuhara[1], Y. Hase[3], H. Inada[1], F. Tashiro[4], J. Miyazaki[4], T. Yamano[1].* 1) Dept Pediatrics, Osaka City Univ Grad Sch of Med, Osaka, Japan; 2) Dept Physiology, Osaka City Univ Grad Sch of Med, Osaka, Japan; 3) Osaka City Environment and Public Health Center, Osaka, Japan,; 4) Div Stem Cell Regulation Res, Osaka Univ Grad Sch of Med, Osaka,Japan.

The hyperinsulinism/hyperammonemia syndrome is caused by 'ggain of function'h of glutamate dehydrogenase (GDH). Several missence mutations have been found; however, cell behaviors triggered by the excessive GDH activity have not been fully demonstrated. This study was aimed to clarify electrophysiological mechanisms underlying the dysregulated insulin secretion in pancreatic beta-cells with GDH mutations. GDH kinetics and insulin secretion were measured in MIN6 cells overexpressing the mutant GDH constructs, site-1 (G446D) and site-3 (L413V) mutations. Membrane potentials and channel activities were recorded under the perforated-patch configuration that preserved intracellular environments during recordings. In mutant MIN6 cells, sensitivity of GDH to GTP was reduced and insulin secretion at low glucose concentrations was enhanced. The basal GDH activity was greatly elevated in L413V bearing a mutation in the antenna-like structure (site-3). The L413V cells were depolarized greatly without glucose, often accompanying by repetitive Ca^{2+} firings. Intracellular dialysis with the ATP-free solution hyperpolarized cells. The KATP channel activity was suppressed and the nonselective cation channel (NSCC) activity was potentiated, while sensitivity of the channels to their specific blockers or agonists was not impaired. The site-3 GDH mutation increased the intracellular ATP/ADP ratio, which in turn caused sustained depolarization not only by closure of the K_{ATP} channel, but also by opening of the NSCC. The resultant activation of the voltage-gated Ca^{2+} channel appears to induce hyperinsulinism. The present study provides evidence that multiple channels co-operate in unregulated insulin secretion in pancreatic beta-cells of the hyperinsulinism/hyperammonemia syndrome.

Homodimerization of DAX1: Complexity in Molecular Pathogenesis of Adrenal Hypoplasia Congenita. *A.K. Iyer[1], E.R.B. McCabe[1,2].* 1) Human Genetics and; 2) Pediatrics, UCLA David Geffen Sch of Med, LA, CA 90095-1752.

Adrenal Hypoplasia Congenita (AHC) is caused by mutations in *NR0B1* encoding the nuclear receptor DAX1. AHC is also caused by mutations in *NR5A1* that encodes SF1. DAX1 functions as an SF1 antagonist, and it is a conundrum how mutations in SF1, or its repressor DAX1, lead to similar phenotypes, and suggests additional complexity in AHC pathogenesis. Nuclear receptors function as monomers, homodimers or heterodimers. Our purpose was to determine if DAX1 forms a homodimer. A DAX1 homodimer was detected using the yeast two-hybrid (Y2H) system, *in vitro* co-immunoprecipitation (Co-IP), and Co-IP in mammalian cells. In Y2H, cotransformation of GAL4DB-DAX1 (GAL4 DNA-binding domain fused to DAX1) and GAL4AD-DAX1 (GAL4 Activation Domain fused to DAX1), resulted in activation of the HIS3 and -galactosidase reporter genes, providing evidence of an interaction; each construct alone did not activate the reporter. Homodimerization was confirmed *in vitro* using Co-IP with *in vitro* translated epitope tagged proteins. Using a myc antibody, HA-DAX1 was co-immunoprecipitated in the presence but not the absence of myc-DAX1. The presence of the DAX1 homodimer was further confirmed in HEK293 and HeLa cells through Co-IP using FLAG- and myc-tagged DAX1. Using a FLAG antibody, myc-DAX1 was co-immunoprecipitated in the presence but not in the absence of FLAG-DAX1. DAX1 localized to the nuclear and cytoplasmic compartments in HEK293 and HeLa cells, and Co-IP experiments with nuclear and cytoplasmic fractions showed that myc-DAX1 co-immunoprecipitated with FLAG-DAX1 in both compartments. A Co-IP based protein interaction competition assay demonstrated a decrease in DAX1 homodimer formation in the presence of increasing amounts of SF1, suggesting that the DAX1 homodimer dissociated to form heterodimers with SF1. We conclude that DAX1 homodimers exist in mammalian cells in the cytoplasmic and nuclear compartments. We speculate that the homodimer functions as a holding pool for DAX1 when not complexed with SF1. DAX1 homodimerization suggests the possibility of a novel function independent of its coregulator role, and additional complexity in the pathogenesis of AHC.

Analysis of the *SLC6A19* D173N allele in Hartnup Disease. *D.N. Azmanov[1], H.J. Rodgers[1], C. Bailey[2], S. Bröer[3], J.E.R Rasko[2], J.A. Cavanaugh[1].* 1) Medical Genetics Research Unit, ANU, Canberra, Australia; 2) Centenary Institute of Cancer Medicine & Cell Biology, University of Sydney, Australia; 3) School of Biochemistry & Molecular Biology, ANU, Canberra, Australia.

We recently identified mutations in *SLC6A19* as the cause of the underlying defect in neutral amino acid transport in Hartnup Disease (1). The D173N mutation displays reduced function *in vitro* and is the most frequent disease associated mutation. We have determined the haplotype surrounding this mutation which has a common origin in all individuals studied to date and estimated the age of this mutation in the Australian population of Caucasian descent. A combination of two microsatellites and seven SNPs covering 200kb were genotyped in a total of 41 individuals. Of these, 23 unrelated individuals carry the D173N mutation, four of whom are unaffected heterozygotes from the normal population. Eight unrelated individuals from the remaining 19 D173N positive individuals were from 7 affected families in which the D173N allele is segregating. Thus 44 D173N negative chromosomes were also genotyped.

We used three different methods to achieve estimates of the age of the D173N allele as follows: 36-81 generations using Bayesian linkage disequilibrium estimation (2); 41 generations (variance 23-205) intra-allelic variability estimation (3); 50.6 generations (variance 29.6-176) inter-haplotype variation (4).

We observed unusually long-range extended haplotype homozygosity in the D173N chromosomes in comparison to normal chromosomes ($p<0.0001$). We estimate the age of this allele to be 1000 - 1500 years, placing its likely origin in Europe and postulate that the survival of the allele may be a consequence of its incomplete functional inactivation and/or positive natural selection.

Gene-dosage influences the age at onset of SCA2. *P. Spadafora[1], N. Cutuli[2], P. Tarantino[1], S. Carrideo[1], I.C. Candiano[1], E.V. De Marco[1], D. Civitelli[1], F.E. Rocca[1], F. Annesi[1], V. Giuffrida[2], G. Annesi[1].* 1) Inst. of Neurological Sciences, National Research Council, Mangone, (CS), Italy; 2) Institute of Neurology, University of Catania, Italy.

Spinocerebellar ataxia type2 is the most frequent cause of autosomal dominant cerebellar ataxia type1 in Southern Italy. Clinically SCA2 is characterized by gait and limb ataxia, dysarthria, slow saccadic eye movements, supranuclear opthalmoplegia, peripheral neuropathy and parkinsonism. Expansion of an unstable CAG repeat in the exon1 of the SCA2 gene, located on chromosome 12q23-24.1, is responsible for this disease. Normal alleles showed a CAG repeat number ranged from 14 to 31 repeats frequently interrupted by one or more CAA trinucleotides, whereas the pathological expanded alleles contain a pure uninterrupted stretch of 33 to 200 repeats or more as reported in neonatal cases. We analyzed a SCA2 Italian family originates from an isolated village of middle-eastern Sicily. Following informed consent, genomic DNA was extracted from peripheral blood leukocyte samplings. SCA2 genotyping was performed by capillary electrophoresis on an ABI 310 Apparatus. Molecular analysis of SCA2 gene in our family revealed a patient carrying two expanded alleles with 35 and 36 uninterrupted CAG repeats. His brother and his nephew were heterozygotes for expanded allele with 35 and 42 CAG repeats respectively. We reported a patient homozygous for SCA2 disease mutation. This patient showed an earlier age at onset and a more severe clinical phenotype than his heterozygous brother who developed SCA2 thirty years later. The age at onset, the progression rate and severity of the SCA2 disease in the homozygous subject were similar to those observed in his heterozygous nephew carrying 42 repeats. These findings suggest a gene-dosage effect of SCA2 mutations on the age at onset of the disease. Similar results have been shown by other authors in the SCA6, SCA3 and DRPLA genes. Accumulation of homozygous SCA2 patients will help to explain the molecular mechanism of gene dosage on the age at onset of SCA2 disease.

Unexplained CAG/CTG expansions in Portuguese and American patients with movement disorders. *A.I. Seixas[1,2], S.E. Holmes[1], P. Coutinho[3], A.E. Hillis[4], C.A. Ross[1,4], J. Sequeiros[2], I. Silveira[2], R.L. Margolis[1,4].* 1) Div of Neurobiology, Dept of Psychiatry, Johns Hopkins Univ School of Medicine, Baltimore, MD; 2) UnIGENe, IBMC, Univ of Porto, Portugal; 3) Serviço de Neurologia, Hospital São Sebastião, Feira, Portugal; 4) Dept of Neurology, Johns Hopkins Univ School of Medicine, Baltimore, MD.

Though great progress has been made in identifying the underlying genetic causes of hereditary movement disorders, the etiology remains unknown for as many as 30% of cases of dominant late-onset spinocerebellar ataxias, most cases of sporadic ataxia, and a smaller but not insignificant number of cases with Huntingtons disease-like syndromes. Twelve neurological disorders are caused by expansions of CAG/CTG repeats, and we hypothesize that additional CAG/CTG repeat expansion disorders exist, though these are likely to be rare. We used the RED (repeat expansion detection) assay to identify new pathogenic CAG/CTG repeat expansions in American and Portuguese patients with movement disorders of unknown cause. After RED analysis, DNA samples from individuals with CAG/CTG repeat length of > 40 triplets were tested for the presence of one of the known nonpathogenic repeat expansions. Among 67 patients from 43 Portuguese families with autosomal dominant ataxia and 95 patients with sporadic ataxia, we detected expansions in RED in 63 cases, all accounted for by nonpathogenic expansions at the *ERDA1* or *SEF2-1 loci*. In 138 patients from the US, at least two individuals have CAG/CTG expansions that cannot be explained by any known expansion. One patient presented with tremor, hyperreflexia, severe apraxia, a somewhat stiff gait, and cognitive impairment with prominent parietal deficits. The second patient has familial dementia, treatment resistant depression, and possible choreiform movements. These results suggest that additional CAG/CTG repeat expansion disorders remain to be described.

Modifier genes are responsible for meconium ileus in cystic fibrosis but a major modifier gene is not located on chromosome 19q13. *R.S. Deering[1], S.M. Blackman[1], K. Naughton[1], R. McWilliams[1,2], B. Coleman[1], T. Lai[1], M. Algire[1], S. Beck[3], J. Hoover-Fong[1], A. Hamosh[1], M.D. Fallin[1], G.R. Cutting[1].* 1) Johns Hopkins University, Baltimore, MD; 2) Rutgers University and the UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 3) St. Christopher's Hospital for Children, Philadelphia, PA.

Meconium ileus (MI) is a potentially fatal intestinal obstruction that afflicts about 15% of newborns with cystic fibrosis (CF). Familial clustering suggests that shared genetic and/or shared environmental factors underlie MI. A role for genetic modifiers has been supported by linkage of MI to a region on chromosome 19 called CF Modifier gene 1 (CFM1). Using clinical data and DNA collected by the CF Twin and Sibling Study, we analyzed 62 monozygous (MZ) twin pairs, 20 dizygous (DZ) twin pairs, one set of DZ triplets and 250 sets of siblings to determine the role of genetic and other factors in MI and in distal intestinal obstruction syndrome (DIOS), a condition clinically similar to MI that occurs in older CF patients. Concordance for the presence of MI was highest in MZ twins (14 of 15 pairs, 93.3%) while concordance was significantly lower in DZ twins (2 of 9, 22%) and siblings (16 of 69 with 2 affected, 23% and 2 of 10 with 3 affected, 20%). Concordance rates for DIOS did not differ among MZ twins, DZ twins or siblings. However, DIOS was found to occur at significantly higher rates and was diagnosed significantly earlier in patients with MI treated by surgery than in patients with MI treated medically or those who did not have MI. One hundred and eighty-six families were typed with 7 DNA markers within the CFM1 region previously linked to MI. Nonparametric linkage analysis, multipoint parametric linkage analyses, single marker and haplotype transmission analyses did not support the existence of a major modifier gene on chromosome 19. Thus, intestinal obstruction in CF patients in the postnatal period is primarily due to non-genetic factors while intestinal obstruction in the neonatal period is due to genetic factors not located within CFM1 on chromosome 19.

The hereditary spastic paraplegias (HSPs) are a clinically and genetically heterogeneous group of neurodegenerative diseases characterized by progressive spasticity in the lower limbs variably associated with neurological and extra-neurological signs. Approximately 30 different loci (SPG) have been mapped so far and 11 genes have been identified. While ~50% of dominant cases are explained by the known loci, less is known about autosomal recessive HSP (ARHSP) since the mapped loci have been identified in few families and account for only few percent of patients. We selected 10 ARHSP families (50 individuals, 20 of which where affected) without mutations in the SPG7 gene (Paraplegin). One large family of Algerian ancestry living in Eastern-France (7 unaffected and 4 affected members), was included in a genome-wide scan. Evidence of linkage was obtained at 2 consecutive markers on chromosome 2 with a multipoint lod score of 3.1. Six other possible locations (lod scores >1) were excluded using additional markers. Analysis of 9 additional microsatellite markers on chromosome 2 generated significant pairwise lod scores >3 with a multipoint lod score of 3.8 obtained in a 5 cM interval where all markers were homozygous in patients. Linkage to this new locus (SPG30) was excluded in 9 other ARHSP families. The phenotype of the SPG30 family consists in spastic paraparesis that started between 12 and 21 and was associated with distal wasting and saccadic ocular pursuit. In one case, electrophysiological examination showed the presence of a peripheral neuropathy. Cerebellar signs when present were very mild and limited to saccadic pursuit in 2 patients and difficult tandem standing in one.

Sebastiao, Santa Maria da Feira and UnIGENe, University of Porto, Portugal; 5) Genethon, 91000 Evry, France; 6) MRC Centre for Developmental Neurobiology, Kings College London, Guys Hospital, London, UK.

Hereditary spastic paraplegias (HSP) constitute a clinically and genetically heterogeneous group of disorders characterized by progressive spasticity in the lower limbs, due to the dysfunction and/or degeneration of the upper motor neurons. Molecular studies have confirmed and extended genetic heterogeneity and ~30 loci have been mapped to date. The pure forms of autosomal recessive HSP (ARHSP), in which pyramidal signs (brisk reflexes, Babinski sign, spasticity, motor deficit, +/- sphincter disturbances) are often associated with deep sensory loss without any additional symptoms, are less frequent than complicated ones and account only for 4 ARHSP loci: SPG5, 24, 27 and 28. We have identified a Portuguese consanguineous family with 3 affected sibs. Affected family members (1 man, 2 women) showed an early onset of pure spasticity within the first decade of life. After the exclusion of known ARHSP loci (namely SPG5, 7, 11, 15 and 28), a genome-wide study using 250 microsatellite markers has allowed the exclusion of more than 90% of the genome with the exception of a large homozygous region on chromosome 14. Linkage analysis using 49 microsatellite markers resulted in a maximal multipoint lod score of 3.13 with the ALLEGRO software whereas a multipoint lod score of 3.74 was reached with 12 markers using MAPMAKER/HOMOZ. Haplotype reconstruction restricted the candidate region to a 31-cM interval encompassing 29 homozygous markers in the 3 consanguineous patients. The critical interval is flanked by markers D14S264 and D14S58. Moreover, linkage to this newly identified locus, SPG29, has been excluded in 18 additional ARHSP pedigrees.

X-Linked Optic Nerve Atrophy. *A. Azimi, L. Xue, J. Baird, E. Pearson, Y. Zhao, S. Kamaya, J. Meyer, Z. Yang, K. Zhang.* Ophthalmology, EIHG Room 2290, Salt lake city, UT.

Introduction: The primary inherited optic atrophy is a heterogeneous group of inherited disorders that result in loss of retinal ganglion cells, leading to the clinical appearance of optic atrophy. It affects between 1:10,000 to 1:50,000 people. The main clinical features are loss of visual acuity, color vision abnormalities, centro-caecal visual field defects, and optic nerve pallor. Optic atrophy may be sporadic or familial. The mode of inheritance may be autosomal dominant, autosomal recessive, X-linked recessive or mitochondrial. Within each of these groups, the phenotypic characteristics vary in such features as the age of onset, the severity of the visual loss, the color deficit and the overall prognosis. Methods: We conducted clinical and genetic investigation on a large family with x-linked optic atrophy. Individuals from a large family with x-linked optic atrophy underwent ophthalmologic and neurologic evaluations, and blood drawing. Six males in four generations were diagnosed with optic atrophy. Clinical features included onset of age in early childhood, decreased central vision and color vision, and optic nerve pallor. No abnormality was described in obligatory heterozygote carriers. Genotyping to X-linked optic atrophy (OPA2) were performed. Results: Genotyping to X-linked optic atrophy (OPA2) were performed. Positive linkage was obtained with STR markers linked to OPA2. Conclusion: We have identified a large family of x-linked optic atrophy. Genetic mapping localized the disease gene to OPA2. The identification of OPA2 gene will further our understanding of the pathophysiology of optic atrophy. It will also improve diagnosis, counselling and management of patients, and eventually lead to the development of new therapeutic modalities.

Branchio-oto-renal syndrome: Seven novel Mutations in the EYA1 gene and possible genetic heterogeneity. *R. Uppala[1], C. Holley[1], F. Hildebrandt[2], CorW.R. Cremers[3], D.J. Orten[1], S. Kumar[1], W.J. Kimberling[1].* 1) Dept. Genetics, Boys Town Natl Research Hosp, Omaha, NE; 2) Dept. of Pediatrics & Communicable Diseases, University of Michigan, Ann Arbor. USA,; 3) Dept. of Otorhinolaryngology, University Hospital Nijmegen, Nijmegen, The Netherlands.

Branchio-oto-renal syndrome (BOR;MIM 113650) is an autosomal dominant disorder characterized by the association of bronchial cysts or fistulae, external ear malformations and/or preauricular pits, hearing loss and renal anomalies. It occurs at a frequency of approximately 1:40,000 live births. Mutations in the EYA1 gene at chromosome 8q13.3 and SIX1 at chromosome 14q23, are associated with BOR. A total of 41 loss-of-function mutations or missense mutations have been detected in EYA1. Recently, 3 different mutations in SIX1 were identified in BOR families (Proc Natl Acad Sci U S A 101:8090-5, 2004). Another locus on chromosome 1q31 was noted (Am J Hum Genet 66:1715-20, 2000), however the causative gene is yet to be identified. We analyzed the EYA1 and SIX1 gene coding regions from 87 independent BOR families/sporadic cases of various ethnic origins and identified seven novel EYA1 mutations in four independent families and 3 sporadic patients. Family SK-105 had a missense mutation, Y494C, in a highly conserved amino acid domain. A frameshift mutation due to 1-nt deletion was found in family SK-365, resulting in a truncated protein of 207 amino acids. Family SK-358 also had a missense mutation, R317S. Family SK-1396 had a frameshift deletion, resulting in a truncated protein of 521 amino acids. Family SK-2164 had a frameshift insertion, resulting in a truncated protein of 260 amino acids. Family SK-2193 had a nonsense mutation, R328X. In family SK-3385, we identified a novel heterozygous splice site mutation in exon 6 of EYA1 which deletes the T within the conserved donor site GT most likely causing loss of function and/or haplo-insufficiency. No pathogenic mutations were identified in the SIX1 gene-coding region in all patients tested. Absence of mutations in EYA1 and SIX1 and exclusion of large families to the 8q13.3, 14q23 and 1q31 loci by linkage analysis indicates genetic heterogeneity within BOR.

Familial autoimmune myasthenia gravis - results of a genome-wide scan. *M.A. Knight, G. Landouré, A.A. Taye, K.H. Fischbeck.* Neurogenetics Branch, NINDS/NIH, Bethesda, MD.

Myasthenia gravis is usually a sporadic condition, but about 4% of myasthenic patients have a positive family history. We studied an Italian-American kindred with parental consanguinity and 5 of 10 siblings affected with autoimmune myasthenia. Affected patients in the family had positive anti-acetylcholine receptor antibodies and other manifestations of autoimmune disease. The age of onset ranged from 50 to 79 years. Previous studies in this family excluded the HLA, T-cell receptor and acetylcholine receptor subunit genes. The consanguinity suggests an autosomal recessive form of myasthenia gravis, although other forms of inheritance are possible. Based on the hypothesis that the mode of inheritance is autosomal recessive, we looked for shared homozygosity in a genome-wide scan with markers spaced at 2 cM intervals. A region of shared homozygosity was found at chromosome 13q13-21. This segment of chromosome 13 is of interest because it has been shown to be deleted in B cell leukemia. We are now mapping the locus more precisely, and candidate genes are being screened to identify the disease-causing mutation. We believe that this represents a new locus for autoimmune myasthenia gravis, and we are seeking additional families to confirm the localization.

Mutation Hot-spot in CHX10 Gene Associated with Non-syndromic Microphthalmia in Qatari Families. *M. Ul Haque[1], S.H.E. Zaidi[2], M. Al-Mureikhi[3], G. Al-Thani[3], L-C. Tsui[4], A.S. Teebi[5].* 1) Molecular Genetics lab, DPLM, King Faisal Specialist Hospital, Riyadh, Saudi Arabia; 2) Division of Cardiology, Dept of Medicine, Univ Health Network, Toronto, ON, Canada; 3) Dept Pediatrics, Hamad Medical Corp, Doha, Qatar; 4) The University of Hong Kong, Pokfulam Road, Hong Kong; 5) Section of Clinical Genetics and Dysmorp, The Hosp for Sick Children, Toronto, ON, Canada.

Severe microphthalmia/clinical anophthalmia is a clinically heterogeneous disorder of eye formation, ranging from small size of a single eye to complete bilateral absence of ocular tissues. Null mutations in the CHX10 gene have been reported in non-syndromic microphthalmia in humans and in mice. CHX10 is expressed early in development in dividing retinal progenitor cells and antisense inhibition of Chx10 mRNA impaired retinal development in zebrafish embryos. We studied two unrelated highly consanguineous large families from Qatar in which affected individuals exhibited autosomal recessive form of non-syndromic microphthalmia. After informed consents were obtained, DNA samples from six affected and eight unaffected individuals from these families were subject to genetic analysis. Assuming a founder effect in each of the families, we performed homozygosity mapping using polymorphic markers adjacent to the CHX10 gene. In both families, linkage was evident for the CHX10 gene. Sequencing of the CHX10 gene of the affected individuals revealed a homozygous G to C substitution at nucleotide 599. The carrier parents were heterozygous for this mutation. This mutation resulted in replacement of the highly conserved arginine with proline (R200P). This R200P mutation has been previously reported in a mutation hot spot in micropthalmia patients from a Turkish family. Arginine 200 lies within the DNA recognition helix of the homeodomain of CHX10 and replacement of which results in severe disruption of the CHX10 binding to the DNA. Identification of the previously reported R200P mutation in ethnically different Qatari families, further confirms the functional importance of arginine 200 and suggests that this mutation may have a wide-distribution among different populations.

Novel HSF4 mutation causes autosomal dominant congenital total white cataract in a Chinese family. *T. Ke*[1], *M.G. Liu*[1], *B.C Ji*[2], *Q. Wang*[1]. 1) Human Genome Research center,Huazhong University of Science and Technology, Wuhan, Hubei, 430074, China; 2) General Hospital of Jinzhushan Industrial Group Corporation, Hunan, 417505, china.

Congenital cataract is one of the most common abnormalities of the eye and a frequent cause of blindness in infants with a prevalence of 1-6 cases per 10,000 births. We report here a Chinese family with autosomal dominant congenital cataract. The cataract in the family appears to be the type of total white. Linkage and haplotype analyses mapped the disease-causing gene in the family to chromosome 16q22, and defined the disease gene to a 24.48-CM region. The disease interval contains the HSF4 gene encoding one member of the family of heat shock transcription factors that regulate the expression of heat shock proteins (Hsps) in response to different stresses. Direct DNA sequence analysis of all exons and exon-intron boundaries of HSF4 identified a nucleotide change c.221G>A in exon 2, which results in substitution of a highly conserved arginine residue by histidine (p.Arg74His) in the DNA-binding domain. The mutation cosegregated with all affected individuals in the family, but not in unaffected family members and more than 150 controls. These results identified a novel missense mutation (p.Arg74His) in the transcript factor gene HSF4 that causes total white cataract in a Chinese family, and provide the first independent confirmation that mutations in HSF4 can cause autosomal dominant congenital cataract.

Novel mutation of the OPA1 gene causes autosomal dominant optic atrophy. *J. Liu[1], T. Ke[1], L. Zhou[1], M. Liu[1], Q. Wang[1,2].* 1) Huazhong University of Science and Technology Human Genome Research Center; 2) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation.

Autosomal dominant optic atrophy (ADOA) is a progressive eye disorder caused by degeneration of the retinal ganglion cell layer with ascending atrophy of the optic nerve. The onset of ADOA is often within the first decade of life. The prevalence rate of ADOA is 1 in 50,000 individuals. Three different ADOA genes (OPA1, OPA3 and OPA4) are located on chromosomes 3q28-29, 19q13.2-13.3 and 18q12.2-12.3, and OPA1 and OPA3 have been identified. In this study, we studied a 9-member, three-generation Chinese family with ADOA. The proband and one of her two affected sons displayed mental retardation, and the other affected son has short stature. We selected markers located at the three regions, and performed linkage analysis. Linkage was identified with two markers that span the OPA1 gene, D3S1601 and D3S1311. The OPA1 gene encodes a 960 amino acid protein with homology to dynamin-related GTPases. The OPA1 gene comprises of 28 exons and spans more than 40 kb of genomic sequence. Direct DNA sequence analysis of all exons and exon-intron boundaries revealed a novel mutation in exon 12, a G-to-A transition at nucleotide 1,202 of the OPA1 gene, resulting in a Gly401Asp substitution in the GTPase domain (encompassing the core central region between amino acid residues 280 and 520). RFLP analysis showed that the Gly401Asp mutation co-segregated with all patients in the family, and did not exist in unaffected family members and 200 unrelated normal controls. The OPA1 gene is widely expressed, but is most abundant in the retina. The Gly401Asp mutation may disrupted the GTPase activation of OPA1 in the retina and causes autosomal dominant optic atrophy in the family. Our results identify a novel mutation in OPA1 gene that causes optic atrophy associated with mental retardation and short stature.

Identification of a novel splice site mutation in collagen type VII gene that causes autosomal dominant dystrophic epidermolysis bullosa pruriginosa in a Chinese family. *X. Ren[1], M. Liu[1], J. Liu[1], Q. Yao[1], L. Zhai[2], Q. Wang[1].* 1) Huazhong University of Science and Technology Human Genome Research Center; 2) Nanyan the First People's Hospital.

The dystrophic form of epidermolysis bullosa pruriginosa (DEB) is characterized by extensive scarring due to sublamina densa blistering of the skin. Both autosomal dominant and autosomal recessive forms of DEB have been reported and are caused by different mutations in the type VII collagen gene (COL7A1). We report here a Chinese family with autosomal dominant DEB. Linkage analysis suggests that the family is linked to COL7A1. DNA sequence analysis and single stranded conformation polymorphism identified a substitution at the 87th exon/intron boundary (IVS87 +1 G -> T) in all affected family members, but not in the unaffected family members and 200 normal controls. Reverse-transcription PCR with total RNA from skin biopsies from the proband revealed that IVS87 +1 G -> T causes the deletion of exon 87. The mutant protein encoded by the truncated transcript is expected to lack a part of the triple helical domain involved in anchor fiber assembling. These results identify a novel splicing mutation in COL7A1 that causes DEB in a Chinese family.

Molecular Characterization of a UK Family with Posterior Polymorphous Corneal Dystrophy. *C. Mok[1], W. Ferrini[1,2], C. Willoughby[3], M.A. Walter[4], Y. He[5], E. Héon[1,2].* 1) Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Ophthamology and Vision Science, Queen's University Belfast, Royal Victoria Hospital, Belfast, Northern Ireland; 4) Chair and Associate professor, Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 5) Cytogenomics Facility, The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada.

We investigated a four-generation family for the genetic causes of posterior polymorphous corneal dystrophy (PPCD) and keratoconus (KC). The family exhibited an autosomal dominant pattern of inheritance along with full penetrance. One affected patient showed some features of rieger malformation. Genotype analysis, using STRP markers, was performed on seven candidate loci for PPCD, KC and Axenfeld-Rieger syndrome. Candidate genes were analysed using direct cycle sequencing. Linkage and haplotype analysis excluded all but one of the candidate loci. Suggestion of linkage was observed for the FOXC1 locus (6p25). Gene dosage and cytogenetic analyses were performed to assess the role of chromosomal rearrangement, gene deletion or duplication. No disease-associated changes or microdeletions/duplications were observed within the FOXC1 locus. No disease-associated coding sequence changes were observed in FOXC1, FOXF2, FOXQ1 and a highly conserved CpG island upstream of FOXC1. Cytogenetic analysis of an affected patient resulted in a normal karyotype while FISH analysis of the 6p25 locus revealed no microdeletions or translocations. Signals were seen at chromosome 16p11.2 (RP11-1083C15) and 11q2 (RP11-1104N17) in both our affected patient and controls. To our knowledge the large-scale polymorphism on chromosome 11 has not been previously described. The disease-associated change does not appear to involve the 6p25 FOX genes family.

Splicing of exon 5 of the MCAD gene and exon 7 of the SMN1/2 genes is dependent on exon splicing enhancers that counteract an identical exon splicing silencer - An example of a common architecture for splicing regulatory elements in two genes. *B.S. Andresen[1,2], K.B. Nielsen[1,2], P.P. Madsen[1,2], S. Sorensen[3], T.K. Doktor[1,2], L. Cartegni[4,5], A.R. Krainer[4], T.J. Corydon[1], J. Kjems[3], N. Gregersen[2].* 1) Inst Hum Genet, Aarhus Univ, DK; 2) Res Unit f Molec Medicine, Clin Inst, Aarhus Univ and Skejby Sygehus, DK; 3) Dept of Molec Biol, Aarhus Univ, DK; 4) Cold Spring Harbor Lab, New York, USA; 5) Sloan-Kettering Cancer Center, New York, USA.

Exon skipping caused by exonic point mutations is an intriguing molecular defect mechanism that is not fully understood even in the best studied examples. In spinal muscular atrophy (SMA) the SMN 2 gene can not compensate for the loss of the SMN1 gene because an exonic C>T mutation causes exon 7 skipping. Different models try to explain this: 1. Inactivation of an SF2/ASF binding exon splicing enhancer (ESE); 2. Creation of an hnRNPA1 binding exon splicing silencer (ESS). We have identified a mutation (362C>T) in exon 5 of the MCAD gene that causes exon skipping in patients. Mutagenesis studies in MCAD minigenes showed that 362C>T inactivates an ESE that is similar to the exon 7 SMN1 ESE. Both ESEs functions in a heterologous context. Moreover, the MCAD ESE could be substituted with the SMN1 ESE, whereas the corresponding SMN2 sequence caused exon 5 skipping. Optimization of the acceptor splice site of MCAD exon 5 normalized splicing from all constructs. Surprisingly, introduction of a flanking polymorphic variation (351A>C) corrected splicing from all mutant MCAD minigenes (Incl. those with the SMN2 seq.). Mutagenesis showed that 351A is part of an ESS, which is identical in the MCAD and SMN genes, and identical to an hnRNPA1 binding ESS in HPV-16 L1. In vitro RNA experiments showed that hnRNPA1 binding was determined by the combined activity of the ESE and the ESS. We suggest a common model for splicing regulation of SMN exon 7 and MCAD exon 5, in which the MCAD 362C>T and the SMN2 C>T mutations inactivates an ESE that is needed to prevent (hnRNPA1?) binding to the flanking ESS. Binding to the ESS inhibits recognition of the weak acceptor splice site and causes exon skipping.

Canadian CF Modifier Gene Project: candidate gene analysis. *J. Zielenski[1], R. Dorfman[1], A. Sandford[2], M. Corey[1], D. Markiewicz[1], X.-W. Yuan[1], A. Master[1], I. Evtoushenko[1], Y. Sang[1], F. Lin[1], V. Wang[1], C. Taylor[1], P. Pare[2], L.-C. Tsui[3], P. Durie[1], and Canadian Cystic Fibrosis Clinics.* 1) Hospital for Sick Children, Toronto, ON, Canada; 2) iCAPTURE/University of British Columbia, BC, Vancouver, Canada; 3) University of Hong Kong, Hong Kong, China.

Severity of clinical phenotype of cystic fibrosis (CF) is determined both by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene as well as variations in other genes (CF modifiers). One of the approaches to identifying CF modifiers is analysis of candidate genes selected on the basis of their relevance to various aspects of CF disease. The Canadian CF Modifier Gene Project is a family based approach to identifying and characterizing genes that modulate clinical severity of cystic fibrosis. The Project involves: (1) blood sample and data collection from CF families and (2) analysis of association of CF modifier loci and genes with various clinical variables in CF patients. To date, 38 Canadian CF Clinics and 7 foreign CF centers participate in the Project. Study consents were obtained from 2039 CF families. Currently, 10020 blood samples were obtained from 4939 individuals (patients and parents) for genomic DNA extraction and lymphoblast cell line establishment (patients only). Demographic, cross-sectional and longitudinal data are being collected from medical charts of participating CF patients. Approximately 65% of the data have been collected from charts of participating patients and reviewed for quality. In our candidate gene approach, 79 genes with relevance to CF have been selected as potential modifiers of clinical severity in CF patients. Genotyping of 161 intragenic markers is at various stages of progress. These include markers from genes previously implicated as CF modifiers. Our preliminary results using Family-Based Association Tests (FBAT) and/or Analysis of Variance (ANOVA) confirm the previously reported association of two of these genes: transforming growth factor beta 1 (TGFbeta1, G74C/R25P) and tumor necrosis factor alpha (TNFalpha, -A308G) with CF patients pulmonary function. (Supported by Genome Canada through Ontario Genomics Institute and Canadian CF Foundation).

DNA analysis in differential diagnosis of hepatic bilirubin metabolism disorders. *A. Krumina[1], I. Micule[1], V. Sondore[2], J. Keiss[1, 2].* 1) Dept. of Medical Biology $ Genetics, Riga Stradins University, Riga, Latvia; 2) Infectology Center of Latvia, Riga, Latvia.

The most common disorder of hepatic bilirubin metabolism in humans is Gilbert syndrome (GS). Traditionally, the diagnosis of GS has been a diagnosis of exclusion, made when mild unconjugated hyperbilirubinaemia has been observed in a patient with no evidence of haemolysis and in whom liver function tests are within normal values. Diagnostic criteria for GS in Latvia includes mild elevation of serum bilirubin, which is at least 90 percent unconjugated, and decreased level of glucuronides in daily urine. A new tool for the definitive diagnosis of GS has been provided by finding TA insertion in the promoter of the gene UGT1A1. Gene UGT1A1 encodes for the enzyme uridine diphosphate-glucuronosyltransferase, which conjugates bilirubin with glucuronic acid. TA insertion in the promoter region of the gene UGT1A1 is observed in nearly all the patients with GS and in 12 - 15% of healthy individuals. The **aim** of the study was to estimate the role of DNA analysis in the diagnosis of GS. **Material** was DNA isolated from the peripheral venous blood. **Objects** were 72 patients with a clinical diagnosis of GS. **Method** used was denaturing polyacrylamide gel electrophoresis of the amplified promoter region of the gene UGT1A1. **Results**. The following variants of TA dinucleotide polymorphisms in the promoter region of the gene UGT1A1 were observed: $(TA)_7/(TA)_7$ - in 69 individuals (95.8%), $(TA)_6/(TA)_7$ - in 2 (2.8%), $(TA)_6/(TA)_6$ - in 1 (1.4%). Elevated level of unconjugated hyperbilirubinaemia and decreased level of glucuronides in daily urine were found in 86.6% and 88.8% patients, respectively. **Conclusion**: The necessity to improve differential diagnosis of GS among all the other cases of unconjugated hyperbilirubinaemia requires the inclusion of DNA analysis in the diagnostic algorithm of Gilbert syndrome.

Embryonic lethality in mice deficient in *tex292*, ortholog of the North American Indian childhood cirrhosis (NAIC) gene *CIRH1A*. *B. Yu, G.A. Mitchell, A. Richter.* Medical Genetics, Sainte-Justine Hospital, Montreal, Canada.

NAIC is a severe progressive nonsyndromic autosomal recessive intrahepatic cholestasis. *CIRH1A*, mapped to 16q22, encodes cirhin, a 686 residue nucleolar protein with an active C-terminal monopartite nuclear localization signal and a unique nucleolar localization signal. All known NAIC patients are homozygous for the exon 15 mutation R565W, which alters the predicted secondary structure of cirhin but produces a stable, accurately-targeted protein. *Tex292* is widely expressed, particularly in liver, both postnatally and in 11.5 days pc mouse embryos. We studied mice generated with the gene trap vector pGT1Lxf, produced from Bay Genomics ES cell line XH230. This vector has a splice acceptor upstream of the -geo reporter gene, a fusion of -galactosidase and neomycin phosphotransferase genes (Stryke et al, NAR 31: 278, 2003). We precisely characterized the insertion in XH230 and found integration between exons 9 and 10 in *tex292*. Two of 3 chimeras produced germ-line transmission. In heterozygote crosses with average litter size of 5.3 we found a ratio of offspring genotypes suggestive of prenatal lethality: normal, 36; heterozygous, 59; homozygous mutant, 0. The oldest heterozygotes are now 24 weeks old and appear normal for growth and activity; evaluation of their liver function and histology is in progress. To investigate the timing of the embryonic lethality, we proceeded to examine embryos at 11.5, 9.5 and 8.5 dpc. A total of 14 gravid females were sacrificed. The genotyping of 81 embryos failed to reveal homozygous targeted embryos while the expected ratios of normals and heterozygotes were detected. Staining of the embryos for -galactosidase confirmed the genotyping. We are now studying earlier embryos. In mice, complete *tex292* deficiency is incompatible with survival past 8.5 dpc, and perhaps earlier. The distinct, liver-specific phenotype of NAIC patients may reflect species specific influences or may be related to the specific properties of the R565W mutation.

MDR3 (ABCB4) mutations are not an uncommon cause of contraceptive pill-induced cholestasis and familial cholestasis. *M. Hrebicek[1], M. Bouckova[1], L. Dvorakova[1], J. Horak[2], J. Sperl[3], P. Trunecka[3], M. Jirsa[3].* 1) Institute of Inherited Metabolic Disorders, Prague, Czech Republic; 2) 2nd Department of Internal Medicine, 3rd Faculty of Medicine, Prague, Czech Republic; 3) Institute of Clinical and Experimental Medicine, Prague, Czech Republic.

The ABCB4 (MDR3) is a phospholipid pump located predominantly at the biliary pole of the hepatocyte. Mutations in the *ABCB4* gene were found in homozygosity or heterozygosity in patients with progressive familiar intrahepatic cholestasis type 3 (PFIC3), cholesterol lithiasis (CL) and intrahepatic cholestatis of pregnancy (ICP). The *ABCB4* gene is located at chromosome 7q21.11 and spans more than 75 kb. We have analysed 27 protein-encoding exons of *ABCB4* gene in 6 Czech families with cholestatic disease, with familiar occurence of cholesterol lithiasis and contraceptive pill induced cholestasis. In three of the families the probands carried on one of the alleles a mutation - c.3608C>G (S1203X), c.1501G>T (E501X), and c.1954A>G (R652G), respectively, and wild type sequence on the other. The fourth proband was a compound heterozygote for mutations c.523A>G (T175A) a c.1371del G (G457X). In two of the families no apparently pathogenic mutations were found. The fifth proband was heterozygous for 3 synonymous mutations (c.175C>T, L59L; c.504T>C, N168N; c.711A>T, I237I) and the sixth proband carried on one of the alleles the IVS28-16C>T that is likely not pathogenic. These findings confirm that mutation analysis of *ABCB4* should be considered in the broadening spectrum of hepatic diseases including cholestasis induced by hormonal contraceptives and familial cholelithiasis with onset before 25 years of age. Treatment with ursodeoxycholic acid has a potential to ameliorate the symptoms of ABCB4 deficiency and the patients may profit from early diagnosis. Supported by grant IGA MZ CR NM/7510-3.

Human Inherited Disorders with CNS Phenotype: Types of Genes. *G. Bruns*[1,2]. 1) Genetics Div, Children's Hosp, Boston, MA; 2) Dept of Pediatrics, Harvard Medical School, Boston, MA.

As part of a study of the nature of genes underlying different types of developmental disorders, the OMIM Morbid Map was sequentially searched for inherited diseases with a significant central nervous system component and known gene mutation. In many of these syndromes, other organ systems were also involved. Disorders with transient neurologic symptoms secondary to acute metabolic decompensation were excluded. When mutation in a gene can lead to more than one syndrome with a CNS phenotype, that gene was tabulated only once. Of the ~300 inherited diseases with known mutations evaluated to date, twenty-two percent (66 disorders) included a CNS phenotype. Among these, mutation of genes specifying biosynthetic metabolic pathway enzymes was the most common - 13 disorders (20 percent). Seven mutations disrupted lipid or lipoprotein catabolism (10.6 percent). Seven involved fundamental neural cell proteins or neural cell growth factors; 6 mutations impacted excision repair DNA binding proteins and DNA helicases; 6 involved signal transduction or cell fate molecules; and 3 disrupted zinc finger or paired box transcription factors. Five mutations affected organelle trafficking proteins, specifically peroxisomal translocases. Two disorders derive from mutation of genes for metal binding/transporting proteins and 2 from alteration of solute carrier family members. In 12 of the disorders with a CNS phenotype (18.2 percent), the mutation(s) involved a novel protein, nearly all with extensive homology in lower Eukaryotes. A number of these have recognizable domains/motifs including TM domains. Although the frequencies and categories of mutations reflect the disorders evaluated to date, alteration in metabolic pathway biosynthetic enzymes, lipid/lipoprotein catabolism, fundamental neural cell proteins, DNA repair factors, signal transduction molecules, and novel proteins of ancient origin appear to be prominent in inherited diseases that involve the central nervous system. Mutations in genes that specify proteins restricted to higher Eukaryotes were infrequent.

Screening for haploinsufficiency of *TCOF1* mRNA in Treacher Collins syndrome patients. *K.H. Shows, R. Shiang.*
Department of Human Genetics, Virginia Commonwealth University, Richmond, VA.

The majority of mutations in *TCOF1* identified to cause Treacher Collins syndrome (TCS) are nonsense, deletion, and insertion mutations that lead to a premature stop codon and can cause truncation of the expressed protein treacle or lead to nonsense-mediated mRNA decay. It has been proposed that the mechanism of action of a heterozygous nonsense mutation is through haploinsufficiency of functional treacle during a critical time point in neural crest cell development, resulting in the craniofacial abnormalities characteristic of TCS. We performed quantitative real time PCR using RNA derived from lymphoblastoid cells to investigate the occurrence of haploinsufficiency of *TCOF1* mRNA in TCS patients with known mutations in *TCOF1*, in TCS patients who showed no mutations after *TCOF1* screening, and in normal individuals. Results show that there is no pattern of association of mRNA level with presence or absence of known or unknown *TCOF1* mutation; therefore, screening for haploinsufficiency of *TCOF1* mRNA in lymphoblastoid-derived RNA is uninformative in our sample.

Study of C2orf34, a novel gene not expressed in the 2p16 deletion syndrome. *S. Buriakovsky, M. Rubinshtein, R. Parvari.* Developmental Molecular Genetics, Ben Gurion University, Beer Sheva, Israel.

We identified Bedouin patients presenting a unique recessively inherited syndrome, with broad clinical manifestations: cystinuria, mental & growth retardation, hypotonia, facial dysmorphism and mitochondrial respiratory chain dysfunction presenting as reduced activity of all mitochondrial encoded respiratory chain enzymatic complexes. Our previous study identified the molecular basis of this syndrome as a homozygous deletion of 179,311 bp on chromosome 2p16, and thus was subsequently named the 2p16 deletion syndrome. Further studies to define the transcription content of this interval showed that it includes 4 protein coding genes: type I cystinuria SLC3A1, protein phosphatase 2C, and two uncharacterized genes PREPL and C2orf34 . In addition, the presence of three transcripts without, or with very short, open reading frames was noted in the deleted region. The C2orf34 gene has its promoter and first exon in the deletion, verification by RT-PCR using patients' RNA demonstrated that it is not expressed in patients lymphoblastoid and fibroblasts cells in contrast to RNA from cells of controls. Bioinformatics investigation suggests that one of the two splice variants of the gene, not expressed in the 2p16 deletion syndrome patients, may have methyltranferase activity and is highly conserved during evolution. RT-PCR using RNA of various tissues demonstrates that the two spliced forms are ubiquitously expressed, including in the tissues affected by the syndrome. GFP tagging suggests different sub cellular localizations of the spliced forms one to the nucleus and the other to the Golgi compartments. We hypothesize that the absence of this gene in the patients may have a major contribution to the clinical presentation of the patients.

Tissue Polyamines and Polyamine Regulation in Arginase Knockout Mouse Models. *J.C. Livesay[1], J.L. Deignan[1], P.K. Yoo[1], A.E. Pegg[2], R.K. Iyer[1], S.D. Cederbaum[1], W.W. Grody[1].* 1) Departments of Pathology and Laboratory Medicine, Psychiatry, Pediatrics and Human Genetics and The Mental Retardation Research Center, David Geffen School of Medicine at the University of California, Los Angeles, CA; 2) Department of Cellular and Molecular Physiology, Penn State College of Medicine, Hershey, PA.

Defining specific and distinct roles for arginases AI and AII has been a complex task. AI was thought to be primarily involved in ureagenesis while AII was thought to be involved in the production of ornithine for all other functions such as the biosynthesis of polyamines and as a part of the inflammatory process. Recent in situ hybridization and RT-PCR studies in our lab have shown that AI is actually more widely expressed than AII in adult animals, contradicting these former assumptions. A plausible new role for AI outside of the liver is the production of ornithine for the biosynthesis of polyamines, which are essential for cell proliferation and differentiation. To test this hypothesis, we previously created an AI knockout mouse, and after acquiring the AII knockout mouse, created the double knockout in order to look for any alterations in tissue polyamines in the absence of arginase. Analysis of polyamines in the liver, brain, kidney, and small intestine of arginase single and double knockout mice revealed a lack of alterations in polyamines in all of these tissues. Subsequent RT-PCR analysis revealed that some of the other arginine metabolic enzymes were slightly altered in specific tissues; however, none of the polyamine regulatory enzymes analyzed showed any dramatic alterations in their expression in the various arginase deficient mice. These data reveal that, at least in the tissues analyzed, AI and AII do not serve a primary role in the production of ornithine for polyamine biosynthesis nor does the absence of either isoform alter the regulation of the polyamine synthetic enzymes in any discernible way. Future studies will determine if alterations in polyamines exist in male and female reproductive tissues in the arginase knockout mice, where arginase expression is likely to be more important for polyamine production.

Is the IP male-phenotype caused by alteration of NEMO protein as in IP -female? *M. Ursini, F. Fusco, G. Fimiani, A. Pescatore, M.G. Miano, M. D'Urso.* Human Genetics Laboratory, IGB/ABT/CNR, Naples, Italy.

Incontinentia pigmenti, or Block-Sulzberger Syndrome, is an X-linked genodermatosis with heterogeneous phenotype. IP, classically considered a male-lethal disorder, results from mutations in the gene for NF-kB essential modulator (NEMO), with deletion of exons 4-10 of NEMO accounting for 180% of new mutations. Loss of function mutations of NEMO gene are lethal in male during embriogenesis while the female survive for an extremely skewed X-inactivation pattern. Less deleterious mutations that preserve the NEMO activity can result in survival of male subjects, but with ectodermal dysplasia and immunodeficiency (EDA-ID). We investigated the NEMO coding region in 18 male patients with clinical hallmarks of IP. Characteristic abnormalities of the skin and alterations of hair, nails, teeth, eyes and central nervous system were present, and EDA-ID phenotype was clinically excluded. We amplified and sequenced the coding region of NEMO from genomic DNA by PCR and we found the genomic deletion in 4 IP male: 3 resulted to be mosaic for the common mutation while 1 had a 47,XXY karyotype. The NEMO protein presence and the normal activation of NF-kB pathway after TNFalfa stimulation was demonstrated in skin fibroblast culture from two male patients carrying wild-type NEMO coding region. In 14 IP male patients that showed wild type NEMO coding gene, we carried out mutational search in the NEMO conserved non coding regions and in its 5-UTR using PCR amplification and direct sequencing methods. To date, 6 point mutations were identified, 4 in the 5UTR and 2 around the transcription start site and are currently under analysis. NEMO transcription regulation underlining IP pathogenesis and/or if other genes are involved in the IP-male phenotype remains to be evaluated.

Detection of muscular dystrophy genotypes via universal condition direct sequencing (UCDS). *R.R. Bennett[1], H.E. Schneider[1], A. Lakdawalla[2], P.S. Lai[3], C.E. Barrett[1], V. Lip[1], B.L. Wu[1], B.T. Darras[1], L.M. Kunkel[1].* 1) Department of Genetics, Children's Hosp, Boston, MA; 2) Applied Biosystems, Foster City, CA; 3) Department of Pediatrics, National University of Singapore, Singapore.

Currently, mutations in many of the genes causing the various forms of muscular dystrophy remain undetected in patients because of the unavailability of a reliable and cost effective assay to detect them. One promising strategy requires the amplification of all salient portions of a gene or many genes at one single set of PCR conditions. This is achieved by designing amplicons of uniform large (~1000bp) size. Internal primers are then used for sequencing (Flanigan et al. 2003). A second strategy which we are developing in collaboration with Applied Biosystems, Foster City Ca. using its VariantSEQr resequencing system is to use automated primer design tools to seek primers for all salient portions of many genes. Using Amplitaq GoldPCR system, these amplicons will all amplify at a single set of PCR conditions. In addition, by using M13F and M13R tails on the primers, a universal sequencing plate can be utilized in this process.We have developed a high throughput 384 well plate robotic process with dried primers using the Applied Biosystems VariantSEQr resequencing system for genes associated with any form of muscular dystrophy. The new sequencing strategy provides more than an order of magnitude reduction in cost, time to detect mutation and complexity of analysis. Detection of mutations is facilitated rapidly using SeqScape v2.1 software (Applied Biosystems, Foster City Ca.). This software incorporates a consensus sequence and a tab process for tabing through all variations between patients and consensus, known polymorphisms versus unknown variants as well as insertions and deletions. As of June 2005, we have all assays working for this process called UCDS (Universal Condition Direct Sequencing) for the DMD, CAV3, TRIM32, CAPN3, FKRP, FCMD, DYSF, SGCA, SGCB, SGCD, SGCG, NEB genes using control DNA. Over the summer, we will be finalizing and publishing this process and continuing next year to develop new assays until all muscular dystrophy and myopathy genes are included.

Sense from nonsense for primary pulmonary hypertension: screening transcripts protected from nonsense mediated decay enhances detection of BMPR2 mutations. *J.A. Phillips III[1], J.D. Cogan[1], L.K. Hedges[1], L.A. Wheeler[1], E.P. Dawson[2], J.E. Loyd[1].* 1) Depts of Pediatrics and Medicine, Vanderbilt University School of Medicine, Nashville, TN; 2) Bioventures Inc, Murfreesboro, TN.

Background: About 50% of cases with familial primary pulmonary hypertension (FPPH) are reported to have mutations in the bone morphogenic protein receptor type 2 (BMPR2) gene. BMPR2 has 13 exons, spans >180 kbs, and is 98% intronic. Since most reported BMPR2 mutations were found by PCR amplification and sequencing of exons and intron boundaries, they reside in exons or splice junctions. **Hypothesis:** Since exonic sequencing can miss duplications, deletions and inversions that cause Nonsense Mediated Decay (NMD), analysis of transcripts protected from NMD should be more efficient and sensitive in detecting BMPR2 mutations. **Methods:** Lymphoblastoid cells from 10 unrelated FPPH patients previously found to not have BMPR2 mutations by exon sequencing were incubated with and without puromycin. RNA was then isolated and reverse-transcriptase PCR (RT-PCR) products containing BMPR2 transcripts were sequenced. **Results:** Analysis of RT-PCR products from lymphoblastoid cells from 6/10 samples showed exon deletions or duplications, and BMPR2 transcripts from 1/2 of these were affected by NMD. Incubation of all cell lines having BMPR2 transcripts degraded by NMD with puromycin, which inhibits NMD, roughly equalized the proportions of mutant and normal BMPR2 transcripts. Of the remaining 4/10 samples without exon duplications or deletions, 3/4 (75%) were homozygous for all exonic SNPs. **Conclusions:** 1) BMPR2 mutations were found outside exons in 60% of unrelated FPPH samples in which exon sequencing was negative and RT-PCR products of 75% of the remaining samples were homozygous for exonic SNPs, 2) transcript analysis is a more efficient and sensitive method to detect BMPR2 mutations than sequencing amplicons containing exons, 3) puromycin can block NMD of BMPR2 transcripts in lymphoblastoid cells and 4) transcripts associated with duplications, deletions, inversions, stop codons, altered splicing and possibly promoter changes (by allelic dropout) can be efficiently detected using this method.

Munc13-4 mutations in North American families with Hemophagocytic Lymphohistiocytosis. *K. Zhang[1], J. Biroschak[1], S. Lee[2], J. Villanueva[2], J. Johnson[1], AH. Filipovich[2], RJ. Wenstrup[1].* 1) Division of Human Genetics, Cinncinnati Children's Hosp, Cincinnati, OH; 2) Division of Hematology /Oncology, Childrens Hospital Medical Center, Cincinnati, Ohio, USA.

Familial hemophagocytic lymphohistiocytosis (FHL) is an autosomal recessive disorder of immune regulation which typically presents in early childhood and has a rapidly fatal course unless aggressively treated with chemotherapy, immune suppression and bone marrow transplant. While earlier reports have identified mutations in the perforin (PRF1) genes in 20-30% of families with HLH, more recently, mutations in Munc13-4 have been observed to be responsible for about 10-30 percent of FHL cases in European and Japanese population. Munc13-4, a member of the human Munc13 family contains 32 exons that encodes a 123-kDa protein, which is involved in vesicle trafficking and membrane fusion. Patients with Munc13-4 mutations have impaired lymphocyte cytotoxic function with normal perforin expression. In this report we describe results of Munc13-4 gene mutation analysis in twenty-five unrelated North American families with children diagnosed with HLH without PRF1 mutations. Mutations of Munc13-4, including nine novel mutations and more than thirty sequence variants were identified in 22 families. Six probands carry bi-allelic pathogenic mutations in the Munc13-4 gene. Eight of ten nonsynonymous sequence variants were not found in the 50 normal individuals that from southern Ohio populations. Varying degrees of deficiency in natural killer (NK) cell function have been detected in this group of patients, indicating that Munc13-4 genotype-phenotype correlations are yet to be established. Interestingly, one patient with classical Macrophage Activation Syndrome and systemic onset Juvenile Rheumatoid Arthritis, who developed HLH-like syndrome, carried bi-allelic mutations in the Munc13-4 genes. Since approximately 25% of cases of HLH in North America are caused by Munc13-4 mutations, DNA-based screening for HLH due to Munc13-4 mutations using DNA sequencing is recommended in affected families when the PRF1 gene found to be normal.

Spastin mutations in patients with sporadic spastic paraparesis. *C. Depienne[1,2], C. Tallaksen[1], J.Y. Lephay[1], B. Bricka[2], S. Poea-Guyon[1], B. Fontaine[3], P. Labauge[4], A. Brice[1,2], A. Durr[1,2].* 1) INSERM U679, Paris, France; 2) Unité de Neurogenetique, Departement de Genetique, Cytogenetique et Embryologie, AP-HP, Groupe Hospitalier Pitie-Salpetrière, Paris, France; 3) Federation de Neurologie and INSERM U546, Groupe Hospitalier Pitie-Salpetriere, Paris, France; 4) Service de Neurologie, CHU Montpellier-Nimes, Hopital Caremeau, Nimes, France.

SPG4, encoding spastin, is the major gene responsible for autosomal dominant hereditary spastic paraparesis (HSP), accounting for 10-40% of families with pure or complicated phenotype. The goal of this study was to assess the frequency of SPG4 mutation in a large series of patients with spastic paraplegia without family histories. We selected 147 mostly European probands with progressive spastic paraplegia of unknown origin and without transmission of the disease. DNA was screened by DHPLC for sequence variants in the 17 coding exons of the SPG4 gene and sequence variants were characterized by direct sequencing. We identified 19 different mutations, 13 of which were novel, in 18 different patients, for an overall mutation rate of 12%. The sporadic nature of the disease resulted from true reduced penetrance in one family in which both parents were found normal. There was no evidence for de novo mutation. The mutations associated with sporadic patients were mostly of the missense type and were sometimes located out of the AAA domain. We showed that the spectrum of mutations in sporadic patients is different from that of familial cases and is associated with a milder SP phenotype and a reduced penetrance. The high frequency of SPG4 gene mutations in patients with sporadic spastic paraplegia argues in favour of gene testing in patients with pure or complicated spastic paraplegia even without family histories, because it permits appropriate genetic counselling.

Haplotype analysis in Indian Wilson disease patients. *G. Kaur[1], S. Kumar[2], B.R. Thapa[3], R. Prasad[2].* 1) Department of Physiology, Chandigarh Medical College, Chandigarh, India; 2) Department of Biochemistry, PGIMER, Chandigarh, India; 3) Department of Pediatric Gastroenterology, PGIMER, Chandigarh, India.

Wilson disease (WD) is a disorder of copper transport due to mutations in ATP7B gene. Till date, mutation screening in Indian WD patients has led to the identification of 22 mutations (1). Till now date, no data is available on alleles distribution and haplotype association with specific mutation in Indian WD population. Henceforth, in the present study, we have determined the alleles distribution and haplotype association with specific mutation by using D13S314, D13S301 and D13S316 dinucleotide markers in 28 WD patients. All three markers were found to be equally distributed. Total of 27 different haplotypes associated with 56 WD chromosomes were determined. Haplotypes 1-7-4, 5-3-2, 5-4-6, 6-8-7, 10-6-5 and 11-8-2 were common and being observed in 35% of WD chromosomes. Haplotypes 1-7-4 and 5-3-2 were most common and each being observed in 7.14% of WD chromosomes. Haplotype 5-3-2 was associated with most common T3305C Indian WD mutation. Statistically significant deviations were seen for D13S314, D13S301 and D13S316 dinucleotide markers. Test of significance was done by the 2 method for large contingency table, with following results: D13S301 gave a value of 42.12 (P=0.465, 42d.f.), D13S314 yielded a value of 50.02 (P=0.184, 42d.f.) and D13S316 resulted in value of 54.2 (P=0.282, 49d.f.). The genetic heterozygosity for D13S314, D13S301 and D13S316 was observed to be 1.0, 0.81 and 1.0 respectively. These loci showed 0.76, 0.80 and 0.88 expected heterogeneity in these patients respectively. The gene diversity among WD patients was observed to be 0.980.007 (MeanSD). This data has provided an explanation about the association of haplotype with a specific mutation which is utmost important for guiding the identification of mutations in reference to both established and currently unidentified.

D85N-KCNE1: A Common single nucleotide polymorphism associated with congenital long QT syndrome. *R.S. Judson[1], B.A. Salisbury[1], M. Pungliya[1], J. Carr[1], J. Hennessey[1], C. Harris-Kerr[1], M. Qi[2], W. Zareba[2], J.L. Robinson[2], A.J. Moss[2], D.J. Tester[3], M.L. Will[3], M.J. Ackerman[3].* 1) Genaissance Pharmaceuticals, New Haven, CT; 2) University of Rochester, Rochester, NY; 3) Mayo Clinic College of Medicine, Rochester, MN.

INTRODUCTION: Rare, often unique, protein-altering mutations in the genes KCNQ1, KCNH2, SCN5A, KCNE1, and KCNE2 cause approximately 75% of congenital Long QT Syndrome (LQTS). We hypothesized that one or more polymorphisms, protein-altering or not, in the five genes above might contribute to LQTS. We predicted that such contributing polymorphisms would be particularly overrepresented in mutation-negative cases of congenital LQTS relative to non-diseased controls. **METHODS:** The five LQTS-associated channel genes were sequenced for 98 unrelated, white cases with clinically identified LQTS but no clear pathogenic mutation (M-) and for 364 white controls. Hundreds of single nucleotide polymorphisms and several indels were identified. We tested for correlation between case/control status and gene variants ranging from single polymorphisms up to 4-polymorphism haplotypes; permutation testing was used to control for multiple comparisons. **RESULTS:** The common KCNE1 polymorphism D85N was significantly more common among M- cases (11/98, 11%) than in controls (9/364, 2.5%) ($p = 0.0007$). Notably, all 11 D85N+, M- cases were female ($p = 0.03$). No other polymorphism or haplotype was significant after multiple comparisons correction. In an effort to validate these findings, we reviewed data from the FAMILION genetic test for LQTS. Nine (five female) of 95 M- patients carried D85N (9.5%, $p = 0.0045$ vs. controls). **CONCLUSIONS:** The one significant genetic difference between controls and M- cases was overrepresentation of D85N among cases, which we have confirmed in a second case sample. Clinical and functional research have previously implicated D85N as a risk factor for drug-induced torsade de pointes. This congruence of findings strongly implicates D85N-KCNE1 as contributing to the phenotypic presentation of LQTS in some patients. However, further studies are needed to determine whether the D85N has a causative or modifying role.

Quantitative Analysis of Dystrophin Genes Based on DHPLC : A Highly Efficient and Reliable Duchenne muscular dystrophy Carrier-Screening Test. *M.J. Lee[1], H.W. Lee[1], C.H. Lee[1], B.B. Park[2], J.S. Lee[2].* 1) Brain Korea 21 Project for Medical Science, Yonsei University, Seoul, Korea; 2) Department of Clinical Genetics, Yonsei University College of Medicine, Seoul, Korea.

The dystrophinopathies - the severe type Duchenne muscular dystrophy (DMD) and the milder type Becker (BMD) are the most common inherited disorders of muscle with a prevalence of 1:3500 live male births. Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are caused in the majority of cases by deletions of the DMD gene and are readily detectable in affected males by multiplex polymerase chain reaction (PCR). However, different approaches must be used for the identification of female carriers, in which deletions are not detectable by PCR, because of the presence of a normal X chromosome. In this study, we show a new, rapid, simple, and highly reliable method for detecting female carrier of DMD by DHPLC. Carrier samples were prepared from patients' family in which patients had shown deletions in their dystrophin gene. Also, we prepared 10 female control individuals from the general population. Carriers have deletion in the dystrophin gene on X chromosome and the amount of PCR product must be half reduced than normal female sample. By DHPLC analysis, we could detect DMD carriers efficiently just by recognizing an only peak that corresponds to a single gene dosage compared to internal standard. The ratio between peaks of carriers and internal controls showed the range from 0.63-0.70. This method is fast, easy and reproducible to detecting gene deletion in DMD carriers and the method might be very helpful for the diagnosis of other diseases that carry a deletion as a mechanism of the diseases such as microdeletion syndrome.

Comprehensive alpha- and beta-thalassemia genotyping by means of reverse-hybridization teststrips. *H. Puehringer[1], H. Najmabadi[2], E. Baysal[3], W. Krugluger[4], H.Y. Law[5], V. Viprakasit[6], C. Oberkanins[1].* 1) ViennaLab Labordiagnostika GmbH, Vienna, Austria; 2) Genetics Research Center, Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 3) Genetics Department, Al Wasl Hospital, Dubai, UAE; 4) Dept. Clinical Chemistry, Municipal Hospital Rudolfstiftung, Vienna, Austria; 5) Genetics Service, KK Women's and Children's Hospital, Singapore; 6) Dept. Paediatrics, Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Alpha- and beta-thalassemia (thal) are among the most common inherited diseases throughout Southeast Asia, India, the Middle East, parts of Africa and the Mediterranean area. Mutations in the beta-globin gene, or in one or both of the two alpha-globin genes, are leading to structural abnormalities (e.g. sickle cell anemia) or to haemoglobin imbalance due to the reduced synthesis or complete absence of the respective globin chains. Unlike the prevalence of point mutations in beta-thal, the majority of alpha-thal alleles are derived from single or double gene deletions. We have developed reverse-hybridization assays (StripAssays) for the rapid and comprehensive genotyping of alpha- and beta-thalassemia. The tests are based on multiplex DNA amplification (including gap-PCR) and hybridization to teststrips presenting a parallel array of allele-specific oligonucleotide probes for each variant. The entire procedure from blood sampling to the identification of mutations requires less than 6 hours, and hybridization/detection may be carried out manually or essentially automated using existing instrumentation. The tests are simple and convenient, and require very small amounts of samples, which is of particular importance for prenatal diagnosis. Although the spectrum of alpha- and beta-thal mutations is known to be highly population-specific, the broad range of variants covered by the StripAssays should make them globally useful diagnostic tools. (oberkanins@viennalab.co.at).

Analysis of Transcription from D4Z4 Repeats and Satellite DNA in FSHD, ICF Syndrome, Cancer, and Control Cell Populations. *M. Ballestas[1], V. Alexiadis[2], M. Warren[2], C. Sanchez[1], S. Winokur[3], V. Vedanarayanan[4], M. Ehrlich[1].* 1) Human Genetics, Tulane Medical School, New Orleans, LA 70112; 2) Genpathway, San Diego, CA 92121; 3) Dept. Biol. Chem., Univ. Cal., Irvine, CA 92697; 4) Dept. Neurology, Univ. Miss. Med. Sch., Jackson, MS 39216.

There is increasing interest in whether large tandem DNA repeats not associated with known genes are transcribed. Tandem arrays of 3.3-kb D4Z4 repeats at 4q35 containing <11 monomers are diagnostic for facioscapulohumeral muscular dystrophy (FSHD). Because D4Z4 repeats have a putative homeodomain-like ORF downstream of a sequence that acts as a promoter in reporter assays, we looked for transcription of D4Z4 or closely related sequences in various cell types by real-time RT-PCR and by chromatin immunoprecipitation (ChIP) with an RNA polymerase II-specific antibody. We analyzed FSHD and control myoblasts and lymphoblastoid cells; lymphoblastoid cells from ICF patients (immunodeficiency, centromeric region instability, facial anomalies), in which D4Z4 is hypomethylated; several normal tissues; and cancers (ovarian carcinomas and Wilms tumors). Despite in-silico predictions of a gene in D4Z4 repeats in the arrays at 4q35 and 10q26 and in related sequences in acrocentric chromosomes and the cataloging of a D4Z4 cDNA Genbank clone, we found no consistent evidence for transcription of four D4Z4 subregions or closely related sequences in these assays or in ChIP with an antibody to RNA polymerase I. In contrast, we found evidence by both RNA polymerase II ChIP and RT-PCR for very low levels of transcription from pericentromeric satellite 2 sequences in some cancer samples. We conclude that the hypothesized differential transcription of D4Z4 sequences in short, FSHD-diagnostic arrays vs. long arrays is unlikely. Furthermore, it has been proposed that transcription of long heterochromatic regions in eukaryotic cells may generally be involved in maintaining their chromatin structure. However, the very low frequency with which satellite 2 sequences were found to be transcribed in our study does not support this hypothesis for human cells. (Supported in part by NIH grant NS048859, the Muscular Dystrophy Association, & Genpathway.).

Improved Analysis of FSHD-Linked D4Z4 Repeat Arrays with D4Z4 Probes. *M. Ehrlich[1], K. Jackson[1], P. Camaño González[2], R.J.F.L. Lemmers[3].* 1) Dept Human Genetics, SL31, Tulane Medical Sch, New Orleans, LA; 2) Hospital Donostia, Unidad Experimental, San Sebastián, Guipúzcoa, Spain; 3) Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

The number of tandem copies of the copy-number polymorphic 3.3-kb D4Z4 repeat at 4q35 plays a critical, albeit enigmatic, role in facioscapulohumeral muscular dystrophy (FSHD). Individuals with <8 repeats at one of the allelic subtelomeric 4q arrays usually have the disease while those with 11 up to ~100 almost always do not. In most cases, disease-causing short arrays on 4q can be distinguished from longer 4q arrays and phenotypically neutral, short D4Z4 arrays on 10q26 by pulsed field electrophoresis using p13E-11, which is adjacent to 4q and 10q D4Z4 arrays, as the probe for blot-hybridization to *Eco*RI or *Eco*RI/*Hin*dIII, *Eco*RI/*Bln*I, and *Xap*I digests. This discrimination relies on a *Bln*I site present in canonical 10q, but not 4q, D4Z4 repeats and an *Xap*I site in canonical 4q, but not 10q, repeats. However, deletions of the p13E-11 region in ~3% of individuals complicate the identification of short FSHD-causing D4Z4 arrays on 4q. For these atypical cases and for samples in which the amount of DNA in agarose plugs for PFGE is limiting, such as prenatal specimens, it would be useful to use D4Z4 sequences as the hybridization probe. Furthermore, a D4Z4 hybridization probe aids research on FSHD and analysis of complicated D4Z4 arrays containing translocations between 4q and 10q. The use of a D4Z4-derived probe presents the complication of numerous sequences not at 4q35 and 10q26 that have high homology to D4Z4. We rigorously tested different hybridization conditions and probe sequences that allow 4q and 10q D4Z4 sequences to be distinguished from D4Z4-like sequences elsewhere in the genome. We found conditions that allow probing of a Southern blot with a D4Z4 subfragment to give hybridization essentially only to 4q35 and 10q26 D4Z4 arrays. We present examples of how the use of this probe in addition to the p13E-11 probe can improve molecular diagnosis of FSHD. (Supported in part by NIH Grant R01 NS048859 to M.E.).

Utility of gross deletion/duplication analysis in Cystic Fibrosis diagnostics. *A. Kammesheidt, T. Vo, K. Schmidt.*
Ambry Genetics, Irvine, CA.

Cystic Fibrosis (CF) is one of the most common autosomal recessive diseases characterized by chronic pulmonary obstructive disease, exocrine pancreatic insufficiency, elevated sweat chloride levels and male infertility. CF is caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR), with over 1300 mutations described to date. The distributions and mutation frequency is extremely diverse and only a handful of mutations occur at frequencies greater than 0.1%, whereas most mutations are rare. Even with full gene sequence analysis now available for diagnostic use, clinically affected individual are not always conclusively genotyped. The inability of most PCR based analysis methods to detect gross deletions, duplications and rearrangements has limited diagnostic capabilities. Homozygous gross deletions may be detected in individuals due to the lack of any amplification, but most heterozygous gross deletions remain undetected due to template masking. Recent work suggests that deletions are more abundant in CF than previously thought.

In the present study, 103 samples were screened for deletions/duplications using the multiplex ligation-dependent probe amplification method (MRC, Holland) following full gene sequence analysis with the Ambry Test: CF. 9/103 cases contained deletions or duplications. All deletions were identified in diagnostic cases with positive or borderline sweat chloride levels, in which only 0 or 1 other mutation had previously been identified with the Ambry Test-CF (9/51). Other tested groups included diagnostic cases with 2 identified mutations (n=22), carrier screens with 1 known mutation (n=8), positive newborn screens with 1 or 2 known mutations (n=11) and atypical diagnostics with 1 known mutation (n=11). Gross deletions or duplications were not observed in these groups.

Gross deletion/duplications were present in 18% (9/51) of unresolved diagnostic cases in this sample set. The data support that gross deletion/duplication analysis is an essential reflex test to improve detection rates in symptomatic individuals undergoing CFTR genotyping.

A preferential association of CF mutations with CFTR-M470 allele. *C. Bombieri[1], F. Pompei[2], B.M. Ciminelli[2], A. Bonizzato[3], A. Holubova[4], P. Zorzi[1], A. Begnini[1], C. Ciccacci[2], V. Vavrova[5], C. Castellani[3], M. Macek jr[4], G. Modiano[2], P.F. Pignatti[1].* 1) Section Biol & Genetics, Univ Verona, Verona, Italy; 2) Dpt. of Biology, Univ. Roma-Tor Vergata, Italy; 3) Veneto Regional CF Center, Verona Hospital, Italy; 4) Inst Biology and Medical Genetics, Czech Republic; 5) Pediatric Clinic, Charles Univ. Prague, Czech Republic.

In a previous study on European non-CF individuals, we found a preferential association of random CFTR gene mutations with the M allele of the M470V common polymorphism. Therefore, we hypothesized that CFTR alleles with the M variant should have an increased risk of carrying a CF-causing mutation. Last year we reported on this association in a first group of Italian CF patients. Now we wish to report the characterization of a larger series of Italian CF patients, and a confirmation in Czech patients. Patients and their parents were selected for the presence of at least one non-F508del mutation (as F508del is associated with M) in the CF child, after screening for the most common CF mutations in the population. In Italian CF patients 221/272 (81%) CF-non-F508del mutations were detected on the M allele. In Czech patients, this figure was 53/86 (62%). As the frequency of the M allele in the non-CF population is 39%, the difference is highly significant. The observed population difference is related to the frequency of some population-characteristic mutations: in particular, dele2,3-21kb in the Czech population only (16/86 on the V allele), and R1162X in the Italian population only (35/272 on the M allele). In the Italian population, MM individuals (15% in the population) will have a relative risk of carrying a CF mutation about 15X that of a VV individual (38% in the population). In conclusion, population screening for the M470V polymorphism may help modify the estimate of the risk to be a carrier of a CF mutation, and further analysis could be suggested for individuals at increased risk.

Two previously unreported COL4A3 mutations in a patient with autosomal recessive Alport syndrome. *G.L. Barnett[1], R. Baliga[2], C.A. Friedrich[1].* 1) Dept Prev Med, Div Med Genet,; 2) Ped Nephrology, Univ Mississippi Medical Ctr., Jackson, MS.

A 14-year-old African-American female with longstanding bilateral hearing loss developed hypertension, hyperkalemia, elevated BUN and creatinine, hematuria, anemia, proteinuria, and a decreased erythropoetin level. Neither of her parents and neither of her sisters had hearing loss, renal disease or hypertension. A distant older relative with hypertension and diabetes mellitus required dialysis but no other relatives were known to have renal disease or hearing loss. Renal biopsy and electron microscopy revealed segmental effacement of podocyte foot processes and changes suspicious for hereditary laminated basement membrane disease. DNA sequencing of COL4A3 was performed by Dr. Mato Nagel (Weisswasser, Germany) and showed two mutations in exon 49. R1496X (CGA>TGA) at codon 1496 and R1516X (CGA>TGA) at codon 1516 are both premature termination codons that have not been reported previously. The most likely explanation is each of these mutations is on a different allele but family studies are needed to confirm this. Presymptomatic diagnosis may be an option for her siblings.

Report of a novel mutation in an Iranian individual affected with Marfan syndrome. *R. Karimi-Nejad[1], V. Hadavi[1], B. Mahshidfar[1], J.S. Saldivar[2], M.H. Kariminejad[1], H. Najmabadi[1].* 1) Kariminejad-Najmabadi Pathology & Genetics Center, 14665/154, Tehran,Iran; 2) Clinical Molecular Diagnostic Laboratory, City of Hope National Medical Center and Beckman Research Institute, Duarte, California, US.

Marfan syndrome, which was originally described in the 19th century, is an autosomal dominant connective tissue disease associated with mutation in the fibrillin-1 gene located on chromosome 15 (locus 15q21.1). A 31 years old male affected with Marfan syndrome was referred to our center. According to family history, there was no one else with the disease. The phenotype of the individual assigned affected status satisfied the established diagnostic criteria for MFS. Progressive high myopia and bilateral lens subluxation have been diagnosed since he was 5, a tall stature and tall extremities, pectus excavatum, high arched palate, a little joint laxity, but no arachnodactyly were noted. Dilated aortic root was diagnosed and MVP found in echocardiography. All coding exons and associated intron junctions of the FBN1 (65 exons) gene were analyzed by direct DNA sequence analysis using an automated fluorescent sequencer. Confirmation of the mutation detection was carried out by sequencing in the opposite direction. The results of sequencing showed deletion of CAC and insertion of 12 bp at nucleotide -5 in intron 50 (IVS 50-5 delCACinsTCATTAATAGAT). This genetic alteration inserts a putative alternative acceptor splice site junction in intron 50. Based on its sequence, it is predicted to insert 2 bp into the current open reading frame, which would result in a frameshift mutation. Thus it is very likely that this alteration results in a major disruption in the structure of the FBN1 protein and is predicted to be deleterious to the normal function of the protein. However, the possibility that this mutation represents a rare polymorphism cannot be completely ruled out. The individual is heterozygous for this alteration, having an apparently “normal” or “wild” type copy of the FBN1 gene along with the altered copy. To our knowledge, this alteration has not been previously reported.

Deletion screening of the *FOXL2* and *FOXC1* region involved in BPES and Axenfeld-Rieger malformations using high-resolution tiling path BAC microarrays. *L. Dejager[1], B. Menten[1], D. Beysen[1], J. Vandesompele[1], E. Michels[1], B.P. Leroy[1,2], B. Lorenz[3], F. Meire[2], P. Kestelyn[2], T. de Ravel[4], Y. Arens[5], S. De Jaegere[1], A. De Paepe[1], F. Speleman[1], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium; 3) Ophthalmogenetics, Klinikum der Universität Regensburg, Regensburg, Germany; 4) Center for Medical Genetics, Leuven University Hospital, Leuven, Belgium; 5) Center for Medical Genetics, University of Maastricht, Maastricht, The Netherlands.

MLPA and microsatellite analysis recently enabled us to detect genomic deletions that either encompass or are located in close vicinity of the forkhead transcription factor gene *FOXL2* in families with blepharophimosis syndrome (BPES). These deletions account for 16% of all molecular defects we found in BPES. The extragenic deletions are located upstream and downstream of the transcription unit of *FOXL2* and represent a new mutational mechanism for BPES.

In addition, changes in gene dosage of *FOXC1*, another forkhead transcription factor gene, are known to result in a spectrum of dominant disorders involving malformations of the anterior segment of the eye (e.g. Axenfeld-Rieger anomalies). In this study, we identified 4 deletions encompassing *FOXC1* in patients with Axenfeld-Rieger malformations using MLPA.

We developed a 2.9 Mb and 3.1 Mb tiling path BAC array for breakpoint delineation in known deletion patients and for detection of deletions in patients in which no genetic defect was found so far. ArrayCGH allowed to delineate the breakpoints in 16 known deletion patients with BPES and 4 patients with Axenfeld-Rieger anomalies respectively. Interestingly, a novel extragenic deletion was identified upstream of *FOXL2* in a sporadic BPES patient.

In conclusion, this study shows that arrayCGH with a tiling path array for the *FOXL2* and *FOXC1* region is a robust and efficient approach to identify and characterize subtle genomic rearrangements in these two regions.

Genotype-phenotype correlation in hereditary hemorrhagic telangiectasia: a French-Italian study. *G. LESCA[1], C. OLIVIERI[2], N. BURNICHON[3], F. BOUTITIE[4], F. ABBAS[4], F. COULET[5], M. RABILLOUD[4], A. CALENDER[1], S. GIRAUD[1], F. SOUBRIER[5], C. DANESINO[2], E. BUSCARINI[6], H. PLAUCHU[3], French Italian Rendu-Osler Network.* 1) Laboratoire de Genetique, Hopital Edouard Herriot, Lyon, France; 2) Genetica Medica, Universita di Pavia, Italy; 3) Service de Genetique, Hotel-Dieu, Lyon, France; 4) Service de Biostatistique, Lyon, France; 5) Laboratoire de Genetique, Hopital Pitie-Salpetriere, Paris, France; 6) 6Gastroenterologia ed Endoscopia Digestiva, Ospedale Maggiore, Crema, Italy.

Hereditary Hemorrhagic Telangiectasia is an autosomal dominant disorder characterized by arteriovenous malformations (AVM) with cutaneomucous (telangiectases), pulmonary (PAVM), hepatic (HAVM) and cerebral (CAVM) involvement. We recruited 342 patients, 93 having a mutation in ENG (HHT1) and 249 in ALK1 (HHT2), respectively, through the Rendu-Osler Network in France and Italy. Epistaxis occurred earlier in HHT1 (12yrs) than HHT2 (19yrs), with incomplete penetrance for HHT2. The number and repartition of cutaneous telangiectases did not differ according to the type. The prevalence of PAVMs was highly significantly different between HHT1 (53%, n=83) and HHT2 (15%, n=175). PAVMs were found in 25% of the patients who underwent systematic screening (n=199), but with a higher occurrence in HHT1 (54%, n=50) than in HHT2 (13%, n=149). The prevalence of HAVMs was globally high (57%, n=179) and significantly higher in HHT2 (61%, n=171) than in HHT1 (43%, n=47). Severe HAVMs requiring liver transplantation were only seen in the HHT2 group. Intestinal telangiectases were found in 38% of the patients who underwent systematic screening (n=57), with no difference between HHT1 and 2. CAVMs were found in 1.5% of the patients after a clinical manifestation and in 6% after systematic screening (n=72), without difference according to the genotype. Severe infections (excluding cerebral abscess) were reported in both groups without noticeable difference. When considering the mutation type, there was a trend toward an association between ALK1 missense mutations and hepatic involvement, as well as between PAVMs and small deletion/duplication of ENG.

Beta-globin cluster linked polymorphisms strongly associated with the variability of disease severity in Thai thalassemia patients with ^{0}/HbE genotype. *Q. Ma[1], K. Abel[2], J. Whitacre[2], V. Angkachatchai[2], W. Makarasara[3], O. Sripichai[3], P. Fucharoen[3], S. Fucharoen[3], A. Braun[2], L.A. Farrer[1].* 1) Boston University, Boston, MA; 2) Sequenom Inc., San Diego, CA; 3) Mahidol University, Thailand.

Thalassemia patients possessing both HbE and ^{0}mutant alleles display remarkable variability in disease severity. We evaluated the contribution of polymorphisms within the -globin cluster to variation in disease severity by genotyping 70 SNPs in this region with an average spacing of 1,066bp in groups of 209 mild and 327 severe unrelated patients from Thailand with ^{0}-thalassemia/HbE disease and normal -globin genes. Eleven SNPs uninformative in this sample were excluded from further analysis. All statistical analyses were adjusted for age, gender, and geographic region. Logistic regression was used to investigate the association between each SNP and disease severity. Thirty-nine SNPs spanning the LCR region and A gene showed strong association with disease severity. The strongest association was observed with the *XmnI* polymorphism located 158 upstream of the G gene (global p=1.4E-12). Subjects with the CC genotype were 4.1 times more likely than CT subjects (p=2.4E-07) and 34.5 times more likely than TT subjects (p=1.7E-12) to have severe disease. Haplotype analysis of five tagging SNPs (*HincII-3′yb*; *HindIII-Gg*; *XmnI*; *HincIIE*; *rs4601817*) showed that disease severity was less among subjects with the haplotype ATT-T (freq=0.4;p=6.3E-16) and increased among subjects with haplotypes GGCAC (freq=0.48;p=5.8E-07) and GGCAT (freq=0.09;p=5.2E-04). Haplotype analysis of the *XmnI* site and the -globin mutation among 536 ^{0}/HbE patients and 50 subjects homozygous for the HbE mutation revealed that T allele of *XmnI* was nearly always in cis with the HbE allele(haplotypes frequencies: T-HbE=0.39; T-^{0}=0.04; C-^{0}=0.43; C-HbE=0.14). Linear regression analysis showed the XmnI genotypes TT and CT were associated with increased expression of fetal hemoglobin (HbF) in both the mild (p=0.004) and severe (p=9.3E-09) patient groups. In summary, our study showed that *XmnI* and other SNPs in the -globin cluster are associated with disease severity and expression of HbF in Thai patients with ^{0}-thalassemia/HbE disease.

Familial hemophagocytic lymphohistiocytosis: Mutation spectrum, genotype/phenotype correlation, and functional analysis of *PRF1, UNC13D, STX11,* and *RAB27A*. *H.C. Hennies[1], K. Beutel[2], S. Kolberg[3], R. Schneppenheim[2], H. Kabisch[2], G. Janka[2], U. zur Stadt[2].* 1) Cologne Center for Genomics, Dermatogenetics, Univ of Cologne, Germany; 2) Dept of Pediatric Hematology and Oncology, Univ Medical Center of Hamburg, Germany; 3) Gene Mapping Center, Max Delbrück Center for Molecular Medicine, Berlin, Germany.

Familial hemophagocytic lymphohistiocytosis (FHL) is an autosomal recessive disease affecting young children. It presents as a severe hyperinflammatory syndrome with activated macrophages and T lymphocytes. Mutations in the perforin 1 gene (*PRF1*) were reported in FHL-2 in 15-50% of all cases. Defective granule exocytosis caused by mutations in the hMunc13-4 gene (*UNC13D*) has been described in FHL-3. FHL-4 patients have mutations in *STX11*, a t-SNARE involved in intracellular trafficking. We have analysed a large group of 63 unrelated patients with FHL from different geographic origins for mutations in *STX11*, *PRF1*, and *UNC13D*. We identified mutations in 38 samples, 20 in *PRF1*, 12 in *UNC13D*, and 6 in *STX11*. Of 32 patients from Turkey, 14 had mutations in *PRF1*, 6 in *UNC13D*, and 6 in *STX11*. The mutation Trp374X in *PRF1* was found in twelve patients from Turkey and was associated with a very early onset of the disease below the age of three months in all cases. In contrast, only 7/23 patients from Germany showed mutations in either *PRF1* or *UNC13D*. Thus FHL-2, FHL-3, and FHL-4 account for 80% of the HLH cases of Turkish origin and for 30% of German patients. Using a mammalian two-hybrid system we have now shown that the missense mutations Ala87Pro in Rab27a, which was found in a patient with FHL-related Griscelli syndrome type 2, and Leu403Pro in hMunc13-4 each prevented the formation of a stable hMunc13-4/Rab27a complex in vitro. Our findings demonstrate extensive genetic and allelic heterogeneity in FHL and delineate an approach to functionally characterize missense mutations in *RAB27A* and *UNC13D*.

A genetic test of the potential role of brain-derived neurotrophic factor (BDNF) in modulating Huntington'fs disease pathogenesis. *S. Kishikawa[1], R.H. Myers[2], S. Williamson[2], T. Gillis[1], M. Hakky[1], M.E. MacDonald[1], J.F. Gusella[1].* 1) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Charlestown, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA.

Huntington'fs disease (HD) is an autosomal dominant neurodegenerative disorder, caused by an expanded polyglutamine tract in the huntingtin protein (htn). The size of the repeat accounts for up to 70% of variance in age at onset, but the remaining variation is strongly heritable, suggesting that genetic modifiers affect the pathogenic process. BDNF is a prosurvival factor that is necessary for survival of striatal neurons in the brain. BDNF also has been suggested to have a specific role in the HD pathogenic process, because htn upregulates transcription of BDNF and promotes BDNF transport with Huntington-associated protein-1 and the p150 (Glued) subunit of dynactin. To test this hypothesis, we analyzed two BDNF SNPs for association with onset age in HD: rs6265 is a functional SNP located in the coding region (V66M) that alters intracellular trafficking and activity-dependent secretion of BDNF. BDNF270 is located in the 5'-flanking region of BDNF. Both have been reported to show genetic association with behavioral disorders. We genotyped six hundred and thirty one (279 unrelated singletons and 352 siblings) HD affected individuals with extremely young or extremely old onset ages (0.5 S.D. from expected repeat adjusted onset age) and 83 additional HD affected persons by direct sequencing or by TaqMan methods. In this dataset, neither rs6265 (p=0.73) nor BDNF270 (p=0.99) was associated with onset age, in models controlling for the HD repeat size. These results, showing that genetic alteration of BDNF activity does not significantly alter age at neurologic onset, suggest that BDNF does not play a major role in influencing the HD pathogenic process that leads to disease onset.

Genotype-phenotype correlation in NF1 microdeletion syndrome: CDKR1 and OMG mutations in mental retarded patients and genes specifically expressed in embryonic heart. *M. Venturin[1], S. Moncini[1], V. Villa[1], S. Brunelli[3], S. Russo[2], M.T. Bonati[2], L. Larizza[1,2], P. Riva[1].* 1) Department of Biology and Genetics, Medical Faculty, University of Milan, Milan, MI, Italy; 2) Istituto Auxologico Italiano, Milan, MI, Italy; 3) Stem Cell Reasearch Institute, HSR, Milan, MI, Italy.

Mental retardation (MR) and cardiovascular malformation (CVM) are significantly present in NF1 patients (pts) with microdeletion syndrome, compared to classical NF1 pts, as a result of 17q11.2 region haploinsufficiency. We identified in the NF1 deleted region the CNS developmental genes CDK5R1 and OMG, as candidate for MR susceptibility. We screened 100 pts affected by unspecific MR for mutations in OMG and CDK5R1 coding regions and in 5/3 UTRs, in which latter we predicted several transcription/translation regulatory elements. Four novel mutations and 2 novel polymorphisms for CDK5R1 and 3 novel mutations for OMG were detected, including 2 missense changes (c.323C>T; A108V in CDK5R1, and c.1222A>G; T408A in OMG), 1 synonymous variant (c532C>T; L178L in CDK5R1), 4 variants in CDK5R1 3UTR and 2 changes in OMG 5UTR. Prediction of mRNA and protein secondary structures revealed that changes in the mutated 2254G CDK5R1 3UTR and OMG 408A gene product, lead to putative structural alterations. We didnt found in 17q11.2 known genes involved in heart development. Expression analysis of 9 genes within the NF1 deleted region showed that CENTA2, SUZ12, C17orf40 are mainly expressed in human fetal heart and mouse embryonic heart during the early stages of development. In situ hybridization on whole mouse embryos and sections from 8.25 to 14 dpc evidenced that CENTA2 is expressed in developing heart starting from 9.25 dpc. These studies allowed us to identify mutations in CDK5R1 and OMG, which pathogenetic role will be investigated and suggested that CENTA2 is involved in heart development and possibly in CVM. Clinical/genetic analyses of NF1 microdeletion syndrome may be functional to disclosing genes involved in complex diseases, enhancing genotype-phenotype correlation.

The Jackson Laboratory Repository: Mouse Models of Human Disease. *S.F. Rockwood, L.R. Donahue, D.B. Lane, M.T. Davisson.* The Jackson Laboratory, Bar Harbor, ME.

Mouse models of human disease continue to fulfill an essential role in facilitating the development of therapeutic applications. To ensure the greatest possible access to these models, The Jackson Laboratory Repository was established to serve as a centralized facility for the purpose of developing, collecting, distributing and cryopreserving mouse models for the international biomedical research community. Approximately 100-150 new strains are added annually to the hundreds of unique mouse strains that comprise the largest collection of characterized mouse strains available to researchers today. Models newly imported and/or developed for distribution have applications in studies focusing on Spinal Muscular Atrophy (SMA), Rett syndrome, Cystic Fibrosis, Diabetes, Huntingtons disease, Alzheimers disease, craniofacial disorders, kidney disease, vision and hearing disorders and spondyloepiphyseal dysplasia (SED). Supplementing these strains are a wide variety of Cre-expressing strains (constitutive or inducible) and a growing number of targeted mutants harboring loxP-flanked genes that are useful for generating tissue-specific mutants. An on-line resource is available (www.jax.org) allowing researchers to retrieve information related to strains maintained in the Repository. On-line strain datasheets typically include a brief phenotype description, strain development, husbandry information, licensing requirements and a list of related references. Donating a strain to the Repository fulfills the requirements for sharing of mice in accordance with NIHs policy for the sharing of research reagents. Researchers wishing to have strains considered for inclusion in the Repository may submit their strains using the form available at The Jackson Laboratory web site: http://www.jax.org/grc/index.html. The Jackson Laboratory Repository is supported by the National Center for Research Resources, the National Institute on Aging, the National Cancer Institute, The Howard Hughes Medical Institute, the Ellison Foundation, and private donations from several charitable foundations. (P40 RR01183, RR09781, RR16049, N01 HD53230, R01 Ey015073, P30 CA34196).

Proximal Inclusion body myopathy, Paget Disease of the Bone and Frontotemporal Dementia (IBMPFD): a model for adult onset complex traits. *V. Kimonis[1], S. Ramdeen[1], S. Mehta[1], C. Smith[2], K. Boycott[3], R. Schröder[4], G. Watts[1].* 1) Div Gen/Metabolism, Child Hosp, Harvard Medical Sch, Boston, MA; 2) Dept of Neuro,Univ. of Kentucky, Lexington, KY; 3) Univ. of Calgary, Alberta Childrens Hospital, Calgary, AB, Canada; 4) Dept of Neurology, Univ. Hosp, Bonn, Germany.

IBMPFD is a dominant progressive disorder that maps to chromosome 9p21.1-p12 and associated with mutations in VCP (valosin-containing protein), a member of the AAA-ATPase superfamily. Among 133 individuals in 20 unrelated families, 93(70 %) had myopathic weakness at a mean age of 42 (Range 3-61 y). PDB was identified in 51(38 %) at a mean age of 42 years (Range 31-61 y) typical distribution including the spine, pelvis, scapulae and skull. FTD was seen in 32(24 %) with a mean age of diagnosis of 55 years. Rimmed vacuolar inclusion bodies were present in 35 % of muscle biopsies. Histological studies reveal filamentous inclusion bodies in muscle cytoplasm and nucleus, Pagetic osteoclasts and brain, which stain positive for VCP, ubiquitin, phosphorylated tau and -amyloid, these deposits being similar to those seen in Alzheimer disease. On further analysis of the data for genotype-phenotype correlations, the R155C individuals had an earlier age of onset for the myopathy and PDB ($p<0.05$) when compared to R155H ($p<0.05$) and other mutations. The A232E mutation in a small family involving the AAA ATPase domain not surprisingly was associated with a more severe phenotype and early demise before the onset of dementia would be expected. Interestingly we found that inheriting 1 or 2 alleles of APOE4 was associated with an increased predisposition for frontotemporal disease ($p<.01$) and women were twice as likely to have dementia. VCP is associated with a variety of cellular activities, including cell cycle control, membrane fusion and the ubiquitin-proteasome degradation pathway. The majority of mutations in VCP cluster in the N terminus, and have been shown to interfere with poly-ubiquitin and co-factor binding thus permitting potential therapeutic targeting strategies for this complex disorder.

Myotonia Congenita in a large consanguineous Bedouin- Muslim family; A unique clinical presentation and identification of a novel mutation in the (CLCN1) Chloride Channel gene. *A. Shalata.* Simon Winter Ins.Human Genetic, Bnai-Zion Medical Center, Haifa, Israel.

Myotonia is the term given to delayed relaxation of skeletal muscle after voluntary contraction. In most situations myotonia is most marked after initial muscle contraction, and usually abates after repeated muscle activity (the warm-up phenomenon). Congenital myotonia, the most common form of non-dystrophic forms of myotonia, may show both dominant (Thomsen disease) and recessive (Becker disease) modes of transmission, both of which may be caused by mutations in CLCN1(7q35), the gene encoding the major skeletal muscle chloride channel. Mutations in this gene may cause myotonic contractions in humans, mice, goats and dogs. Today, more than 80 different mutations have been identified in the CLCN1 gene in both types of human myotonia congenita, in various ethnic groups. We describe herein, to the best of our knowledge, the clinical characterization and the molecular analysis of the first Arab family of Bedouin-Muslim origin, affected with myotonia congenita. We identified a novel mutation, the G190S mutation, located in a conserved CLC1-chloride channel motif which is transmitted in a dominant mode of inheritance with incomplete penetrance.

Identification of novel mutations in *MMP20* and *ENAM* underlying amelogenesis imperfecta. *S. Hart[1], D. Ozdemir[2], O.K. Ryu[3], S.J. Choi[3], E. Firatli[2], M. Ozdemir-Karatas[2], G. Aren[2], N. Piesco[4], T.C. Hart[3].* 1) Office of the Clinical Director, NHGRI, Bethesda, MD; 2) School of Dentistry, Istanbul University, Istanbul Turkey; 3) Section of Craniofacial and Dental Genetics, NIDCR, Bethesda, MD; 4) University of Pittsburgh, School of Dental Medicine, Pittsburgh, PA.

The amelogenesis imperfecta (AI) are a group of disorders that affect enamel formation. Mutations in 3 genes have been reported to cause autosomal hypomaturation (*MMP20, KLK4*) or hypoplastic forms of AI (*ENAM*). We analyzed 25 Turkish families segregating autosomal AI for mutations in the *MMP20* and *KLK4* (hypomaturation phenotype) or *ENAM* (hypoplastic phenotype) genes. Of the 15 hypomaturation families, 1 family was found to have a novel (g.16250T>A) *MMP20* mutation that changes the conserved active site His226 residue of the zinc catalytic domain to Gln (p.H226Q). Zymogram analysis confirmed that this missense mutation abolished MMP20 proteolytic activity. This represents the second *MMP20* mutation described. Of the 10 families segegating hypoplastic AI, *ENAM* mutations were found in 2. A novel transversion mutation (g.12663C>A; p.S246X) was found in a family segregating local hypoplastic AI as a dominant trait. In the second family segregating generalized thin hypoplastic AI, affected individuals were compound heterozygotes for a novel insertion mutation (g.12946_12947insAGTCAGTACCAGTACTGTGTC) and a previously described insertion mutation (g.13185_13186insAG). Heterozygous carriers of either insertion had a localized enamel pitting phenotype, substantiating that enamel phenotypes of *ENAM* mutations may be dose dependent with generalized hypoplastic AI segregating as a recessive trait and localized enamel pitting segregating as a dominant trait. This brings to seven the total number of *ENAM* mutations reported and represents the second mutation associated with pitting in the carrier state. These results suggest that while *MMP20* and *ENAM* mutations are responsible for some cases of AI in Turkey, other genes as yet unknown are responsible for the majority of cases.

Prevalence and distribution of exonic mutations in Interferon Regulatory Factor 6 (IRF6) identified in two large cohorts with Van der Woude syndrome. *R. de Lima[1], M. Ghassibe[2], N.K. Rorick[3], S.A. Hoper[3], L. Katz[3], D.J. Schipper[3], M.J. Dixon[5], U. Hehr[4], J.G. Compton[6], M. Vikkula[2], A. Richieri-Costa[7], D. Moretti-Ferreira[1], J.C. Murray[3], B.C. Schutte[3].* 1) Genetics, UNESP, Botucatu, Sao Paulo, Brazil; 2) University of Louvain, Brussels, Belgium; 3) Pediatrics, University of Iowa, Iowa City, IA; 4) Humangenetik, Regensburg, Germany; 5) University of Manchester, Manchester, England; 6) GeneDx, Gaithersburg, MD; 7) USP, Bauru, Sao Paulo, Brazil.

Mutations in IRF6 cause Van der Woude (VWS) and Popliteal Pterygium syndromes (PPS), two related orofacial clefting disorders. IRF6 belongs to the IRF family of nine transcription factors. Both VWS and PPS display an autosomal dominant pattern of inheritance with high penetrance but variable expressivity. The phenotype of VWS includes pits in the lower lip, clefts of the lip and/or palate and hypodontia. In addition to these features, PPS includes webbing of the lower limbs, syndactyly of the toes and digits, ankyloblepheron, oral synechia, and genital abnormalities. We performed direct sequence analysis on the exons of IRF6 on samples from two large geographically defined cohorts, one from Brazil (113 VWS and 1 PPS) and one of mixed origin (197 VWS and 36 PPS). In both cohorts, we identified mutations in IRF6 exons in 69% of all families with VWS, and 97% of families with PPS. The distribution of VWS-causing mutations was not random, with exons 3, 4, 7, and 9 accounting for 80%. In total, we identified 87 protein truncation mutations, scattered throughout the gene, and 127 missense mutations that are concentrated in the DNA-binding and protein-binding domains. With 50% of the samples sequenced from the CEPH diversity panel, none of these mutations have been observed. In addition, PolyPhen and SIFT analyses of the missense mutations suggest that they are more likely to be damaging to gene function than all possible missense mutations ($p<.001$). This extensive mutation screen of IRF6 will assist clinicians to provide a DNA diagnosis for patients with orofacial clefts and assist researchers to identify genotype-phenotype and structure-function relationships.

Search for protein interactors of ribosomal protein S19, mutated in Diamond Blackfan Anemia. *I. Dianzani[1], A. Chiocchetti[1], L. Gibello[1], A. Carando[2], P. Secco[1], A. Biava[1], A. Aspesi[1], U. Dianzani[1], U. Ramenghi[2], S. Orrù[3], M. Angelini[4], M. Caterino[3], M. Ruoppolo[3], F. Loreni[4], C. Santoro[1].* 1) Dept Medical Sciences, Univ Piemonte Orientale, Novara; 2) Dept Pediatric Sciences, Univ.Torino; 3) Dept.Biochemistry and Biotechnology, Univ.Federico II, Napoli; 4) Dept of Biology,Univ.Tor Vergata, Rome.

Diamond Blackfan Anaemia (DBA) (MIM 205900) is a congenital disease characterized by defective erythroid progenitor maturation. Patientsbone marrow progenitors do not respond to eryhtropoietic growth factors, such as EPO. Mutations in the gene encoding for ribosomal protein (RP) S19 account for 25% of patients. The link between defective erythropoiesis and rps19 is still unclear. Two not mutually exclusive hypotheses have been proposed: altered protein synthesis and loss of unknown extraribosomal functions. Several ribosomal proteins have been shown to have a second function besides their structural role in the ribosome. We have used two different approaches to search for proteins interacting with RPS19. Yeast two hybrid screening has been used to screen a human liver cDNA library obtained at 19-24 weeks of gestation, when hepatic erythropoiesis is efficient. We have found that RPS19 binds PIM-1, an ubiquitous serine-threonine kinase whose expression can be induced in erythropoietic cells by several growth factors, such as EPO. The PIM-1/RPS19 interaction was demonstrated both in vitro and in living cells and lead to phosphorylation of RPS19 in an in vitro kinase assay. We also show that in human 293T cells PIM-1 interacts with ribosomes and may be involved in translational control. Three DBA-associated RPS19 mutations alter the binding between RPS19 and PIM-1. An LC/MS/MS approach was performed on the eluate obtained after affinity purification using a GST-RPS19 resin on a lysate from K562 cells. Twenty-six interactors, all nucleolar, were identified. In conclusion, our data show that RPS19s main roles are in ribosome biogenesis and translation. A link between erythropoietic growth factor signaling and RPS19 has been identified for the first time: it may lead to translational control.

Two Novel *KCNQ2* Mutations in Benign Familial Neonatal Convulsions. *A. Shankar[1], J. Hunter[1], S. Maljevic[2], A. Siegel[1], L. Olson[2], B. Weissman[2], P. Holt[2], H. Lerche[2], A. Escayg[1].* 1) Dept. of Human Genetics, Emory University, Atlanta, GA; 2) Departments of Neurology and Applied Physiology, University of Ulm.

Benign familial neonatal convulsions (BFNC) is a rare autosomal dominant epileptic disorder that results from mutations in two voltage-gated potassium channels, *KCNQ2* and *KCNQ3*. Two BFNC families were identified at the Emory University Epilepsy Clinic. Mutation screening of *KCNQ2* and *KCNQ3* was performed in order to identify the disease-causing mutations. In each family, a novel heterozygous single base substitution was found in the coding region of *KCNQ2*. In Family 1, the nucleotide substitution C740A was identified in the five affected family members. This substitution results in the truncating mutation S247X, which generates a protein that is 37% shorter at the C-terminal end. In Family 2 the nucleotide substitution C365T, leading to the amino acid substitution S122L, was detected in the three affected members. S122L was not observed in 800 control chromosomes. The S122L mutation was functionally expressed in *Xenopus* oocytes and analyzed using the two-microelectrode voltage clamp. Comparison of the biophysical properties of the mutant channel with wildtype *KCNQ2* revealed a 10 mV depolarizing shift in the voltage dependence of activation, as well as slowing of activation upon depolarization. Co-expression of the S122L mutant with *KCNQ3* yielded currents with about 10-fold increased current amplitudes, consistent with functional *KCNQ2*/*KCNQ3* heteromers. In comparison to wildtype channels, these currents were characterized by a 5 mV shift of voltage-dependent activation and slowing of activation upon depolarization. These results demonstrate the significance of the S2 segment in the function of *KCNQ2* channels and suggest that the seizures in Family 2 arise from a reduction in the potassium currents that regulate membrane potential at the sub-threshold range.

MED25 transcription activator is mutated in CMT2B2, carries a SH3 recognition motif and is coordinately expressed with Pmp22 in CMT1A animal models. *B. Rautenstrauss[1], A. Leal[1, 2], K. Huehne[1], H. Sticht[3], F. Bauer[3], P. Berger[4], U. Suter[4], G. Del Valle[2], R. Barrantes[2], M. Saifi[5], J. Lupski[5], B. Neundoerfer[6], M. Meisterernst[7], M. Berghoff[8], C. Berghoff[8], D. Heuss[6], M. Sereda[9], G. Zu Horste[9], K. Nave[9], A. Reis[1].* 1) Institut of Human Genetics, Erlangen, Germany; 2) School of Biology and INISA,San Jose, Costa Rica; 3) Institute of Biochemistry, Erlangen, Germany; 4) Institute of Cell Biology, ETH Zurich, Switzerland; 5) Baylor College of Medicine, Houston TX, USA; 6) Department of Neurology, Erlangen, Germany; 7) GSF, Munich, Germany; 8) Department of Neurology, Muenster, Germany; 9) MPI of Experimental Medicine, Göttingen, Germany.

We identified an A335V mutation in the MED25 (ARC92/ACID1) gene in an extended Costa Rican family with autosomal recessively inherited Charcot-Marie-Tooth (CMT) neuropathy linked to the CMT2B2 locus in chromosome 19q13.3. MED25, also known as ARC92 and ACID1, is a subunit of the human activator-recruited cofactor (ARC), a family of large transcriptional coactivator complexes related to the yeast Mediator. MED25 was identified by virtue of functional association with the activator domains of multiple cellular and viral transcriptional activators. Its exact physiological function in transcriptional regulation remains obscure. The A335V missense amino acid substitution is located in a proline rich region with high affinity for SH3 domains of the Abelson type and represents a novel transcription activation site. The mutation causes a decrease in binding specificity leading to the recognition of a broader range of SH3 domain proteins. Furthermore, Med25 expression correlates with Pmp22 gene dosage and expression in transgenic mice and rats. Progesterone increases MED25 expression coordinatively with Pmp22. After permanent sciatic nerve transsection, without allowing nerve regeneration, Pmp22 transcript levels were strongly reduced while Med25 expression was only moderately decreased. These results establish the molecular etiology of CMT2B2 and suggest a potential, more general role of MED25 in gene dosage sensitive peripheral neuropathy pathogenesis.

CRYAB Mutation Causes Autosomal Dominant Posterior Polar Cataract in a Chinese Family. *M. Liu[1], T. Ke[1], Z. Wang[2], Q. Yang[1], Q. Wang[1,3].* 1) Human Genome Research Center, Wuhan, Hubei, China; 2) People's hospital of Linyi, Shangdong, China; 3) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation,Cleveland,Ohio,USA.

Congenital cataract is a leading visual disease, and is responsible for approximately one third of blindness in infants. Inherited isolated (nonsyndromic) cataract represents a significant proportion of cataracts. Six different crystalline genes, including CRYAB that encode alpha-B (aB)-crystallin, have been identified as the causes of autosomal dominant cataract. To date, only one mutation (450delA) in CRYAB has been identified in one cataract family from U.K., and one other mutation (R120G) was identified in a French family with desmin-related myopathy. In this study, we studied a four generation Chinese family with non-syndromic posterior polar cataract. A genome-wide scan and haplotype analysis mapped the disease gene to chromosome 11q22-22.3 with a maximum LOD score of 3.85, where CRYAB is located. SSCP and directly DNA sequence analysis of the complete coding region and exon-intron boundaries of CRYAB revealed a heterozygous CT transition at nucleotide 58, resulting in a novel c.58 CT (p. Pro20Ser) mutation. The p.Pro20Ser mutation co-segregated with all affected individuals, and was not present in unaffected members in the family and 200 normal controls. The mutation occurs at the evolutionally conserved residue Pro20 in the crystallin_N region of CRYAB. Our study identifies the second mutation in CRYAB associated with congenital isolated cataract, and demonstrates that the mutations in CRYAB cause isolated congenital posterior polar cataract.

Novel DSPP Mutation Causes dentinogenesis imperfecta type II. *X. Zhang[1], L. Chen[2], M. Liu[1], Q. Wang[1,3].* 1) Center for Human Genome Research, Huazhong University of Science and Technology,P.R.China; 2) Department of Bioenjineering, Henan Urban College of Engineering, P. R. China; 3) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation Cleveland ,Ohio 44115,USA.

Hereditary defects of tooth dentin are classified into two main groups: dentin dysplasia (DD) (types I and II) and dentinogenesis imperfecta (DGI) (types I, II, and III). Type II DGI is one of the most common tooth defects with an autosomal dominant mode of inheritance, and one disease-causing gene, the dentin sialophosphoprotein (DSPP) gene, has been reported. To date, only 8 mutations have been reported in DSPP. In this study, we characterized a four-generation Chinese family with type II DGI that consists of 31 living family members, including 12 affected individuals. Linkage analysis with polymorphic marker D4S1534, 2.3 Mb from DSPP, showed complete linkage with the disease. Direct DNA sequence analysis identified a novel mutation (c.49CT, p.Pro17Ser) in exon 1 of the DSPP gene. The mutation was identified in all affected individuals, but not with normal family members and 100 controls. These results suggest that p.Pro17Ser causes DGI in the Chinese family. Interestingly, a different mutation, p.Pro17Thr, was previously identified at codon 17 in another Chinese family with type II DGI. All carriers with mutation p.Pro17Thr were associated with progressive high frequency hearing loss, however, carriers with p.Pro17Ser have normal hearing. This study identifies a novel mutation in the DSPP gene, and expands the spectrum of mutations that causes DGI.

A new locus for autosomal dominant amelogenesis imperfecta. *G.A. Mendoza[1], T.J. Pemberton[1], M. Karaman[1], C. Gonzalez[1], V. Ninis[2], R. Scarel-Caminaga[3], J. Haartiala[1], K. Lee[4], S. Leal[4], M.L. Snead[5], J. Hacia[1], H. Allayee[1], S.R.P. Line[6], P.I. Patel[1,5].* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Department of Neurology, Baylor College of Medicine, Houston, TX; 3) Faculty of Odontology of Araraquara-UNESP, Brazil; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA; 6) Faculty of Odontology of Piracicaba-UNICAMP, Brazil.

Amelogenesis imperfecta (AI) is a collective term used to describe phenotypically diverse forms of defective tooth enamel development. Its prevalence varies between populations with it being common in Sweden where 1 in 700 are affected but less common in the United States where 1 in 14,000 are affected. AI has been reported to exhibit a variety of inheritance patterns and several loci have been identified that are associated with AI. To date, X-linked dominant AI has been associated with the amelogenin locus on Xq22.3, while autosomal dominant AI has been associated with the enamelin gene at 4q21 and the distal-less homeobox 3 gene at 17q21, and autosomal recessive AI has been associated with the kallikrein gene at 19q13.4. We have mapped a novel locus underlying AI to a region on the long arm of chromosome 8 by linkage analysis in a large Brazilian family segregating an autosomal dominant form of AI. Due to the large size of the region identified and limited meioses available, conventional fine mapping techniques to refine the critical interval were not possible. To identify positional candidate genes, we have performed microarray analysis of gene expression during molar tooth development in the mouse between post-natal days 1 through 10. These developmental stages encompass those where enamel is formed, thereby allowing the identification of candidate genes within our region of interest. Conventional fine mapping techniques can now be employed to analyze these candidate genes and identify the mutation causing AI in this family. (Supported by NIH grant DE014102).

CDKL5 and the early onset seizure variant of Rett syndrome: clinical and molecular characterization. *C. Pescucci[1], F. Mari[1], S. Azimonti[2], R. Caselli[1], E. Scala[1], I. Longo[1], F. Ariani[1], V. Broccoli[3], F. Bolognese[2], I. Bertani[2], P. Balestri[4], M. Zappella[5], C. Kilstrup-Nielsen[2], N. Landsberger[2], A. Renieri[1].* 1) Medical Genetics, Siena, Italy; 2) Structural and Functional Biology, Busto Arsizio, Italy; 3) DIBIT, Milan, Italy; 4) Pediatrics, Siena, Italy; 5) Child Neuropsychiatry, Siena, Italy.

MECP2 is responsible for both classic and preserved speech variant of Rett syndrome (RTT). We report here the identification of mutations in the CDKL5 gene, encoding a putative kinase, in 4 RTT female patients: 2 early truncating mutations interrupting the catalytic domain (c.163_166del4; c.838_847del10) and 2 late truncating mutations (c.2635_2636del2, c.2343delG). The clinical course of patients is strikingly similar: they had seizures in the first months of life and subsequently developed recognizable RTT features. Two of them showed convulsions in the first days of life, the third at 1,5 months and the fourth at 6 months. Later on, they all had stereotypic hand activities, hand apraxia and the older patient (9 years) showed acquired microcephaly. RTT features were more evident in the older patients, in whom a clinical diagnosis of early onset seizure variant of RTT was promptly suspected. In the younger patient (2 years) the phenotype was less characteristic and clinical features were intermediate between early onset seizure variant of RTT and autism. We demonstrate that CDKL5 is a nuclear factor whose expression in the brain of developing mice significantly overlaps that of MeCP2. Moreover, we show in vitro and in vivo a direct interaction between MeCP2 and CDKL5. Functional characterization of CDKL5 showed that CDKL5 harbors an autophosphorylation activity, demonstrating that indeed it is a kinase. Furthermore we were able to demonstrate that CDKL5 mediates MeCP2 phosphorylation. In conclusion, our results contribute to the clarification of the phenotype associated with CDKL5 mutations and trace out a molecular link between MeCP2 and CDKL5. Further studies are necessary to firmly establish whether MeCP2 is the main target of CDKL5 in vivo and whether the biological significance of the interaction is limited to phosphorylation.

Identification and functional analysis of the mouse homologue of the D4Z4 repeat that is mutated in facioscapulohumeral muscular dystrophy. *J.E. Hewitt, L. Mitchell, P.J. Scotting, J. Clapp.* Inst Genetics, Queens Med Ctr, Univ Nottingham, Nottingham, United Kingdom.

Facioscapulohumeral muscular dystrophy (FSHD) is caused by a unique genetic rearrangement close to the telomere of human chromosome 4q. The disease is causally associated with deletions within a tandem DNA repeat (D4Z4). Initially, because of homeobox sequences within D4Z4, it was thought that the mutation might alter a protein product encoded by the repeat. However, although cDNAs and RT-PCR products containing closely related sequences have been identified, none of these originate from D4Z4. An alternative mechanism is that the deletion alters the local chromatin environment, resulting in a position effect on one or more nearby genes. Although changes in 4q35 gene expression levels in FSHD muscle have been reported, these findings remain controversial. It is apparent that the function of D4Z4 and its role in FSHD remains to be defined. In light of this, we have returned to study the evolution of D4Z4 as this may shed further light on its function. Although DNA hybridization techniques have previously identified D4Z4 homologues only in primates, here we show that the mouse genome also contains sequences homologous to D4Z4. These are arranged in a large (100-200kb) tandem array, with each 5kb repeat unit having an open reading frame containing two homeobox sequences. The rat genome contains an orthologous array at the equivalent genome location. Phylogenetic analysis indicates that human and mouse D4Z4 homeodomains are more closely related to each other than to other homeodomains. By RT-PCR and in situ hybridisation we have shown that the mouse array (mD4Z4) is transcribed in a wide range of embryonic and adult tissues, including skeletal muscle. Transfection of epitope-tagged mD4Z4 into C2C12 cells shows the protein to localise to the nucleus. This is the first time that any D4Z4 homologous sequence, apart from very closely related primate species, has been identified and suggests that the hypothesis that the human D4Z4 repeat encodes a protein should be revisited.

Identification of Novel Mutations in the SOX2 Gene in Patients With Microphthalmia/Anophthalmia. *T. Young[1,2], J. Zhou[1,2], T. Bardakjian[3], F. Kherani[1], J. Katowitz[1], N. Hughes[2], L. Schimmenti[4], A. Schneider[3].* 1) Division of Ophthalmology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Genetics, Albert Einstein Medical Center, Philadelphia PA; 4) Division of Genetics, University of Minnesota, Minneapolis MN.

The SOX2 gene, located at chromosome 3q27-q28, encodes a Sry-related transcription factor containing an HMG (high-mobility-group) DNA-binding domain and plays a key role in cell fate determination. Mutations of the SOX2 gene have been reported in 13 sporadic cases of patients with anophthalmia or microphthalmia. In this study, a set of 31 anophthalmic/microphthalmic patient DNA samples were screened for sequence changes by gel shifts in the SOX2 gene initially by conformation-sensitive gel electrophoresis. Abnormal amplicon patterns were subsequently screened by direct sequencing. Two novel heterozygous mutations were identified in two patient samples. The first sequence alteration was a single nucleotide mutation G737T located in the HMG DNA binding domain. The mutation changes the codon from glutamic acid (GAG) to a stop codon (UAG). The predicted product would produce a truncated protein and disable the DNA binding function. The second mutation was a single nucleotide deletion-C976del in the activation domain, resulting in a frameshift with premature termination of the coding sequence. However, the truncated protein would most likely be destroyed by non-sense mediated decay. Both mutations strongly suggest loss of function. In addition, 3 single nucleotide polymorphisms (SNPs), G1603A, C2050A, and G2138A, were identified in the 3-untranslated region in 3 other patients. The C2050A SNP (rs11915160) has been reported previously in normal individuals. The relationship between the remaining two SNPs and anophthalmia/microphthalmia is indeterminate. These results support the role of SOX2 in ocular development, and provide evidence that SOX2 loss of function mutations result in severe eye malformations.

Genetic analysis of congenital generalized lipodystrophy type 2 in Chinese. *YJ. Lee, CY. Huang, SP. Lin, CL. Lin, HF. Liu, CD. Tsai, HJ. Li.* Dept Pediatrics & Medical Res, Mackay Memorial Hosp, Taipei, Taiwan.

Congenital generalized lipodystrophy (CGL) was originally described by Berardinelli and Seip. It is a rare autosomal recessive disorder and characterized by a near total lack of adipose tissue from early infancy, acanthosis nigricans with severe insulin resistance, hypertriglyceridemia, and hepatomegaly with fatty change. Early childhood is marked by accelerated linear growth, an advanced bone age, and a voracious appetite. Later in childhood, marked acanthosis nigricans usually develops in the neck, axilla, groin, and trunk. Clinically it is classified into two types. The patients with CGL type 2 often have mental retardation, whereas those with CGL type 1 rarely show intellectual impairment. The mutations of the AGPAT2 and Seipin genes have been detected in CGL type 1 and type 2, respectively. **Patients and healthy adult controls:** Three pediatric patients with typical clinical manifestations of CGL and mental retardation and their families as well as 50 normal adults were recruited. The parents denied consanguinity. The study was approved by the IRB of the hospital and all subjects gave informed consents. **Methods:** Genomic DNA was extracted by the standard method. Primers to amplify the exons of the Seipin gene including exon-intron junctions were designed by using PrimerQuest. The entire coding regions of the gene were sequenced and homology search was done by using BLAST. **Results:** Two mutations were detected. Mutation nt890insCCG was in exon 5 and caused a change of amino acid and an insertion of an additional amino acid (Glu182Asp;182insArg). The other mutation nt1127insG was in exon 7 and caused a change of amino acid and a frameshift which resulted in a premature termination of translation and a truncated protein (Ile262His fsX273). The patients were homozygous and the parents were heterozygous. None of the mutations were detected in normal controls. We searched Human Gene Mutation Database and NCBI and confirmed that the two mutations were novel. **Conclusion:** Mutations of the Seipin gene in Chinese are different from those reported in Caucasians and Japanese. More extensive analysis in a larger dataset is necessary to detect similar mutations.

Identification of novel Edar and Edaradd gene mutations and their impact on NF-kB activation in anhidrotic ectodermal dysplasia. *C. Cluzeau[1], S. Hadj-rabia[2], H. Turki[3], C. Bodemer[2], JP. Bonnefont[1], A. Munnich[1], A. Smahi[1].*
1) Departement de Génétique, U393 INSERM, 75015 Paris, France; 2) Service de Dermatologie, Groupe Hospitalier Necker-Enfants Malades, Paris, France; 3) Service de dermatologie, CHU Hedi-Chaker, 3029 Sfax, Tunisie.

Anhidrotic ectodermal dysplasia (EDA) is a disorder of ectodermal differentiation characterized by sparse hair, abnormal or missing teeth and inability to sweat. X-linked EDA is the most common form, caused by mutations in ectodysplasin, a member of the TNF family. Autosomal dominant and recessive forms of EDA, indistinguishable from the X-linked form, have been also described. Two different disease genes, EDA-2 or EDA-3, have been identified. Mutations in EDA-3 encoding EDAR, a TNF receptor, result in either dominant or recessive forms. In addition, mutations in a recently identified gene, EDA-2 encoding EDARADD (for Edar-Associated Death Domain) have also been shown to cause recessive EDA. We performed genetic analysis in two unrelated consanguineous families with autosomal recessive EDA. In family 1 originating from Tunisia, we found linkage at the EDA-2 locus and identified a deletion of exon 4 in EDA-2, which likely results from mis-appariement of repeated sequences flanking exon 4. The resulted protein is about 50 amino-acid long and lacks the death domain (DD) which is involved in interaction between Edar and Edaradd via their respective DD, and in homodimerization of Edaradd molecules. We showed that Edaradd mutant lacking the DD is unable to activate an NF-kB-driven luciferase reporter construct. In family 2, originating from Koweit, linkage was found at the EDA-3 locus. Screening of 12 exons of the gene revealed a mutation (1207, C to T) which changed threonine into a methionine at amino acid 403 of the Edar protein. We demonstrated that the T403M mutation observed in Edar receptor DD severely impairs NF-kB activation. The exon 4 deletion in the Edaradd gene and the T403M Edar mutation impaired NF-kB activation and probably resulted in abnormal differentiation of skin appendages responsible for EDA phenotypes in our families.

Caspase-1-mediated cleavage of pyrin, the familial Mediterranean fever protein, activates NF-B. *J. Chae[1], K. Richard[1], G. Wood[1], H. Jaffe[2], D. Gumucio[3], N. Shoham[1], D. Kastner[1].* 1) Genetics and Genomics Branch, NIAMS/NIH, Bethesda, MD; 2) Protein/Peptide Sequencing Facility, NINDS/NIH, Bethesda, MD; 3) Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI.

Autoinflammatory diseases such as familial Mediterranean fever (FMF) represent inherited disorders of innate immunity, and are characterized by seemingly unprovoked fevers and serosal, synovial, or cutaneous inflammation. FMF is caused by recessive mutations in MEFV, encoding a 781-amino acid (aa) protein denoted pyrin. Carrier frequencies as high as 1:3 have been observed in the Middle East. The N-terminal 92 aa of pyrin define a death domain-like motif, PYD (PAAD, DAPIN), that mediates cognate interactions with the adaptor protein ASC, thereby regulating caspase-1 and IL-1 activation. However, most FMF mutations are in the C-terminal B30.2 domain, the function of which is unknown. . Here we demonstrate that pyrin can regulate caspase-1 by direct interaction through the catalytic domains of caspase-1 and B30.2 domain of pyrin, where most of the major FMF mutations are present. The binding affinity of caspase-1 is decreased with the three major pyrin mutants in comparison with normal pyrin. Moreover, caspase-1 cleaves pyrin at Asp330, producing an N-terminal fragment that translocates to the nucleus. The N-terminal fragment also interacts with IB- which is associated with degradation of IB- and NF-B activation. B30.2 mutants undergo increased caspase-1-mediated cleavage, relative to wild type. Moreover, absolute and relative quantities of cleaved pyrin are substantially increased in leukocytes from FMF patients compared with healthy controls, and the relative amount of cleaved N-terminal fragment is correlated with the degradation of IB-. These data identify a new pyrin/caspase-1 pathway for NF-B activation, and suggest a molecular basis for selection of pyrin mutants in man.

Genetic susceptibility to neonatal-onset multisystem inflammatory disease (NOMID/CINCA): novel *CIAS1* mutations and genomic strategies to resolve locus heterogeneity. *I. Aksentijevich[1], J. Balow Jr.[1], J. Jones[2], N. Dailey[2], S. Canna[2], E.F. Remmers[1], R. Goldbach-Mansky[2], D.L. Kastner[1].* 1) Genetics & Genomics Branch, NIH/NIAMS, Bethesda, MD; 2) Office of Clinical Director, NIAMS/NIH, Bethesda, MD.

Neonatal-onset multisystem inflammatory disease (NOMID/CINCA) is a rare autoinflammatory disease characterized by fever, chronic meningitis, uveitis, sensorineural hearing loss, urticarial rash, and a characteristic deforming arthropathy. NOMID is caused by missense mutations in *CIAS1* (also known as NALP3, PYPAF1) that encodes cryopyrin. NOMID is allelic with Muckle-Wells syndrome (MWS) and familial cold autoinflammatory syndrome (FCAS), two dominantly inherited disorders with some similarities to NOMID. Currently, over 35 disease-associated mutations have been found and all are clustered in the NACHT domain of the protein. We previously reported 6 mutations in 13 NOMID cases. Subsequently, we analyzed 23 new patients and collected PBMC from 17 patients for gene expression studies. In 6 patients we identified new missense changes: V262A, L264F, V351L, G326E, F443L, and F523C, while 8 patients carried previously described mutations. Thus, including our previous report we evaluated 36 NOMID patients and we found mutations in 20/36. There was no clinical difference between mutation positive and negative patients and they both responded dramatically to anakinra treatment. We used Affymetrix U133A microarrays to identify disease-specific gene expression profiles in PBMC of 17 NOMID patients at baseline and during their treatment with the IL-1RN (anakinra). 14 samples were paired; therefore we carried out both paired and unpaired t-test analysis. Among the genes that are at least 2 fold up-regulated in patients prior to treatment at a significance level of p 0.01 are several cytokines, cytokine receptors (including IL-1RN), genes that are involved in the immune response, regulation of apoptosis, and cell adhesion. We identified *CIAS1* as 2.6 fold up-regulated in NOMID patients during inflammation. Through these studies we hope to uncover novel candidate genes for the screening of *CIAS1* mutation negative patients.

Genetic mapping of autosomal dominant ocular coloboma. *S. Duan, L. Wang, Y. Zhao, Z. Yang, K. Zhang.*
Ophthalmology, University of Utah, Salt Lake City, UT, 84112.

Purpose: Ocular coloboma is a congenital abnormality caused by defective closure of the embryonic fissure of the optic cup. The defect is typically located in the lower part of the eye. Iris, ciliary body, choroids, retina and optic nerve can be affected. The purpose of this study is to identify a locus responsible for ocular coloboma in a Chinese family. Methods: A large Chinese family with an autosomal dominant form of ocular coloboma was investigated. No other systemic malformations were observed. Genotyping with STR markers linked to known loci/genes associated ocular coloboma was performed. Candidate loci included VAX2,SHH,PAX2,VAX1,PAX6,CHX10 on the regions of chromosomes 2, 7, 10, 11, 12, and 14 respectively. Results: There were nine affected individuals spanning three generations. Affected individuals presented with iris, retina, choroids, and optic nerve coloboma. Central vision was affected in two patients. No other systemic malformations were observed. Linkage to candidate loci VAX2,SHH,PAX2,VAX1,PAX6,CHX10 were excluded. Conclusions: Our results suggested a novel locus related to ocular coloboma. Genome wide scan is in progress to map this disease gene. Idnetification of a gene for ocular coloboma may provide valuable insight into ocular development.

Genetic study of a large Chinese amyotrophic lateral sclerosis family. *Y.Q. Song[1, 2], W.L. Ho[3], H.H. Kwok[3], C.Y. Chu[3], Y. Li[1], S.L. Ho[3].* 1) Dept Biochemisty, Univ Hong Kong, Hong Kong, China; 2) Genome Research Centrre, Univ Hong Kong, Hong Kong, China; 3) Dept Medicin,Univ Hong Kong, Hong Kong, China.

Amyotrophic lateral sclerosis (ALS) is a lethal neurodegenerative disorder arising from the progressive death of motor neurons in the cortex, brain stem, and spinal cord, and resulting in muscle weakness, wasting, and respiratory paralysis and the life expectancy is about 3 to 5 years after symptom-onset. About 10 % of cases are familial (FALS), but there are several subtypes with different modes of inheritance and different clinical features. We have recently identified a large multigenerational Chinese family in Hong Kong with autosomal dominant ALS. This family displayed typical ALS, with onset in the 30s to 40s of mixed upper and lower motor neuron degeneration, bulbar dysfunction and rapid progression to respiratory failure. However, some members had a more slowly progressive, predominantly lower motor neuron lesion in the lower limbs, with relatively sparing of the upper limbs. So far, we have documented over 130 members and collected 70 DNA in this four-generation family. We have screened all five exons of the SOD1 gene for mutations using both single-strand conformational polymorphism (SSCP) and direct nucleotide sequencing methods. A mutation of T/C transition, at codon 151 in exon 5 was identified. This mutation results in the substitution of an isoleucine for a theronine, and is thought to affect the formation of dimers in SOD1. Moreover, As the different branches showed different severity of the phenotypes, a modifier or modifiers may exist in this family. We are now sequencing the known MND modifier genes (ie, VEGF and CTNF). At the same time, we have done a genome wide screen using the Illumina 5,900 SNP panel. The data is being analyzed and we will report our results during the meeting.

Atypical Presentations of Hereditary Lymphedema Type I Associated with Mutations in *Vascular Endothelial Growth Factor Receptor 3*. *A. Ghalamkarpour[1], A. Raas-Rothschild[2], R. Spiegel[3], A. Utkus[4], S.A. Shalev[3], L.M. Boon[1,5], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute and University of Louvain Medical School, Brussels, Belgium; 2) Department of Human Genetics, Hadassah Hebrew University Hospital, Jerusalem, Israel; 3) Genetics Institute, HaEmek Medical Center, Afula, Israel; 4) Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania; 5) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires Saint-Luc, Brussels, Belgium.

Genetic studies have identified mutations in the *vascular endothelial growth factor receptor 3* gene, *VEGFR3/FLT4*, in some families with hereditary lymphedema type I (Milroy disease; MIM 153100). Individuals carrying a *VEGFR3* mutation exhibit congenital edema in the lower limbs, usually bilaterally and below the knees, sometimes associated with cellulitis, prominent veins, papillomatosis, upturned toenails, and hydrocele. In this study, we present clinical variability in four families in which we identified a *VEGFR3* mutation. The clinical findings in two families varied from spontaneous resorption of the edema to elephantiasis. The index case in the third family was discovered to have polyhydramnios, massive bilateral hydrothorax, skin edema, scalp edema and minimal ascites at 33 weeks of gestations. The index case in the fourth family presented prenatally with bilateral leg edema, bilateral hydrothorax and lung hypoplasia at 22 weeks of gestation. The association of prenatal pleural effusion and hydrops fetalis with a *VEGFR3* mutation has not been described earlier. Therefore, mutations in *VEGFR3*, similar to the mutations in the two other lymphedema associated genes, i.e. *FOXC2* and *SOX18*, can cause hydrops fetalis. These results are consistent with animal models with a *Vegfr3* mutation (chy mouse) presenting edema elsewhere than the limbs (chylous ascites). We conclude that the phenotypic spectrum of hereditary lymphedema type I associated with a *VEGFR3* mutation is much wider than previously appreciated. Molecular Chaperones in Gaucher disease. *D. Urban[1, 2], O. Goker-Alpan[1, 2], B.K. Stubblefield[1, 2], E. Sidransky[1, 2].*
1) NSB/NIMH, NIH, Bethesda, MD; 2) MGB/NHGRI, NIH, Bethesda, MD.

Protein folding is crucial not only for generating biologically active proteins, but also for maintaining many vital intra-cellular processes, such as trafficking. It depends on many factors such as pH, temperature and protein quality control systems within the cell. During cellular stress, molecular chaperones are activated to ensure folding and prevent protein aggregation. In Gaucher disease, the inherited deficiency of the lysosomal enzyme glucocerebrosidase, most mutations are missense, and are expected to result in the synthesis of an unstable protein. We investigated protein folding and the effects of quality control systems in fibroblasts from patients with Gaucher disease. As mutant proteins refold at lower temperatures without the need of chaperones, cell lines with different Gaucher genotypes were grown at 37C and 30C to test the stability of mutant glucocerebrosidase. In most, mutant glucocerebrosidase was misrouted to early endosomes at 37C. At 30 C, trafficking appeared to be corrected and the residual enzyme activity and steady-state protein levels were increased, especially in cell lines carrying mutation L444P. These findings suggest that mutant glucocerebrosidase is misfolded. The molecular chaperones HSP-90, 70 and 60 were examined in fibroblasts from patients with Gaucher disease, and the steady state HSP levels were followed at the different temperatures. HSP90, a chaperone that prevents aggregation, was decreased in most of the cell lines. The mitochondrial chaperone HSP-60 also showed some variation, but HSP-70 levels remained constant. Since HSP-90 deficiency results in proteosomal dysfunction, mutations in glucocerebrosidase may lead to both aggregation and decreased degradation and clearance by interfering with the ubiquitin-proteosome system. Molecular chaperones may act as genetic modifiers in Gaucher disease and contribute to atypical phenotypes, such as parkinsonism, that are related to protein misfolding and aggregation.

Fabry disease: Identification of 48 novel -galactosidase A mutations and 3-D structural analysis of 29 missense mutations. *J. Shabbeer[1], M. Yasuda[1], S.D. Benson[2], R.J. Desnick[1].* 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Dept Chemistry, Oklahoma State University, Stillwater, OK.

Fabry disease, an X-linked recessive inborn error of glycosphingolipid catabolism, results from the deficient activity of the lysosomal exoglycohydrolase, -galactosidase A (EC 3.2.1.22; -Gal A). The molecular lesions in the -Gal A gene causing the classic phenotype of Fabry disease in 64 unrelated families were determined. In 47 families, 48 new mutations were identified, including: 29 missense (N34K, T41I, D93V, R112S, L166G, G171D, M187T, S201Y, S201F, D234E, W236R, D264Y, M267R, V269M, G271S, G271V, S276G, Q283P, A285P, A285D, M290I, P293T, Q312H, Q321R, G328V, E338K, A348P, E358A, Q386P), eight nonsense (C56X, E79X, K127X, Y151X, Y173X, L177X, Q306X, E338X), five splicing defects (IVS4-1G>A, IVS5-2A>G, IVS5+3A>G, IVS5+4A>G, IVS6-1G>C), four small deletions (18delA, 457delGAC, 567delG, 1096delACCAT), one 3.1 kb Alu-Alu deletion which included exon 2, and one complex mutation (K374R, 1124delGAG). In 18 families, 17 previously reported mutations were identified, with R112C occurring in two families. Two classically affected males had -Gal A alleles with two mutations, D264Y/V269M and A143T/Q312H. Transient expression of the individual mutations revealed that D264Y and Q312H were localized in the ER and had no detectable or markedly reduced activity, whereas V269M and A143T were localized in lysosomes and had ~10% and ~35% of expressed wild-type activity, respectively. Structural analyses based on the enzymes 3-D structure predicted the effect of the 29 novel missense mutations on the mutant proteins structure. Of note, three (~10%) were predicted not to alter the enzyme's structure, but were disease causing, indicating the limitation of structure function predictions. These studies further define the molecular heterogeneity of the -Gal A mutations in classical Fabry disease, and provide insights into the structural enzyme alterations that cause the classic phenotype.

Nonsense and frameshift ESCO2 mutations in Roberts syndrome and SC phocomelia. *B. Schuele[1], K. Johnston[2], U. Francke[1].* 1) Department of Genetics, Stanford University, Stanford CA; 2) Department of Genetics, Kaiser Permanente, San Francisco CA.

Roberts syndrome (RBS, MIM# 268300) is a rare AR disorder characterized by craniofacial anomalies, microcephaly, mental deficiency, profound growth deficiency, and tetraphocomelia. SC phocomelia syndrome (MIM# 269000) has a milder phenotype with a lesser degree of limb reduction. Since repulsion of heterochromatin regions (PCD) is characteristic for both disorders and complementation studies placed both into the same group, it is likely that the disorders are allelic. Recently, mutations in the ESCO2 gene on 8q21.1 have been reported in 15 families with RBS (Vega et al., Nat Genet 37:468, 2005). The yeast homolog Eco1 is required for the establishment of sister chromatid cohesion during S phase. We have studied 5 affected individuals from 4 families for mutations in ESCO2. PCD was documented in all affected individuals. Two of the families had previously been reported as SC phocomelia with a milder phenotype and survival into adulthood. In the other two families, severe limb and craniofacial abnormalities, detected by fetal ultrasound, led to a diagnosis of RBS and termination of pregnancy. PCR amplicons of all 10 coding exons, including the intron-exon boundaries, were sequenced bi-directionally. We identified six mutations in three compound heterozygotes in the non-consanguineous families and one homozygous deletion in a consanguineous family: two nonsense mutations Q202X (c.604 C>T) and W423X (c.1269 G>A), three frameshift mutations (c.752delA, c.751_752insA, c.307_311del AGAAA), and one mutation probably involved in splicing (c.1132 -7A>G). One of the frameshift mutations (c.752delA) was identified in two unrelated families. All mutations we detected are different from the 8 previously reported ones. These data provide proof that RBS and SC phocomelia are caused by mutations in the same gene. As inactivating nonsense and frameshift mutations were identified in mildly as well as severely affected individuals, no phenotype-genotype correlation could be made. To discover the modifying mechanisms which lead to the phenotypic variability will be an important future task.

Cryptic genomic imbalances as a cause of syndromic X-linked mental reatardation. *A.M. Vianna-Morgante[1], J. Knijnenburg[2], P.A. Otto[1], A.C. Krepischi-Santos[1], R.M.P. Nascimento[1], C. Rosenberg[1,2].* 1) Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, São Paulo, Brazil; 2) Laboratory of Cytochemistry and Cytometry, Department of Molecular Cell Biology, Leiden University Medical Center, Leiden, The Netherlands.

We used array-CGH with approximately 3500 large insert clones spaced at ~1 Mb intervals through the genome, constructed at the Leiden University Medical Center, to investigate DNA copy number changes in three unrelated mentally impaired Brazilian males, the probands from syndromic X-linked recessive mental retardation families (S-XLMR). Their karyotypes were normal and they tested negative for fragile X syndrome. The normal mothers of affected individuals had completely skewed X-inactivation as demonstrated by the methylation status of the AR locus. Two of these X-linked cases showed DNA copy number imbalances, respectively a duplication of one BAC clone at Xq28 (confirmed by MLPA in the propositus and in an affected maternal cousin), and a partial deletion of a single clone at Xp11.23 (confirmed by FISH in an obligate heterozygote). Since these inherited imbalances had not been previously reported or detected by us in more than 100 X-chromosome control observations, they were considered causative of S-XLMR. The imbalanced segments contained several genes. One of these genes may have a major effect, but the abnormal phenotypes may well represent contiguous gene disorders. We show here that genomic rearrangements producing DNA copy imbalances on the X-chromosome may segregate in families in a pattern similar to recessive gene mutations.

Deletion of FMR1 in Purkinje cells enhances parallel fiber LTD, enlarges spines, and attenuates eyelid conditioning in a manner which phenocopies human Fragile X syndrome. *B. Oostra[1], S. Koekkoek[2], K. Yamaguchi[3], R. Maex[4], M. Vellema[2], F. van der Werf[2], E. De Schutter[3], C. Bakker[1], R. Willemsen[1], D. Nelson[5], E. Mientjes[1], M. Ito[3], C. De Zeeuw[2].* 1) Dept Clin Genet, ErasmusMC, Rotterdam, Netherlands; 2) Dept Neuroscience, ErasmusMC, Rotterdam, Netherlands; 3) Lab for Memory and Learning and Lab for Behav Genet, Brain Sci Institute, RIKEN, Japan; 4) Lab Theor Neurobiol, Univ Antwerp, Belgium; 5) Dept of Mol and Hum Genet, Baylor College of Medicine, Houston, Texas.

Absence of functional FMRP causes fragile X syndrome. Before we have generated an *Fmr1* knockout mouse, in which FMRP is absent, and which shows behavioral and cognitive abnormalities comparable to the symptoms found in fragile X patients and several of them can be linked to a dysfunction of a particular brain region. Abnormalities in synaptic processes in the cerebral cortex and hippocampus contribute to cognitive deficits in fragile X patients. So far the potential roles of cerebellar deficits have not been investigated. Metabotropic GluR1-dependent LTD, which appears to require rapid translation of mRNA, can also be induced at the parallel fiber to Purkinje cell synapse in the cerebellum. To investigate the possibility that cerebellar deficits contribute to fragile X syndrome we tested cerebellar learning capabilities of global and Purkinje cell specific Fmr1 knockout mice as well as of fragile X patients using classical eyeblink conditioning procedures. We demonstrate that both global and Purkinje cell specific knockouts of Fmr1 show deficits in classical delay eyeblink conditioning in that the percentage of conditioned responses as well their peak amplitude and peak velocity are reduced. Purkinje cells of these mice show elongated spines and enhanced LTD induction at the parallel fiber synapses that innervate these spines. Moreover, fragile X patients display the same cerebellar deficits in eyeblink conditioning as the mutant mice. These data indicate that a lack of FMRP leads to cerebellar deficits at both the cellular and behavioral level and they raise the possibility that cerebellar dysfunctions can contribute to motor learning deficits in fragile X patients.

PLP2-deficient mice have increased sensitivity to ER stress and apoptosis. *L. Zhang[1], D. Valle[1,2].* 1) Inst. of Genet. Med., Johns Hopkins Univ; 2) Howard Hughes Med. Inst., Baltimore, MD.

Mental retardation (MR) is a common cause of handicap in children and young adults. Previously, we identified a functional promoter SNP (-113C>A) in the proteolipid protein 2 (PLP2) gene which abolishes the core-binding site of a neuronal transcription factor, ELK1, results in significant reduction (> 4-6 fold) of PLP2 mRNA and protein and is over-represented in males with X-linked MR, particularly those with mild cognitive impairment (relative risk = 2.5). To understand PLP2 function, we generated Plp2 null mice by gene targeting. PLP2 -/- and -/Y mice have normal viability and fertility and have no gross anatomical abnormalities. Since PLP2 has been shown to interact with BAP31, an ER protein involved in apoptosis, we examined programmed cell death in the Plp2 -/- and -/Y cells by culturing them in agents that stimulate specific apoptotic pathways: VP16 (intrinsic pathway), Fas ligand (extrinsic pathway), thapsigargin (ER stress), and tunicamycin (ER stress). Plp2-deficient cells are indistinguishable from control cells in their response to stimulation of the intrinsic and extrinsic pathways but showed increased sensitivity to ER stress. Thapsigargin (2uM) killed 3.5 fold more Plp2-deficient cells (54%) than the controls (12%); tunicamycin (2uM) killed 2.7 fold more Plp2-deficient cells (59%) than the controls (16%). In agreement with these results, stimulating ER stress in Plp2-deficient cells resulting in a higher level of the apoptotic markers (caspase 3 and its nuclear target, PARP; caspase 12, an ER stress-specific caspase and GRP78, an ER chaperone that is elevated during ER stress). Interestingly, we also found an elevated level of basal ER stress (increased caspase 12 and GRP78) in the Plp2-deficient cells grown under standard conditions. These results suggest that PLP2 deficiency is associated with an increased basal level of ER stress and an exaggerated apoptotic response to agents that induce apoptosis. We speculate that individuals with the PLP2 -113C>A SNP may also have increased sensitivity to ER stress, and that PLP2 could be a modifier gene for missense mutations in proteins that traverse the ER.

Inactivation of the *Drosophila* Neurotrypsin homolog results in long-term memory defect. *G. Didelot[1], F. Molinari[2], A. Munnich[2], T. Preat[1], L. Colleaux[2].* 1) DEPSN, CNRS, Gif-sur-Yvette, France; 2) INSERM U393, Hôpital Necker-Enfants Malades, Paris, France.

Neurotrypsin is a neuronal serine protease predominantly expressed in neurons of the cerebral cortex, the hippocampus and the amygdala. Truncating mutation of the human gene (PRSS12) causes autosomal recessive nonsyndromic mental retardation and several studies in mice suggested that this protein may be a regulator of adaptative synaptic functions. However, the precise function of neurotrypsin protein remains elusive.

To gain insight into the pathophysiological basis of cognitive impairment in patients with neurotrypsin mutation, we studied the Drosophila *tequila* gene, the drosophila ortholog of Neurotrypsin. Drosophila is indeed an attractive system to unravel molecular and cellular mechanism involved in associative learning and memory as it is easily amenable to genetics, biochemical, molecular and behavioural analyses. We first showed, by immunohistochemistry, that Tequila protein is preferentially expressed in the mushroom bodies (MBs), a prominent bilateral structure of the insect brain essential for learning and memory . We then constructed a *tequila* knock-down Drosophila line using RNA interference and designed to specifically inactivate *tequila* expression in the MBs.

Here we report results from the analysis of *tequila* "knock-down" flies and show that mushroom bodies organogenesis, learning and short-term memory (STM) were all normal. By contrast, long-term memory (LTM) is clearly defected in *tequila* "knock-down" flies compared to controls. Moreover, we observed that, in wild-type flies, LTM conditioning induces a transient increase of *tequila* expression.

These data strongly support that Drosophila is a suitable model for the studying the pathophysiological mechanism resulting from neurotrypsin mutation. In addition our results suggest that tequila, and therefore neurotrypsin, is likely involved in synaptic plasticity and that this protease may be a key player in the pathway underlying LTM formation.

Conditional knockout mouse model for the *Fxr2* gene. *S. Pataskar[1], B.A. Oostra[2], D. Nelson[1].* 1) Molecular & Human Genetics,Baylor College Of Medicine, Houston, TX, USA; 2) CBG Department Of Clinical Genetics, Erasmus University, Rotterdam,The Netherlands.

Fragile X syndrome is a common form of mental retardation caused by the absence of the *Fmr1* protein, FMRP (Fragile X Mental Retardation Protein). Two paralogs of FMRP have been identified , FXR1P and FXR2P (Fragile X Related Protein). All three proteins share highly conserved RNA binding domains, high sequence similarity and show overlap in their tissue distribution. FXR2P shows high expression in brain and testes similar to FMR1P. It is likely that FXR1P and FXR2P provide functional redundancy for FMR1P. This redundancy masks the phenotypic consequences of loss fucntion mutations in humans and mice. To unravel the biological mechanisms involved in the normal and abnormal functioning of FXR2P and FMR1P, we are developing knockout mice lacking each of the genes, and combinations, including mutations that can be conditionally expressed via the *Cre/loxP* system. To make a conditional mutation in mouse *Fxr2* gene, we have elected to construct a targeted allele with *loxP* sites flanking exon 7. This mutation should provide the capability to conditionally ablate the gene using tissue specific or time dependent expression of *Cre* recombinase. The mutant mice will be analysed by biochemical, histological and behavioral methods in order to determine the consequences of absence of *Fxr2* gene in specific tissues. A targeting construct has been introduced into mouse ES cells and homologous recombinations have been identified. *Cre* recombinase has been introduced and ES cell lines are being characterised for correct recombination. A conditional mutation in *Fxr2* will allow us to investigate tissue specific or developmental timing effect of gene ablation. Mutations in *Fxr2* gene especially in combination with *Fmr1* mutation should help to resolve the question of functional redundancy.

Identifying Proteins that modify the neurodegenerative phenotype of the Fragile X CGG90 repeats in Drosophila melanogaster. *O. Sofola, D. Nelson, J. Botas.* Human Genetics, Baylor College of Medicine, Houston, TX.

Fragile X Syndrome is the most common form of hereditary mental retardation. It is caused by a large expansion of the CGG trinucleotide repeat (>200 repeats) in the 5 untranslated region of FMR1 that leads to transcriptional silencing of the gene. Individuals with CGG repeat expansions between 60 and 200 are referred to as premutation carriers. These premutation carriers are able to transcribe FMR1 and hence are phenotypically normal with respect to the features of Fragile X syndrome. However, a neurodegenerative disorder has recently been described in premutation carriers. A transgenic fly model expressing the 5 UTR of the human FMR1 gene with CGG90 repeats was designed by Jin and colleagues to examine whether the premutation length repeat could cause neurodegeneration. The repeats are transcribed into RNA but are not translated into protein; flies expressing these CGG repeats display a disorganized eye phenotype, a characteristic marker of neurodegeneration in flies. Furthermore, the eye phenotype could be suppressed by over expressing hsp70, a chaperone involved in protein folding. These results suggested that transcription of the CGG90 repeats lead to an RNA mediated neurodegenerative disease, possibly via influencing RNA binding proteins. We are in the process of identifying potential RNA binding proteins using a genetic screen in CGG90 flies. This effort to define modifiers is being carried out using a set of candidate binding proteins and with an unbiased screen using ~450 fly strains deleted in different parts of their genome. The screen involved mating the CGG90 transgenic flies with other mutant flies that expressed either a reduced or an increased level of different proteins. The progeny were examined for potential suppression or enhancement of the disorganized eye phenotype seen in control CGG90 transgenic flies. Three deficiency stocks (7713, 7723, 7772) appear to suppress and two (7707, 7544) appear to enhance the CGG90 eye phenotype. At the moment, we are currently trying to narrow down which gene within the deleted region may be responsible for the modification of the eye phenotype and utilize other assays to confirm these modifiers.

Role of Dp71 in the stability of the dystrophin associated proteins complex in the nucleus of PC12 cells. *M. Villarreal Silva[1], R. Rodriguez Munoz[1], F. García Sierra[2], B. Cisneros[1].* 1) Genetics & Molecular Biology Department; 2) Cellular Biology Department, CINVESTAV-IPN, D.F, Mexico.

Dp71, the major product of DMD gene in brain, is the smallest isoforms of the DMD gene. Due to the presence of mental retardation in a third of the DMD patients, it is believed that Dp71 has an important neuronal function. We have reported that aminoacids codified by exon 78 determine the nuclear localization of Dp71d isoform in PC12 and HeLa cell lines. In addition, we have observed the existence of some dystrophin-associated proteins in the nuclei of HeLa cells, and their interaction with the nuclear matrix proteins lamin and actin, suggesting the presence of a new DAPC in this organelle. Based on the preceding information, we have adopted the PC12 cell line as neuronal model for studying the nuclear function of Dp71, due to their ability to differentiate into sympathetic-like neurons. In this study, we have analyzed the effect of Dp71 levels in the DAPs distribution in the nuclear matrix of a wild type clone and Dp71-antisense clones (ASC). Our results show that decreased levels of Dp71 affect the levels of -dystroglycan and - and -dystrobrevins in the nucleus and nuclear matrix of ASC. Surprisingly, lamin B1 is also affected by Dp71 deficiency. Our results suggest that Dp71 has a role in the nuclear organization of PC12 cells.

Increased glutamic acid decarboxylase expression in the fragile X mouse brain is independent of Fmrp expression. *W.T. Brown[1], A. El Idrissi[2], D. Ziemnicka[1], X.H. Ding[1], C. Dobkin[1].* 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) Center Developmental Neuroscience, College of Staten Island/CUNY, Staten Island, NY.

Increased seizure susceptibility is a feature of the mouse model for fragile X that has parallels in the hyperarousal and prevalence of seizures in the fragile X syndrome. Our investigation of the basis for the increased seizure susceptibility of the fragile X mouse indicated a reduction in GABAA receptor expression (El Idrissi et al. Decreased GABAA receptor expression in the seizure-prone fragile X mouse. Neuroscience Letters, 2005; 377:141-146). This receptor is a major component of the inhibitory (GABAergic) system and its reduced expression probably contributes to the increased seizure susceptibility observed in this mouse model for fragile X. We also found a potentially related alteration of the GABAergic system--increased expression of glutamic acid decarboxylase (GAD), the enzyme responsible for GABA synthesis. To investigate the intracellular dependence of GAD expression on Fmrp expression, we examined heterozygous female mice that expressed Fmrp and enhanced green fluorescent protein (EGFP) from one X chromosome and no Fmrp from the other X. Due to X inactivation only one chromosome is expressed in any somatic cell. Thus, these females were mosaic for Fmrp expression and cells expressing Fmrp were marked by EGFP. Analysis of the brains of these mice by immunostaining and confocal microscopy indicated that GAD expression was essentially uniform in these mosaic females. At the level of individual cells, GAD expression was independent of Fmrp. This was shown using monoclonal antibodies to the two isoforms, GAD-65 and GAD-67. Thus, the increased GAD observed in the fragile X mouse appears to be a compensatory response to other changes that are induced by the absence of Fmrp. The changes in the GABAergic system may be a factor in the seizure susceptibility of the fragile X mouse. Decreased inhibitory GABA system activity may also be relevant to the increased prevalence of childhood seizures and hyperactivity in the fragile X syndrome.

Cellular model of lysinuric protein intolerance. *M.P. Sperandeo[1,2], P. Annunziata[1], P. Piccolo[1], M. Brancaccio[1], G. Parenti[1], S. Fecarotta[1], E. Christensen[3], A. Pota[4], A. Pepe[1], G. Andria[1], G. Sebastio[1].* 1) Dept Pediatrics, Federico II University, Naples, Italy; 2) Dulbecco Telethon Institute, Telethon Foundation, Rome, Italy; 3) Metabolic Laboratory, Department of Clinical Genetics, The Juliane Marie Centre Rigshospitalet, Copenhagen, Denmark; 4) Nephrology Unit, Santobono Hospital, Naples, Italy.

Lysinuric protein intolerance (LPI; MIM 222700) is a congenital amino aciduria caused by a defective transport of cationic amino acids (CAA) at the basolateral membrane of the epithelial cells of intestine and kidney. Clinical manifestations include: vomiting, diarrhea, failure to thrive, visceromegaly, osteoporosis, episodes of coma, mental delay, and severe pulmonary and renal involvements. The molecular basis of LPI is a defective transport of CAA normally exerted by system y+L activity, which is induced by a heterodimer composed of: 4F2hc (gene SLC3A2) and y+LAT1 (gene SLC7A7). We isolated the SLC7A7 gene and characterized 21 causative mutations in LPI patients and identified two independent patients with severe tubular nephropathy. Urines from both patients were collected and cells were selectively grown in an appropriate medium to isolate those of renal tubular origin. CAA transport was tested in these cells and found to be defective as expected in LPI. This is the first LPI cellular model where the functional defect is demonstrated. To investigate the fate of the arginine entrapped intracellularly, the expressions of arginase and iNOS, two key-enzymes of the arginine intracellular metabolism, were studied by Real-Time PCR. The results showed increased expression of both enzymes indicating a constitutional activation of both the early and the late repair phase of the inflammatory response as seen in experimental glomerulonephritis. Interestingly, also the expression of SLC7A6 mRNA, another gene exerting a y+L transport activity at the basolateral membrane, was higher than controls. This might suggest an attempt to restore normal intracellular arginine levels. Acknowledgments: EUGINDAT EC FPVI (EC ref: LSHM-CT-2003-502852) to G. Sebastio and Telethon Foundation (Grant TCP99029) and Compagnia San Paolo to MP Sperandeo.

Establishment of mouse model for muscle AMP deaminase deficiency. *T. Morisaki[1,2], A. Dohi[1,2], E. Kimura[1], J. Cheng[1], M. Shirai[1], M. Okabe[3], H. Morisaki[1].* 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Mol Pathophysiol, Osaka U Grad Sch Pharm Sci, Suita, Osaka, Japan; 3) Dept Exp Genome Res, Genome Info Res Ctr, Osaka U, Suita, Osaka, Japan.

Muscle AMP deaminase (AMPD1) gene is expressed at high levels in skeletal muscle and this enzyme, AMPD, is thought to play an important role in energy metabolism. AMPD1 deficiency, which is one of the most common enzyme defects especially in Caucasian, has been reported to be associated with symptoms of a metabolic myopathy, though not all of individuals with this defect exhibit symptoms. To obtain information of AMPD1 functions in skeletal muscle, we generated knock out mice lacking the muscle isoform of AMPD. Homozygous AMPD1 KO mice showed normal growth and no obvious abnormality. The activity of AMP deaminase in homozygous AMPD1 KO mice was extremely low in skeletal muscle, and mRNA expression or protein expression of AMPD1 was not detected in skeletal muscle of these mice, while other tissues of these mice exhibited normal level of AMPD activity. In skeletal muscle of homozygous AMPD1 KO mice, no histological abnormality or other enzyme defect was found as in that of human individuals with AMPD1 deficiency. In addition, adenine nucleotide level and phosphorylated AMP-activated protein kinase (AMPK) was found to be elevated in skeletal muscle of homozygous AMPD1 KO mice. Based on these findings, AMPD1 KO mice are thought to be a good model for AMPD1 deficiency, and it is indicated that AMPD1 may play an important role for glucose and lipid metabolisms through AMPK pathway as well as nucleotide metabolism.

Rapid detection of prothrombotic genetic variations of Factor V (G1691A), Prothrombin (G20210A) and Methylenetetrahydrofolate Reductase (C677T) by multiplex single base primer extension and DHPLC. *G. Wu[1], J. Zhu[1], B.L. Wu[2, 3], B. Legendre Jr.[1], S.L. Lilleberg[1].* 1) Translational and Clinical Res, Transgenomic, Inc., Omaha, NE; 2) Department of Laboratory Medicine, Childrens Hospital Boston, Boston, Massachusetts; 3) Department of Pathology, Harvard Medical School, Boston, Massachusetts.

Three allelic sequence variations have been considered as risk factors of hereditary thrombolic disorders: factor V G1691A, prothrombin G20210A, and methylenetetrahydrofolate reductase C677T (MTHFR). We have developed a novel multiplex single base primer extension (PE) protocol in combination with denaturing high-performance liquid chromatography (DHPLC) for simultaneously detecting and genotyping these three genetic variations. A multiplex PCR consisting of three amplicons was designed to amplify the sequences of interest from three target genes. After purification of the PCR product, a multiplex PE reaction, which does not require labeled oligonucleotides, was performed. PE products were then analyzed on the WAVE Nucleic Acid Analysis System under fully-denaturing conditions. The alleles were distinguished by differences in retention time depending on the ddNTP incorporated. Compared to traditional approaches, we demonstrated that this method is rapid, highly accurate and cost effective. It has been successfully validated on patient samples which will be presented.

Frataxin has a direct role in the mitochondrial electron transport chain. *F. Palau[1], P. Gonzalez-Cabo[1], R.P. Vazquez-Manrique[1,2], S. Ros[1], M.A. Garcia-Gimeno[1], H. Aziz[2], H.A. Baylis[2], P. Sanz[1].* 1) Genetics & Molec Medicine, Inst de Biomedicina, CSIC, Valencia, Spain; 2) Dept of Zoology, Univ of Cambridge, Cambridge, UK.

Frataxin deficiency causes Friedreich ataxia, a neurodegenerative disorder affecting sensitive neurons of dorsal root ganglia and spinocerebellar tracts. Physiological function of frataxin in mitochondria has not been established yet, although several hypotheses have been postulated including mitochondrial iron homeostasis, iron storing, response to oxidative stress, iron-sulphur cluster biogenesis, modulation of mitochondrial aconitase activity and a role in oxidative phosphorylation. We show that frataxin and its *Saccharomyces cerevisiae* orthologue Yfh1p, interact with proteins from the mitochondrial electron transfer chain. We demonstrate that Yfh1p co-immunoprecipitates with yeast succinate dehydrogenase complex subunits Sdh1p and Sdh2p, and with yeast putative orthologues of the electron transfer flavoprotein complex subunits ETFalpha and ETFbeta. Synthetic interaction experiments confirmed a functional relationship between *YFH1* and succinate dehydrogenase genes. We also demonstrate synthetic genetic interaction in *Caenorhabditis elegans* between *frh-1*, the frataxin orthologue gene, and *mev-1*, the nematode gene encoding the succinate dehydrogenase cytochrome b subunit of complex II in mitochondria. We suggest that both yeast frataxin, Yfh1p, and worm frataxin, FRH-1, might regulate the delivery of electrons via complex II towards ubiquinone. We also demonstrate a physical interaction between human frataxin and human succinate dehydrogenase complex subunits, suggesting also a key role of frataxin in the mitochondrial electron transport chain in humans. Consequently, we postulate a direct participation of the respiratory chain in the pathogenesis of the Friedreich ataxia, which we propose to be considered as an OXPHOS disease.

Peripheral neuropathy with optic atrophy caused by mutations in mitofusin 2. *S. Zuchner[1], P. De Jonghe[2,3], A. Jordanova[2], K. Claeys[2,3], S. Cherninkova[4], V. Guerguelcheva[4], S.R. Hamilton[5], J. Staijch[1], I. Tournev[4], K. Verhoeven[2], M. Pericak-Vance[1], T. Bird[6], V. Timmerman[2], M. Shy[7], J.M. Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Molecular Genetics Department, Flanders Interuniversity Institute for Biotechnology, University of Antwerp, Antwerpen, Belgium; 3) Division of Neurology, University Hospital Antwerpen, Antwerpen, Belgium; 4) Department of Neurology, Medical University, Sofia, Bulgaria; 5) Neuro-ophthalmology Unit, Neuroscience Institute, Swedish Medical Center, Seattle, Washington, USA; 6) Department of Neurology, University of Washington, Seattle, WA, USA; 7) Department of Neurology, Wayne State University School of Medicine, Detroit, MI, USA.

Charcot-Marie-Tooth (CMT) neuropathy with visual impairment due to optic atrophy has been designated hereditary sensorimotor neuropathy type VI (HMSN VI). Sporadic reports of affected families indicated autosomal dominant and recessive forms but the genetic basis of this disease remained elusive. We present five HMSN VI families with subacute onset of optic atrophy and subsequent slow recovery of vision in 70% of the cases. We identified unique mutations in mitofusin 2 (MFN2) in all pedigrees including one nonsense mutation and three de-novo mutations. MFN2 is a mitochondrial fusion factor that was recently reported underlying CMT type 2A. Intriguingly, MFN2 spans the outer mitochondrial membrane and fulfills similar functions in mitochondrial fusion than OPA1, the gene underlying the most common form of autosomal dominant optic atrophy (DOA). We conclude that CMT2A is allelic with HMSN VI both caused by unique mutations in MFN2.

Targeted deletion of the *Trpm6* gene in mouse results in embryonic lethality. *R.Y. Walder[1], B. Yang[2], M.P. Andrews[1, 4], K.E. Bugge[1], X. Cao[2], J.B. Stokes[3], V.C. Sheffield[1, 4].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Obstetrics and Gynecology; 3) Dept Internal Medicine; 4) Howard Hughes Medical Institute, Iowa City, IA.

In humans, mutations in *TRPM6* cause familial hypomagnesemia with secondary hypocalcemia (HSH) (OMIM 602014). HSH is an autosomal recessive disease that is detected shortly after birth. Affected individuals have severe hypomagnesemia and hypocalcemia, which lead to tetany and seizures, and can be lethal if left untreated. HSH patients with mutations in *TRPM6* have defects in the renal and intestinal transport of magnesium. We have developed a mouse model with a targeted deletion of the *Trpm6* gene. No live mice homozygous for the deletion of *Trpm6*, *Trpm6 (-/-)*, have been detected. Seventeen litters of animals genotyped from intercrosses among mice heterozygous for the *Trpm6* deletion gave an observed F2 ratio for *Trpm6 (+/+)/Trpm6 (+/-)/Trpm6 (-/-)* of 0.38/0.62/0.0, significantly different from the predicted Mendelian ratios of 1:2:1 (^{2} = 32.7, P = 2.4 x 10^{-16}). *Trpm6 (-/-)* mice were present during gestation, up to 18.5 dpc. Expression of *Trpm6* in mouse embryonic RNA samples showed a peak at embryonic day 10.5. Some of the male *Trpm6 (+/-)* animals died within 50 days of birth, suggesting that the *Trpm6 (+/-)* animals might exhibit a difference in Mg handling. Preliminary dietary Mg studies showed that male *Trpm6 (+/-)* animals showed a more rapid decrease in the plasma Mg concentration on a low Mg diet, in comparison to wild type *Trpm6* animals. The plasma Mg levels of the *Trpm6 (+/-)* animals were consistently lower than the wild type *Trpm6 (+/+)* mice ($P < 0.05$). These mutant mice and cell lines derived from them will be useful models for studying the role of *Trpm6* in development, and in the cellular processes of Mg homeostasis.

Exploring mouse models of human disease in the Mouse Genome Informatics (MGI) system. *H. Dene, C.L. Smith, A. Anagnostopoulos, S. Bello, M. Tomczuk, K. Forthofer, H. Onda, L.L. Washburn, D.L. Burkart, M. Cassell, I. Lu, J.T. Eppig.* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

The laboratory mouse is an important model for studying human biology because all life stages are accessible to investigation and there are exceptional genetic tools available for use. These tools include high-resolution genetic maps, myriad inbred strains, a sequenced genome, and technology to specifically alter the mouse genome. The Mouse Genome Informatics Database (MGI, http://www.informatics.jax.org/) provides integrated access to extensively curated data on the genetics, comparative genomics and mapping, gene expression, mutational phenotypes, strains and tumor biology of the laboratory mouse.

Phenotypic information on mouse mutations, QTL, and strain characteristics is annotated using structured vocabularies that facilitate query-based information retrieval and computational access. Many human conditions are well modeled by engineering mice to carry specific genetic mutations, complex genomic changes, and conditionally expressed genes that have phenotypes comparable to human hereditary diseases. Within MGI, the relationships of mouse genotypes displaying particular phenotypes are curated to the relevant human disease using terms found in Online Mendelian Inheritance in Man (OMIM). These human disease relationships can be searched in MGI from either the perspective of mouse phenotype or human disease. Results of such searches are reported on newly designed web pages that detail the mouse genotype analyzed and human disease for which it is a model. Links are provided to OMIM and to phenotypic allele detail pages where specifics of the phenotypes are described. MGD is supported by NIH/NHGRI grant HG00330.

Lysinuric protein intolerance: intrauterine growth retardation in Slc7a7 null mice and Igf1/Igf2 expression. *G. Sebastio[1], P. Annunziata[1], G. Corso[2], P. Piccolo[1], M. Brancaccio[1], A. Pepe[1], S. Banfi[3], A. Ballabio[3], G. Andria[1], M.P. Sperandeo[1,4].* 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Department of Biomedical Sciences, University of Foggia, Italy; 3) Telethon Institute of Genetics and Medicine, TIGEM, Naples, Italy; 4) Dulbecco Telethon Institute, Telethon Foundation, Rome, Italy.

Lysinuric protein intolerance (LPI, MIM 222700) is an autosomal recessive defect of cationic amino acid (CAA) transport at the basolateral membrane of epithelial cells of intestine and kidney, caused by mutations of the SLC7A7 gene. The unknown pathogenesis of this multisystem disorder and lack of an effective treatment have prompted the creation of an animal model. A constitutive KO of Slc7a7 was generated by random insertional mutagenesis in ES cells (Lexicon Genetics Inc, Texas). More than 400 Slc7a7+/- intercrosses led to only two Slc7a7-/- live animals. Since birth, both animals showed growth failure compared to siblings. Fed on a low protein diet and citrulline supplementation, the first one survived till 25 months of age, when the treatment was interrupted and replaced by a normal diet. After 2 weeks this animal presented hypotonia, tremors, progressive weight loss and death. The second animal cannibalised their pups and, probably, this overload of proteins caused its death. Metabolic studies confirmed the LPI phenotype: massive urinary CAA and orotic acid excretions. At E 16.5 stage, the proportions of Slc7a7 genotypes were found as expected for an autosomal recessive transmission and the Slc7a7-/- embryos were already smaller than controls. Most of Slc7a7-/- pups were lost at birth because of cannibalism. None of the null embryos showed gross morphological abnormalities apart from a marked delay of renal development. Genes known to play key-roles in the intrauterine growth were tested in SLC7A7-/- embryos and in placentas by Real-Time PCR. The results indicated down-regulation of Igf1, Igf2, Igf2r in SLC7A7-/- embryos and placentas at E. 18.5 stage when compared to controls.

Introduction of subtle mutations into murine *Smn* exon 7 to alter *Smn* splicing-creating additional animal models for spinal muscular atrophy (SMA). *S. Hammond[1], V. Rao[1], R.G. Gogliotti[1], C. Heier[1], R. Kothary[2], C.J. DiDonato[1].*
1) Human & Molecular Genetics, Children's Memorial Research Center (CMRC); Feinberg School of Medicine, Northwestern University, Chicago, IL. 60614; 2) Ottawa Health Research Institute, Ottawa Ontario, Canada.

We have sought to create an allelic series of *Smn* mice that would mimic human *SMN2* by producing full-length *Smn (FL-Smn)* transcripts as well as those lacking exon 7 *(7Smn)*. To determine if we could develop this type of animal, we previously generated *Smn* minigenes containing either wild type *Smn* exon 7 or an altered exon 7 containing the CT nucleotide transition found in the *SMN2* gene. When expressed in cultured cells or transgenic mice, the wild type minigene produced only full-length transcripts while the modified minigene alternatively spliced at exon 7 (DiDonato et al., 2001). We also analyzed the regulation of *Smn* exon 7 and demonstrated that it contains an exonic splice enhancer sequence (mESE) that is structurally and functionally similar to the human AG-rich splice enhancer within *SMN* exon 7. Subtle mutations within the mESE, once again in the context of a minigene, caused a variation in the transgene transcript levels which ranged from 0.7% to 83.4%; *FL-Smn* depending on the alteration. Based upon these results, we engineered into the mouse germline two different subtle mutations within *Smn* exon 7. We have now confirmed germline transmission of both alleles and found that these mutations induce *Smn* exon 7 to be alternatively spliced. We will present our results and our characterization of the animals to date. In the long-term these animals will be useful for assessing various treatment modalities for SMA.

Germline origins of F9 mutation show type-specific sex ratios but no parental age effects. *W.A. Scaringe[1], J. Drost[1], A. Karlea[1], X. Li[1], A. Halangoda[1], K.A. Hill[2], C.K. Kasper[3], J. Liu[4], J. Gill[5], S.S. Sommer[1].* 1) Dept of Molecular Genetics, City of Hope Ntnl Med Ctr, Duarte, CA; 2) Dept of Biology, Univ of Western Ontario, London, Canada; 3) Orthopaedic Hospital, Los Angeles, CA; 4) Beijing Red Cross, Beijing, China; 5) Children's Hospital, Milwaukee, WI.

Germline mutations underlie Mendelian disease and genetic predisposition to complex disease. It has long been hypothesized that most germline mutations occur in the male, and that they increase dramatically with age. These hypotheses can be tested by ascertainment of germline mutation origins, enabling direct estimation of sex ratios of mutation and parental age effects. We ascertained origins of germline mutation in the factor IX gene (F9) by analysis of hemophilia B families. Ascertainment of nearly all hemophilia B probands is enabled by modern medical systems but ascertainment of the other family members needed for molecular determination of the origin is a difficult process which must be carefully monitored for bias. We present analyses of 129 molecularly identified F9 germline mutation origins (65 female, 64 male). The sex ratios of six types of mutations (transitions at CpG, G:C>A:T and A:T>G:C transitions not at CpG, transversions, small and large insertions/deletions) were estimated by two direct methods: by the ratio of maternal grandfather to maternal grandmother origins, and from all origins by Bayesian estimation based on the prior knowledge of the pedigree of each origin family. The results of both methods are similar with the same conclusion: dramatic differences in the sex ratio for different types of mutations. Most single base substitutions occur at significantly higher rates in the male germline. The notable exception is G:C>A:T transitions not at CpG which, like deletions and insertions, occur at about the same rate in males and females. Parental age effects were analyzed by comparing the age of each origin on the date of birth of the child to whom the mutation was transmitted to the population distribution of parental ages in that year. There is no significant skewing to higher age percentiles for either male or female germline origins for any mutation type or all types combined.

Genetic Modifiers of Severe Liver Disease in Cystic Fibrosis. *K.J. Friedman[1], S.C. Ling[3], E.M. Lange[2], M. Macek Jr[4], A.J. Handler[2], R.G. Pace[2], F. Zou[2], S.C. Bell[5], G. Castaldo[6], F. Salvatore[6], C. Colombo[7], M.J. Phillips[3], J. Zielenski[3], L.C. Tsui[3], M.L. Drumm[8], L.M. Silverman[9], F.A. Wright[2], P.R. Durie[3], M.R. Knowles[2].* 1) Molecular Genetics, LabCorp, RTP, NC; 2) Dep'ts Medicine, Genetics & Biostatistics, UNC-Chapel Hill, NC; 3) Pediatrics, Molecular & Medical Genetics, Univ Toronto, Prog. in Genetics & Genomic Biology, & Prog. in Integrative Biology, Hosp for Sick Children, Toronto; 4) CF Center, Charles Univ, Prague, Czech Republic; 5) Prince Charles Hosp, Brisbane, Australia; 6) CEINGE & Biochimica, Univ Naples, Italy; 7) Pediatrics, Univ Milan, Italy; 8) Pediatrics, CWRU, Cleveland OH; 9) Dep't Pathology, Univ Virginia, Charlotteville VA.

Cystic fibrosis (CF) is complicated by dramatic variation in disease severity & organ involvement among patients. Although some of the variability in pulmonary & pancreatic symptoms is associated with CFTR genotype, it is not known why 2-7% of CF patients develop severe CF liver disease (CFLD), marked by portal hypertension & multilobular cirrhosis. Mutations or polymorphisms in other genes, i.e., those associated with inflammation, hepatic collagen production, immune or cytokine function, may further compound risk for CFLD. We have evaluated 5 genes (1-antitrypsin, angiotensin converting enzyme, glutathione-S-transferase P1, mannose binding lectin 2, transforming growth factor beta-1) previously reported to modify risk for developing CFLD. 133 patients with well-characterized severe CFLD were compared to ~900 controls (CF patients without CFLD, 15 years & older). Initial analyses identified two significant associations. CF patients who carry the AAT-Z allele are more likely to develop CFLD (p=0.0002), an effect most pronounced in females (p=0.0001). Variants in the -509 & codon 10 alleles of TGFB1 suggest an association with CFLD in males (p=0.07 and 0.04, respectively). No significant associations were detected between CFLD & ACE, GSTP1, or MBL2 variants when evaluated individually. More complex analyses are underway including logistic regression analysis & assessment of gene-gene interactions. Evaluation of interplay between gender & CFLD may provide mechanistic insights relevant to diagnostic and therapeutic advancements.

Expression of hypoxia inducible factor (HIF-1 alpha) and some of its target genes in guinea pig after exchange transfusion with a hemoglobin-based blood substitute. A preliminary investigation. *L. Yeh, P. Buehler, N. Tayebi, A. Alayash.* DH/CBER, FDA, Rockville, MD.

Expression of many mammalian genes is regulated by oxygen (O_2) tension. This study was designed to test the concept that administration of a cell free hemoglobin (Hb) based oxygen carrier (Oxyglobin) in its various oxidative and oxygenation states can be correlated to the expression of HIF-1 alpha, a global transcriptional factor and potentially to other hypoxia sensitive genes such as erythropoietin (EPO), and heme oxygenase (HO-1). We performed 50% and 75% blood / Oxyglobin exchange transfusions in conscious guinea pigs (N = 20). Blood sampling was performed at set times from 0 hr (end of exchange) until 72 hours post end of exchange in. In separate animals, following euthananasia at set times (0-72 hrs), the right and left kidneys were harvested, immediately frozen in liquid nitrogen followed by total RNA extraction using Trizol. The cDNA for HIF-1a, EPO and HO-1 were generated by reverse transcription with primer pairs designed and synthesized based on human HIF-1 alpha gene sequence. By semiquantitative RT-PCR, mRNA of HIF-1 alpha were detected using a nested PCR technique. Genes were amplified using PCR and the products were separated using 1.5% agarose gel. The oxygenation and redox states of the Hb in plasma obtained was monitored by spectrophotometry and the plasma disappearance of Oxyglobin monitored via HPLC. O_2 carrying ferrous Hb (HbFe2+) monitored in plasma following transfusion declined linearly as a function of time. This was coupled with a proportional elevation of the ferric (HbFe3+) or non-O_2 carrying form of Hb, indicating a loss of the oxygen carrying capacity. The expression of HIF-1 alpha was increased three-fold over baseline (Sham = surgery + recovery + sacrifice) at 4 hours post exchange transfusion and this level of expression was sustained until 72 hr. Exchange transfusion with a non-oxygen carrying oncotically matched Albumin and Oxyglobins ferric form result in higher expressions of HIF. The levels of both EPO as well as HO-1 mRNAs were also elevated in the kidney tissues of these animals.

Differential gene expression profiles unraveled by microarray analysis in periosteal fibroblasts deriving from Apert syndrome patients. *R.D. Fanganiello[1], A.L. Sertie[1], E.M. Reis[2], N. Oliveira[1], F. Kok[3], S. Cavalheiro[4], N. Alonso[3], S. Verjovsk[2], M.R. Passos[1].* 1) CEGH-IBUSP, Brazil; 2) IQ-USP, Brazil; 3) FMUSP, Brazil; 4) UNIFESP, Brazil.

Several signaling pathways can be initiated by ligand activation of fibroblast growth factor receptors (FGFRs), leading to phenomena such as cell proliferation, differentiation and apoptosis, which are critical in skeletal development. FGFR2 gene mutations with dominantly acting mechanisms are responsible for a variety of craniosynostosis syndromes. The most severe of the craniosynostosis is known as Apert syndrome (AS), essentially characterized by premature closure of coronal sutures, severe syndactyly of hands and feet and mental retardation. Almost in all cases of AS, FGFR2 ligand biding affinity and specificity are respectively enhanced and violated by one of two gain of function missense mutations, S252W or P253R. It is known that AS osteoblast mutations cause overexpression of PKC pathway, increased ossification and apoptosis, but the abnormal FGFR2 signaling is not fully understood. To gain further information concerning the signaling pathways and transcription factor networks unchained by FGFR2 activation we are examining, through oligonucleotide microarrays technology, the gene expression profile of primary cultured fibroblasts from the coronal suture periosteum of four AS patients (S252W mutation) and comparing them to those of four wild type cultured periosteal fibroblasts. We detected expression of *FGFR2* gene in these cells by RT-PCR and the protein was detected by immunocytochemical and western blot experiments. In this study we used a batch of 8 oligonucleotide arrays (CodeLink system) representing 20,000 nonredundant human genes. After data mean normalization, with p values 0.05, changes in the expression profile were found in 131 cDNAs, and using the Expression Analysis Systematic Explorer (EASE), the category cell cycle seems to be an enriched biological theme. Among them 20 genes showed signal/noise ratios (SNR) |1.5|. To further investigation we intend to use quantitative RT-PCR and RNA interference experiments. Mutation in NIZP1, a NSD1-interacting zinc finger protein, as a novel cause of Sotos-like conditions. *G. Borck[1], A.L. Nielsen[2], P. Edery[3], D. Sanlaville[1], A. Munnich[1], R. Losson[4], V. Cormier-Daire[1], L. Colleaux[1].* 1) INSERM U393, Hosp Necker-Enfants Malades, Paris, France; 2) Department of Human Genetics, Aarhus University, Aarhus, Denmark; 3) Clinical Genetic Service, Lyon, France; 4) IGBMC, Illkirch, France.

Sotos syndrome is an overgrowth condition characterized by pre-and postnatal overgrowth, macrocephaly, variable degree of mental retardation and typical facial features. Haploinsufficiency caused by whole gene deletions and point mutations of the NSD1 (Nuclear receptor SET domain containing protein 1) gene, a SET-domain histone lysine methyltransferase involved in transcriptional regulation account for 70% of cases. However the disease causing mechnanism in other cases remain unexplained.

A novel NSD1-interacting zinc finger protein: NIZP1 has been recently identify using NSD1 as a bait in a yeast two-hybrid screen. This protein belongs to the SCAN-KRAB subfamily of C2H2-type zinc finger proteins.

Owing to the functional relationship between the two proteins, we investigated whether unexplained cases of Sotos or Sotos-like syndrome could be related to NIZP1 anomalies. 44 patients were first tested for deletion of the NIZP1 gene using polymorphic markers genotyping but, in all cases, a microdeletion encompassing NIZP1 was excluded. The eight coding exons of the NIZP1 gene were subsequently sequenced. We identified a missense mutation (R72Q) which occurs de novo and was not found in 226 unrelated control individuals. Interestingly, this mutation alters an highly conserved amino-acid located within the SCAN domain, a region of the protein which mediates dimer formation between SCAN-domain containing proteins.

These data suggest that NIZP1 mutations may account for some cases of unexplained overgrowth syndromes and provide new evidence for the role of the NSD1/NIZP1 pathway in growth regulation .

Interaction of fibroblast growth factor and C-natriuretic peptide signaling: implications for achondroplasia. *W.R. Wilcox[1], P. Krejci[1], B. Masri[2], V. Fontaine[2], P.B. Mekikian[1], M. Weiss[3], H. Pratts[2].* 1) Med Genet Inst, Cedars-Sinai Med Ctr, Los Angeles, CA; 2) INSERM U589, Institut Louis Bugnard, Toulouse, France; 3) Univ Wash, Seattle, WA.

Activating mutations in fibroblast growth factor receptor-3 (FGFR3) result in several forms of human dwarfism including achondroplasia. Although the mechanism of FGFR3 action remains obscure, both chondrocyte proliferation and differentiation appear to be disturbed by aberrant FGFR3 signaling. Several reports have shown that sustained activation of the Erk MAP kinase pathway accounts for the inhibitory effect of FGF signaling on chondrocyte proliferation. Furthermore, the murine achondroplasia phenotype can be partially rescued by over-expression of C-natriuretic peptide (CNP) in cartilage.

We studied the interaction of fibroblast growth factor (FGF) and CNP signaling in chondrocytes. CNP antagonized FGF2-induced growth arrest of rat chondrosarcoma (RCS) chondrocytes by inhibition of the Erk MAP kinase pathway. This effect of CNP was protein kinase G-dependent and was mimicked by the cGMP analog pCPT-cGMP. We found that CNP blocks the Erk pathway at the level of Raf-1. CNP also counteracted the FGF2-mediated degradation of the RCS extracellular matrix. CNP partially antagonized FGF2-induced expression, release and activation of several matrix metalloproteinases. In addition, CNP compensated for the FGF2-mediated matrix loss by upregulation of matrix production independent of its interference with FGF signaling.

FGF signaling thus affects chondrocyte behavior by inhibition of proliferation and degradation of the extracellular matrix. CNP can reverse both phenotypes by inhibiting the Erk pathway and independently increasing extracellular matrix synthesis. Thus, CNP utilizes both direct and indirect ways to antagonize the outcomes of FGF signaling in chondrocytes. Pharmacologically increasing cGMP in cartilage may represent a therapeutic approach for achondroplasia.

Efficiency of splicing inversely correlates with clinical severity in dystrophinopathy due to deep intronic splice site activation mutations. *K.M. Flanigan[1,2,3], C.B. Anderson[1], K.J. Hart[1,2], M.T. Howard[1], T. Tuohy[1].* 1) Dept of Human Genetics, Univ Utah, Salt Lake City, UT; 2) Dept of Neurology, Univ Utah, Salt Lake City, UT; 3) Dept of Pathology, Univ Utah, Salt Lake City, UT.

Becker and Duchenne Muscular Dystrophy (BMD and DMD) can be caused by deep intronic mutations which create splice sites resulting in the inclusion of pseudoexons in the DMD mRNA. Such mutations account for at least half of the 5-7% of mutations not detected in lymphocyte-derived DNA samples by modern mutation detection methods. We detected two such mutations in patients with dystrophinopathy. One patient, with BMD, carries an intron 11 mutation (c.1331+17770C>G) which creates a splice donor site, resulting in the incorporation of a 79 nucleotide (nt) out-of-frame insertion. A second patient, with DMD, carries an intron 45 mutation (c.6614+3313G>T), resulting in a 139 nt out-of-frame insertion. We hypothesized that the milder phenotype may result from less efficient alternate splicing. In order to investigate the relationship of splicing efficiency to phenotype, quantitative RT-PCR was performed using forward amplification primers which span the junction between the wild type exon (11 or 45) and the pseudoexon (11a or 45a) and compared to amplification with primers spanning the wild-type (11-12 or 45-46) junction. Each reaction product was normalized against the EEF gene, and compared to results found in normal control muscle tissue. In the DMD sample, the alternatively-spliced transcript was present at the level of 41% compared to a normal control, and no wild-type transcript was detected. In the BMD sample, the alternatively-spliced transcript was present at the level of 40%, but the wild type transcript was detected at a level of 13%. These results suggest that in the setting of cryptic splice site mutations, clinical phenotype is dependent upon splicing efficiency, which can be determined using quantitative RT-PCR methods.

Transgenic mouse model faithfully reproduces clinical symptoms of LGMD1A. *S.M. Garvey[1], D.R. Claflin[2], J.A. Faulkner[2], M.A. Hauser[1].* 1) Duke University, Durham, NC; 2) University of Michigan, Ann Arbor, MI.

The myotilinopathies are a group of autosomal dominant, adult-onset, progressive, and clinically heterogeneous muscle disorders that includes both Limb-Girdle Muscular Dystrophy Type 1A (LGMD1A) and a subset of myofibrillar myopathy (MFM) patients. Seven independent missense mutations in the *myotilin* gene have been characterized in LGMD1A and MFM patients. We generated transgenic mice expressing the LGMD1A thr57ile *myotilin* mutation (TgT57I) specifically in skeletal muscle. The transgene includes the human myotilin cDNA and an N-terminal c-myc epitope tag. Three independent lines of TgT57I mice develop progressive myofibrillar pathology. Sections of multiple muscles show an age-dependent increase in the size and number of dense myofibrillar plaques or aggregates. Ultrastructural analysis reveals rimmed vacuoles, Z-disc streaming, and large patches of myofibrillar disarray similar to those seen in human patients. Using a c-myc antibody, we show that the TgT57I product localizes properly to the Z-disc, yet also localizes heavily to the myofibrillar aggregates. A similar pattern of immunoreactivity is observed for endogenous myotilin, -actinin, -filamin, and desmin, reproducing the aggregate staining seen in MFM patients. Ubiquitin also localizes to the aggregates, suggesting a role for the proteasome in aggregate clearance. Intriguingly, the integral sarcomeric protein, titin, does not localize to the aggregates. To further characterize the TgT57I mice, we performed whole muscle physiology. The EDL muscles mass is reduced by 33%, its cross-sectional area is reduced 30%, and its maximum specific force is reduced 23%. In contrast to the largely fast-twitch EDL muscle, TgT57I soleus muscle physiology remains normal; the soleus is also spared of any myopathology. The slow-twitch fiber composition of soleus may protect it from the toxic accumulation of aggregates. Similarly, in LGMD1A and MFM patients, the muscle group specificity of pathology and weakness may be due to the underlying fiber type composition. We will also discuss single-fiber physiology and the effect of treadmill exercise on the pathology observed in this promising mouse model of LGMD1A.

Possible common founder effect of the G526R mutation in 4 dSMA-5 Algerian Sepharadic Jewish families. *H. Azzedine, O. Dubourg, D. bouteiller, R. Benyaou, A. Brice, E. Leguern.* INSERM U679 (exU289)-NEB, Hosp de la Salpetriere, Paris, France.

CMT is a pathological and genetic heterogeneous group of hereditary motor and sensory neuropathies characterized by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished on anatomopathological and electrophysiological grounds: demyelinating and neuronal CMT. Up to now, 5 different loci have been reported and 4 genes have been identified in neuronal autosomal dominant forms of the disease. Recently, the GARS (Glycyl tRNA synthetase) gene has been implicated in distal spinal muscular atrophy type V (dSMA-V) and CMT2D both disease mapped to 7p14 chromosome. We screened eight families with neuronal CMT for 7 microsatellites markers covering the the 7p14 locus. Assignment of the families for this locus was established by halotype segregation. Three families Algerian of Sepharadic Jewish nacestry were putatively linked to the CMT2D/dSMA-V locus. Sequencing of the 17 exons of GARS gene was performed in all examined consent individuals of the 3 families. We identified a unique G526R mutation that segregated with the same haplotype in all 3 families. This mutation was previously reported in the literature in another Algerian Sepharadic Jewish family. The common origin of the 4 families with the same mutation and a common hapltotype segregating with this mutation in our 3 families suggest a founder effect in the Algerian Jewish ethnic group.

Development of a high-throughput DNA microarray-based resequencing system for comprehensive mutational analysis for hereditary and sporadic spastic paraplegias. *H. Ishiura, Y. Takahashi, J. Goto, S. Tsuji.* Department of Neurology, The University of Tokyo, Tokyo, Japan.

[Background] Spastic paraplegias (SPGs) are heterogeneous neurodegenerative disorders characterized by progressive lower limb spasticity and pyramidal weakness. Up to present, SPG1-28 have been known for the loci for hereditary spastic paraplegia(HSP), and causative genes have been identified for *SPG1, 2, 3A, 4, 6, 7, 10, 13 and 20*. However, little is known about genotype-phenotype correlation. In addition, a substantial number of sporadic cases present with clinical manifestations similar to those of hereditary cases. Since it is difficult to make a correct diagnosis only from clinical information, we are confronted with a strong demand for a high-throughput system for mutational analyses. The purpose of this study is to design a system and to elucidate molecular epidemiology of SPGs in the Japanese population. [Method] We have designed a high-throughput DNA microarray system based on GeneChip^{TM} CustomSeq resequencing system (Affymetrix), which is capable of analyzing complete nucleotide sequences of all the exons and splicing junctions of 5 causative genes (*SPG1:L1CAM, SPG2:PLP1, SPG3A:atlastin, SPG4:spastin and SPG7:paraplegin*). The study includes 7 patients with autosomal dominant inheritance (ADHSP), 3 patients born to consanguineous parents, one patients with undetermined mode of inheritance, 2 cases with Pelizaeus-Merzbacher disease (PMD) and 16 sporadic patients. [Results] We identified 3 *SPG4* mutations (Q178X, I440V, Q280X) among the ADHSP patients, and one *PLP1* mutation (W145X) in a patient with PMD. In addition, we found one *SPG4* mutation (K502X) in a sporadic case. [Discussion] Our findings indicate that SPG4 is the most frequent HSP in the Japanese population, which is compatible with previous reports on other ethnic populations. We furthermore found 1 *SPG4* mutation in an apparently sporadic case, raising a possibility that some of the sporadic cases are caused by mutations of *SPG4* with a reduced penetrance. The microarray resequencing system is comprehensive and highly efficient for mutational analyses of disorders with such tremendous locus heterogeneity.

Allele specific analysis of familial pulmonary arterial hypertension patients reveals pathogenic defects not detected by DNA mutation screening. *V. James, M.A. Aldred, R.D. Machado, R.E. Harrison, R.C. Trembath.* Dept. Genetics, Univ Leicester, Leicester, United Kingdom.

Heterozygous mutations in the gene bone morphogenetic protein receptor II (*BMPR2*) underlie familial pulmonary arterial hypertension (FPAH). Some 70% of *BMPR2* mutations introduce a premature termination codon (PTCs) that results in transcripts likely to be rapidly degraded by the nonsense mediated decay pathway (NMD). Direct sequencing of coding regions and exon-intron junctions of genomic DNA results in approximately 30% of FPAH index cases without identified mutations despite evidence of linkage to the *BMPR2* locus.

We developed an allele specific assay to quantify RNA transcript levels to search for defects in *BMPR2* expression. Lymphocyte mRNA was extracted from five FPAH subjects, 2 with known mutations (IVS7968+3delA and deletion of exon 2) and 3 without detected mutations. Allelic imbalance (quantitative reduction in allelic expression) was detected for informative subjects with known mutations but also in an FPAH cases without. To further elucidate the mechanism leading to allelic imbalance we analysed a patient derived lymphoblastoid cell line. Allele specific expression was quantified before and following treatment with the protein synthesis inhibitor, puromycin. Preliminary data shows a significant increased in the abundance of transcripts derived from the risk allele suggesting that NMD explains the steady-state difference leading to allelic imbalance. Direct sequencing of a 2.2kb region 5 of the translation start site identified a substitution -944/5GC-AT, which was not seen in 160 control chromosomes.

These data suggest NMD leads to degradation, not only of nonsense *BMPR2* transcripts but also non-coding mutations and supports haploinsufficiency as the predominant molecular mechanism predisposing to FPAH.

Mutations in the gene for ichthyin, a minor gene for congenital ichthyoses, found in patient samples and also in controls. *K.M. Eckl[1], W. Küster[2], H. Traupe[3], H.C. Hennies[1].* 1) Cologne Center for Genomics, University of Cologne, Germany; 2) TOMESA Clinic, Bad Salzschlirf, Germany; 3) Dept Dermatology, University of Munster, Germany.

Autosomal recessive congenital ichthyoses (ARCI) form a group of rare, severe disorders of keratinization with a prevalence of 1 in 100.000 to 200.000 in the European population and in the US. Both phenotypes and genetic etiology are extremely heterogeneous. Up to date six different gene loci were described: *TGM1* on 14q11.2, *ALOX12B* and *ALOXE3* on 17p13.1, *ABCA12* on 2q34-q35, and the gene for ichthyin on 5q33. Two loci were described on chromosome 19 but corresponding mutations underlying ARCI are still unknown. Here we describe the analysis of a collection of 118 non-related ARCI patients for mutations in the gene for ichthyin described recently. All samples were previously checked to be free of any mutation in one of the genes *TGM1*, *ALOX12B*, or *ALOXE3*. In 15 families we have found four different mutations, whereof one is a nonsense mutation and three are missense mutations. Two mutations are novel, two further mutations, Arg83X and Ala114Asp, were described before in patients from consanguineous families of Turkey, Algeria, and Colombia, whereas our patients originate mainly from Germany and Turkey. All patients but two showed homozygosity for the respective mutations, although no consanguinity was reported. Healthy controls showed neither the mutation Arg83X nor two of the missense mutations. In contrast, the mutation Ala114Asp, which we have found in ichthyosis patients from 11 families and which was described in patients from 7 families before, was also present in 4 of 100 ethnically matched control chromosomes (4%), indicating that this mutation is most probably a polymorphism. In summary, we have found potentially pathogenic mutations in 3% of our ichthyosis patients. Thus we conclude that the gene for ichthyin is an uncharacterized, minor ARCI gene. Functional analysis of this gene must be the next task in order to further analyze the impact on ichthyosis. As a first step, we have cloned the gene and determined the genomic organization, which has still been equivocal until now.

A novel GH-1 gene splicing mutation in an Italian family with Isolated Type II Growth Hormone Deficiency (IGHD II). *P. Momigliano-Richiardi[1], D. Vivenza[1], L. Guazzarotti[2], B. Di Natale[2], M. Godi[1], S. Mellone[1], G. Bona[1], M. Giordano[1].* 1) Dept Medical Sci, Eastern Piedmont Univ, Novara, Italy; 2) Dept of Pediatrics, L. Sacco Hospital, University of Milan, Milan, Italy.

A new mutation responsible of IGHD-II was detected in a 9 month old girl (the proband) with severe growth failure (-5.8 SDS) and GH peaks after stimulus < 0.4 ng/ml, and her mother (-6.9 SDS and GH peaks < 0.5 ng/ml). Sequencing of the entire GH1 gene in the proband evidenced an heterozygous 22 bp deletion in IVS3 (+54-75) encompassing the branch site. RT-PCR of her peripheral blood mRNA showed both a normal length fragment, corresponding to the wild-type allele, and an equally intense shorter band corresponding to the IVS3 +54-75 allele that, when sequenced, revealed exon 3 skipping. Its predicted product is a shorter protein lacking aminoacids 32-71, corresponding to the 17.5 kDa isoform physiologically present at a very low dose. The same IVS3 mutation was present in the proband's mother and absent in her normal stature relatives. Haplotype analysis in all the family members using GH1 promoter SNPs revealed that this was a de novo mutation in the proband's mother. To better evaluate the effect of the IVS3 +54-75 on mRNA splicing, an expression construct containing the GH1 allele with the IVS3 deletion was transfected into GHC4 rat pituitary cells. The mutated allele produced at least four differently spliced products: the full-lengh cDNA, visible as a weak band, the exon 3 skipped mRNA and two new aberrantly spliced products correponding to the GH1 mRNA deleted of the first 86 bases of exon 4 (leading to a premature stop codon) and to an mRNA lacking the entire exon 4 (leading to a protein lacking aa 72-126). Thus the 22 bp deletion has two main effects: 1) Exon3 skipping, as observed in all the previously described cases of IGHD-II. This effect is likely caused by the relevant reduction in size of the IVS3 (Ryther et al, 2004). 2) Partial or total exon 4 skipping, likely due to the depletion of the branch site that does not allow the use of the IVS3 acceptor splice site. The consequence is either the activation of a criptic splice site in exon 4 or the total skipping of exon 4.

A comparison of mutation patterns in suspected cases of congenital long QT syndrome and controls. *M.S. Pungliya[1], B.A. Salisbury[1], R.S. Judson[1], D.J. Tester[2], M.L. Will[2], M.J. Ackerman[2].* 1) Computational Genomics, Genaissance Pharmaceuticals, New Haven, CT; 2) Mayo Clinic College of Medicine, Rochester, MN.

Congenital long QT syndrome (LQTS) affects about one in 5000 individuals. LQTS is a heritable condition often characterized by prolonged QT intervals as seen by a 12-lead electrocardiogram. Although nearly half of susceptible hosts experience a lifelong asymptomatic course, LQTS can present with sudden cardiac death even in infancy. Among the most definitive cases, about 75% are found to have rare or unique protein-altering mutations in the cardiac ion channel genes KCNQ1, KCNH2, SCN5A, KCNE1, and KCNE2; hundreds of such mutations have been reported, few of which have been observed in healthy controls. Here, we compared the patterns of mutation discovery in 611 healthy controls with that of 541 cases published in a recent compendium. While 50% of the published cases had protein-altering mutations in one of the five LQTS causing genes, we found that almost 5% of the controls also had such mutations. In addition to the overall rates, the relative numbers of mutations among the five genes was also significantly different between cases and controls ($p = 5.9 \times 10^{-8}$), as seen in the table below. From these relative rates, it is clear that causality can be confidently assigned to case mutations found in KCNQ1 and KCNH2, and less so for SCN5A. Further, when a case has two mutations, we can be confident that at least one of the mutations is causative, but we can estimate that for half of those cases, one of the mutations may represent a rare but clinically insignificant background variant.

Percentages and counts among Cases and Controls in the 5 genes.

	KCNQ1	KCNH2	SCN5A	KCNE1	KCNE2	Multiple Mutations
Controls (611)	1.0% (6)	1.1% (7)	2.3% (14)	0.3% (2)	0.5% (3)	0.2% (1)
Cases (541)	22.2% (120)	17.2% (93)	4.8% (26)	0.6% (3)	0.2% (1)	5.4% (29)

Clinical Molecular Diagnosis of Hypertrophic Cardiomyopathy: the First 50 Cases. *M. Peng, E. Duffy, H. Rehm, P. Verlander, V. Joshi, R. Madore, J. Seidman, C. Seidman, C. Ho, R. Kucherlapati.* Harvard Medical School-Partners Healthcare Center for Genetics and Genomics, Cambridge, MA.

Hypertrophic cardiomyopathy (HCM) is a primary disorder of the myocardium with a genetics base. The prevalence of the disease is estimated to be one in 500. At least 14 genes have been reported to cause the disease. More than 200 sarcomere mutations have been found in 50-70% of the HCM patients. Molecular diagnosis has been a challenge because of genetic and allelic heterogeneity. Laboratory for Molecular Medicine at Harvard Partners Center for Genetics and Genomics has offered a sequencing based mutation detection test for more than a year. Five sarcomere genes (MYH7, MYBPC3, TNNT2, TNNI3 and TPM1) were included in this test. The first 50 individuals tested are reported here. 17 out of 31 (54.8%) probands were positive for at least one mutation among the five major sarcomere genes. 3 out of 17 (17.6%) probands have two mutations. 3 out of 17 (17.6%) families with a mutation positive probands have sent other family members to test. In two families, the novel changes were found to be co-segregated with the disease. Altogether 20 different mutations (13 in MYBPC3, 4 in MYH7. 2 in TNNT2 and 1 in TNNI3) were identified. Fifteen (75%) were novel mutations that have not been described previously in the literature or the mutation database (http://cardiogenomics.med.harvard.edu). In conclusion, a comprehensive analysis of genes implicated in HCM continues to be necessary to identify the private mutations uncovered in clinically affected individuals. More than half of the mutations in clinical samples have never been reported despite the fact that more than 800 HCM probands have been genetically screened in research studies worldwide. A cost-effective DNA diagnostic test to scan every single base of the major HCM genes for the private mutations of the probands followed by a known mutation testing for the family members, is the appropriate genetic test approach with our current knowledge of the sarcomere gene mutations.

Clinical and genomic data bank of subjects with sporadic and familial cavernous angiomas of the nervous system of Italian origin. *F. Gianfrancesco[1], V. Maglione[2], T. Esposito[1], M. Cannella[2], C.L. Liquori[3], D.A. Marchuk[3], F. Squitieri[2].* 1) Institute of Food Science, National Research Council, Avellino, Italy; 2) Neurogenetics Unit IRCCS Neuromed, Pozzilli (IS), Italy; 3) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC.

Cavernous angiomas of the nervous system (CCMs) are cerebral/medullar y malformations causing intracerebral haemorrhage, seizures, headache and focal neurological symptoms. During these last years, the linkage analysis approach allowed the discovery of three different loci on chromosomes 7q21.2 (CCM1), 7p13 (CCM2) and 3q25.2-q27 (CCM3). The DNA screening of the mapped genes highlighted a number of mutations in KRIT1 (CCM1), MGC4607 (CCM2) and PDCD10 (CCM3). We set up a clinical and genomic bank with patients and families affected with CCMs, all of Italian origin, at the Neurogenetics Unit of Neuromed and started to screen the DNA of familial and sporadic affected subjects. In total, we have so far tested subjects from five unrelated families and 6 sporadic cases. Family CAV01, which has previously contributed to the identification of CCM2 locus and whose affected people had CCMs confined to brain, showed a frameshift mutation (56delG) in the exon 2 of MGC4607. Family CAV17 showed a new KRIT1 mutation, never reported yet, changing a CAA triplet in 238 with a TAA stop codon. Such non sense mutation caused a phenotype, variably expressed among the subjects, characterized by cerebral, medullary and cutaneous angiomas. Interestingly, this family generated a number of consanguineous marriages potentially generating homozygosity for mutation and an increased concentration of cases in that particular geographical area. Family CAV02 was analyzed for all three gene mutations and is presently contributing to the identification of a fourth gene locus on chromosome 3q. Two more CAV families from our bank have been screened and mutations in all the three CCM genes excluded, thus potentially of help for further identification of new genetic loci.

Three severe cases of EBS Dowling-Meara caused by missense and frameshift mutations in keratin 14 gene. *J. Mazereeuw-Hautier[1], M. Titeux[2], S. Hadj-Rabia[3], C. Prost[4], L. Tonasso[2], C. Bodemer[3], A. Hovnanian[2,5].* 1) Service de Dermatologie, Purpan Hospital, Toulouse, France; 2) INSERM U563, Purpan Hospital, Toulouse, France; 3) Service de Dermatologie, Saint Louis Hospital, Paris, France; 4) Service de Dermatologie, Necker Hospital, Paris, France; 5) Service de génétique médicale, Purpan Hospital, Toulouse, France.

Epidermolysis bullosa simplex (EBS) is a group of blistering diseases classified into three major subtypes caused by mutations in the genes encoding keratin 5 (KRT5) and keratin 14 (KRT14). In this study, we analysed three patients affected with an unusually severe form of EBS Dowling-Meara type (EBS-DM), with early and marked hyperkeratosis. Sequencing of the KRT14 gene revealed a heterozygous mutation p.M119T in two of the three patients. Amino acid 119 in keratin 14 is located within the highly conserved Helix Initiation Peptide at the a position of the first heptad and is predicted to face, at the d position, leucine 176 of keratin 5. The conversion of this hydrophobic residue into a threonine, which is hydrophilic, is predicted to destabilise the helix and impair coiled-coil interactions. Interestingly, the same mutation was previously reported in two severe cases of EBS-DM, whereas mutations, conserving the hydrophobicity of this residue (p.M119V and p.M119I) led to milder phenotypes. In the third patient, a novel c.1246delC mutation was identified. This mutation, located at the very beginning of the Helix Termination Peptide, leads to a frameshift and to a premature termination codon, predicting the synthesis of a 25 amino acid missense carboxyterminal sequence. The keratin 14 tail domain, which is replaced by an aberrant sequence, is thought to be important for the bundling of the filaments. Since a previously described K14 tailless mutant was not associated with severe EBS-DM we suggest that the severity of the phenotype may result from the presence of the abnormal K14 tail. Accordingly with the EBS-DM diagnosis, keratin aggregates were found in basal keratinocytes of two of the three patients These cases illustrate the extreme severity of some EBS-DM at the neonate period and further document genotype-phenotype correlations.

New BBS mutations in known BBS genes. *H. Dollfus[1], C. Stoetzel[1], V. Laurier[1], D. Bonneau[2], A. Verloes[3], A. Megarbane[4], F. Perrin-Schmitt[1], JL. Mandel[5], M. Cossee[1,6].* 1) Laboratoire de génétique médicale EA,Faculté de médecine-ULP, Hôpitaux Universitaires,Strasbourg, France; 2) Service de génétique, CHU Angers, France; 3) Hôpital Robert Debré, Paris, France; 4) Université Saint-Joseph, Beirut, Lebanon; 5) IGBMC, Illkirch, France; 6) Laboratoire de diagnostic génétique,Strasbourg, France.

Introduction

Bardet-Biedl syndrome (BBS) is a genetically heterogenous condition characterized by retinitis pigmentosa, obesity, polydactyly, renal and genital malformations and learning disabilites. To date 8 genes have been identified (BBS1, BBS2, BBS3, BBS4, BBS5, BBS6, BBS7 and BBS8) and triallelic inheritance demonstrated for some families. A cohort of BBS families is being explored for all the BBS genes (Hichri et al, 2005). We present herein 12 new BBS mutations.

Families and methods:

We are studying a large cohort with BBS for which the analysis of 40 families has revealed new BBS mutations.

Results:

Although screening for all the families is not completed in extenso we report on twelve previously unreported BBS mutations. BBS2: C307Y; BBS3: R122Q; BBS4: Q247X (homozygous); BBS5: 123 delA - K41fsX52 (homozygous); BBS6: I297T ; BBS7: 340A>G, M114V splicing mutation, 52843;1G>A - splicing mutation , S574C, 1967-1968delTAinsC - L656fsX673 (long isoform) L656fsX678 (short isoform), BBS8: 459G>A - T153T splicing mutation (homozygous) , 594 43;1G>A - splicing mutation (homozygous), 59443;1-2delGT - splicing mutation.

Conclusions:

Summarizing the litterature and our results recurrent mutations in BBS seems to be rare. An excess of heterozygous mutations are reported herein (8/12) and this is in favor of the triallelic possible inheritance for these families. Reporting on new mutations in BBS is important in the perspective of setting micro-array based mutation analysis.

Screening for DJ-1 mutations in early onset PD. *P. Tarantino, F. Annesi, F.E. Rocca, P. Spadafora, I.C. Cirò Candiano, S. Carrideo, D. Civitelli, E.V. De Marco, G. Annesi.* Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy.

Mutations in DJ-1 gene cause a clinically characteristic autosomal recessive juvenile onset form of Parkinsons disease (PD). Such mutations are thought to lead to a loss of DJ-1 function. DJ-1 is composed of eight exons; the open reading frame is encoded within exons 2-7, while exon 1 is alternatively spliced (1a/b). In this study we analysed the DJ-1 gene in 40 sporadic patients with early onset PD (age of onset 45 years of age) and 100 appropriate controls, originated from Southern Italy. These patients were evaluated previously for the presence of Parkin and PINK1 mutations and found to be negative. DNA was extracted from peripheral blood using standard protocols. Exons were amplified and obtained fragments were directly sequenced on ABI3100 automated DNA sequencer. Absolute quantification was performed by real time PCR 7900 HT-SDS, using TaqMan probes for exons 2,3 and 7. For remaining exons 1,4,5 and 6 we set up a Sybr Green assay. In a patient with an age at onset of 35 years, we detected an heterozygous nucleotide change (CG) in intron 1 (nucleotide 10703, ref. AL034417) and a single heterozygous deletion mutation (IVS4+3insA) in intron 4 splice site. These novel variants were not found in 100 control subjects. In the same patient genomic rearrangements were excluded by absolute quantification in real time PCR. By sequence analysis, no mutations were found in remaining patients. Nevertheless, absolute quantification is still to be performed. The IVS4+3insA mutation results in a single nucleotide insertion in a conserved sequence of the invariant AG splice acceptor site of intron 4. We hypothesized that this variant could have consequences on DJ-1 RNA, leading to an aberrant transcript. Moreover, the detected intronic change is potentially functional because it is localized 159 bp after the transcriptional activate site and approximately 42 bp downstream of an SP1 binding site. Synergic action of both heterozygous variants could account for clinical features of examined patient.

Mutation analysis in nephronophthisis (NPHP) applying a combined approach of homozygosity screening and heteroduplex cleavage with CEL I nuclease. *E. Otto, J. Helou, S. Allen, F. Hildebrandt.* Dept Ped, Univ Michigan, Ann Arbor, MI.

NPHP is an autosomal recessive kidney disease that causes chronic renal failure in children. Five genes (NPHP1-5) have been identified to date. Tubular basement membrane disintegration, fibrosis, and cyst formation are the prominent features. We report here on a straightforward and inexpensive method of mutation screening in a worldwide cohort of 645 unrelated patients to identify homo- and hemizygous mutations in this disease entity. First, homozygous deletions of NPHP1 were detected in 152 NPHP-families (24%) by a multiplex PCR approach. In order to identify additional families with point mutations in NPHP1 or NPHP4, we screened one affected member of each of 400 NPHP families for homozygosity of 3 consecutive highly polymorphic microsatellite markers within the NPHP1 (common 250 kb deleted region) and NPHP4 loci. As a result, 64 (10) patients showed homozygosity for all markers tested in the NPHP1 (NPHP4) region. Thereafter, we PCR amplified each of the 20 (30) exons of the NPHP1 (NPHP4) gene along with their exon/intron boundaries. These samples were combined with wildtype PCR products and heteroduplex formation was performed. Using single strand specific nuclease CEL I (crude celery plant extract) mismatch cleavage was performed at 45C for 5 min and analyzed on an agarose gel for aberrant bands. The CEL I enzyme recognizes single base mismatches present in the heteroduplex DNA and cleaves both strands. In order to test the sensitivity of the CEL I enzyme we digested the exon PCR products of formerly published mutations and were able to detect 73 out of 79 different mutations (92%). Sequencing of the CEL I detected exons revealed new NPHP1 point-mutations in 14 patients and homozygous NPHP4 mutations in 8 patients. Furthermore, we used the CEL I enzyme mutation approach to analyze 20 patients with infantile NPHP (end stage renal disease before age 5 years) and 10 patients with NPHP combined with Retinitis pigmentosa (Senior Løken Syndrome) and discovered 2 new NPHP2/Inversin mutations and 2 families with NPHP5 mutations, respectively. The combined mutation analysis approach allowed us to rapidly identify rare mutations in a large number of patients.

A Nonsense Mutation in the Corneodesmosin Gene in a Mexican Family with Hypotrichosis Simplex of the Scalp.

N.O. Davalos[1], A. García-Vargas[2], J. Pffor[4], I.P. Dávalos[3], V.J. Picos-Cárdenas[3], L.E. Figuera[3], M.M. Nöthen[5], R.C. Betz[4]. 1) Instituto de Genética Humana "Dr. Enrique Corona Rivera", CUCS-UdeG, Guadalajara, Mexico; 2) Instituto Dermatológico de Jalisco Dr. José Barba Rubio SSJ, Guadalajara, México; 3) División de Genética, CIBO-IMSS, Guadalajara, Mexico,; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany; 5) Life & Brain Center, University of Bonn, Bonn, Germany.

Hypotrichosis simplex of the scalp (HSS; MIM 146520) is a rare autosomal dominant form of non-syndromic alopecia that affects men and women equally. Up to now, only a small number of families with HSS have been reported. The affected individuals experience a diffuse progressing hair loss from childhood to adulthood that is confined to the scalp. Recently, HSS has been mapped to the short arm of chromosome 6 (6p21.3), allowing mutations in the corneodesmosin gene (CDSN) to be identified as the cause of the disorder. To date, two stop mutations have been found in three unrelated families with HSS of different ethnic origin. Here, we describe a Mexican family presenting HSS. The pedigree extends over six generations comprising 156 individuals, 42 of whom are affected. By direct sequencing of the two exons of the CDSN gene, a novel nonsense mutation was identified in the index patient in exon 2, resulting in a premature stop codon (Y239X). The mutation co-segregated in the family (28 family members, 9 of whom were affected) and was not found in 300 control chromosomes using a restriction enzyme analysis with PsuI. Two additional, so far unknown SNPs in the coding region of the CDSN gene co-segregating in the family were found. Our data provide molecular genetic evidence for a 3rd stop mutation in exon 2 of the CDSN gene being responsible for HSS. All to date known nonsense mutations responsible for HSS are clustered in a region including 40 amino acids of exon 2 in the CDSN gene. Further families should be investigated to elucidate if this region of the CDSN gene might have a special effect on hair growth.

Novel mutations of *ZFHXIB* responsible for the Mowat-Wilson syndrome. *Y. Yamada[1], K. Yamada[1], N. Nomura[1], N. Ishihara[1], Y. Kondo[1], K. Yokochi[2], T. Kuroda[3], A. Ota[4], N. Okamoto[5], M. Iwakoshi[6], J. Abe[7], S. Hamano[8], M. Saeki[3], M. Nagaya[9], N. Wakamatsu[1].* 1) Dept Genet, Inst Develop Res, Aichi Human Service Ctr, Aichi, Japan; 2) Seirei Mikatahara Hosp, Shizuoka, Japan; 3) Natl Ctr Child Health Develop, Tokyo, Japan; 4) Natl Kagawa Child Hosp, Kagawa, Japan; 5) Osaka Med Ctr Res Inst Maternal Child Health, Osaka, Japan; 6) Nishinomiya Municipal Wakaba-en, Hyogo, Japan; 7) Hyogo Pref Nishinomiya Hosp, Hyogo, Japan; 8) Saitama Child Med Ctr, Saitama, Japan; 9) Ctrl Hosp, Aichi Human Service Ctr, Aichi, Japan.

The mutations of *ZFHXIB* cause an autosomal dominant disorder of Mowat-Wilson syndrome associated with profound mental retardation, delayed motor development and specific facial features. We performed molecular analysis of *ZFHXIB* to confirm diagnosis of Mowat-Wilson syndrome. To screen for mutation, DNA fragments including each exon of *ZFHXIB* from patients and normal controls were amplified by PCR and subjected to direct sequencing analysis. Six novel mutations were found in the typical patients with Mowat-Wilson syndrome, one nonsense mutation (936C>A, C312X) and five frame-shift mutations including two mutations inserted one base (313insA, 105fs121X; 2254insA, 752fs754X) and three mutations deleted one base (1175delG, 392fs395X; 1535delG, 512fs515X; 1822delG, 608fs620X). We have identified 31mutations in *ZFHXIB* up to the present. In 29 typical cases with profound mental retardation and specific facial features, 14 nonsense mutations and 15 frame-shift mutations were detected. These mutations generated truncated protein without the zinc finger domain located in the C-terminal region.

Novel Mutations and Variants Identified in the MECP2 Gene. *W. Sun[1], M. Peng[1], A. Buller[1], M. McGinniss[1], F. Quan[1], S. Potts[2], J. Taylor[3], C. Strom[1].* 1) Molec Gen Dept, Nichols Inst, Quest Diagnostics Inc, San Juan Capistra, CA; 2) Advanced Diagnostics Information Technology, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA 92690; 3) Quest Diagnostics, Inc., Wood Dale, IL 60191.

Rett syndrome (RTT) is one of the most common genetic causes of mental retardation in females. It is a neurodevelopmental disorder caused by mutations in the X-linked methyl CpG binding protein 2 (MECP2) gene. Direct sequence analysis of the MECP2 gene has been offered at Quest Diagnostics Nichols Institute to aide the diagnosis of RTT in affected individuals and to test for the potential presence of MECP2 mutations in patients parents. In more than 600 consecutive unique patients subjected to MECP2 mutation detection in our institute, 45 were found to have MECP2 mutations previously described to be associated with RTT. In addition, we report that we also detected 16 novel mutations and variants in the MECP2 gene. Four were frameshift mutations which are most likely to be pathogenic. There were also 5 missense changes located in the N-terminus, MBD, and the C-terminus domains. Interestingly, we detected 5 different in-frame deletions affecting the proline-rich region (aa. 384 to 393), a putative DNA-binding motif, in the C-terminus domain. The in-frame deletion of 2 to 6 amino acids in this region are likely polymorphic changes to the gene as 2 of the deletions were detected in both the symptomatic girls and their asymptomatic mothers. Proline-rich regions are commonly believed to adopt a secondary structure known as a left-handed polyproline helix (PPII). The polyproline region and other likely PPII regions in MeCP2 are variable in length in different orthologs, suggesting that the actual length of the PPII helices is less important in the interaction with DNA. We also detected two single nucleotide substitutions in the 3 untranslated region of the MECP2 gene. Our results shed new light on the genotype-phenotype relationship of the MECP2 mutations, and a better understanding of the MECP2 protein structure.

Robot-assisted procedures prior to direct sequencing of the entire fibrillin 1 (*FBN1*) coding sequence as a strategy for the rapid mutation identification in patients with Marfan syndrome. *L. Tjeldhorn[1], S. Rand-Hendriksen[2], K. Gervin[1], K. Brandal[1], E. Inderhaug[1], O. Geiran[3, 4], B. Paus[1].* 1) Dept. of Medical Genetics, Ulleval University Hospital, Oslo, Norway; 2) TRS National Resource Centre for Rare Disorders, Sunnaas Rehabilitation Hospital, Nesoddtangen, Norway; 3) Dept. of Thoracic and Cardiovascular Surgery, Rikshospitalet University Hospital, Oslo, Norway; 4) University of Oslo, Norway.

The amplification and sequencing of the entire 235 kb gene, fibrillin 1 (*FBN1*), which is required for the identification of new mutations causing Marfan syndrome (MFS) and other type-1 fibrillinopathies, has been tedious. Most of the more than 600 known mutations in *FBN1* have been identified by indirect methods like SSCP, CSGE, and TGGE, screening for conformational changes prior to sequencing of selected fragments. However, it is not obvious that all mutations will be detected by screening for conformational changes. Optimizing conditions is time consuming and hence costly. Due to the size of the gene, new methods for high througput amplification and analysis is of particular interest to identify mutations in *FBN1*. We have been sequencing the entire *FBN1* coding sequence and flanking intronic sequences in 95 patients with suspected MFS, taking advantage of devices allowing for high throughput. The automated sequencing was preceeded by exonwise robot-assisted PCR setup, purification, and sequencing reactions. This allowed for a small reaction volume, reducing the costs. Using the programmed robot, preparation of PCR, purification, and preparation of sequencing reactions required less than one fifth of the time compared to manual workout. After sequencing all fragments once, mutations were identified in 62 individuals (65%). In the subgroup of patients fulfilling the diagnostic criteria for MFS (Ghent nosology) (n=76), mutations changing the amino acid sequence were identified in 57 individuals (75%), being in line with the mutation detection rate reported by others. We conclude that the robot-assisted method, making direct sequencing feasible as a primary strategy, is well suited for the rapid and accurate diagnostic mutation detection in the large gene, *FBN1*.

Mutation analysis of *DNAI1* in large cohort of patients with Primary Ciliary Dyskinesia (PCD). *M. Zariwala[1], M.P. Kennedy[1], M.W. Leigh[1], P.G. Noone[1], J. Horvath[2], H. Omran[2], H.M. Mitchison[3], R. Chodhari[3], E.M.K. Chung[3], L.M. Morgan[4], R.U. De Iongh[4], J. Rutland[4], U. Pradal[5], M.R. Knowles[1].* 1) UNC-Chapel Hill, NC; 2) the Universitats-Kinderklinik, Freiburg; 3) Royal Free and University College Medical School, London; 4) Concord Hospital, Sydney; 5) Univeristy of Verona, Verona.

Primary Ciliary Dyskinesia (PCD) is characterized by sino-pulmonary disease and half the patients have situs inversus (Kartagener syndrome [KS]). This disease is inherited as an autosomal recessive trait and results from axonemal abnormalities; 80% have dynein arm defects in cilia. Pathogenic mutations have been identified in *DNAI1* and *DNAH5*. Without careful categorization of the PCD/KS patients, genetic heterogeneity is a significant limitation for large-scale genetic testing. As part of an overall effort to study the phenotype and genetics of PCD, we have studied a large number of PCD/KS patients, including detailed analyses of clinical features, nasal ciliary ultrastructure, and nasal nitric oxide measurement. The current study reports mutation analysis in this cohort of PCD for *DNAI1*, which is an intermediate chain dynein that encodes an outer dynein arm (ODA). There were 140 unrelated patients and ODA defects were noted in 65 and axonemal defects in the other 75. 13 families were excluded from linkage to *DNAI1* and remaining 127 patients were completely sequenced. A total of 11 patients (8%) harbored mutations and the rate of mutation detection was higher (12%) in patients with defined ODA defect. Of the 11 patients, 3 were homozygous for the previously identified 219+3insT mutation, 4 were compound heterozygous and 4 had monoallelic mutations. Taken together, the previously published and current studies show 219+3insT mutation in 16 of 30 known mutant alleles and analysis is underway to find a founder effect. Exon 17 is emerging as a mutation hot spot (6 of 30 known mutant alleles). In conclusion, we have detected that 12% of PCD patients with ODA defect harbor mutations in *DNAI1*, which will be useful in developing a clinical genetic assay for PCD. This abstract was funded by GCRC#00046, MO1 RR00046-42, 1 RO1 HL071798, 5 U54 RR019480.

The Libyan Jewish mutation in dysferlin gene is common in Miyoshi myopathy patients from central Italy. *J. Mela[1,2], R. Di Giacopo[1], M. Catteruccia[1], R. Verardo[1], S. Servidei[1], G. Galluzzi[1,2].* 1) Neuroscience, Catholic University, Roma, Italy; 2) UILDM Rome-Section, Italy.

Miyoshi myopathy (MM), a distal muscular dystrophy, is caused by mutations in dysferlin gene on 2p13 that encompasses 55 exons and codes a 237 kDa protein localized to the plasma membrane of muscle fibers. Dysferlin function is not fully elucidated, but recently a central role in membrane-repair mechanisms was hypothesized. More than 100 pathogenic changes have been reported until now, but a common mutation (4872_4876delinsCCCC) was identified in the Libyan Jewish cluster with LGM2B/MM that was important for dysferlin gene characterization. We analyzed 23 Italian patients from 17 families with MM and reduction/absence of dysferlin protein on Western blot (WB) of muscle extracts. Onset affecting calf muscles varied from 14 to 20 years and progression was slow. Muscle biopsies showed dystrophic changes and marked inflammation. Genetic studies were performed by multiple heteroduplex analysis of all 55 exons and sequencing of DNA fragments with electrophoretic abnormalities. We found the mutation in 5 unrelated patients from non consanguineous families, all coming from a small area of central Italy around Rome. The mutation was absent in patients from the rest of Italy and beside the Libyan Jews cluster has been found in only one consanguineous French family. Four patients were homozygous and one was a compound heterozygote carrying in the second allele a new missense mutation in exon 51. The mutation causes a premature stop codon and accordingly dysferlin was absent on WB in homozygous patients, and reduced to 50% in a 14-year-old heterozygous asymptomatic carrier with high CK. In the compound heterozygote dysferlin was reduced to 10% of normal. Microsatellite analysis with polymorphic markers internal to dysferlin gene, showed identical haplotype associated with the mutation in all of the patients. The finding of 4872_4876delinsCCCC in two geographical clusters of populations strongly suggests the existence of a founder effect for this mutation and the importance of identifying common mutations in order to avoid time consuming genetic analyses in complex genes such dysferlin.

Mutation analysis of the FGF14 gene in Portuguese patients with ataxia. *I.F. Bento[1], I. Alonso[1,2], P. Coutinho[3], J. Sequeiros[1,2], I. Silveira[1].* 1) UnIGENe, IBMC, Universidade do Porto, Porto, Portugal; 2) ICBAS, Universidade do Porto, Porto,Portugal; 3) Serviço de Neurologia, Hospital de São Sebastião, Feira, Portugal.

Spinocerebellar ataxias (SCAs) are a large group of neurodegenerative disorders with autossomal dominant inheritance and clinical overlapping, as well as a highly variable phenotype. Until now, 25 different loci have been identified, and 12 genes are associated with these diseases, showing a large genetic heterogeneity. Two different mutations were recently described in the fibroblast growth factor 14 gene (FGF14) in a Dutch family and in one German patient with SCA. These patients have a particular phenotype, presenting with slowly progressive cerebellar ataxia, early-onset tremor, memory loss, dyskinesia and mild mental deterioration. The gene FGF14 maps to chromosome 13q34 and encodes a member of a subclass of fibroblast growth factors involved in a variety of biological processes such as mitogenic and cell survival activities. FGF14 is expressed in the developing and adult central nervous system with functions in neuronal signaling, axonal trafficking and synaptosomal function. In order to determine the underlying mutation in a large group of Portuguese patients with ataxia, we performed mutation analysis of the FGF14 gene. We have thus analyzed 204 unrelated SCA patients of Portuguese origin, previously excluded for other known forms of ataxia. Clinical manifestations included progressive ataxia, associated or not with other symptoms, such as epilepsy, mental retardation or tremor. Molecular analysis of the FGF14 gene was performed by PCR amplification of the 5 exons, followed by SSCP and sequencing. Variants were detected in exons 1, 2, 4 and 5. Sequencing analysis of fragments with these variants is now being carried out and results will be presented.

***De novo* G59V mutation in the *GJB2* (Connexin26) gene: a mutation hotspot for syndromic form of deafness and hyperkeratosis?** *R. Mao[1,2], B. Clifford[3], J. Palumbos[3], J. Metz[1], J.C. Carey[3].* 1) ARUP Laboratories; 2) Department of Pathology; 3) Department of Pediatrics, Division of Medical Genetics, University of Utah Health Sciences Center, Salt Lake City, Utah.

Connexin 26, encoded by the beta-2 gap junction protein (*GJB2*) gene, is one of the connexin proteins that play a major role in the gap junctions of cell-to-cell channels. It is expressed mainly in the brain, skin and cochlea. Mutations in GJB2 gene are the cause for more than 50% of profound pre-lingual genetic deafness. While most *GJB2* mutations are recessive, distinct dominant mutations in this gene are also demonstrated to underlie either skin disease or deafness or both. We present a *de novo* finding of G59V mutation in the *GJB2* gene in a 15-year-old girl having profound congenital hearing loss and hyperkeratosis on the palms. She was born after an uncomplicated pregnancy and family history of this condition is unremarkable. Sequencing analysis for the 5UTR and entire coding region of the *GJB2* gene for this patient showed a nucleotide substitution at position n.176 G>T, causing an amino acid alteration of Valine for Glycine at codon 59 (G59V). Both parents tested negative for this variant and misparentage was ruled out. In addition, the mutations of A1555G and A7445G in mitochondrial DNA tested negative in this individual. The G59V has not been previously reported. However, a G59A has been seen in a family with an autosomal dominant syndrome of palmoplantar hyperkeratosis and high-frequency hearing loss and a G59S was seen in a father and son with Bart-Pumphrey syndrome. Our patient has congenital hearing loss and similar skin findings as these two cases. Moreover, the Glycine59 is located within the highly conserved first extracellular loop of connexin 26, which is crucial for voltage gating and connexon-connexon interactions. Therefore, the G59V replacement may seriously compromise these functions. Our results demonstrate additional evidence that the G59 is one of the mutation hotspots in *GJB2* gene, associated with a dominant form of hearing loss and hyperkeratosis.

Two novel mutations in Fz4 cause familial exudative vitreoretinopathy. *Z. Yang[1, 2], D. Shukla[3], K. Howes[1], E. Pearson[1], Y. Zhao[1], G. Karan[1], K. Zhang[1].* 1) Ophthalmology, University of Utah, Salt Lake City, UT; 2) Sichuan Medical Science Academy & Sichuan Provincial Peoples Hospital, China; 3) Anna Nagar, Madurai - 625 020, Tamilnadu, India.

Purpose: To describe two novel mutations in the Fz4 gene that result in familial exudative vitreoretinopathy. Methods: Ophthalmic examination and genetic study were conducted in two kindreds with familial exudative vitreoretinopathy (FEVR). Genomic DNA was extracted from blood samples of members of those kindreds. Each of the 2 exons of Fz4 gene was amplified by PCR and sequenced using ABI 3100 genetic analyzer. Wild-type and FEVR-causing mutants of hFz4 were assayed for hNorrin binding and hNorrin-dependent activation of classical Wnt pathway by cell surface binding assays and luciferase assays. Results: Of 8 individuals and 6 individuals who were at risk of inheriting the disease gene in two families with familial exudative vitreoretinopathy (FEVR), 5 and 3 were diagnosed with FEVR respectively based on decreased visual acuity and ophthalmic examination. DNA sequence analysis identified two novel missense mutations 133 G>A (C45Y) and 172 A>G (Y58C). This sequence changes segregated with the disease phenotype and were not observed in 200 normal controls. The C45Y and Y58C mutants are produced at wt levels in 293 HEK cells by immunoblotting, the two Fz4 CRD region mutations affected the Norrin-Fz4 binding and are severely defective in hNorrin-dependent classical Wnt signaling. Conclusions: We identified two novel mutations in FZ4 causing FEVR. This study identified a new type of Fz4 gene mutation in which the Fz4 CRD mutations affect the Norrin-Fz4 binding and consequent classical Wnt signaling defect.

Screening of the dup(24bp) mutation of the *ARX* gene in mentally retarded patients with negative fragile X screening: First report in Thailand. *S. Rujirabanjerd[1], K. Tongsippunyoo[1], T. Sripo[1], J. Wirojanan[2], P. Limprasert[1].*
1) Department of Pathology, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand; 2) Department of Pediatrics, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand.

The frequency of X-linked mental retardation (XLMR) is estimated to be 1 in 600 males. The most common disease is fragile X syndrome. Nevertheless, there are several genes which have been thought to cause XLMR. One of them is the Aristaless related homeobox *(ARX)* gene. Phenotypic effects of *ARX* mutations are varied depending on types and locations of the mutations in the gene. The most common mutation is an inframed-duplication of 24 bp in exon two resulting in an addition of 8 alanines to the second alanine tract in the protein. Here we report the first series of *ARX* mutation screening in Thai pediatric patients. The majority of samples were from southern Thai population, and ~40% were from hospitals in Bangkok. Genomic DNA from 192 mentally retarded patients was extracted from peripheral blood. All samples were initially screened for fragile X syndrome by PCR and Southern blot. None of them showed abnormal results. All samples were subsequently screened for dup(24bp) mutation in exon 2 of the *ARX* gene by PCR. Only one patient showed abnormal results. The duplication was confirmed by direct PCR sequencing. Clinical and DNA analysis were performed in all family members of the affected individual. The inheritance pattern of the affected family showed typical X-linking where the patient was confirmed to inherit a mutational allele from his mother. Clinical examination of three affected individuals in the family showed moderate to severe developmental delay. No history of seizure or infantile spasm was observed in any affected individuals. Dystonia, one of the most common clinical symptoms reported, or other abnormal movement was not detected at the time of examination. No other remarkable anomalies were seen. Considering pleiotropic effect in individuals with *ARX* mutation, the clinical variation found in this family was expected. Genetic counseling was subsequently provided to the first Thai family with *ARX* mutation.

Characterization of hemophilia A and B mutations in Switzerland and a comparison of SSCA and direct sequencing approaches. *M.A. Morris[1], I. Surkova[1], A. Honsberger[1], P. de Moerloose[2], M. Schmugge[3], K. Peter-Salonen[4], E.O. Meili[5], G.A. Marbet[6], S. Hartmann[7], M. Neerman-Arbez[1], R. Kobelt[8].* 1) Service of Medical Genetics, University Hospital, Geneva, Switzerland; 2) Service of Angiology and Haemostasis, University Hospital, Geneva; 3) Department of Haematology, University Childrens Hospital, Zurich; 4) Central Haematology Laboratory, University Hospital, Bern; 5) Division of Haematology, University Hospital, Zurich; 6) Haemostasis Laboratory, University Hospital, Basle; 7) Medical Practice, Chur; 8) Swiss Hemophilia Association, Bern.

A nationwide program to characterize the mutations in all known hemophilia A and B patients was undertaken with the aim of providing better genetic services for families. The protocol was initially designed to provide good sensitivity of mutation detection at reasonable cost and then completed by direct sequencing of all F8C and F9 coding regions. Hemophilia A: 176 unrelated patients participated, 102 were defined as clinically severe. Patients were initially tested for the recurrent IVS22 inversions by Southern blotting. Inversions were found in 39 patients. The F8C gene was then screened by PCR-SSCA of all coding regions and exon-intron boundaries (for exon 14 only exon-intron boundaries). Exon 14 was also screened for nonsense mutations by PTT. All abnormal variants were sequenced. 39 patients with no identified mutations were screened by direct sequencing of all coding regions. Mutations were identified in 164/176 of all haemophilia A patients (93%), including 94% of severe, and 89% of mild and moderate patients. 102 discrete mutations were found, 54 of which have not been previously reported in the mutation databases. Hemophilia B: 39 unrelated patients participated in the study. The F9 gene was analysed by direct sequencing of the promoter region, all coding regions and exon-intron boundaries and the polyadenylation site. Mutations were identified in all patients but one (97%). We found 28 discrete mutations, of which 7 were novel. The results provide a national database of mutation data, the implications of which for phenotype-genotype correlations and genetic counselling will be discussed.

Screening for Novel Mutations in the Coding Region of the Ryanodine Receptor in Individuals with Malignant Hyperthermia Susceptibility. *S. Levano, M. Singer, A. Urwyler, Th. Girard.* Departments of Anesthesia and Research, University Hospital, Basel, Switzerland.

Malignant hyperthermia (MH) is a dominantly inherited pharmacogenetic disorder of skeletal muscle. MH is triggered by inhalative anesthetics in genetically predisposed individuals and the ryanodine receptor 1 (RYR1) has been identified as it's primary locus. In our MH center 40 % of Swiss families have shown causative mutations after sequencing the three hot spots of the RYR1 gene. We decided to analyse the entire coding region of RYR1 in the remaining Swiss families with unidentified mutations in order to increase the number of mutations eventually used for molecular genetic testing in MH. We selected 36 unrelated individuals from Swiss MH families, with ? 0.5g contracture following 2% halothane and 2mM caffeine in the in vitro contracture tests (IVCT). The RYR1 transcript was amplified by polymerase chain reaction (PCR) and analysed by direct-sequencing. Restriction fragment length polymorphism method was used within families with identified mutations in order to further investigate this mutation. Our mutation detection rate was 70% (26/36). Of the identified mutations 5 have previously been reported and 22 are novel. Eight individuals carried two different mutations, while two individuals had three mutations in the RYR1 transcript. Two novel mutations, R2336H and D2730G, were examined in detail. The mutation R2336H was detected in 7 families, and D2730G in one family. Results of the genetic analysis for both mutations showed good correlation with IVCT results. Out of 21 MH susceptible (MHS) patients evaluated for R2336H, 17 were mutation carriers and all 17 MHS in the family with mutation D2730G were mutation carriers. All MH normal patients were negative for both mutations. In a preliminary screening of 20 normal control chromosomes both mutations were not found. Analysis of the RYR1 transcript by PCR and sequencing showed a high detection rate of RYR1 mutations. In further steps we will investigate the functional effect of the novel mutations and will hopefully be able to offer molecular genetic diagnosis of MH susceptibility to a higher number of Swiss MH families.

LRRK2 G2019S mutation is common in North-African Parkinsons disease. *S. Lesage[1], L. Hafid[1], P. Ibanez[1], E. Lohmann[1, 3], A. Dürr[1, 2, 3], A. Brice[1, 2, 3, 4].* 1) INSERM U679 (formerly U289), Neurologie et Thérapeutique Expérimentale, Hôpital de la Pitié-Salpêtrière, AP-HP, 75013 Paris, France; 2) Département de Génétique, Cytogénétique et Embryologie, Hôpital de la Pitié-Salpêtrière, AP-HP, 75013 Paris, France; 3) Fédération de Neurologie, CHU Pitié-Salpêtrière, AP-HP, 75013 Paris, France; 4) UFR Pierre et Marie Curie, AP-HP, 75013 Paris, France.

Background : Mutations in the LRRK2 gene at the PARK8 locus have recently been identified in Parkinsons disease (PD), the second most frequent neurodegenerative disease. Preliminary studies from us and others indicate that the most common LRRK2 G2019S mutation is implicated in 3-6% and 1-2% of autosomal dominant PD and apparently sporadic forms of PD, respectively. Aim : To determine the relative frequency of the LRRK2 G2019S mutation in a sample of familial and sporadic PD index cases from North-African origin and to investigate for a shared haplotype in the G2019S mutation carriers. Patients and methods : Our North-African sample included 68 PD index cases (24 familial cases and 44 sporadic cases) and 48 ethnically matched controls. Exon 41 of the LRRK2 gene was screened by dHPLC and direct sequencing. Shared haplotype by LRRK2 G2019S was estimated by typing microsatellites and SNPs located within and in the vicinity of the LRRK2 gene. Haplotypes were constructed using the Merlin program. Results : The LRRK2 G2019S mutation was identified in 22 index cases including 2 homozygotes resulting from consanguineous families. Of them, 11 were familial cases (11/24, 46%) and 11 were sporadic cases (11/44, 25%). No mutation was found in controls. By analysing microsatellites and SNPs, we found a 60 Kb shared haplotype. Genotype/phenotype correlation analyses are in progress. Conclusion : Our results suggest that the LRRK2 G2019S mutation is highly common in North-African Parkinsons disease with an overall frequency of 32%. In addition, the G2019S carriers from North Africa shared the same common haplotype than PD patients from European origin, suggestive of a founder effect.

MEDICAL-GENETIC COUNSELING OF THE NERVOUS SYSTEM HEREDITARY DISORDERS IN MOLDOVA. *V.C. Sacara.* Medical Genetics, NCRHMGFP, Chisinau, Moldova, Republic of.

The first population genetic study of hereditary disorders of the nervous system (HDNS) in Republic of Moldova was carried out. A total of 19 nozological forms were revealed, included ten autosomal dominant (43 families with 80 affected individuals), six autosomal recessive (95 families with 99 affected) and two X-linked (106 families with 117 affected) diseases. Pooled prevalence of HDNS in Moldova didnt correspond to the average prevalence for other populations, for example Russian. Substantial differences between urban and rural populations were not observed. The composition of the HDNS spectrum nucleus in Moldova displayed number of difference from that in the majority of other examined. DNA analysis of the DMD/B families consists of detects deletions in 13 different exons of dystrophin gene and RFLP-analysis (pERT87-8/TaqI, pERT87-15/BamH1 and 16intron/TaqI), the algorithm of DMD/B molecular researches to define informative in 93%. The molecular studies at the SMNI locus (SMA disease) were performed. Homozygous deletions of the 7 and/or 8 exons were in 91%.. Some genetics features of the hereditary motor-sensory neuropathies have been revealed (intrafamilial polymorphism of different degree, effect of the ancestor in the dominant forms). According to publication date most CMT1A cases (>98%) are caused by a duplication of a 1.5 Mb region on the chromosome 17 containing the PMP22 gene. We test 2 STRs located within the duplication (tetra- and pentanucleotide repeats) 54 DNA samples of unrelated CMT1 patients . The CMT1A duplication was determine in 24.07% cases (gene dosage for heterozygous samples- different fluorescent intensity and /or three alleles). The presence of two alleles (59.3%) was used to indicate that no duplication was present in samples. Homozygous samples 16.6% required a competitive gene dosage test. The data obtained may constitute a basis for regional registration of HDNS in Moldova.

New CFTR gene variants in Cystic Fibrosis and Chronic Rhinosinusitis Chilean patients. *G. Molina[1], C. Musri[1], M. González[1], A. Vera[1], V. Lezana[2], A. Milinarsky[2], F. Krause[3], FJ. González[1].* 1) Laboratorio de Biología y Genética Molecular. Escuela de Medicina. Universidad de Valparaíso. Valparaíso. Chile; 2) Departamento de Pediatría. Escuela de Medicina. Universidad de Valparaíso. Valparaíso. Chile; 3) Cátedra de Otorrinolaringología. Escuela de Medicina. Universidad de Valparaíso. Valparaíso. Chile.

Cystic Fibrosis (CF) is the most prevalent autosomal recessive disease in the Caucasian population (1/2000 newborns). Its prevalence in Chile could vary between 1/4000 to 1/2000 newborns in different regions. CF is caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene, which encodes a protein that functions as a chloride channel. This protein regulates electrolytes and water transport through secretory cells. The failure of this protein produces a greater viscosity of mucus and other secretions. Chronic Rhinosinositis (RC) is a CFTR related disease, since greater viscosity of mucus is one of its causes. More than 1000 CFTR gene mutations have been described. We have searched for new mutations in 20 CF patients, using SSCA and sequencing of exon4, exon7, exon10 and exon17b. We have already found two variants(p.T351S, p.G528G) in three chromosomes. We have not detected the p.T351S variant in 100 chromosomes of individuals from Valparaisos general population, thus it could be a CF causative mutation. Conversely, p.G528G is a common polymorphism. Furthermore, we have determined that homozygous individuals for this variant have an exon 10 normal splicing, despite the fact that it modifies the last base of exon 10. In RC patients we have performed a complete screening of CFTR coding sequencing using RT-PCR of peripheral lymphocytes RNA. In one patient, we have found a splicing variant causing exon 5 skipping. This approach could lead us to discover new mutations responsible for the unknown 50% of CF causative mutations in our CF patients and to clarify the relationship between CF and RC. DIPUV 39/2004.

Variants in Tissue Necrosis Factor Increase Survival While Variants in Mannose Binding Lectin 2 Decrease Survival in Cystic Fibrosis. *K. Buranawuti[1], M. Boyle[2], G. Cutting[1].* 1) Inst of Genetic Medicine; 2) Dept of Pulmonary Medicine, Johns Hopkins School of Medicine.

Cystic Fibrosis (CF) patients with the same mutations in the CF Transmembrane Conductance Regulator (CFTR) gene can differ widely in survival suggesting other factors play a substantial role in mortality. Since dysregulated inflammation is believed to play a major role in CF pathogenesis, we determined whether variation in 36 genes (51 single nucleotide polymorphisms; SNPs) involved in innate immunity and inflammatory response influence survival of CF patients. The 51 SNPs were typed in 4 Caucasian groups recruited from the same medical center: 115 CF survivors (patients > 16 y.o.), 101 CF children (16 y.o.), 176 disease controls (chronic sinusitis patients), and 127 normal controls. Three comparisons of genotype frequencies were performed using Monte-Carlo permutation analysis; CF survivors vs. CF children, CF survivors vs. disease controls and CF survivors vs. normal controls. Five SNPs demonstrated unequal genotype frequencies in two of the three comparisons (IL1, IL5R, IL6, IL13, and TGF1) and two SNPs were unequal in all three comparisons (TNF and MBL2). The genotype frequencies of these seven SNPs were then compared between CF survivors and 38 CF patients from the same birth cohort and same medical center who had died (21) or had lung transplantation (17) after 16 years of age. Single SNPs from only two of the seven genes displayed significant differences in genotype frequencies: TNF-238 G/A genotype ($p<0.001$) and MBL2 O/O genotype ($p< 0.009$; Fishers exact). Kaplan-Meier plots of age at death revealed that survival of patients bearing TNF-238 G/A was increased significantly vs. G/G ($p= 0.02$) and survival of patients bearing MBL2 O/O was decreased significantly vs. A/A or A/O ($p =0.004$; Log Rank P value). These effects were independent of CFTR genotype. The logistic regression analysis indicated that the odds ratio for survival is 9 times greater for CF patients with the TNF-238 G/A while the odds ratio for survival of the MBL2 O/O is 8 fold lower. Thus, TNF-238 G/A and MBL2 O/O appear to be positive and negative modifiers of CF survival, respectively.

Alternative splicing analysis of *Pkhd1*, the ARPKD gene, in kidney and liver. *R. Punyashthiti, C.J. Ward, S.L. Whelan, J.R. Woollard, V.E. Torres, P.C. Harris.* Nephrology, Mayo Clinic College of Medicin, Rochester, MN.

Autosomal recessive polycystic kidney disease (ARPKD) is caused by mutations to *PKHD1*, a large multi-exon gene on chromosome 6. The *PKHD1* protein product, fibrocystin, is predicted to be a large glycosylated transmembrane protein with a short cytoplasmic tail. Northern and RT-PCR data has let to the proposal that *PKHD1* has multiple differentially spliced transcripts that give rise to several protein isoforms, including secreted products.

Here we describe analysis of *Pkhd1* variants by northern blotting, RT-PCR, and 5RACE in mouse to assess the full level of variability. A major 13kb mRNA transcript was detected by northern blotting on adult kidney by several probes with additional faint products of 9 and 7.5kb detected by probes to the 5 part of the gene. Long-range RT-PCR was also consistent with a modest level of variability with a single product generally detected, but with a number of smaller variants in the exon 52 to 62 region. One of the products was found to have 961 nt of exon 61 missing, and generate a premature stop codon before nucleotides encoding the transmembrane domain. This mRNA could encode a secreted fibrocystin isoform lacking the cytoplasmic tail. This splice form is found in kidney and biliary tree, suggesting functional significance.

At the other end of the gene, we have sought novel mRNAs by 5RACE that may explain the lack of/ mild kidney phenotype in a mouse model with the first coding exon (exon 2) removed. The major detected transcript was that predicted, splicing from exon 1 to 3, but a variant that has lost exon 5, and is predicted to utilize a novel start codon in exon 4, when exon 2 is missing, was also found. However, this product does not have a classical signal peptide and does not seem to function as an efficient signal peptide in an in vitro assay.

Our studies suggest that *Pkhd1* does not generate countless fibrocystin molecules, but that specific splice variants are generated in kidney and liver and that some specific variants may be critical for normal function.

APTX, spinocerebellar ataxia protein, is an exonuclease and releases blocked DNA 3-ends. *M. Tada[1], T. Takahashi[1], S. Igarashi[1, 2], A. Yokoseki[1], H. Date[3], H. Takano[1], M. Oyake[1], S. Tsuji[3], M. Nishizawa[1], O. Onodera[1, 2].*
1) Department of Neurology; 2) Department of Molecular Neuroscience, Resource Branch for Brain Disease Research, Center for Bioresource-based Research, Brain Research Institute, Niigata University; 3) Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

Purpose: To investigate the function of aprataxin (APTX) on DNA substrates. Background: APTX is the causative gene product for the early-onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH/AOA1), a spinocerebellar ataxia with peripheral axonal neuropathy. APTX binds to X-ray repair cross-complementing group 1 protein, which is the scaffold protein for base excision repair machinery in SSBR. The lymphoblastoid cells of EAOH/AOA1 patients are sensitive to agents which cause single strand breaks. These findings support the idea that APTX plays an important role in SSBR. The roles of APTX in SSBR, however, remains unclear. Materials & Methods: His-tagged human full length APTX was expressed using baculovirus expression system and was purified to homogeneity by metal affinity and gel filtration chromatography. Nicked double strand or single strand DNA substrates labeled by fluorescein were incubated with APTX protein at 37C. The products were analyzed by electrophoresis in a 20% polyacrylamide denaturing gel. Results: APTX had bidirectional exonuclease activities. Although some 3'5' exonucleases preferentially excise a mismatched DNA 3'-terminus to increase fidelity of DNA repair system, the APTX equally excised matched and mismatched DNA termini. Furthermore, APTX hydrolyzed the phosphate and phosphoglycolate at 3'-end. Conclusions: We showed that the APTX had the bidirectional exonuclease, 3'-phosphatase and 3'-phosphoglycolate hydrolase activities. These findings suggest that APTX removes blocked 3'-ends which interfere SSBR. Spinocerebellar ataxia with axonal neuropathy-1 is caused by mutation of tyrosil DNA phosphodiesterase 1 (TDP1), which also removes a tyrosyl-modified 3'-end. The mechanism of neurodegeneration by impairment of removing blocked 3'-end should be elucidated.

Identification of a functional nuclear localization signal in the human -dystroglycan. *M. Bermudez de Leon[1], L. Fuentes-Mera[1], P. Gomez[1], V. Tapia-Ramirez[1], F. Garcia-Sierra[2], B. Cisneros[1].* 1) Dept. Genetics & Mol. Biol; 2) Dept. Cell Biol., CINVESTAV-IPN, Mexico city, Mexico.

The dystroglycanopathies are a novel group of human muscular dystrophies caused by gene mutations in essential transmembrane adhesion receptors. -dystroglycan is an extracellular protein that interacts with both; laminin at the extracellular matrix and -dystroglycan (DG) at the cellular membrane. In turns, DG is a transmembranal protein that interacts with dystrophin and actin via its cytoplasmic domains. Recently, we have observed that DG is present in the nucleus of HeLa cells suggesting that this protein could have a nuclear function. To determine the cellular signals controlling the nuclear localization of DG, we fused its cDNA to that of the green fluorescent protein (GFP). We found, by immunofluorescence and confocal microscopy analyses that the GFP-DG protein fusion immunostaining localized primarily in the cytoplasm of HeLa cells showing also a punctuate pattern in nucleus, which was excluded from the nucleoli. Such subcellular localization pattern was similar to that of the endogenous DG. We identified a stretch of basic amino acids in the DG C-terminal domain that could correspond to a nuclear localization sequence (NLS). Interestingly, the removal of the putative NLS prevented the nuclear localization of the GFP-DG fusion protein and caused an abnormal cytoplasmic accumulation. Currently, by site-directed mutagenesis, identification of the essential amino acids in the NLS is underway. Finally, the presence of a potential nuclear exporting signal was evaluated by leptomycin B-treatment. No alterations in the DG subcellular localization were observed in the leptomycin B-treated HeLa cells. In conclusion, the DG contains a functional NLS that regulates its subcellular distribution and might modulate its cellular functions.

Axonal swellings and impaired axonal transport in a mouse model of spastic paraplegia linked to spastin mutation. *C. Fassier[1,4], A. Tarrade[1,4], S. Courageot[1], D. Charvin[1], A. Thorel[2], N. Roblot[1], A. Dierich[3], J. Melki[1].* 1) Dept Molecular Neurogenetics, INSERM E-223, Evry, France; 2) Centre des Matériaux, Evry; 3) IGBMC, Illkirch; 4) equal contribution.

Hereditary spastic paraplegia (HSP) is a neurological disorder characterized by axonal degeneration of corticospinal tracts. The most prevalent form of autosomal dominant HSP is linked to spastin (Sp) mutations, a microtubule severing protein. To elucidate the pathophysiology of HSP, homologous recombination in murine ES cells has been used to create a deletion of Sp exons 5 to 7. Mice carrying heterozygous (Sp/+) or homozygous (Sp/) deletion have been generated and characterized. Deletion of Sp was confirmed at the genomic, transcript and protein levels. Transverse semi-thin sections of spinal cord revealed axonal swellings in mutant but not control mice. The frequency of axonal swellings was increasing with aging. In addition, they were more frequent in (Sp/) than in (Sp/+) mutant mice of the same age suggesting a haploinsufficiency mechanism. No abnormality of sciatic nerve axons was observed. Spinal cords were then processed for electron microscopic analysis. Axonal swellings were filled with mitochondria, multilamellar bodies, lysosomes, membrane dense bodies and neurofilaments which strongly suggest an axonal transport defect in vivo. Interestingly, primary culture of cortical neurons derived from 14 d.p.c. embryos revealed neurite swellings in mutant but not control cells, features in agreement with in vivo data. The number of neurite swellings was higher in (Sp/) than in (Sp/+) cells, suggesting once again a haploinsufficiency mechanism underlying HSP linked to Sp mutation. Moreover, the lack of glial cells in our neuron culture indicated that Sp acts cell autonomously in neurons by contributing to neurite integrity. Our results show for the first time that Sp mutations are responsible for a progressive axonopathy restricted to the central nervous system and characterized by axonal swellings and axonal transport defect. Such results provide strong evidence that microtubule severing activity is an essential process for maintaining axonal integrity and transport in vivo.

Transgenic strategy to determine new sites of WNK1 expression, a gene responsible for FHHt. *C. Delaloy, M. Clemessy, J. Hadchouel, X. Jeunemaitre.* INSERM, Collège de France, Paris, France.

WNK1 and WNK4, two genes belonging to a new serine-threonine kinase family are responsible for FHHt, an autosomal dominant form of hypertension. The biological and clinical features of the syndrome have highlighted the importance of their expression in the renal tubule and their role in the regulation of ionic transport. However WNK1 gives rise to several isoforms, some ubiquitously expressed with a complete kinase domain (LI: Long Isoforms) and one specifically expressed in the distal nephron wich is kinase defective arising from alternate promoter. Expression of both isoforms may be affected in FHHt patients bearing large deletions of WNK1 first intron. To understand the mechanism of the pathology and the role of WNK1 in blood pressure regulation we characterized the expression of WNK1 isoforms by using a transgenic approach. The nlacZ reporter gene was inserted in a BAC transgene that includes 160kb of the mouse WNK1 locus. Three founder lines from this construct showed ubiquitous LacZ staining which recapitulated the expression pattern seen by northern blot in different tissues and by immunostaining in polarized epithelia. We analysed in more detailed the LI-WNK1 expression in embryos of various stages and in adult organs and compared the results to those of in situ and in toto hybridizations. LI-WNK1 expression was detected in the early developing cardiovascular system. In adults positive staining was observed in arteries and veins, in endothelial cells as well as smooth smooth muscle cells. Whereas a diffuse and weak expression in the kidney was expected we observed an expression mainly restricted to the CTAL and DCT. In the central nervous system the transgene was expressed specifically in the cerebellum. These results suggest that WNK1 may be involved in the morphogenesis of cardiovascular development and cardiovascular function in adult. Together with the lethality of LI-WNK1 deficient embryos and the low blood pressure observed in heterozygous mice without any metabolic disorder, they also suggest that a perturbation of the LI-WNK1 expression might play a role in the increased BP observed in FHHt.

Over-expression of Syntaxin 1A in mice results in abnormal glucose homeostasis similar to that seen in patients with Williams-Beuren syndrome. *P.P.L. Lam[1,2], Y.M. Leung[1,2], L. Sheu[1,2], J. Ellis[3], R.G. Tsushima[1,2], H.Y. Gaisano[1,2], L.R. Osborne[1].* 1) Medicine, University of Toronto, Toronto, Ontario, Canada; 2) Physiology, University of Toronto, Toronto, Ontario, Canada; 3) Developmental Biology, Sick Kids Hospital, Toronto, Ontario, Canada.

The SNARE protein Syntaxin 1A (STX1A) plays an essential role in exocytosis, and also binds and regulates $Ca2^{+}$ and K^{+} channels to influence the sequence of events leading to insulin secretion. Pancreatic islet levels of STX1A are reduced in type-2 diabetic rodents, but normal glycemic function can be restored by adenoviral transfer of STX1A. Patients with Williams-Beuren syndrome (WBS), who harbor a 1.5 Mb deletion on chromosome 7 encompassing the STX1A gene, also exhibit a variety of endocrine phenotypes, including an increased incidence of diabetes mellitus and a high frequency of impaired glucose tolerance. Taken together, these studies suggest that fluctuating levels of STX1A in pancreatic islets have an exquisite control over the different components of insulin secretion. We investigated the specific role of STX1A in pancreatic -cells by generating transgenic mice with a 30% increase in STX1A protein in pancreatic islets. The STX1A mice displayed fasting hyperglycemia and a more sustained elevation of plasma glucose levels after an intraperitoneal glucose tolerance test, with correspondingly reduced plasma insulin levels. Surprisingly, -cells from the STX1A male mice also exhibited abnormal insulin tolerance. We employed single cell analyses of exocytosis by patch clamp membrane capacitance (Cm) measurements and ion channel recordings to determine the -cell secretory defects. Depolarization-evoked Cm increases were reduced in the STX1A mouse islet -cells and the mice also exhibited reduced currents through $Ca2^{+}$ channels. These results suggest that even moderate changes in the level of STX1A protein can have a dramatic influences on the differential regulation of -cell ion channels and the exocytotic machinery. We hypothesize that the impaired glucose homeostasis seen in patients with WBS is a direct effect of the deletion of one copy of the STX1A gene, causing a change in STX1A protein levels in -cells.

Developmental Pathways Involved in Synostosis of Coronal Sutures in Twist1 Heterozygous-Null Mice. *Y. Wang, J. Cai, E.W. Jabs.* Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Saethre-Chotzen syndrome is an autosomal dominant condition with both craniosynostosis of the coronal sutures and limb abnormalities. Most Saethre-Chotzen patients have loss of function mutations in TWIST1, a basic helix-loop-helix transcription factor critical in craniofacial and limb development. Some patients have a FGFR3 P250R mutation. TWIST1 has been implicated in the inhibition of differentiation of multiple cell lineages, including muscle and bone, but the molecular signaling pathways related to TWIST1 are poorly understood. The DNA binding sequences for TWIST1 are not well known either. There is some evidence in mouse and Drosophila that Twist1 and Fgfrs may be components of the same molecular pathway. Twist1 heterozygous-null mice have been created and have variable expression of craniofacial and limb defects consistent with Saethre-Chotzen syndrome. To investigate the downstream targets of TWIST1 signaling pathways involved in craniosynostosis, we dissected developing coronal sutures from heterozygous-null Twist1 mice as well as normal littermates, and performed microarray gene expression analysis on sutural RNA samples. We were able to identify 33 and 203 genes differentially expressed (p0.05) in coronal sutures between mutant and wildtype mice, at E16 and E18 stages, respectively. Interestingly, one of these genes expressed at E18 is Spry1, which is known to be induced by activating mutations in Fgfr3. Only three genes (Tac1, Osmr and 1110017D07Rik) as well as Twist1, were differentially expressed at both stages. These differentially expressed genes are overrepresented from functional categories of morphogenesis, organogenesis, and bone mineralization/remodeling. Some of these genes may be directly controlled by Twist1, and may share common promoter sequences that would be overrepresented in these genes. The identification of downstream targets of Twist1 could provide valuable information about additional factors that may be important in Twist1 and Fgfr3 signaling pathways and the pathogenesis of Saethre-Chotzen syndrome.

Mouse Model for Apert Syndrome Fgfr2 +/P253R. *M. Sun, Y. Wang, R. Xiao, D. Huso, E.W. Jabs.* Johns Hopkins Univ, Baltimore, MD.

Apert syndrome (OMIM 101200), an autosomal dominant disorder characterized by severe skull malformations and syndactyly of the hands and feet, is caused by gain-of-function mutations in fibroblast growth factor receptor 2 (FGFR2). Approximately 33% of Apert syndrome patients have a FGFR2 P253R mutation while the others have a FGFR2 S252W mutation. It has been hypothesized that the P253R mutation is associated with milder craniofacial abnormalities and more severe syndactyly than the S252W mutation. Our laboratory previously created and characterized a mouse model for the S252W mutation (Wang et al. Development, in press). The generation of a knock-in mouse model with the P253R mutation will be very useful to study phenotype-genotype correlations between the two Apert syndrome FGFR2 mutations and the pathogenesis of this condition.

We engineered an Fgfr2 +/P253R knock-in mouse model. Necropsy, histological analysis, and bone and cartilage staining were conducted on heterozygous mutant mice at postnatal day 0 (P0), P5 and P10. Many abnormalities of the skeleton, including skull, long bone and sternum were found. An incompletely fused palate was present in all the mutant mice from embryonic 16.5 (E16.5) to P0. Abnormal cartilage at the midline sagittal suture, the coronal suture and long bones were noted. Presynostosis/synostosis was found at the mutant coronal suture. Abnormal proliferation and differentiation were found at the midline sagittal suture. There was no apparent difference in apoptosis between mutants and control littermates at the sagittal suture at P0. None of the mutants exhibited syndactyly. These observations are similar to those found in the Fgfr2 +/S252W mice except that the Fgfr2 +/P253R mice can survive longer and may have milder phenotypes. Both Fgfr2 mutations result in abnormal cartilage as well as bone formation which may give insight into the molecular process of cell fate determination of the chondrocyte and osteoblast lineages. [This work has been supported by the International Collaborative Genetics Research Training Program (NIH D43 TW 06176)].

Mouse Model of Adenylosuccinate Lyase Deficiency. *E.K. Spiegel[1], S. Forbes[2], D. Patterson[2].* 1) Human Medical Genetics, University of Colorado Health Sciences Center, Denver, CO; 2) Eleanor Roosevelt Institute, University of Denver, Denver, CO.

Adenylosuccinate lyase deficiency is a disease of purine metabolism which affects patients both biochemically and behaviorally. The symptoms include psychomotor retardation, autistic features, hypotonia, and seizures. Patients also accumulate the substrates of ADSL in body fluids. Both the presence of normal levels of ADSL enzyme activities in some patient tissues and the absence of a clear correlation between mutations, biochemistry, and behavior show that the system has unexplored biochemical and/or genetic complexity. It is unclear whether the pathological mechanisms of this disease result from a deficiency of purines, a toxicity of intermediates, or perturbation of another pathway or system. Our goal is to produce a mouse model of this disease using mutations found in patients, which will aid in elucidating the *in vivo* mechanisms of this disease. A patient with autistic features and mild psychomotor delay carries two novel mutations in this gene, E80D and D87E. Using site-directed mutagenesis, we have engineered these mutations and the most common ADSL mutation, R426H, in a human genomic ADSL P1 clone. Transgenic mice have been created with these constructs and with the wild type human ADSL gene. We have also used mouse ES cells with an inactivated ADSL gene to introduce this ADSL knockout mutation into mice. The creation of a mouse model of ADSL deficiency will be accomplished by crossing lines with mutated human ADSL transgenes to the knockout ADSL line. These ADSL deficient mice will be analyzed biochemically for levels of purines and intermediates, and for enzyme activity. These mice, humanized for ADSL mutations, will allow us to investigate the roles of purine deficiency and intermediate accumulation in ADSL pathology, to test for behavioral changes resulting from specific ADSL mutations, and to test therapies to reverse the biochemical deficits in the mutant mice.

A2E Accumulation Associated with Mutant *ELOVL4* Expression in Mice. *J. Cameron[1,2], G. Karan[1,2], Y. Chen[1,2], Z. Yang[1,2], Y. Zhao[1,2], S. Kamayama[1,2], A. Azimi[1,2], E. Pearson[1,2], H.R. Vollmer-Snarr[3], K. Zhang[1,2].* 1) Department of Ophthalmology and Visual Sciences, University of Utah, Salt Lake City, UT; 2) Program in Human Molecular Biology and Genetics, University of Utah, Salt Lake City, UT; 3) Department of Chemistry and Biochemistry, Brigham Young University, Provo, UT.

The gene *ELOVL4* causes dominant Stargardt-like macular dystrophy (STGD), a juvenile onset macular degeneration that shares many features with age-related macular degeneration (AMD), including lipofuscin accumulation in retinal pigment epithelial cells (RPE) and degeneration of photoreceptors. Recently we have shown that transgenic mice expressing the mutant human *ELOVL4* are a good model for both STGD and AMD. These mice have significant declines in their retinal electrophysiological responses, as well as, substantial photoreceptor degeneration and lipofuscin accumulation. Here we further demonstrate that A2E, a major component in lipofuscin, increases in a dynamic fashion with *ELOVL4* expression and severity of RPE degeneration.

Using HPLC and MS to analyze RPE homogenates from *ELOVL4* transgenic mice we see an increase in A2E levels associated with a moderate to high expression of *ELOVL4* and a moderate loss of photoreceptors. However, allowing photoreceptor degeneration to become more severe in the moderate and high *ELOVL4* expressing mice results in a significant decrease in A2E levels. Such a decrease can be attributed to the lack of photoreceptors and RPE atrophy in the central retina. This data suggests that A2E formation varies due to *ELOVL4* expression and severity of degeneration in the central RPE. *ELOVL4* mice provide a valuable model for therapeutic trial of macular degeneration.

Epistatic interaction between fibrillin-1 and effectors of TGF signaling in the pathogenesis of aortic aneurysm in Marfan syndrome. *T.M. Holm[1], B. Loeys[1], J. Habashi[1], L. Meyers[1], D. Bedja[1], E. Neptune[1], D. Judge[1], H. Dietz[1,2].* 1) Institute for Genetic Medicine; 2) HHMI, Johns Hopkins Univ., Baltimore, MD.

Marfan Syndrome (MFS) is a connective tissue disorder caused by mutations in the fibrillin-1 gene (FBN1). Clinical manifestations include ectopia lentis, aortic dilatation and dissection, and long bone overgrowth. Previous studies of Fbn1-targeted mice demonstrated that failure of distal lung septation and myxomatous change of mitral valves are correlated with excessive TGF activation and were rescued by TGF antagonism in vivo. We hypothesized that decreasing the expression of Smad4, a positive effector of TGF signaling, would rescue phenotypes due to excessive TGF activation. Smad4-haploinsufficient mice were crossed to Fbn1-targeted mice. Surprisingly, compound mutant mice die at six times the rate of mice carrying the Fbn1 mutation alone. Furthermore, echocardiograms showed large aneurysms above the sinotubular junction that were unique to compound-mutant mice. Vascular disease was absent or limited to the root of the aorta in the single mutants (Smad4+/- and Fbn1+/-, respectively). As opposed to the Fbn1+/- mice, which show wall thickening and excess collagen deposition, compound mutants showed thinning and collagen paucity. Nuclear pSmad2 (marker of TGF signaling) was enriched in Fbn1+/- mice compared to controls, but greatly reduced in compound mutants. It seemed possible that excessive TGF signaling induced by fbn-1 deficiency might limit signaling through other Smad4-dependent cascades (eg BMPs); this effect would be amplified in the Smad4-deficient state. In support of this view, we found that TGF neutralizing antibody attenuates aortic dilatation in Fbn1+/- mice, while prenatal BMP antagonism by conditional overexpression of Smad6 induces synthetic lethality. Curiously, Smad4 haploinsufficiency rescues the TGF-induced failure of lung septation in fibrillin-1 deficient mice. These data suggest tissue-specific differences in the secondary effects attributable to excess TGF signaling. While the complexity of crosstalk between TGF signaling cascades requires further elucidation, these data will inform the effort to identify genetic modifiers of MFS in humans.

Mutant Wnk4 reveals mechanisms of hypertension and hyperkalemia. *M.D. Lalioti[1], J. Zhang[2], K.T. Kahle[1], K. Hoffmann[1], H.R. Toka[1], C. Nelson-Williams[1], C.J. Booth[3], Y. Lu[1], D.S. Geller[2], R.P. Lifton[1,2,4].* 1) Depts of Genetics; 2) Nephrology; 3) Section of comparative Medicine, Yale Univ Sch Medicine, New Haven, CT; 4) Howard Hughes Medical Institute.

Point mutations in the serine-threonine kinase gene *Wnk4* cause pseudohypoaldosteronism type II (PHAII), an autosomal dominant disorder featuring hypertension, hyperkalemia, and metabolic acidosis. *In vitro* studies have shown that wild-type (WT) WNK4 inhibits the NaCl cotransporter NCCT and the K+ channel ROMK and that PHAII mutations have divergent effects: inhibition of NCCT is lost and inhibition of ROMK increases. To extend these observations *in vivo*, we used a bacterial artificial chromosome (BAC) containing the mouse *Wnk4* and introduced the PHAII-specific Q562E mutation by recA-assisted recombination. We have also engineered a control BAC carrying a single nucleotide polymorphism (SNP) in the Wnk4 gene. In animals carrying two copies of the transgene, its tissue distribution and expression was virtually identical to the endogenous gene. Compared to WT littermates, PHAII mice displayed significantly elevated blood pressure (Sys/diaBP of PHAII mice was 125.1 2.5 / 92 2.5 mmHg (n=6) and of WT mice was 117.4 0.6 / 85.5 1.4 mmHg (n=14), Psys<0.0005, Pdia<0.005), higher serum K+, Cl- and Mg+, lower bicarbonate levels, lower renin, and hypercalciuria. The levels of sodium and calcium were normal. In cotrast, the control animals carrying two copies of the WT transgene (WTpol) had lower BP and higher serum Cl- and all other parameters were normal. qPCR and immunohistochemistry of mouse kidney sections stained with anti-NCCT and anti-Calbindin D-28K antibodies (a marker of the distal nephron) revealed increased expression of NCCT in PHAII mice. These features recapitulate PHAII in humans and comfirm that the mutation is a gain-of-function. These data indicate the essential role of WNK4 in determining the balance between Na+ reabsorption and K+ secretion in the distal nephron.

Epistasic Effects of the Gene Encoding the Gamma Subunit of cGMP-phosphodiesterase on Retinal Dystrophies.

S. Tsang[1], M.L. Woodruff[2], C.K. Chen[3], C.K. Yamashita[2], S.P. Goff[1], D.B. Farber[2], G.L. Fain[2]. 1) Columbia U., NY, NY; 2) UCLA, CA; 3) VCU, Richmond, VA.

The gamma subunit of rod phosphodiesterase (PDE6gamma) inhibits the catalytic alpha and beta subunits in darkness; binding of activated GNAT1-GTP removes this inhibition, stimulating PDE activity. PDE6gamma has also been shown to act as a GTPase Accelerating Protein (GAP) for GNAT1-GTP by potentiating the action of another GAP, Regulator of G-protein Signaling 9 (RGS9). Previous experiments have suggested that excess PDE6gamma could turn off transduction and modulate the decay of the light response. We have tested this idea by over-expressing wild-type PDE6gamma in a transgenic mouse. While Pde6gtm1/Pde6gtm1mice mice have severe photoreceptor degeneration as in human retinitis pigmentosa, over-expression of the wild type transgene in the knockout Pde6gtm1/Pde6gtm1mice background prevents this degeneration. Rods with overexpressed PDE6gamma were desensitized ~4-fold compared to wild-type controls; the intensity of light (20ms flashes, 500 nm) needed for 50 percent of saturation was about 6 photons/microm2 for controls, but about 25 photons/microm2 for PDE6gamma over-expressors. Single photon analysis revealed that the light response wave form of PDE6gamma over-expressors was similar to wild-type during the rising phase of the response, but recovery of current following the flash occurred more rapidly. The single photon time-to-peak for controls was about 200 ms, with a full return of the current to the dark level at about 1 s; whereas the PDE6gamma over expressers had a time-to-peak of 150 ms, and a return of current to the dark level at about 0.5s. Acceleration of the turn-off of PDE then speeds the waveform of decay of the light response. Humans or mice with defects in the RGS9 also deactivates of their phototransduction cascades slowly. Patients with RGS9 defects generally complain of being completely blinded by rapid changes in light levels, as when they drive into a tunnel. This bradyopsia phenotype could be so severe that it necessitated immobility or assistance for a few seconds. However, introduction of our PDE6gamma allele masks this bradyopsia phenotype.

Dynamic Expression of Hsp27 in the presence of mutant ataxin-3. *M. Hsieh[1, 2], W.H. Chang[1], C. Cemal[3], Y.H. Hsu[4], N. Nukina[5], C.S. Liu[6].* 1) Dept Life Sci, Tunghai University, Taichung; 2) Life Science Research Center, Tunghai University, Taichung, Taiwan; 3) Hereditary Ataxia Research Group, Imperial College of Science, Technology and Medicine London SW7 2AZ, UK; 4) Department of Medicine, Tzu-Chi University, Hualien, Taiwan; 5) Laboratory for Structural Neuropathology, RIKEN Brain Science Institute, RIKEN, Wako-shi, Japan; 6) Department of Neurology, Changhua Christian Hospital, Changhua, Taiwan.

Machado-Joseph disease (MJD)/Spinocerebellar Ataxia Type 3 (SCA3) is an autosomal dominant spinocerebellar degeneration characterized by a wide range of clinical manifestations. In this study, human SK-N-SH neuroblastoma cells stably transfected with full-length MJD with 78 CAG repeats were assayed for the dynamic expression of Hsp27, known as a suppressor of poly (Q) mediated cell death, in the presence of mutant ataxin-3 in different passages of cultured cells. A dramatic decrease of Hsp27 expression was observed in the earlier passage of cultured SK-N-SH-MJD78 cells, however, the later passage of cells showed a significant increase of Hsp27 to almost the same level of the parental cells. Furthermore, immunohistochemical analysis of MJD transgenic mice and post-mortem human brain tissues showed increased expression of Hsp27 compared to normal control brain, suggesting an up-regulation of Hsp27 in the end stage of MJD. However, mutant cells of earlier passages were more susceptible to serum deprivation than mutant cells of later passages, indicating weak tolerance toward stress in cells with reduced Hsp27. Taken together, we proposed that during the early disease stage, the reduction of Hsp27 synthesis mitigated the ability of neuron cells to cope with cytotoxicity induced by mutant ataxin-3, triggering the cell death process during the disease progress. In the late stage of disease, after prolonged stressful conditions of polyglutamine cytotoxicity, the increased level of Hsp27 may reflect a dynamic process of the survived cells to unfold and remove mutant ataxin-3. However, this increased Hsp27 still cannot reverse the global dysfunction of cellular proteins due to accumulation of cytotoxic effects.

Somatic instability of expanded triplet repeats occurs after organogenesis and is tissue and age-dependent. *I. De Biase[1], R.M. Clark[1], S. Al-Mahdawi[2], A. Monticelli[3], S. Cocozza[3], M. Pook[2], S.I. Bidichandani[1].* 1) Dept Biochemistry & Molecular Biology, Univ Oklahoma HSC, Oklahoma City, OK; 2) Dept of Medical Genetics, Imperial College, London, UK; 3) Dept of Molecular and Cellular Biology and Pathology, Frederico II University, Naples, Italy.

Friedreich ataxia (FRDA) is characterized by gait and limb ataxia associated with cardiomyopathy and diabetes mellitus. The primary sites of pathology are the dorsal root ganglia (DRG). Loss of Purkinje cells in the cerebellum has been described late in disease. FRDA is caused by an abnormal expansion of a GAA triplet repeat sequence (GAA-TR). Repeat length is the main determinant of phenotypic severity. When expanded, the GAA-TR is highly unstable in somatic and germ cells. Using small pool PCR (SP-PCR) analysis, which allows us to detect changes in repeat length in individual chromosomes, we examined whether there are tissue-specific differences in GAA-TR instability. We analyzed multiple tissues from three autopsies of FRDA patients. As previously described in leukocytes, all the tissues analyzed showed a contraction bias. Instability did not correlate with proliferative capacity. However, the frequency and magnitude of expansions was higher in DRG and in cerebellum. To confirm our data, we used a transgenic mouse model, carrying expanded GAA-TR tract within the context of the human FRDA gene. Interestingly, the only tissue that showed significant instability was the cerebellum, although mouse DRG samples were not available for analysis. Our data indicate that non-replication dependent mechanisms have a role in mediating triplet-repeat instability. A higher level of instability was seen in two-month old mice compared to that observed in twelve-month old mice, indicating that instability is also age-dependent. To further address this issue, SP-PCR analysis was performed in multiple tissues from an 18-week fetus with a molecular diagnosis of FRDA, which revealed very low levels of somatic instability compared to corresponding adult tissues. Taken together, our data indicate that somatic instability occurs after organogenesis. Expansions of high magnitude develop in DRG and cerebellum and the process is age-dependent.

Molecular genetic analysis of Spanish Spinocerebellar Ataxias (SCA). *V. Volpini[1], H.S. Nicolás[1], J. Corral[1], I. Banchs[1], O. Combarros[2], J. Berciano[2], D. Genís[3].* 1) Molecular Genetic Diagnosis , Cancer Research Inst - IDIBELL, Barcelona, Spain; 2) Neurology Service. Valdecillas Hospital. Santander, Spain; 3) Neurology Unit. Josep Trueta Hospital. Girona, Spain.

Autosomal dominant cerebellar ataxias (ADCA) are a clinically heterogeneous group of neurodegenerative disorders caused by unstable trinucleotide repeat expansions. Sevent spinocerebellar ataxia genes: SCAs1-3, SCAs6-7, SCA12 and SCA17 have been cloned with the finding of an expansion of a CAG repeat which encodes a polyglutamine tract. The exception is SCA8, which consists of an exonic but untranslated CTG repeat. We present here the molecular analysis of 237 unrelated familial and 576 sporadic and idiopathic Spanish cases of spinocerebellar ataxia. Over the ADCA familial cases in which we have found a triplet expansion mutation, 7,93% were SCA1; 30,69% SCA2; 34,65% SCA3; 4,95% SCA6; 8,91% SCA7; 11,88% SCA8; and 0,99% SCA17. We have found 12 familial index cases with SCA8 expansions whose expansion allele range goes from 86 to 184 repeats (110,97 22,13; Pearson Coef. =19,93%). Maternal transmissions presented elongations of the triplet CTG sequence ranging from +2 to +13 repeats (7,5 5,5; Pearson Coef = 73,33%). In contrast, paternal transmissions presented contractions ranging from -1 to -17 repeats (-9,75 5,97; Pearson Coef = -61,23%). We have found several giant SCA8 expansions in our casuistic, and all of them were present in unaffected adult individuals. The giant SCA8 expansions seems to be originated from homozygous SCA8 females with alleles of moderate expanded size; whereas homozygous males in the same allele range size have transmited contracted alleles to their respective offspring, as in heterozygous cases occurs. None of SCA mutated cases also coexists with SCA8 expansions in their reported pathogenetic range. About 60% of familial ADCA cases remained genetically unclassified. No SCA mutations were detected in the 576 isolated and idiopathic cases of spinocerebellar ataxia.

Expanded FMR1 CGG repeats induce intranuclear inclusion formation and abnormal lamin A/C organization in human cultured cells. *D. Garcia Arocena[1,2], C. Iwahashi, S. Beilina[1], N. Won[1], F. Tassone[1], P.J. Hagerman[1].* 1) Biochemistry and Molecular Medicine, School of Medicine, University of California, Davis, CA; 2) Departamento de Genetica, Facultad de Medicina, UDELAR, Montevideo, Uruguay.

Fragile X-associated Tremor/Ataxia Syndrome (FXTAS) is a neurodegenerative disorder affecting some adult carriers of premutation alleles (55-200 CGG repeats) of the fragile X mental retardation 1 (*FMR1*) gene. FXTAS is thought to be caused by a toxic gain of function of the expanded-CGG-repeat *FMR1* mRNA, which is found in the neuronal and astrocytic intranuclear inclusions that are associated with the disorder. Using *FMR1* 5untranslated region (5UTR) reporter constructs with CGG repeats in the premutation range, we have demonstrated that intranuclear inclusions can be formed in both primary astrocytic and long-term established neural cell cultures. As with the inclusions found in post-mortem tissue, the inclusions induced by the expanded CGG repeat are B-crystallin-positive; however, inclusions in culture are not associated with ubiquitin, suggesting that incorporation of ubiquitinated proteins may be a later event in the disease process. The absence of ubiquitinated proteins suggests further that inclusion formation does not reflect a failure of the proteasomal degradative machinery. The presence of the expanded CGG repeat, as RNA, results in reduced cell viability as well as the disruption of the normal architecture of lamin A/C within the nucleus. This last observation, and the findings that lamin A/C is present in both the inclusions of FXTAS patients and the inclusions in cell culture, suggests that lamin A/C dysregulation may be a mediator of FXTAS. This work was funded by the National Institute of Child Health and Development (HD40661, PJH).

Molecular consequences of PHOX2B missense, frameshift and alanine expansion mutations leading to autonomic dysfunction. *D. Trochet[1], S.J Hong[2], J.K LIM[2], J.F Brunet[3], A. Munnich[1], K.S Kim[2], S. Lyonnet[1], C. Goridis[3], J. Amiel[1].* 1) Genetics, INSERM U393, Hosp Necker, Paris, France; 2) Molecular Neurobiology, MRC 216, Harvard Medical School, USA; 3) CNRS, UMR 8542, ENS, Paris, France.

Heterozygous mutations of the PHOX2B gene account for a broad variety of disorders of the autonomic nervous system (ANS), either isolated or combined, including congenital central hypoventilation syndrome (CCHS), tumours of the sympathetic nervous system (TSNS) and Hirschsprung disease. In CCHS, the prevalent mutation is an expansion of the 20 alanine stretch ranging from +5 to +13 alanines, while frameshift and missense mutations are found occasionally. To determine the molecular basis for impaired PHOX2B function, we assayed the transactivation and DNA binding properties of wild-type and mutant PHOX2B proteins. Furthermore, we investigated aggregate formation by proteins with a polyalanine tract expansion ranging from +5 to +13 alanines using immunofluorescence of transfected cells and gel filtration of in vitro translated proteins. We found that transactivation of the dopamine beta-hydroxylase promoter, a well characterized natural PHOX2B target, by PHOX2B proteins with frameshift and missense mutations is abolished or severely curtailed, as is in vitro DNA binding. However, the missense and frameshift mutations tested showed a nuclear localization, excluding protein instabity. The transactivation potential of proteins with polyalanine tract expansions declines with increasing length of the polyalanine stretch, starting with the +6 alanines allele, while in vitro DNA binding was affected for an expansion of +9 alanines and above. Cytoplasmic aggregation in transfected cells is observed only for the longest expansions, although the +5 alanines mutant is already more prone to form multimers in vitro than the wild-type protein. Such a tendency to protein misfolding (leading at most to nuclear exclusion) could explain loss of transactivation for alanine expansion mutations. Altogether, our data show a loss of transactivation irrespective of the nature of the mutation, although the disease-causing mechanism seems to vary according to the nature of the mutation.

An enhanced PCR assay to detect pre- and full mutation alleles of the *FMR1* gene. *A. Saluto[1], A. Brussino[1], F. Tassone[2], C. Arduino[3], C. Cagnoli[1], P. Pappi[3], P.J. Hagerman[2], N. Migone[1,3], A. Brusco[1,3].* 1) Dept. Genetics Biology & Biochemistry, University of Turin, Turin, Italy; 2) Department of Biochemistry and Molecular Medicine, University of California, Davis, California 95616, USA; 3) Medical Genetics Unit, San Giovanni Battista Hospital, Turin.

Several diagnostic strategies have been applied to the detection of *FMR1* gene repeat expansions. Here we report a novel PCR strategy using the Expand Long Template PCR kit (Roche Diagnostics) and betaine. Repeat expansions up to 330 CGGs in males and to at least 160 CGGs in carrier women could be easily visualized on ethidium bromide agarose after amplification with standard primers c and f (Fu et al., 1991), the buffer 2 (2.25 mM $MgCl_2$) and 1.7 M betaine. Fluorescence analysis of PCR products in both male and females with pre- (26 subjects, range 55-200 CGG) and full mutations (13 subjects, 200 CGG) showed a peculiar profile with an array of stutter bands, which were never observed in over 178 controls (11-54 CGG). These series of peaks therefore appear to be specific for the presence of expanded alleles, although the lower limit of this phenomenon has not been defined. We sequenced the *FMR1* repeat in 18 subjects and 10 clones containing the *FMR1* repeated region, and demonstrated that there is a direct, approximately linear correlation between the size of the PCR fragments - measured by capillary electrophoresis - and the number of repeats, with a 212.4 bp apparent size of the constant region of instead of the real 221 bp, and an increase of 2.7 bp for each additional triplet. We provide a quick reference ladder to estimate the number of CGG repeats from the apparent size of the PCR fragment up to 100 triplets. Furthermore, we noted that an intrinsic measurement error (1 triplet), probably due to technical artifacts, is always present. Southern blot methods are still necessary to size the number of expanded repeats above 100 CGG, and to evaluate the methylation status of the expanded allele; however, the use of this fluorescence method will dramatically reduce the number of Southerns required for screening studies. Grants acknowledgment: Regione Piemonte CIPE36/2002 N.Migone, N.I.H. HD40661 P.J.Hagerman.

Screening of a Compound Library to Identify Modifiers of Ataxin-1 Phosphorylation. *K.M. Carlson[1], M.D. Kaytor[1], O. Rainwater[1], C.E. Byam[1], H.Y. Zoghbi[2], H.T. Orr[1].* 1) Lab Medicine and Pathology, Institute of Human Genetics, Univ of Minnesota, Minneapolis, MN; 2) Howard Hughes Medical Institute, Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Spinocerebellar Ataxia-Type 1 (SCA1) is an autosomal dominant neurodegenerative disease resulting from a glutamine tract expansion in the ataxin-1 protein. Studies implicate both inherent properties of the mutant ataxin-1 protein as well as misregulation of cellular pathways in SCA1 pathogenesis. S776 of ataxin-1 is phosphorylated and has been demonstrated to be an important intragenic modifier of SCA1 pathogenesis in vivo. Previously, a cell-based assay was developed to identify compounds that alter ataxin-1 phosphorylation. In this assay, stably transfected cell lines expressing GFP-tagged ataxin-1 are exposed to a compound of interest. GFP levels are measured to determine the total amount of ataxin-1. An ELISA, using an antibody specific to ataxin-1-p776, is performed to measure the amount of pS776-ataxin1. Using this assay, we now report the results of a screen against a library of 2000 compounds (The Spectrum Collection) made up of natural and FDA approved agents. A screen at 10uM was performed in triplicate against both mutant and wild type ataxin-1. 333 compounds were identified that altered the phosphorylation of mutant ataxin-1 specifically. Of these compounds, 35 decreased phosphorylation by greater than 50%. We identified 88 compounds that altered the phosphorylation state of both mutant and wild type ataxin-1. Finally, we identified 83 compounds that altered the phosphorylation state of wild type ataxin-1 only. Classes of compounds identified in our screen include anti-inflammatory, antineoplastic agents, and antibiotics. We are currently working to prioritize our hits for further studies. The identification of compounds that modulate ataxin-1 S776 phosphorylation will provide us with a greater understanding of the signaling pathways involved in both the wild type function of ataxin-1 as well as SCA1 pathogenesis. In addition, compounds identified in this screen might be good candidates for future studies aimed at identifying effective therapeutics for SCA1.

The impact of polyglutamine expansion on TBP function. *M.J. Friedman[1,2], SH. Li[2], XJ. Li[2].* 1) Graduate Program in Genetics and Molecular Biology; 2) Dept. Human Genetics, Emory University, Atlanta, GA., USA.

Transcriptional dysregulation is widely thought to be involved in the molecular pathogenesis of the polyglutamine (polyQ) diseases. In most of the polyQ diseases, the mutant protein or a polyQ-containing fragment thereof can localize to the nucleus. Study of spinocerebellar ataxia 17 (SCA17), which is caused by a polyglutamine expansion in the TATA-binding protein (TBP), may provide insight into this pathogenic mechanism. TBP mediates transcription by all three eukaryotic RNA polymerases as a fundamental component of multiple nuclear complexes. Unlike the C-terminal domain (CTD) of TBP, the function of the evolutionarily divergent N-terminus as well as the polyglutamine tract therein is largely unknown. To gain insight into the functional importance of this polyQ tract, we have generated TBP cDNA constructs containing 15, 31, 71, and 105 CAGs. When expressed in HEK 293 cells, only mutant TBP (71 and 105 CAGs) formed nuclear aggregates. Reporter assays revealed an elevated transactivation capacity for polyQ-expanded TBP at TATA-containing promoters. The same effect was not observed at a RNA polymerase II promoter that lacks a TATA box. In addition, polyQ expansion antagonized the formation of transcription-incompetent TBP dimers. These results are consistent with a gain-of-function phenomenon in which polyQ expansion, presumably by inducing a conformational change, unmasks the activation potential of the N-terminus of TBP and interferes with normal transcriptional regulation.

Decreased palmitoylation of mutant huntingtin leads to disturbed trafficking and increased neuronal toxicity *in vivo*. *A. Yanai[1], R. Kang[2], K. Huang[2], R.R. Singaraja[1], P. Arstikaitis[2], L. Gan[1], P.C. Orban[1], A. Mullard[2], R.C. Drisdel[3], W.N. Green[3], A. El-Husseini[2], M.R. Hayden[1].* 1) Center for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada; 2) Department of Psychiatry, University of British Columbia, Vancouver, Canada; 3) Department of Neurobiology, Pharmacology and Physiology, University of Chicago, Chicago, IL.

Expansion of the polyglutamine tract of huntingtin (htt) is the mutation underlying Huntington Disease (HD). Htt is associated with specific intracellular membranes and interacts with proteins involved in vesicle trafficking. Post-translational modification by the fatty acid palmitate is an important and reversible modification, crucial for correct sorting and functional modulation of different membrane proteins and their signaling pathways. The association of htt with detergent resistant membranes (rafts) as well as its interaction with the palmitoyl transferase HIP14 raised the possibility that palmitoylation of htt may be an important mechanism for regulating its trafficking and function.

Here we show that htt is palmitoylated at cysteine 214. Furthermore, palmitoylation is modulated by CAG size as demonstrated by a marked decrease in palmitoylation of mutant htt from HD mouse brain ($p=0.01$). Trafficking of palmitoylation resistant wt and mutant htt is disturbed in COS and HEK293 cells as well as in primary neuronal cultures. Reduced palmitoylation of mutant htt in an HD mouse model and down regulation of HIP14 in neurons from HD mouse brain are associated with disturbed trafficking of mutant htt, leading to a significant increase ($p=0.002$) in inclusion body formation. Moreover, palmitoylation-resistant wt and expanded htt show a marked increase (23%; $p=0.01$ and 28%; $p=0.03$, respectively) in neuronal toxicity. Decreased palmitoylation of mutant htt and its effect on trafficking and neuronal toxicity identifies a novel pathway in the pathogenesis of HD.

Large untranslatable CAG repeats are pathogenic in vivo: using Caenorhabditis elegans as a model system. *K.-M. Hsiao[1], K.-Y. Chen[2], H. Pan[1], L.-C. Wang[1].* 1) Department of Biomedical Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Institute of Medicine, Chung Shan Medical University, Taichung, Taiwan.

Recent studies on the molecular mechanisms of myotonic dystrophy (DM) as well as on the secondary structure formed by expanded CAG repeats and its toxic effects raise the possibility that RNA repeats, in addition to CUG repeats, may play a prominent role in trinucleotide repeat diseases. Here, we used the nematode *Caenorhabditis elegans* as a model system to test this hypothesis by expression of green fluorescent protein gene (*GFP*) with various lengths (5, 30, 83, 120, and 200) of untranslated CAG and CTG repeats under the control of body wall muscle-specific promoter. Interestingly, both CAG and CTG repeats cause size-dependent pathogenic effects with a threshold of more than 83 repeats. Animals expressing GFP transcripts with 120 repeats, although developed normally, showed age-dependent abnormality of muscle structure, uncoordinated motility, shortened life span, and much lower brood size than those expressing shorter repeats. Animals expressing 200 or more repeats either died during embryogenesis or showed retarded growth at early larval stages, and thus could not produce offspring. Although the GFP expression was reduced in animals expressing large repeats, the RNA levels remained unaltered. These results strongly suggest that in addition to the CTG repeats, the expansion of untranslated CAG repeats is deleterious to living organisms as well. Furthermore, they show that pathogenic threshold of untranslated CAG repeats seems longer than those frequently observed in polyglutamine disease genes, indicating that RNA pathogenesis may not play a major role in those diseases.

Long tract of untranslated CAG repeat is pathogenic in transgenic mice. *H. Pan[1], R.-J. Hsu[2], C.-Y. Li[2], K.-M. Hsiao[1].* 1) Department of Biomedical Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Institute of Medicine, Chung Shan Medical University, Taichung, Taiwan.

The most frequent trinucleotide repeats found in human disorders are CAG and its complementary sequence, CTG. CAG repeats are mostly found in coding regions whereas CTG expansions are located in untranslated regions. To investigate whether an untranslated CAG repeat expansion has pathogenic effect *in vivo*, we generated transgenic mice expressing muscle-specific *EGFP* transcripts with different sizes of CAG repeats in its 3-untranslated region. While the expression levels of the *EGFP* transcripts were comparable in all transgenic lines, the EGFP protein levels were significantly reduced in mice expressing 200 CAG repeats. Histological analysis of the muscle revealed atypical cell morphology, as well as altered activities of succinate dehydrogenase and NADH reductase in CAG_{200} mice. These mice showed signs of low grip strength, less cage activity, and reduced fertility. The sperm counts of male CAG_{200} mice were normal but the sperm motility was significantly decreased. The reduction of sperm motility was associated with structural and mitochondrial defects in the sperm tails. Furthermore, abnormal muscle contracture was elicited in the skeletal muscle of CAG_{200} mice, suggesting an impaired energy metabolism. These results demonstrate, for the first time, that untranslated CAG repeat expansion in an unrelated mRNA can have pathogenic effects *in vivo*, consistent with the RNA gain-of-function model. It also suggests a possible role for untranslated CAG expansion in human disorders.

A novel missense mutation in the Sodium Bicarbonate Cotransporter (NBCe1/SLC4A4) in a patient with proximal renal tubular acidosis and ocular pathology. *M.B. Gorin[1, 2], F.Y. Demirci[1], M-H. Chang[3], T.S. Mah[1], M.F. Romero[3, 4].* 1) Dept. of Ophthalmology, UPMC Eye Center, Ophthalmology and Visual Science Research Center, Univ. of Pittsburgh SOM, Pittsburgh, PA; 2) Dept. of Human Genetics, Univ. of Pittsburgh GSPH, Pittsburgh, PA; 3) Dept. of Physiology and Biophysics, Case Western Reserve Univ., Cleveland, OH; 4) Dept. of Pharmacology, Case Western Reserve Univ., Cleveland, OH.

The electrogenic Na^+/HCO_3^- cotransporter (NBCe1/SLC4A4) plays a major role in renal bicarbonate absorption via the proximal tubules that is crucial for maintaining the normal blood pH. The human NBCe1 (chr 4q21) produces 2 major variants by alternative promoter usage [kNBCe1 (cryptic promoter) is originally cloned from kidney, pNBCe1 (normal promoter) is pancreatic/general form]. Though rare, recessive NBCe1 mutations have been reported for a small number of patients with proximal renal tubular acidosis (pRTA), short stature, and ocular pathology. A 27 year-old adopted male patient with no available family history presented with pRTA, short stature, and bilateral ocular disease (cataract, glaucoma, and band keratopathy). Using direct PCR sequencing, we screened the NBCe1 exons and identified a novel, homozygous, missense mutation (Leu522Pro in kNBCe1). We functionally characterized this mutation by expressing the wild-type NBCe1 and the L522P-NBCe1 in Xenopus oocytes. When injected into oocytes, the mutant RNA failed to induce electrogenic transport activity. Since L522 is located in the middle of transmembrane span 4, the L522P-protein is predicted to not properly fold for membrane insertion. Further experimentation showed that the L522P-protein is not effectively transported to the oocyte membrane and thus is unable to act as a transmembrane transporter. These data would explain both the insufficient renal bicarbonate absorption (proximal RTA) and the inappropriate ocular fluid transport (cataract, glaucoma, band keratopathy) in this patient. Identification and characterization of novel mutations increase our understanding of the structural-functional aspects of the NBCe1 and the molecular basis of the multi-organ pathologies associated with NBCe1 defects.

Linkage studies in an Ecuadorian population with Keratoconus. *R.A. Lewis[1], M. Gajecka[2], D. Winters[2], A. Molinari[3], J.A. Pitarque[3], M.H. Chahrour[1], S.M. Leal[1], B.A. Bejjani[2,4].* 1) Cullen Eye Institute, Baylor College of Medicine, Houston, TX; 2) Health Research and Education Center, Washington State University, Spokane; 3) Hospital Metropolitano, Quito, Ecuador; 4) Sacred Heart Medical Center, Spokane, WA.

Keratoconus (KC) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers, and altered visual acuity. Although both genetic and non-genetic factors have been associated with KC, its molecular basis is still elusive. We identified an Ecuadorian cohort in which KC without other ocular or systemic features is transmitted as an autosomal dominant trait with incomplete penetrance. Here we present the results of sequencing and linkage analyses which were performed to verify the association between KC in these families and one or more of the previously reported KC loci. To date, we have examined, collected blood, and purified DNA from 68 affected individuals, 75 unaffected individuals and 27 unknown/young/possible individuals from 23 multiplex families with KC. Subjects were diagnosed clinically with KC by slit lamp examination and corneal topography. We excluded previously assigned KC loci on chromosomes 2, 3, 15, 16, and 20 by linkage analysis and finished a genome-wide screen with an average spacing of 10 cM for a KC locus. We found no evidence for linkage between KC and the markers tested. Recently, a second genome-wide screen with a more dense marker set was performed. We have genotyped 170 individuals with fluorescent markers with an average spacing of 5 cM spanning chromosomes 3, 4 and 15-22. Data are being generated before linkage analysis. Additionally, the coding exons of *VSX1* in 60 affected individuals from the Ecuadorian families and two ethnically matched control individuals (Ecuadorian individuals with no ocular abnormalities) were sequenced. Three single nucleotide polymorphisms (SNPs) in the *VSX1* coding region (18GT, 174GT and 542AG) were identified, but no mutation was found in the gene. Keratoconus in our families is not linked to any of the previously defined KC loci. A genome-wide screen is in progress.

Identifying familial high myopia candidate genes in a Polish population. *A. Frajdenberg[1], M. Rydzanicz[2], M. Podfigurna-Musielak[3], S.M. Leal[4], B.A. Bejjani[5,6], K. Pecold[1], M. Gajecka[2,5].* 1) Department of Ophthalmology, Marcinkowski University of Medical Sciences, Poznan, Poland; 2) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 3) Department of Ophthalmology, Lezno Hospital, Lezno, Poland; 4) Baylor College of Medicine, Houston, TX; 5) Health Research and Education Center, Washington State University, Spokane; 6) Sacred Heart Medical Center, Spokane, WA.

Myopia is the most common of all ocular conditions. Affecting about one-fourth of the world population, it constitutes a significant public health problem. Although high myopia (myopia in excess of 6.0 diopters [D]) is far more rare than mild/moderate myopia, the importance of high myopia is significant because its development involves anterior-posterior enlargement of the eye, abnormal changes in the eye and frequent detachment of the retina. The etiology of myopia is not known, but both genetic and environmental factors seem to play a role. In high myopia, genetic factors appear to play a predominant role. Nineteen Polish families have been ascertained which appear to have myopia that is inherited as an autosomal dominant trait. To date, we have examined, collected blood, and purified DNA from 110 individuals from these families, each with multiple individuals with high myopia. Simulation studies revealed that the families have sufficient power to establish linkage in these families which may lead to the identification of familial high myopia gene(s). Preliminary genotyping of high myopia associated loci [7q36 (*MYP4*), 12q21-23 (*MYP3*), 18p11.31 (*MYP2*), and 17q21-23 (*MYP5*)] in the Polish families by genotyping of all subjects with well-spaced polymorphic markers was initiated. Additionally, evaluation of the candidate genes for familial high myopia by sequence analysis of *LUM*, *FMOD* and *TGIF* genes in the Polish families was performed.

Prevalence of retinal dehydrogenase 12 (RDH12) mutations in Leber congenital amaurosis and genotype-phenotype correlations. *I. Perrault[1], S. Hanein[1], S. Gerber[1], H. Dollfus[2], C. Hamel[3], J.L. Dufier[4], A. Munnich[1], J. Kaplan[1], J.M. Rozet[1].* 1) Dept Genetics, INSERM U393, Hopital Necker, Paris, France; 2) Dept Genetics, Hopital Hautepierre, Strasbourg, France; 3) Neurosciences, INSERM U583, Montpellier France; 4) Ophthalmology, Hopital Necker, Paris, France.

Leber congenital amaurosis (LCA), the most early-onset and severe form of all inherited retinal dystrophies, is responsible for congenital blindness. Eleven LCA genes have been mapped, and eight of these have been identified. Recently, we reported the respective frequencies of mutations in each of the first seven LCA genes in a series of 179 unrelated patients. The purpose of this study was to determine the prevalence of mutations in the newly identified LCA gene, RDH12, in an enlarged series of 300 patients affected with LCA. The 7 exons encoding RDH12 were screened for mutations by DHPLC and direct sequencing using specific primers designed from intronic, 5 and 3 UTR sequences. Patients to be screened at first were selected on the basis of their retinal phenotype i.e. affected with the "severe yet progressive rod dystrophy" form of the disease (LCA subtype II). Mutations were identified in 13/300 patients of our series (4.3 %). When patients affected with the second subtype of the disease were considered alone, mutations of RDH12 accounted for 10.8% (13/119) of cases. This study demonstrates that the natural history of the disease since birth, associated with the light behaviour of patients, the refraction data and the description of the fundus are essential to selected LCA genes to screen in priority and thus to lighten the molecular diagnosis of this highly genetically heterogeneous condition.

Striking increased expression of endothelin-2 in mouse models of inherited photoreceptor degenerations (IPDs).

A. Bramall[1,2], M. Szego[1,2], L. Pacione[1,2], R.R. McInnes[1,2], J. Labonte[3], MH. Fecteau[3], P. D'Orleans-Juste[3]. 1) Dept Developmental Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Molecular and Medical Genetics, University of Toronto; 3) Dept of Pharmacology, Med School, Universite de Sherbrooke, Quebec, Canada.

Although more than 150 genes have been shown to lead to IPD, the mechanisms underlying the apoptotic death of the photoreceptors (PRs) in these disorders is unknown. We showed previously that the mutant PRs are at a constant increased risk of death, but can nevertheless function normally for years to decades in humans (Pacione et al. Ann Rev Ns 2003). To account for these findings, we proposed the mutant steady-state (MSS) hypothesis (Clarke et al., 2000), suggesting that changes in the abundance or activity of one or more mutant response proteins may confer or resist the increased risk of death. To identify differentially expressed genes in IPDs, we performed microarray and real-time PCR experiments. We established that the gene for endothelin-2 (*Edn2*) was up-regulated 32-fold in the $Rds^{+/-}$ mouse model and 14-fold in a *RHO P347S* mouse model of IPD. Endothelin-2 belongs to the family of endothelin neuropeptides (i.e. endothelin-1, endothelin-2, endothelin-3), and is a potent vasoconstrictor. Whereas *wt* retinas gave virtually no in situ hybridization signal for *Edn2* transcripts, a strong *Edn2* signal was found in the PRs, but no other retinal cell types, of $Rds^{+/-}$ mice. Moreover, we found that the concentration of total endothelin peptides, determined by radioimmunoassay (RIA) was 3.2-fold increased in the retinas of $Rds^{+/-}$ mice: 0.122 fmol/retina for *wt* retinas vs. 0.395 fmol/retina for $Rds^{+/-}$ retinas (12 retinas per genotype). Since neither *Edn1* nor *Edn3* mRNA was increased by real-time PCR in $Rds^{+/-}$ retinas, the increase in total endothelin in $Rds^{+/-}$ retinas is most likely due an increase in Edn2 peptide alone. We conclude that i) the mutant PRs in IPDs have a dramatically increased expression of *Edn2* mRNA, ii) this increase is translated into increases in the abundance of the Edn2 peptide, and iii) the expression of Edn2 in stressed PR neurons is likely to be a survival response that resists the death of these cells.

Development of Dominant Cone Dystrophy Depends on Expression Levels of GCAP1 (Y99C) in Transgenic Mice. *N. Roychowdhury[1], S. Thirumalaichary[1], K. Zhang[2], J. Frederick[1], W. Baehr[1].* 1) Dept Ophthalmology, Moran Eye Ctr, Salt Lake City, UT; 2) University of California San Francisco, San Francisco.

Photoreceptor Guanylate Cyclase Activating Protein 1 (GCAP1) is a Ca2+ -binding protein belonging to the calmodulin gene family with four EF hand motifs (EF1-4). Several mutations in EF3 and EF4 of GCAP1 have been linked to autosomal dominant cone dystrophy and cone-rod dystrophy in independent pedigrees. We generated mice expressing a transgene consisting of the entire GCAP1 (Y99C) gene including upstream and downstream regions, and EGFP fused to the C-terminal of mutant GCAP1. Different lines with various levels of expression of Y99C-GFP were obtained. Lines with high levels of mutant GCAP1 expression showed expression of green fluorescent mutant GCAP1 in rods and cones, while a low expressor line expressed exclusively in cone photoreceptors. High expressor lines exhibited a slow cone-rod dystrophy developing over a time range of 15 months, as judged by electroretinography and histology. The low expressing line (approximately 10% of normal levels) showed no cone dystrophy even at age one year. This line was used for cone mapping studies in whole retina mounts. The distribution pattern of cones in the retina was shown to be uneven, with green fluorescent cones more concentrated towards inferior-nasal part. The results show that the development of a dominant cone dystrophy depends on mutant GCAP1 expression levels.

ARHGEF9: An Xcellent mental retardation candidate gene. *E.J. Marco[1], J. Bristow[2], P.D. Cotter[3], R.E. Stevenson[4], L. Pennacchio[2], C.E. Schwartz[4], E.H. Sherr[1].* 1) Dept Neurology, Univ California, San Francisco, San Francisco, CA; 2) Joint Genome Institute, LBNL, Berkeley, CA; 3) Dept of Medical Genetics, Univ California, San Francisco, CA; 4) Geenwood Genetic Center, Greenwood, SC.

Our study aimed to identify the genes affected by a chromosomal rearrangement in a patient with mental retardation. We evaluated a non-dysmorphic female with mental retardation (FSIQ 54) and a paracentric X chromosome inversion (46,X, inv (X) (q13.1; q26.3). The inverted X underwent early replication in 100/100 lymphocytes studied. Metabolic testing and a high resolution MRI were unrevealing. Using fluorescent in situ hybridization with bacterial artificial chromosomes, we found that the centromeric breakpoint transected ARHGEF9, a RhoGEF encoding gene. The telomeric breakpoint resided in a gene poor region. Based on this finding, we sequenced the ARHGEF9 coding region and intron/exon boundaries in 384 individuals (99 probands from families with X-linked mental retardation and 285 males with non-Fragile X mental retardation.) We found a splice site change (IVS5+5 g>a) in a male from the unlinked group. This G in the 5'splice site is quite invariant. Similar mutations are known to cause alternate splicing in other disease associated genes (i.e. SMS and SCL6A8.) We also identified a non-synonymous polymorphism (I10V) in brothers from an X-linked family. Isoleucine in this position is highly conserved among vertebrates and occurs at the start of the SH3 domain. Neither of these changes has been reported in the dbSNP database (build 124.) Investigation is underway to assess the functional significance of these changes and further characterize the phenotype of affected individuals.

ARHGEF9 (Xq11.1) encodes Collybistin (hPEM) which activates the Rho GTPase, Cdc42. It is ubiquitously expressed in the human brain and may regulate actin cytoskeleton dynamics and cell signaling. A mutation in this gene has been previously associated with hyperekplexia and epilepsy. A related gene, ARHGEF6, has already been linked to non-syndromic mental retardation. This knowledge plus our results strongly suggest a role for ARHGEF9 in non-syndromic X-linked mental retardation.

Identification of differentially expressed genes in RNA inhibition by siRNA against *MECP2*. *I.J. Kim[1], C.R. Kim[4], M.A. Yoo[5], C.M. Kim[1, 2, 3].* 1) Department Biochemistry, College of Medicine, Pusan National University, Busan; 2) BioMedical Informatics Unit, College of Medicine, Pusan National University, Busan; 3) Medical Research Institute, Pusan National University Hospital, Busan; 4) Department Statistics, College of Natural Science, Pusan National University, Busan; 5) Department Molecular Biology, College of Natural Science, Pusan National University, Busan.

Rett syndrome (RTT) is an X-linked dominant childhood neurodevelopmental disorder. *MECP2* has been reported to be the RTT-causing gene. The MeCP2 participates in transcriptional silencing via DNA methylation. We investigated the profile and function of the downstream genes regulated by MeCP2. To identify the MeCP2-regulated genes, we performed RNA inhibition using siRNA against *MECP2* and microarray experiment. We used the linear amplification of the isolated RNA in order to get enough RNA. Amplified aRNA was labeled and hybridized to human 8K cDNA microarray. *MECP2* expression in HEK293 cells was decreased by 65.8% in the siRNA group compared to the control group using semi-quantitative RT-PCR and Western blot. Among the differentially expressed 279 genes, 188 genes were upregulated greater than 2-fold threshold and 91 genes were downregulated after silencing the *MECP2* in HEK293 cells. We found that neurodegenerative disorder-related, metabolismic disorder-related, and apoptosis-regulated genes were overexpressed in *MECP2*-inhibited HEK293 cells. Down-regulated genes were the ones related with cell proliferation, differentiation, and growth, and muscle functions. Of these upregulated genes, c-jun of apoptosis group had the greatest change. Meanwhile cystathionase (CTH2) of cell proliferation/differentiation group had the greatest change of these downregulated genes. Consequently, the differentially expressed genes may be influenced by MeCP2 inhibition, either directly or indirectly, and will provide valuable information for understanding the mechanisms of MeCP2 in gene expression regulation.

Maternal Inherited Thrombophilia and Fetal Growth Restriction: A Meta-Analysis. *K. King[1], J. Lau[2], L. Demmer[3].* 1) Molecular and Medical Genetics, Oregon Health & Science Univer, Portland, OR; 2) Clinical Care Research, Tufts-NEMC, Boston, MA; 3) Pediatrics, Tufts-NEMC, Boston, MA.

Objective: The purpose of this study was to conduct a systematic review examining the association between intrauterine growth restriction (IUGR) and common inherited thrombophilias, specifically Factor V Leiden (FVL), Prothrombin G20210A mutation (PTM), and homozygous methylenetetrahydrofolate C677T variant (MTHFR).

Study Design: MEDLINE and manual bibliography searches were used to identify case-control and cohort studies evaluating the association between IUGR and three common inherited thrombophilias.

Results: The meta-analysis included 14 studies investigating FVL, 14 studies investigating PTM, and 11 studies investigating MTHFR. There was a significant association between IUGR and FVL (OR 2.07; CI 1.35-3.16), PTM (OR 2.11; CI 1.42-3.15), and MTHFR (OR 1.41; CI 1.07-1.84). The strongest association was between IUGR and FVL homozygotes (OR 4.55; CI 1.10-18.74). Sensitivity analyses were performed which included analysis of (1)the largest studies, (2)different definitions of IUGR, (3)gestational age at the time of delivery, and (4)studies that excluded patients with maternal hypertension or preeclampsia. When patients with maternal hypertension or preeclampsia were excluded, the associations became non-significant (FVL: OR 1.62; CI 0.84-3.10; PTM: OR 1.26; CI 0.51-3.12; MTHFR: OR 1.07; CI 0.52-2.20).

Conclusion: Although there appears to be an association between maternal inherited thrombophilias and IUGR, it is still not fully established. In particular the potential confounding effect of preeclampsia on fetal growth restriction needs to be resolved before setting forth any clinical recommendations based on these findings. It may be reasonable to consider screening for thrombophilia in the setting of early, severe IUGR or IUGR associated with preeclampsia.

Prenatal diagnosis of a rare radio-ulnar synostosis and amegakaryocytic thrombocytopenia syndrome by ultrasound. *G.G. Fraley[1], A.A. Thompson[2], M.J. Dinsmoor[1], M.J. Kim[1], L. Liu[1], S.N. MacGregor[1], J.S. Sholl[1], P.C. Weiss[1], I.S. Salafsky[1].* 1) Evanston Northwestern Healthcare, Feinberg School of Medicine, Northwestern University, Evanston, IL; 2) Children's Memorial Hospital, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Radio-ulnar synostosis (RUS) with congenital amegakaryocytic thrombocytopenia is a rare autosomal dominant syndrome associated with HOXA11 mutations. Neonatal thrombocytopenia has been reported in three cases. This is the first reported case with in utero detection of skeletal defects and bone marrow failure. The family was known to be at risk for this condition based on genetic testing and clinical findings in the father, his brother and a paternal niece. Ultrasound examination at 20w 5d revealed abnormal hand alignment. Another scan at 28w 5d revealed crossing of the proximal radius and ulna consistent with RUS and deviation of the phalanges. All other measurements were normal. The option of percutaneous umbilical blood sampling (PUBS) to assess platelet count prenatally was declined by the parents due to the procedure-related risk and absence of previous reports of fetal thrombocytopenia. The patient presented four days later at 29w 2d with decreased fetal movement and hydrops. A male infant weighing 1500 grams was delivered by emergency Cesarean section with Apgars of 1 and 1. The platelet count was 5 thou/cu mm and the hemoglobin was 11.1 gm/dL. The child died on day 1 of life. Preliminary autopsy findings noted moderate non-immune hydrops secondary to anemia, petechial hemorrhage of multiple internal organs including brain, pleural effusion and confirmed the finding of RUS and deviated phalanges. Mutation analysis of the HOXA11 gene and bone marrow histology are pending. We theorize that low platelet levels in utero predisposed this fetus to a hemorrhagic event and led to anemia and hydrops. This is the first reported case of antenatal thrombocytopenia and fetal crisis with this syndrome. Prenatal diagnosis using ultrasound is possible for this syndrome. In affected cases, the risk for antenatal thrombocytopenia should be discussed and PUBS may be considered with possible platelet transfusion.

PREnatal VENTriculomegaly Clinical Classification(Part 1). *R.D. Wilson[1,2,3], J. Ilagan[1], R. Finkel[1,3], E. Simon[1,3], L. Bilaniuk[1,3], B. Coleman[2,3], S. Horii[2,3], M.P. Johnson[1,2,3], M. Bebbington[1,2,3], N.S. Adzick[1,3].* 1) Ctr Fetal Diag/Treatment/Wood, Children's Hosp Philadelphia,; 2) Hospital of the University of Pennsylvania; 3) University of Pennsylvania, Philadelphia, PA.

Introduction : Prenatal second trimester ultrasound assessment identifies CNS anomalies. Prenatal classification is required as part of an organized follow-up protocol . PREVENT Part 1 presents a classification based on the imaging evaluation of fetuses with a referring diagnosis of ventriculomegaly / hydrocephalus .Methods : Retrospective review of a clinical database with a referring diagnosis of ventriculomegaly / hydrocephalus (IRB 2005-1-4121) using ultrasound and MRI to group fetuses into clinical imaging categories(part 1)and identify groups for longterm follow-up (part 2). Additional clinical information from history , echocardiography , and chromosomes was used to assist with isolated and multiple anomalies .Results : Initial review of CNS referrals identified 123 fetuses with prenatal diagnosis that included ventriculomegaly . Three clinical categories were used cerebral ventricles < 10mm , 10-15mm , and > 15mm with subcategories of symmetric , asymmetric , +/-imaging impression of bleeding (intra or periventricular).

vent size	no pts	Symm	Asymm	Sym blood	Asym blood
< 10 mm	22	7	10	3	2
10-15 mm	65	31	12	13	9
> 15 mm	36	18	5	5	8

Conclusions : Asymmetric ventricles were more likely to have evidence of bleeding (41% vs 27%)while ventricles >15mm were more likely to have additional CNS anomalies. Longterm follow-up/ morbidity is necessary for appropriate prenatal counseling .

Rapid determination of the genetic origin by quantitative fluorescent PCR in hydatidiform moles. *O. Samura, N. Miharu, M. Hyodo, N. Fujito, M. Tanigawa, Y. Kudo.* Dept OB/GYN, Hiroshima Univ Sch Medicine, Hiroshima, Hiroshima, Japan.

Hydatidiform mole (HM) is classified into partial(PHM) and complete(CHM) subtypes according to histopathologic and genetic criteria. Traditionally, it is believed that PHM carries a better prognosis and rarely develops metastasis. However, making a distinction between PHM and CHM using histologic criteria alone may be difficult. Fifteen women with HM attending the Department of Obstetrics and Gynecology at Hiroshima University Hospital provided written, informed consent to participate in the study, which was approved by the Research Ethics Committee of Hiroshima University. Samples of DNA, extracted from molar tissue, maternal blood and paternal blood were investigated by quantitative fluorescent PCR (QF-PCR) with short tandem repeat markers specific for loci on each of chromosomes 21, 18, X and Y. Quantitative analysis of the amplification products allowed the diagnosis of the genetic origin of HM. Among 15 samples of HM, DNA from only paternal origin was found in 14 cases(93.3%) and from both parents in one cases (6.7%); and in the former, the homozygous CHM and the heterozygous CHM were 12 cases(80.0%) and 2 cases(13.3%), respectively. Multiplex quantitative fluorescent analyses were performed in about 8 hours from collection of the samples. QF-PCR is useful method for the rapid determination of the genetic origin of the hydatidiform mole.

Rapid Detection of Chromosomal Aneuploidies in Uncultured Amniocytes by Multiplex Ligation-dependent Probe Amplification (MLPA). *R.J. Sinke[1], J. Meijer[1], I. van de Brug[1], I. Vossebeld-Hoff[1], R. Jansen[1], R.B. van der Luijt[1], G.C.M.L. Page-Christiaens[2], J.M. de Pater[1], J.K. Ploos van Amstel[1], P.F.R. Hochstenbach[1].* 1) Dept. of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Dept. of Perinatology and Gynaecology, University Medical Center Utrecht, Utrecht, The Netherlands.

Trisomy of chromosome 13, 18 and 21 and sex chromosome aneuploidy account for 60-80% of abnormal fetal karyotypes detected in cultured amniotic fluid cells. Recently, multiplex ligation-dependent probe amplification (MLPA) has emerged as an alternative PCR-based technique for the relative quantification of genomic DNA sequences. To test whether multiplex ligation-dependent probe amplification (MLPA) can be used for the detection of aneuploidy of chromosomes 13, 18, 21, X, and Y in uncultured amniocytes, the chromosome copy numbers were determined by analysing the relative amount of PCR-product of chromosome-specific MLPA-probes. Results were available within 48 hours and were compared with those of karyotyping. Based on a prospective, clinical study of 527 amniotic fluid samples, we investigated whether MLPA can be used for the detection of common chromosomal aneuploidies in uncultured amniotic fluid cells. There were 517 conclusive MLPA tests. In 514 tests results were concordant with those of karyotyping. There were 2 cases of 69,XXX triploidy that can not be detected by MLPA and there was 1 false positive result. Here, MLPA indicated a 47,XXY fetus whereas the karyotype was 46,XY. We correctly identified all 23 cases of autosomal trisomy and the single case of monosomy-X in samples collected from 16 up to 36 weeks of gestation. In 10 cases (2%) the result was inconclusive due to an insufficient amount of DNA. Sensitivity, specificity and failure rate of MLPA were comparable to those of FISH and QF-PCR. Aneuploidy screening in uncultured amniocytes by MLPA is feasible in a clinical diagnostic setting, yielding an informative and rapid result in 98% of cases.

The identification of a dicentric X-chromosome in embryos undergoing preimplantation genetic diagnosis (PGD) for aneuploidy screening in a couple with normal karyotypes and eight previous losses. *W.G. Kearns[1], R. Pen[1], J. Kaminsky[1], L. Timmreck[2].* 1) Shady Grove Center for Preimplantation Genetics; 2) Shady Grove Fertility Reproductive Science Center Rockville, Maryland.

In vitro fertilization and PGD for aneuploidy screening was performed on a couple with 8 previous losses. The 38 year-old woman and her 39 year-old husband have normal karyotypes, and he has abnormal semen parameters. Laser assisted embryo biopsy was performed on 6 day-3 cleaving embryos. Cell lysis, fixation, hybridization, and stringency washes were performed according to routine laboratory protocols. Multi-color fluorescence in situ hybridization (FISH) was used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. Five of 6 embryos were aneuploid. Three embryos were aneuploid for 2 different chromosomes, one was abnormal for 3 chromosomes and one embryo was abnormal for 4 separate chromosomes. Two of 6 embryos had X chromosome fluorescent signals consistent for the presence of a dicentric chromosome. Therefore, we used telomere FISH probes to identify telomeric sequences on the putative dicentric X chromosomes. Dicentrics whose centromeres are joined by their q arms will have two p-arm and no q-arm telomeric sequences, whereas dicentrics joined by their p arms will have two q-arm and no p-arm sequences. Both nuclei with a putative dicentric X chromosome showed two p-arm sequences but no q-arm sequences. These dicentric chromosomes are daughter cells from a parental cell containing a q-arm paracentric inversion of one X chromosome. The presence of a dicentric X chromosome in two of six cleaving embryos in a couple with normal somatic cell karyotypes and eight previous losses suggests possible gonadal mosaicism for an X-chromosome with a q-arm paracentric inversion. When a day-3 embryo includes a dicentric X chromosome with two active centromeres, subsequent cell divisions may result in chromosome breakage and the loss of the putative dicentric X chromosome. This results in cells with just a Y chromosome and subsequent lethality or embryos with Turner or mosaic Turner syndrome and likely miscarriages.

Deletion 2q37.3 in a prenatal case followed for over 5-years: Review of the literature to trace the natural clinical history for genetic counseling and clinical monitoring. *C. Atzinger[1], C. Greene[1], K. Reddy[2].* 1) Department of Clinical Genetics, Univ of Maryland, Baltimore, MD; 2) US Labs, Irvine, CA.

A 20-year-old woman had amniocentesis because of abnormal maternal serum triple marker screen. The fetus was found to have an apparent de novo deletion of 2q37.3 by cytogenetics and fluorescence in situ hybridization (FISH) and the fetal ultrasound was normal. Following counseling the couple decided to continue the pregnancy. The clinical course of the child was followed over the next five years. At 5-years of age the proband shows developmental delay, behavioral problems including hyperactivity. The physical findings were alopecia, eczema, and brachydactyly. The natural history of our proband and other reported cases was contrasted. This detailed clinical comparison [in an excel worksheet] will provide additional information useful in genetic counseling and serve as a clinical monitoring tool when 2q37 deletion is detected.

Subtelomeric FISH in abnormal offspring reveals familial cryptic translocations in two couples with habitual abortions and normal G-banded chromosomes. *E. Zackai, N. Unanue, D.M. McDonald-McGinn, K.L. Ciprero, S. Purandare, N. Sondheimer, S. Saitta, D.A. Driscoll, B.S. Emanuel, N.B. Spinner.* Division of Human Genetics, The Children's Hospital Philadelphia, Philadelphia, PA.

Chromosome analysis in couples with habitual abortions has been useful in diagnosing translocation carriers and has become standard of care. In contrast the yield is low in series of couples with habitual abortion tested with subtelomeric FISH (Fan and Zhang AJMG 109:154, 2002; Jalal et al. Genet in Med 5:28, 2003; Benzacken et al. Hum Reproduct 17:1154, 2002). Here we discuss two couples with histories of multiple miscarriages who had normal conventional G-banded chromosome analyses prior to the birth of an affected child. Both couples had normal prenatal chromosomal analysis of the affected fetuses. One amnio was performed because of multiple fetal anomalies including diaphragmatic hernia and congenital heart disease. Whereas, the second woman underwent CVS due to advanced maternal age. Both neonates had cytogenetic studies at birth. The second because of microcephaly, bicuspid aortic valve and butterfly thoracic vertebrae. Chromosomes were again interpreted as normal. Subtelomeric FISH studies revealed a maternally inherited unbalanced translocation in both cases [46,XY,der(15)t(1;15)(q44;q26.3); 46,XY,der(22)t(19;22)(q13.33;q13.31)]. Upon review of the original karyotypes with conventional G-banding, the chromosomal ends involved in the translocations appear identical under the microscope. Therefore, it is quite plausible that without subtelomeric FISH studies these familial translocations would have remained undetected. The breakpoints are currently being mapped in both cases. We presume them to be proximal to the subtelomeric regions. Of note, regarding Case I, diaphragmatic hernia is known to be mapped to the 15q24-26 region (Slavotinek et al. AJHG 75:150(a733), 2004) whereas in Case II the ARSA gene, which maps to 22q13.31-13.33, is deleted. The importance of developing cost effective methods to detect cryptic translocation carriers presenting with habitual abortions, before the birth of a child with multiple anomalies, will be discussed.

Thoracoamniotic shunting in a case of fetal Down syndrome with hydrops. *H. Sago[1], S. Hayashi[1], T. Isojima[2], T. Nakamura[2], Y. Itoh[2], M. Kitagawa[1].* 1) Dept Fetal Medicine, Natl Ctr Child Health & Dev, Tokyo, Japan; 2) Dept Neonatology, Natl Ctr Child Health & Dev, Tokyo, Japan.

Fetuses with Down syndrome, a major cause of hydrops fetalis, have a higher rate of spontaneous death than normal fetuses and the prognosis is generally poor. Thoracoamniotic shunting is an appropriate treatment option for fetal hydrops caused by pleural effusion. However, this treatment is not usually applied in the case of Down syndrome. In this report, we describe the successful treatment of a case of fetal Down syndrome with hydrops by pleural effusions by thoracoamniotic shunting. Ultrasonogrphy at 29 weeks gestation revealed fetal skin edema, ascites, bilateral hydrothorax and polyhydramnios. The fetal morphological evaluation and heart rhythm were normal. Immune hydrops or a viral infection was excluded. Bilateral pleural aspiration and amniodrainage were performed. The lymphocyte count of the aspiration was consistent with chylothorax. The effusions reaccumulated and thoracoamniotic shunting using a double-basket catheter were performed bilaterally at 30 weeks gestation. The pleural effusions and hydrops resolved. The fetal karyotype was trisomy 21. An emergency Cesarean section was performed due to premature rupture of the membrane at 33 weeks gestation. A 1410g female neonate with typical facial features of Down syndrome was delivered. The neonate responded well to mechanical ventilation and thoracic drainers that were inserted for a month, and made a gradual transition from parental to intestinal nutrition. Currently, aged 8 months, she was as well as a Down syndrome child without cardiac defects. We therefore conclude that thoracoamniotic shunting can be used as a treatment option for fetal Down syndrome with pleural effusions.

Quantification of palindrome-mediated de novo translocations in human sperms by multi-PCR. *J. Li-Ling[1], T. Wen[1], X. Ji[2], J. Zhang[1], Y. Zhao[1].* 1) Department of Medical Genetics, China Medical University, Shenyang 110001, China; 2) Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Kunming 650091, China.

Following the confirmation that the most common human non-Robertsonian translocation, t(11;22)(q23;q11), is mediated by palindromic sequences from relevant genomic regions, researchers have recently discovered several other translocations by similar mechanism, including t(1;22)(p21.2;q11.21), t(4;22)(q35.1,q11.2), t(17;22)(q11;q11) and t(x;22)(q27;q11.21). As discovered by Kurahashi and Emanuel (2001), unexpectedly high rate of de novo t(11;22) translocations occur in sperms from normal males. For those with more mutations are at a higher risk to produce offspring with birth defects and mental disabilities, we explored to quantify common palindrome-mediated translocations in sperm samples coming from genetic counseling. Based on the results of BLAST by palindromic sequence from 22q11 LCR22-B, multi-PCR primers were designed by using Primer 5 or derived directly from the literature, which included five known translocations and three predicted ones, i.e., t(5;22)(5q33.3;q11), t(9;22)(p13.1;q11) and t(16;22)(p12.3;q11) (Homo sapiens clones RP11-342F17, RP11-271O3 and RP11-295M3). Nested PCR was used to increase the sensitivity of detection. Quantification of the mutations was achieved by repeat measurement, as described by Kurahashi and Emanuel. Results of PCR were confirmed with position of electrophoretic bands with predicted lengths as well as direct sequencing. So far we have found that, in addition to t(11;22), several other translocations, including t(1;22), t(15;22), t(17;22) and t(x;22) are also common in sperm samples from normal males as well as oligospermic patients. The overall mutation rate varied significantly. t(4;22), t(5;22) and t(9;22) were only occasionally seen. However, it seems too early to decide whether similarity between palindromes may have an influence on the rate of relevant translocations. Simultaneous measurement of 5 most common translocations based on multi-PCR is underway. Real-time PCR is also being tried, which may help to simplify the test.

Post-natal follow-up of prenatally diagnosed trisomy 16 mosaicism. *S. Langlois[1], P.J. Yong[1], S.L. Yong[1], D. Kalousek[1], P. Miny[2], W.P. Robinson[1].* 1) Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) Abt Medizinische Genetik, Universitatskinderklinik, Basel Switzerland.

Pregnancies diagnosed with trisomy 16 (T16) mosaicism by either chorionic villus sampling (CVS) or amniotic fluid testing (AF) are known to be at significant risk of intrauterine growth restriction, fetal malformation (especially septal defects of the heart), maternal preeclampsia, and intrauterine or neonatal death. However, there is little data on the long-term prognosis for these infants in terms of their health and development. We report on the outcomes of 30 pregnancies diagnosed prenatally with T16 mosaicism where data on children greater than 1 year (ages 1-13 years) was available. Postnatal outcome data was collected through completion of a questionnaire, direct clinical evaluation or through review of published data. Sixteen cases were diagnosed with trisomy 16 on CVS with normal follow up AF in 15 cases and no AF performed in one case. Of these cases, growth parameters at birth were below - 2SD for length in 3/11 cases and for weight in 4/10 cases. Catch up growth was seen for length in all 3 cases and for weight in 2 of the 4 cases. In terms of development, no cases of mosaicism detected only on CVS had global developmental delay, and only one case had speech delay. In fourteen cases, mosaicism for T16 was diagnosed on AF. Growth parameters at birth were below - 2SD for length in 5/8 and for weight in 6/7 cases and catch-up growth was seen in all cases. Amongst the AF detected cases, 4/14 cases had global developmental delay. The risk of developmental delay was also associated with the presence of major and minor malformations: 4/9 cases with anomalies had associated developmental delay compared to 0/5 cases with no abnormalities. Uniparental disomy was present in 8 cases diagnosed by CVS and 5 cases diagnosed at AF but was not associated with adverse longterm outcome. In conclusion, the majority of prenatally diagnosed T16 mosaic cases have a good outcome. However the finding of mosaicism on amniocentesis plus major/minor abnormalities is associated with an increased risk of developmental delay.

A new molecular method to measure the copy numbers of chromosomes or genes. *K.M. Hong[1], M.H. Ko[1], Y.B. Choi[1], N.H. Kim[2], I.H. Kim[1], Y.J. Kim[1].* 1) Research Institute, National Cancer Center, Goyang, Gyeongggi-do, Korea; 2) Department of Internal Medicine, Wonkwang University College of Medicine, Iksan, Korea.

Karyotyping is currently the gold standard for the diagnosis of chromosomal aneuploidies. Karyotyping takes about two weeks and needs qualified technicians, so several molecular techniques were recently introduced. The relative amplification during PCR was stabilized with the introduction of MLPA (multiplex ligation-dependent probe amplification). However, the standard deviation values from MLPA are relatively big (0.13-0.3). Here we introduce a new molecular method to measure the copy numbers with the SD values of 0.02-0.05. For the detection of trisomy 21 and 18, the relative ratios of three genes (*DSCR1* for trisomy 21, *.DCC* for trisomy 18 and hexokinase gene for control) were tested by our new method. All the ratios from about 30 control samples were within 0.9-1.1 after normalization. All the ratios from 10 Down syndrome samples were in the trisomy category (two normalized ratios were over 1.4). This molecular assay takes about 3-4 hours to get the final results when the genomic DNA is ready and is easily expandable to dozens without changing the total assay time. This method can be used for the screening of chromosomal anomalies replacing the FISH (fluorescence *in situ* hybridization) before reporting the results with karyotyping and for the detection of exonal deletions in inherited diseases including Duchenne muscular dystrophy. Also this method can be used for the detection of chromosomal changes in cancer samples, and for finding new candidate gene deletions or amplifications.

Improved second trimester prenatal screening for Down syndrome: Addition of invasive trophoblast antigen (ITA). *C. Strom, P. Peterson, E. Carlton, P. Vendeley, J. Neidich, R. Pandian.* Med Dir, Genetics Testing Ctr, Nichols Inst/Quest Diagnostics, San Juan, Capis, CA.

ITA, formerly known as hyperglycosylated hCG (hhCG), is elevated in Down Syndrome (DS)-affected pregnancies. Recent studies have shown that ITA is a useful marker for maternal serum prenatal screening. Based on archived case control material, Palomaki, et al. (Clin Chem. 2004) predicted addition of ITA to AFP, hCG, uE3, and inhibin A (DIA) would result in a DS detection rate of 83% in the second trimester, up from 72% (triple screen) and 79% (quad screen). We subsequently developed a risk assessment algorithm that included all 5 markers and used it to determine the DS detection rate in a prospective study involving 1480 pregnancies, 19 of which were DS-affected. This penta screen detected 16 of the 19 (84%) cases as predicted. Since screening programs use fixed odds ratios (usually 1:270 - 1:300) as the cut-off between positive and negative screens, we would expect the screen positive rate to decrease as the programs detection rate improves. To test this hypothesis, we have analyzed data from screening programs that use the triple (n=3764), quad (n=3441), and penta screens (n=1967). For women under the age of 35, the screen positive rate was 5.0%, 4.6%, and 3.6% in the triple, quad, and penta screens, respectively. For women over the age of 35, the screen positive rate was similar in the triple and quad screens (22%) but lower in the penta screen (16.7%). Thus, the penta screen appears to increase the Down syndrome detection rate while decreasing the screen positive rate. Theoretically, this should lead to a decrease in the number of amniocenteses performed for each affected fetus detected.

Frequencies of chromosomal abnormalities at amniocentesis: over 4 years of cytogenetic analyses. *M. Kasap, O. Demirhan, A. Pazarbasi, D. Suleymanova-Karahan, E. Tunc, D. Tastemir.* Medical Biology and Genetics, University of Cukurova, Adana, Turkey.

Invasive methods in prenatal diagnosis has been recognized as safe reliable methods for couples at high risk of giving birth to child with chromosomal abnormalities. Amniocentesis is an important prenatal diagnostic technique offered to pregnant women at increased risk of chromosome abnormalities. It is usually performed between 15 and 17 weeks of gestation and is the most widely used invasive technique. Here, we have reported the 2660 amniocentesis results from Department of Medical Biology and Genetics, Fakulty of Medicine, University of Çukurova between March 2001 and May 2005. The total abnormal karyotype rate was found 4.3% (114/ 2660). Among these abnormal karyotypes, the frequency of numerical and structural chromosomal abnormalities were 58% (66/114 case) and 42 % (48/114 case), respectively. In the numerical abnormalities, the frequency of trisomy 21 was the highest 25% (28/114), followed by sex chromosome aneuploidies in 16 cases (14%). In the structural chromosomal rearrangements, 25 cases had familial inversions on chromosome 9 (22%). Chromosomal deletions in 4 case (3.5%), translocations in 11 cases (10%) and duplication in two case (2%) were detected. The maternal age was the most common indication (44.6%), followed by abnormal serum levels of screening test results (38.6%), abnormal ultrasound screening results (6.1%), parental chromosome aberrations (4.2%), previous fetus/child with chromosome abnormalities (2.3%). Maternal age ranged from 18 to 49 years (Mean: 32.6 years) and mean of gestational age was 19 weeks. The 51% and 49% of the total karyotypes were male and female, respectively.

Relationship between gestational age and fetal karyotype in levels of cell-free fetal DNA in amniotic fluid. *O. Lapaire[1], K.L. Johnson[1], H. Stroh[1], I. Peter[2], J.M. Cowan[1], U. Tantravahi[3], B. OBrien[1], D.W. Bianchi[1].* 1) Division of Genetics, Tufts University School of Medicine, Boston, MA; 2) Institute of Clinical Research and Health Policy Studies, Tufts University, Boston, MA; 3) Department of Pathology, Women and Infants Hospital, Providence, RI.

Amniotic fluid (AF) is a promising source of cell-free fetal DNA (cffDNA), with an approximately 100-200 fold greater concentration compared to maternal plasma. However, its potential role in non-invasive prenatal diagnosis has been rarely studied. Residual AF supernatant samples (5.5-10 mL) were obtained from 25 euploid, 13 trisomy 21 and 5 trisomy 18 fetuses, collected after clinically indicated amniocenteses. Median gestational age (GA) at amniocentesis was 16.85 weeks (16.43; 18.14). DNA was isolated from AF samples using the DNA Blood and Body Fluid Protocol (Qiagen, Inc.) and quantified using real-time PCR (Applied Biosystems, Inc.). The median amount of GAPDH DNA detected from all samples was 1515 genome equivalents/mL (1091; 3903). A significant positive correlation was observed between cffDNA levels of euploid fetuses and GA (r=0.71) as well as between trisomy 18 fetuses and GA (r=0.82). In contrast, no correlation was observed between cffDNA from trisomy 21 fetuses and GA (r= -0.03). We speculate that differences in AF cffDNA levels between euploid and some aneuploid fetuses may be due to tissue-specific kinetic mechanisms (e.g. DNA release and/or clearance) or developmental abnormalities. These results differ from those obtained from cffDNA isolated from maternal plasma/serum, where cffDNA levels increase with GA in both euploid and aneuploid fetuses, which may be due to the origin of cffDNA (e.g. fetal organs that come in direct contact with amniotic fluid such as lung and kidney versus placental or circulatory cells).

Prenatal karyotypes from different organic material besides the traditional ones. *R. Gus[1, 2], M.T.V. Sanseverino[1, 2], J.A.A. Magalhães[2], O.A. Magalhães[2], R. Giugliani[1].* 1) Genetics Department, Hospital de Clinicas de Porto Alegre; 2) Fetal Medicine Group, Hospital de Clinicas de Porto Alegre, RS, Brazil.

The study of fetal karyotype became, in the last decades, a very important tool for either genetic counseling or fetal diagnosis itself. In our public hospital we offer such service since 1989, being a very unique situation in Brazil. Nowadays, at our laboratory, fetal health can be detected at three different levels: biochemical, molecular and chromosomal. Also, with the development of the ultrasound technology, many fetal malformations can be detected; therefore, specific studies can be done. The objective of this study was to describe the experience of the Fetal Medicine Service at Hospital de Clinicas de Porto Alegre, South Brazil, from December 1989 to December 2003. Here, we emphasize the utilization of different fetal materials for karyotyping, such as: amniotic fluid, chorionic villus sampling, blood, urine, intraperitoneal fluid, cerebro-spinal fluid and fluid from kidney cysts. During the period described above, 2021 exams were done, and the patients had consultation of genetic counseling before and after the results. Amniocentesis were done in 1638 patients, 320 chorionic villus sampling, 54 cordocentesis, 4 bladder punctures and from hydronephrosis, 2 intraperitoneal fluid collection, 1 puncture collection from multicystic dysplastic kidney, 2 punctures from lymphatic fluid in cystic hygromas. Those last 9 cases, with uncommon materials, were collected because of severe oligohydramnios. From the total of 2021 exams, 1995 were successful (98.71%), and only 26 cases (1.29%) had no results, 18 of them failed during the set up of the cytogenetic laboratory. The failed cultures referred to amniotic fluid or chorionic villus sampling. All the other cultures, including the uncommon materials, had their culture grown with success, achieving the desired results. With these results we are able to demonstrate that sometimes it is necessary to collect others materials from the fetus (like severe cases of oligohydramnios), besides the traditional ones. These materials can be an excellent alternative for karyotyping, sometimes with better results.

Tay Sachs screening in HIV positive pregnant women. *A.M. Roe, G. Zapantis, S. Nakagawa, S.J. Gross.* Obstetrics and Gynecology, Albert Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY.

Background: Pre-conceptual carrier testing for Tay Sachs disease (TS) is offered to patients with a family history of TS and individuals of Ashkenazi Jewish (AJ) or French Canadian descent. Carrier testing for TS is currently performed by examining the activity of -hexosaminidase A (Hex A) in serum, leukocytes (wbc), or platelets. Approximately 7000 pregnant women in US have HIV and due to great strides in therapy it is now regarded as a chronic infectious process. We present a case of a woman who was HIV positive and underwent prenatal wbc screening for TS with ambiguous results. The benefit of platelet assay in chronic illness is addressed. **Case Study:** A patient of half AJ and half African American descent underwent TS carrier screening during an evaluation for tubal factor infertility and was found to have an "ambiguous" result of 62% on wbc Hex A activity (normal range 63-75%). She was HIV positive and was taking nevirapine and zidovudine/lamividine. Her viral load was 50 and her wbc count was 7.0 thousand/cu mm with a normal differential (62.9% neutrophils, 30% lymphocytes, 5.8% monocytes, 0.9% eosinophils, 0.3% basophils). She had no other medical problems. Molecular genetic testing of the three most common AJ mutations was negative. Measurement of platelet Hex A activity was performed and was normal (62%, 64%).

Discussion: The wbc assay for TS is a common and reliable testing method in pregnancy. However, disorders that can affect wbc count or function may alter results and lead to ambiguous findings. HIV disease has been associated with an increase in the plasma activity of Hex A and with an increase in the percentage of the Hex I fraction. Leukocytes are a mixture of cell types and higher levels of Hex A are found in granulocytes, therefore, the range of error is greater in the wbc assay than in specific tissue or cell types such as platelets. Furthermore, as of yet, there is limited data regarding anti-retroviral medications and Hex A activity. We recommend that HIV in pregnancy be regarded as a chronic infectious process and that the platelet assay modality may be a better choice for such circumstances.

Current opinions about the use of X-linked carrier embryos in preimplantation genetic diagnosis. *A. Perez[1], L. Demmer[2], J. Jonas[2], N. McIntosh[1].* 1) Biology, Brandeis University, Waltham, MA; 2) Pediatrics, Tufts-New England Medical Center, Boston, MA.

Use of carrier embryos of X-linked conditions (CE-XLC) in preimplantation genetic diagnosis (PGD) is controversial. Using such embryos may produce females who have health concerns related to their carrier status, and such women will also be faced with reproductive decisions related to the X-linked condition when they start their families. On the other hand, excluding the use of CE-XLC may be unethical because most resulting individuals would be healthy. Currently no guidelines exist regarding the use of CE-XLC in PGD. The purpose of this study was to survey providers and consumers/potential consumers about their views regarding the use of CE-XLC in PGD. 143 physician providers of PGD identifited from PGD websites were invited via email to participate in an anonymous online survey consisting of 22 questions regarding demographic information, experience with, and attitudes toward PGD. Carriers of X-linked conditions were invited through 11 online support groups to participate in a similar anonymous online survey consisting of 24 questions related to their experiences and attitudes with being X-linked carriers, potential symptoms, reproductive planning, PGD, use of carrier embryos, need for regulation of PGD, as well as demographics. 32 providers and 116 consumers completed surveys. Results show that while most providers (61%) felt that CE-XLC should be used in PGD, potential consumers of PGD were divided in their opinions (43% Yes, 38% No, 19% unsure). The majority of providers (57%) also felt that the US should not adopt guidelines for the use of PGD, versus 70% of potential consumers who felt that guidelines might be beneficial. Of consumers who had undergone PGD (n=4), 50% stated that using CE-XLC was discussed with them. While results suggest differences in opinion regarding the use of CE-XLC, open discussions between consumers and providers may mitigate their differences and facilitate achievement of common goals. In addition, there does not appear to be a consensus between these groups regarding the need for guidelines in this area.

Genometer, Amniometer and Genetic Ginnie - novel web based programs for comprehensive prenatal individualized information. *M. Shohat, D. Keynan, A. Labrov, N. Harel, G. Snir, M. Shohat, R. Wardenfeld.* Medical Genetics Institute, Rabin Medical Center, Petah Tikva, Israel.

Because the field of medical genetics is expanding, more time is required to explain genetic data to patients. We have developed three different web based programs that cover most of the information required by couples before genetic counseling. 1. Genometer: A self-completed computerized program that calculates the couples carrier risk for each of 22 diseases offered by the genetic services in Israel. The program can be easily adjusted for any country/populations by adding the relevant diseases, ethnic groups and carrier frequencies in each group. Carried out prior to or in early pregnancy and based on the ethnic origin of the couple, it provides a list of diseases based on the calculated combined ethnic risks. It is offered before referring couples for genetic screening. 2. Amniometer: A program to assist the physician with normal cases (where the results of all the routine tests performed during the pregnancy are normal and there are no other issues that require genetic counseling) in the decision-making whether or not to perform amniocentesis. The program combines all the different risks and depicts the final risk on a scale that can be easily understood. If there are any abnormalities the couple can enter more information in advance of genetic counseling. The geneticist can control the program easily. 3. Genetic Ginnie: A complete genetic questionnaire for couples with a positive family history or abnormal findings. In addition to an encyclopedia the program asks all the standard questions - some will appear only if the person gives specific answers. The report is long, written for lay people, and allows them to obtain additional relevant information. It saves time during the genetic counseling session and is intended for couples before they come to the geneticist. All these programs have been tested and are helpful both to the staff and the couples. Based on analysis by geneticists as well as on a general random telephone survey, it was concluded that this individualized genetic information provides a real professional need to the public.

A new personalized genetic information program for carrier screening - acceptance by the population screened.

D. Weiss[1], P. Zimmerman[2], N. Liberman[2], S. Almog[2], R. Optovski[2], Z. Sadeh[2], R. Ben-Yair[2], D. Levin[2], M. Shohat[1]. 1) Medical Genetics Institute, Rabin Medical Center, Petah Tikva, Israel; 2) Community Health Services, 101 Arlozorov Street, Tel Aviv, Israel.

Over the last 10 years tests for carrier screening for 22 common genetic diseases have been introduced and offered to the Jewish population in Israel, according to the ethnic origins of the couples. This has caused confusion among both public and physicians regarding which tests to recommend to each couple. In order to assist couples in their decision, a major HMO in Israel has analyzed the impact of a new strategy for personalized genetic information for carrier screening. The service is based on a self-completed computerized program (Genometer), which calculates the couples carrier risk for each of the 22 diseases. Based on their frequency and severity, the diseases are ranked in 4 categories: 1. Recommended tests (e.g. Ataxia Telangiectasia in North African Jews) 2. Tests for other severe diseases that should be considered (e.g. Bloom syndrome in Ashkenazim) 3. Tests for common but mild/treatable diseases (e.g. Gaucher disease in Ashkenazim) 4. Tests not relevant to the couples ethnic origin (e.g. cystic fibrosis in Iraqi Jews). The computerized program is web based and can be easily updated. 120 trained Ob/Gyn nurses have been recruited to offer the program to couples prior to or in early pregnancy in 90 countrywide clinics. The tests are self-paid by the couples ($25 per disease). Since its initiation over 1000 women have been using the program each month. A telephone survey was carried out among 300 who were asked about different parameters regarding its benefits. 90% said they were very satisfied with the information provided, 83% recommended the service to their pregnant friends, and 67% underwent the genetic tests following the information session. The program has been tested and approved by geneticists and genetic counselors in Israel, who found that the personalized information was accurate and there were no errors in the categorization of the diseases/tests to the different recommendation groups. It was concluded that this program provides a real professional need to the public.

Congenital nephrosis in the offspring of two consanguineous couples from the same Afghani family. *F.H. Morris[1], J. Taylor[1], J. Shields[2], D.B. Rogers[1].* 1) Genzyme Genetics, Orange, CA; 2) Valley Perinatal Medical Group, Tarzana, CA.

Case A: A 27-year-old G2P1 Afghani woman presented at 17 weeks gestation (GA) because of an elevated maternal serum alphafetoprotein (MSAFP) on an Expanded AFP test. The patient and her spouse were first cousins once removed. A fetal ultrasound was normal but amniocentesis revealed a 46,XY fetal karyotype with amniotic fluid AFP (AF-AFP) elevated at 26.45 multiples of the median (MoM) and negative acetylcholinesterase (AChE). Repeat amniocentesis yielded an AF-AFP of 29.97 MoM and negative AChE. After genetic counseling the patient elected to continue her pregnancy and delivered a normal-appearing newborn at term who was discharged home after only two days. Several days later the infant required acute hospitalization and was subsequently diagnosed with congenital nephrosis.

Case B: Eighteen months after Case A presented, a 31-year-old G3P1SAB1 Afghani woman with a different last name was seen at 18 weeks GA due to an elevated MSAFP. The patient stated that she and her spouse are second cousins through her father and first cousins once removed through her mother. She also has a nephew who needs a kidney transplant. Following a normal ultrasound, amniocentesis revealed a 46,XY karyotype, AF-AFP = 31.14 MoM, and negative AChE. Repeat amniocentesis found an AF-AFP = 41.52 MoM. The patient terminated the pregnancy. Molecular analysis of cultured amniocytes found an amino acid change of uncertain significance in the Finnish Congenital Nephrosis (NPHS1) gene. The variant appears to be present in a homozygous state.

Our patients were confirmed to be from the same family, each having married the others brother! The multiple layers of consanguinity between these couples are quite complex, but the variant detected in Case B likely represents a disease-causing mutation in the NPHS1 gene that has also caused congenital nephrosis in Case As son. The variants significance will be confirmed via subsequent molecular analyses of both couples and the affected child. Effective early prenatal diagnosis should then be possible by screening for the variant in future pregnancies.

Is Pallister-Killian Syndrome associated with advanced maternal age? A review of the Genzyme Genetics Database. *R.L. Arvon[1], G. Bega[1], J. Pelham[2], S. Weiner[1].* 1) Dept OB/GYN, Thomas Jefferson Univ, Philadelphia, PA; 2) Washington Hospital Center Washington DC.

Our aim was to investigate the relationship of Pallister-Killian Syndrome (PKS) and advanced maternal age (AMA - maternal age over 35 years at delivery) by reviewing the Genzyme Genetics database for cases of Pallister-Killian Syndrome and/or Tetrasomy 12p. Pallister-Killian syndrome is a very rare syndrome that can be diagnosed prenatally. It is due to a maternally derived isochromosome (12 p10). The Genzyme Genetics data base of invasive prenatal procedures was queried from January of 1995 to December of 2004 for PKS and/or Tetrasomy 12p. A total of 20 cases were identified out of 608,792 reported invasive procedures, all by amniocentesis and not by CVS (known to miss mosaicism). The overall incidence in the second trimester of PKS in our population was 1 in 30,300. Of these, 13/20 were AMA with an incidence of 1 in 47,000. In comparison, the incidence in women under the age of 35 was almost half at 1 in 87,000. The most common reason found for invasive testing was abnormal ultrasound finding and the most common finding reported on the ultrasound was congenital diaphragmatic hernia (CDH) and then increased nuchal translucency (NT).

	AMA only	Abn. u/s only	AMA/Abn. u/s	Abn serum	AMA/Abn serum
Over 35 yrs.	5	1	4	0	3
Under 35 yrs.	0	5	0	2	0
Total	5	6	4	2	3

Conclusion: This study confirms that PKS is more common in women 35 and over. Women of advanced maternal age who originally declined invasive testing and found to have CDH on ultrasound should be offered karyotype and interphase FISH to rule of PKS.

Evaluation of Genetic Variation in the Fetus as Risk Factors for Preterm Delivery. *D. Caprau[1], M. Marazita[2], M. Cooper[2], J. Dagle[1], C. Zimmerman[1], K. Johnson[1], K. Orr[1], J. Murray[1].* 1) Univ Iowa, Dept Pediatrics, Iowa City, Iowa; 2) Univ Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania.

Preterm delivery currently affects more than 400,000 infants born annually in the US and more than four million world-wide. Mortality of these infants remains substantial and morbidities which include chronic lung disease, intra-cranial hemorrhage, patent ductus arteriosus, retinopathy of prematurity, cognitive delay, cerebral palsy, and others remains substantial despite dramatic improvements in both treatment and prevention. Preterm labor resulting in delivery of a premature infant is a complex problem whose etiology likely encompasses both genetic and environmental effects. Genetic risks for prematurity have been evaluated using candidate gene approaches but have focused primarily on the mother rather than the fetus as the risk factor. In this study we undertook a comprehensive examination using cases defined by preterm delivery in an infant coupled with DNA samples from the parents to determine whether fetal genetic variation could be one component of the stimulus to preterm delivery. A total of 490 premature babies with gestational ages between 22-36 weeks (mean= 31.2 +/- 3.6 weeks) and their parents have been enrolled in this study. DNA was extracted from cord blood for the babies and from venous blood or buccal swabs for the parents. Genotyping for all other markers was performed using the TaqMan chemistry as designed by Applied Biosystems. We performed TDT analysis using FBAT approach to assess allelic association with preterm birth. Thirty-seven genes and 90 SNPs were investigated. Significant results have been identified for several genes: Factor 5 (p=0.015), OPRM1 (p=0.021), MTHFR (p=0.043), MTRR (p=0.02) and others. No evidence of fetal risks was associated with IL 6, TNF- or HLA-B or G as had been reported in previous studies. The methods employed here can be extended to additional genes as well as to a similar approach using the mother as a risk case and eventually to look at interactions between mother and fetus. Genes identified in this study should now be evaluated more thoroughly using functional studies and additional genetic variations.

Genetic study of Sirenomelia, exclusion of major genes (HLXB9, SHH, Patched...) in human sirenomelia. *M. Gerard[1], A. Bourillon[2], M. Sinico[3], C. Touboul[4], JM. Levaillant[4], T. Costa[5], Y. Roumazeilles[6], B. Haddad[4], A. Boutron[7], A. Bazin[8], J. Martinovic[8], F. Encha-Razavi[3], B. Gerard[2].* 1) Medical genetics, CHIC, Creteil, France; 2) Molecular genetics, Bichat, France; 3) Fetal pathology, CHIC, Creteil, France; 4) Obstetrics, CHIC, Creteil, France; 5) Medical genetics service, Sainte Justine Hospital, Montreal, Canada; 6) Website designer, Paris, France; 7) Fetal cell bank, Kremlin-Bicêtre, France; 8) Pasteur-CERBA laboratory, Pontoise, France.

Sirenomelia is a rare fatal condition characterized by fusion of the lower extremities, and genito-urinary malformations. Sirenomelia is usually sporadic, and monozygotic twins are usually discordant for this malformation (Stocker, 1987). Nevertheless, there are strong evidences for genetic predisposition in sirenomelia (i) reports showed a familial recurrence of sirenomelia (Rudd et al., 1990), or sacral anomaly in a sister of a child afflicted with sirenomelia (Costa, personal communication) (ii) minor defects such as imperforate anus, anomaly of the lumbar spine or renal dysplasia are frequently observed in the family (Rudd et al. 1990; Selig et al., 1993; Akbiyik et al., 2000) (iii) srn mice strain showed 12 percent of recurrence (Orr and al., 1982), (iv) the occurrence of sirenomelia in different mating of mutants mice for Brachyury (T gene), Fused, t and u (Gluecksohn and Dunn, 1942). Thus, sirenomelia could be considered as a complex genetic disease, with possibly a inherited predisposing mutation of one of the several genes essential for the caudal mesoderm induction and additional somatic mutations affecting either the second allele of the inherited mutated allele or others genetic loci (multihit hypothesis). Here, we report the first human genetic study of sirenomelia, on fetuses and sib. Molecular studies were done on HLXB9 gene (Currarino triad), with sequencing of the coding sequence and search for heterozygous deletions using real time PCR, sequencing of the coding sequence of SHH and PTCH. Extension of the study is underway, on the Brachyury gene and the receptor of retinoic acid, CYP26A1 (international collaborative study on the website : www.sirenomelia.org).

Prenatal diagnosis for Fragile X syndrome using methylation-specific PCR. *P. Limprasert, C. Charalsawadi, T. Sripo.* Human Gen/Dept Pathology, Medicine, Prince Songkla Univ, Songkhla, Thailand.

Fragile X syndrome (FXS) is the most common X-linked mental retardation. It is caused by CGG-repeat expansion within the *FMR1* gene. Affected individuals (full mutation, FM) have greater than 200 CGG repeats, correlated with methylation of the gene. The standard diagnoses are the determination of CGG repeats by PCR (CGG-PCR) and methylation status by southern blot (SB). Methylation-specific PCR (MS-PCR) has been developed for diagnosis of methylation in FXS. We used the MS-PCR protocols of Weinhäusel and Haas *(Hum Genet 2001;108:450-458)* for males and Zhou et al *(J Med Genet 2004;41:e45)* for females. We tested MS-PCR in 25 postnatal FM-FXS cases and 55 controls to verify the protocols in our setting. All results corresponded to the CGG-PCR or SB. We herein report the first time for prenatal diagnosis (PND) for FXS using these MS-PCR protocols. Three FXS female carriers were referred for PND. Amniocentesis was performed at 16-18 weeks gestational age. Fetal sex was determined by using PCR on the *SRY* gene. MS-PCR revealed a full mutation male and a normal male corresponding to the results from the standard diagnoses. Although it is difficult to use MS-PCR for a female due to random X-inactivation, we could identify a suspected premutation/full mutation female in the last PND case. We confirmed that this case was a full mutation female using SB. The advantages of MS-PCR compared to SB are that it requires only a small amount of DNA, and it is less time consuming and less expensive. Integration of MS-PCR into the current practice might reduce the number of cases which require SB, particularly in known FXS families.

HEXA gene as a model of single cell genetic testing: credibility, precision, implications. *K. Dotan, B. Goldman, B. Feldman, G. Barkai, L. Peleg.* Human Genetics, Sheba Medical Center, Ramat Gan, Israel.

Tay Sachs disease (TSD) is an autosomal recessive disorder due to impair activity of hexosaminidase A. In its severe form it leads to death during infancy. TSD is frequent among Ashkenazi Jews, with a carrier frequency of 1/29. Two mutations underlie nearly 100% of the infantile form +1278TATC (73% of carriers) and IVS12-1G to C (13%). An adult-onset chronic form, caused by the mutation G805A (4% among carriers) is usually in compound with a common one. Preimplantation genetic diagnosis (PGD) was performed in few cases of couples at risk after terminations of affected pregnancies. Our objective was to measure quantitative aspects of single cell analysis: amplification efficiency and allele-dropout rates in uni, simultaneous (of the two common mutations) and multiplex reactions in: peripheral lymphocytes, fibroblasts (amniotic), mesenchymal (CVS) and blastomeres. A set of nested PCR protocols was designed for the three mutations in different combinations. Each of the protocols can be performed in multiplex with one of two markers flanking the HEXA gene found to be highly polymorphic in the carrier population. Mutations were detected by agarose electrophoresis and two fluorescent computerized genotyping systems. Amplification rate was not significantly different among cell types: 86.3% in lymphocytes (82/95) and 82% in the embryonic cell (64/78). ADO rate was significantly lower (1.3%) in embryonic cells as compared to lymphocytes (12%). Lymphocytes treated with PHA to induce cell-divisions showed a 1.8 fold lower ADO rate than non-dividing lymphocytes. Hypothesis: ADO rate is lower in dividing cells having a less compact nucleus structure.

Preeclampsia and Cell-Free DNA Levels: An In Vivo Model to Study Placental Damage. *M.L. Tjoa[1], T. Cindrova-Davies[2], K.L. Johnson[1], G.J. Burton[2], D.W. Bianchi[1].* 1) Tufts University, Boston, MA; 2) Cambridge University, UK.

Background: Increased cell-free (CF-) DNA levels are present in the plasma of pregnant women with preeclampsia. The underlying pathophysiology for this is presumed to be increased placental apoptosis due to shallow trophoblast invasion and consequent oxidative stress. An *in vivo* model was developed to study the effects of stress-inducing conditions on placental function and release of CF-DNA.

Study Design: Placentas were cultured under normoxic and two stress-inducing conditions (hypoxia/reoxygenation (H/R) and H_2O_2 supplementation) for 7 (n=4) or 15 hours (hr)(n=6). CF-DNA was isolated from the supernatant and quantified by real-time PCR of the beta-globin gene. The amount of isolated CF-DNA was normalized to the placental weight and expressed as pcg of CF-DNA per mg of tissue.

Results:

Culture Condition	7 hr culture	15 hr culture
Normoxic	8798 (2417)	20110 (3748)
H/R	6849 (1279)	26109 (5191)
H_2O_2	6337 (1872)	29583 (5171)

Mean CF-DNA levels are 2-4 times higher in the 15 hr cultures. At 7 hr, there is no difference in CF-DNA levels between the normoxic and the stress-inducing conditions. After 15 hr, a trend showing elevated levels of CF-DNA in the supernatants of stress-induced cultures compared to the normoxic group is observed.

Discussion: Increased culture time under stress-inducing conditions is needed to observe differences in CF-DNA levels. Increased levels of CF-DNA in the plasma of pregnant women may reflect placental dysfunction caused by oxidative stress.

Accuracy of Down syndrome risk generated by the integrated prenatal screening. *A. Summers, T. Huang, C. Meier.* Genetics Program, North York General Hosp, Toronto, ON, Canada.

Integrated Prenatal Screening (IPS) was firstly described in 1999. It uses 1st. trimester nuchal translucency (NT) and pregnancy-associated plasma protein A (PAPP-A), and 2nd. trimester alpha fetoprotein (AFP), unconjugated estriol (uE3) and total human chorionic gonadotrophin (hCG) to assign women a single risk of having a baby with Down syndrome (DS). IPS can detect 85% of DS at term with a false positive rate of 1.8%. This study evaluates the accuracy of the risk of DS assigned by IPS based on women who completed 5 or 6-marker IPS at North York General Hospital between 11/1999 and 8/2004. During the study period, 31991 women entered the IPS. 30093 (94.1%) women completed IPS and 1898 (5.9%) dropped out, and were assigned a risk based on 1st. trimester screening. The median maternal age was 32 years. 64 (47 in women who completed 5 or 6-marker IPS) cases of DS were identified. The screening software used for IPS is Alpha. The risk cut-off for DS is risk 1 in 200 at term. All screening markers were converted to multiples of the median (MoM). Sonographer specific medians were used for the calculation of NT MoM. Using an established technique, women were ranked and divided into 9 groups according to their risk estimates. Each risk group covered an appropriate risk range and contained similar numbers of DS case except for the group with the highest risk. The mean estimated risk of each risk group was calculated and compared with the observed birth prevalence of DS of that particular group. As approximately 23% of DS pregnancies will miscarry spontaneously, number of DS cases with positive screen results and diagnosed prenatally were allowed for spontaneous miscarriage. Overall, the estimated risks assigned by IPS were close to the observed prevalence although the observed prevalence was slightly lower than the estimated risk in high risk groups. The slightly over estimated DS risk by IPS could be caused by miscarriage in high risk groups as low PAPP-A, increased NT and second trimester DS risk are associated with spontaneous fetal loss. In conclusion, DS risk estimates assigned by IPS were in good agreement with the observed birth prevalence of DS.

Free-Beta hCG vs. Total-Beta hCG in First Trimester Down Syndrome Screening. *T. Hallahan, D. Krantz, J. Curtis, V. Macri, J. Macri.* Research Div., NTD Laboratories, Huntington Stat, NY.

We analyzed free-Beta, total-Beta hCG and PAPP-A in 105 cases of Down syndrome and 1133 controls. The regressed median MoM in Down syndrome was substantially higher for free-Beta (1.53, 1.65, 1.79, 1.94 and 2.10) than for total-Beta (0.92, 1.09, 1.28, 1.52 and 1.80) at 9, 10, 11 12 and 13 weeks respectively. False positive and detection rates for the combined protocol including NT and PAPP-A were determined by modeling based on biochemical reference data from the present study and published NT distributions. At a 5% false positive rate NT/ PAPP-A alone achieved 90, 86, 83, 80, and 77% detection while including free-beta increased detection to 92, 91, 89, 88 and 87% at 9, 10, 11, 12 and 13 weeks respectively. Substituting total-Beta for free-Beta hCG reduced detection rates to 90, 87, 84, 85 and 85% respectively. The percent of cases detected by each marker that would have been missed by NT/PAPP-A alone are listed below based on the gestational age at blood draw and NT performed between 11w1d and 13w6d.

NT/PAPP-A	9 Weeks	10 Weeks	11 Weeks	12 Weeks	13 Weeks
+ Total-Beta hCG	2%	9%	4%	24%	33%
+ free-Beta hCG	28%	32%	36%	39%	43%

At a fixed 85% detection rate, the false positive rate with NT/ PAPP-A alone was 2.7, 4.3, 6.5, 9.0 and 11.7% while including free-beta hCG decreased these false positive rates to 1.5, 2.1, 2.8, 3.4 and 3.8% at 9, 10, 11, 12 and 13 weeks, respectively. Substituting total-Beta for free-Beta hCG increased false positive rates to 2.5, 3.7, 4.7, 5.4, and 5.2%, respectively. The data confirm previous studies that total-beta hCG is not a marker prior to 13 weeks and that substitution of free-beta with total-beta hCG at 13 weeks in a combined screening protocol would lead to a reduction in early detection of Down syndrome while increasing the false positive rate.

CLINICAL APPLICATIONS OF PLASMA CIRCULATING mRNA ANALYSIS IN CASES OF GESTATIONAL TROPHOBLASTIC DISEASE. *K. Miura, H. Masuzaki, S. Miura, T. Ishimaru.* Dept OB/GYN, Nagasaki Univ Sch Medicine, Nagasaki, Japan.

Objective: We tried to apply the measurement of plasma mRNA concentration by real-time RT-PCR as a follow-up test for GTD. Material and Method: Three cases with complete hydatidiform moles (CHM) and a case with choriocarcinoma were included. Blood samples (10 ml) were collected at times, before and after suction evacuation or chemotherapy. Plasma mRNA was extracted and a one-step real-time RT-PCR assay was performed as described by Ng et al. HCG-b mRNA was selected as a tumor marker of GTD and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA was measured as a housekeeping gene. Results: In three cases with complete hydatidiform mole (CHM), the day of 1st evacuation and that of 2nd evacuation were expressed as Day 0 and Day 7, respectively. The level of plasma hCG-ƒÀ mRNA in all three cases fell rapidly to undetectable levels by Day 7, and the corresponding hCG protein levels by an immunoradiometric assay (IRMA) also fell to below 1,000 mIU/ml until 35 days after 1st evacuation. In a case with clinical choriocarcinoma, etoposide and actinomycin D therapy was given on Day 0-3, 15-18, 29-32 and 43-46. Her plasma hCG-b mRNA level showed a decreasing tendency similar to the pattern for hCG protein level, but exhibited a transient increase after the first course of therapy and then decreased to 44 copies/ml. The same transient tendency was detected after all subsequent courses of therapy. The concentration of plasma GAPDH mRNA in all three cases with CHM also increased after both evacuations, and that in a case with choriocarcinoma also increased after therapy with etoposide and actinomycin D. Conclusion: Our results suggest that the measurement of plasma mRNA by real-time quantitative RT-PCR can be used as a non-invasive diagnostic, prognostic and follow-up test for GTD.

Fetal mustache visualized by 3D ultrasonography: first case report. *D.B. Rogers[1], W. Doany[2].* 1) Genzyme Genetics, Orange, CA; 2) Comprehensive Maternal-Fetal Medicine Consultations, Tarzana, CA.

A 40-year-old G6P0SAB5 woman was evaluated at 16 weeks gestation with transabdominal 2D and 3D fetal ultrasound. The examination revealed a single live fetus of a size consistent with dates and no apparent fetal, cord or placental abnormalities except that the fetal mouth appeared to have a soft-tissue overgrowth in the mid upper lip of no larger than two millimeters. On lateral 2D and 3D views a short, tube-like entity could be seen to protrude from the upper lip. AP views by 3D imaging revealed the overgrowth to be two adjoined, but distinct short rods located in the midline of the upper lip, just anterior to the philtrum. There was no evidence of a cleft. Follow-up ultrasonography at 20 weeks revealed a normal-appearing upper lip with apparent total resolution of the previously seen overgrowth.

In 1998 Bronshtein et al. reported finding 7 out of 3000 consecutive fetuses at 14-16 weeks gestation with a rod-like structure on the upper lip (which they termed mustache). Using 2D ultrasonography, they determined that the mustache consisted of two rod-like structures and were located on both sides of the midline on the upper lip. None of the fetuses had any other structural defects. Follow-up ultrasound examinations of the seven fetuses at 20-22 weeks gestation found in each case that the mustache had disappeared. Postnatal examinations also documented completely normal lips.

The fetal mustache described in our case is consistent with those detected by Bronshtein et al. and is likely to represent a delay in the normal embryological development of the human lip. More specifically, this delay is in the degeneration of the tissue remnants of upper lip fusion. Our 3D visualization of the fetal mustache should assist others who might encounter this rare entity on prenatal ultrasound examination. Normal lip development must be confirmed on follow-up ultrasonography and postnatal examination.

M. Bronshtein, E. Z. Zimmer, H. Offir, & S. Blazer. Ultrasound Obstet Gynecol. 12: 252-253, 1998.

Preimplantation HLA Typing with Aneuploidy Testing. *S. Rechitsky, T. Sharapova, K. Laziuk, R.S. Ozen, I. Tur-Kaspa, A. Kuliev, Y. Verlinsky.* Reproductive Genetics Institut, Chicago, Il.

We presently performed 756 preimplantation genetic diagnosis (PGD) cases for more than one hundred different single gene disorders, resulting in birth of 244 unaffected children. One quarter of these cycles were performed for preimplantation HLA typing, to establish an HLA compatible donor progeny for siblings with bone marrow disorders requiring stem cell transplantation. Because of the majority of such patients being of advanced reproductive age, aneuploidy testing is currently one of the approaches for improving the patients pregnancy outcomes. Using a standard IVF procedure, oocytes or embryos were tested for causative gene mutations or chromosomal aneuploidy, simultaneously with HLA alleles, selecting and transferring only those unaffected embryos, which were HLA matched to the affected siblings and free of aneuploidy. Of 204 embryos tested for HLA and aneuploidy, only 21 of 36 HLA matched embryos were found to be aneuploidy free and transferred in only 13 (48%) of 27 cycles, resulting in clinical HLA compatible pregnancies in 7 (54%) of these cycles. Overall, 1136 embryos were tested for HLA in 125 cycles, resulting in preselection and transfer of 197 (17.3%) HLA matched embryos in 82 (65.6%) cycles, including 107 (16.4%) also free of genetic disease and 88 (18.6%) only HLA matched, which yielded 23 (28%) clinical pregnancies and birth of 19 healthy HLA compatible children. Despite the controversy of PGD use for HLA typing, the data demonstrate the usefulness of the approach for the at risk couples not only for avoiding the birth of affected children with an inherited disease, but also for having unaffected children who may also be potential HLA matched donors of stem cells for treatment of affected siblings.

Pre-embryonic diagnosis for Sandhoff disease. *Y. Verlinsky, S. Rechitsky, I. Tur-Kaspa, A. Kuliev.* Dept Molec Genet, Reproductive Genetic Inst, Chicago, IL.

Embryos found to be abnormal during preimplantation genetic diagnosis (PGD) are discarded or analyzed to confirm the diagnosis. Because this is ethically unacceptable in some communities and ethnic groups, we developed a pre-embryonic genetic diagnosis, which is based on the sequential first (PB1) and second polar body (PB2) removal, followed by the culture and transfer of mutation free oocytes, while freezing the pronuclear stage oocytes predicted to contain the mutant gene. This was applied to PGD for Sandhoff disease caused by 16 Kb deletion of hexosaminidase B gene, in a couple with a religious objection to the embryo destruction, even if the embryos are affected. Eighteen oocytes were obtained in a standard IVF protocol, from which PB1s were removed following maturation, 4-5 hours after aspiration. PB2s were then removed 6 hrs after ICSI, and both PB1 and PB2 were tested for 16 Kb deletion, involving exons 1, 2, 3, 4 and 5, simultaneously with 5 linked polymorphic markers D5S1982, D5S1988, D5S2003, D5S349 and D5S1404. Based on the results of PB1 and PB2 analysis, 8 oocytes were predicted to contain 16 Kb deletion and frozen at the pronuclear stage (prior to embryos formation), while the remaining 8 oocytes, predicted to be 16 KB deletion free, were cultured and confirmed to be unaffected using blastomere biopsy at the 8-cell stage. Two of these embryos reaching blastocyst stage were transferred back to patient, resulting in an ongoing unaffected singleton pregnancy, representing the first case of pre-embryonic diagnosis, which opens the prospect of PGD in the communities where no embryo testing and discard is presently acceptable.

Polar Body biopsy based Preimplantation Genetic Diagnosis (PGD) for N-Acetylglutamate Synthase Deficiency (NAGS), and an analysis of ADO rates. *P. Renbaum[1], B. Brooks[2], E. Margalioth[2], T. Eldar Geva[2], Y. Kaplan[1], E. Levy-Lahad[1], G. Altarescu[1].* 1) Medical Genetics and; 2) IVF Units, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Preimplantation genetic diagnosis (PGD) for a single gene defect is presented for a family where both parents are carriers of a rare metabolic disorder, N-acetylglutamate synthase deficiency, causing progressive neurological deterioration and hyperammonia. The N-acetylglutamate synthase (NAGS) gene, located at 17q21, encodes a mitochondrial enzyme that catalyzes the formation of N-acetylglutamate, an essential component of the urea cycle. We have developed a polar body (PB) based multiplex fluorescent PCR protocol to analyze the 2729insC NAGS mutation and five closely spaced, highly polymorphic microsatellite markers D17S902, D17S1861, D17S1868, D17S965 and D17S791 that were informative in this family. Polar bodies 1 and 2 were sequentially biopsied for PGD diagnosis. Of sixteen PB1s analyzed, 13 were heterozygote, one carried the wild type allele, one was inconclusive, and one presented total amplification failure. Heterozygote PB1s are the result of crossover in meiosis and enable the identification of Allele Drop Out (ADO) in PCR analysis. The 13 heterozygote PB1s biopsied were each analyzed with six informative assays for a total of 78 individual reactions. We observed ADO in 17 reactions, resulting in an allele drop out rate of 22%. Of the Sixteen PB1s analyzed, eight of these fertilized, extruded PB2s and developed into 6-8 cell embryos on day 3. Of these, PB1 and 2 analysis showed that three oocytes carried the wild type copy of the NAGS allele and all three relevant embryos were transferred to the mother precluding the need to perform blastomere biopsies. This single cycle of PGD resulted in an ongoing twin pregnancy. The occurrence of ADO in single cell analysis is the primary cause of misdiagnosis in PGD, and the main reason for including polymorphic markers in the analysis. The high rate of ADO seen in PB1s emphasizes the necessity of using polymorphic markers in PGD in order to prevent misdiagnosis. To our knowledge this is the first report of PGD for this rare metabolic disorder.

Preimplantation genetic diagnosis for tuberous sclerosis. *P. Burlet[1], N. Frydman[2], N. Gigarel[1], V. Kerbrat[3], S. Lebon[1], JP. Bonnefont[1], E. Feyereisen[3], G. Tachdjian[2], R. Frydman[3], A. Munnich[1], J. Steffann[1].* 1) Service de génétique, U393, Hopital Necker Enfants-Malades, Paris, France; 2) Service de biologie de la reproduction, Hôpital Antoine Béclère, Clamart, France; 3) Service de gynécologie-obstétrique, Hôpital Antoine Béclère, Clamart, France.

Tuberous sclerosis (TSC) is a frequent autosomal dominant condition caused by various mutations in either the hamartin (TSC1) or the tuberin gene (TSC2). Disability in TSC patients most often results from brain involvment, including seizures and mental retardation. However, variable expressivity of the symptoms precludes any assumption as to the clinical outcome of an affected foetus, and makes genetic counselling difficult. For some couples, the only acceptable manner to ensure the birth of an unaffected child consists in preimplantation genetic diagnosis (PGD), an alternative to prenatal diagnosis because it circumvents termination of pregnancy. PGD was offered to an at risk couple owing to a paternal c.737+1G>A mutation in the intron 8 donor site of the TSC1 gene. The single-cell test was based on multiplex fluorescent PCR amplifiying simultaneously TSC1 exon 8 and a closely linked microsatellite marker (D9S1830), followed by MboII restriction analysis for the mutation. Single-cell amplification efficiency was assessed on 30 individual lymphocytes. Amplification rates of the mutation and the marker were both 100% with an allele drop out rate of 0 and 15% respectively. The PGD procedure involved a standard IVF protocol, resulting in 2 embryos at day 3. The four blastomeres tested were mutation-free, and this result was confirmed by the marker analysis, showing the wild type allele. The two embryos were transferred, and a singleton pregnancy is ongoing. These results suggest that PGD is a valuable alternative to prenatal diagnosis for tuberous sclerosis.

Development of an improved PGD test for Fragile X syndrome. *J. Steffann[1], N. Frydman[2], N. Gigarel[1], R. Gesny[1], J-P. Bonnefont[1], G. Tachdjian[2], V. Kerbrat[3], E. Feyereisen[3], R. Frydman[3], A. Munnich[1], P. Burlet[1].* 1) Service de génétique, U393, Hôpital Necker-Enfants Malades, Paris, France; 2) Biologie de la reproduction, Hôpital Antoine-Béclère, Clamart, France; 3) Service de gynécologie-obstétrique, Hôpital Antoine-Béclère, Clamart, France.

Fragile X (FX) syndrome is the most common familial cause of severe mental retardation inherited as an X-linked trait caused by expansion of a CGG repeat in the FMR1 gene. Both males and females can be affected leading to a high recurrence risk for this disorder, so that at-risk couples often ask for preimplantation genetic diagnosis (PGD). PGD involves removal of single cells from preimplantation embryos and analysis using highly sensitive PCR amplification. PGD of FX is difficult because of the large number of CGG repetitions in affected, precluding any attempt at sizing the mutant allele. Therefore two alternative methods are used for blastomere analysis: the detection of the non expanded allele, or the use of linked polymorphic markers. Direct detection of the normal alleles has been described but remained difficult due to the lack of PCR sensitivity. The main drawback of the indirect method is the non-informativity of the marker. Recently, multiple displacement amplification (MDA) has been reported to yield large quantities of high-quality DNA from single-cell. In order to increase the sensivity and the reliability of the FXS diagnosis, we developed a combined analysis of polymorphic markers with the study of the CGG normal allele, using MDA as a first step. Single-cell amplification efficiency was assessed on 56 lymphocytes for both normal CGG alleles and four linked microsatellite markers: FRAXAC1, DXS998, DXS1215, DXS548. Amplification and allele drop-out rates ranged from 88 to 95% and 4 to 34%, respectively. A couple requesting PGD was shown to be informative for both the expansion and the markers. A standard IVF protocol was performed resulting in 8 embryos including 4 shown to be unaffected. Two healthy embryos were transferred, resulting in a singleton pregnancy. PGD results were confirmed later in the four carrier embryos. In conclusion, MDA as a first step is a powerful tool for PGD in Fragile X.

Expression Microarray Analysis to Detect Unique Fetal Markers and Fetal-Maternal RNA Trafficking in Maternal Whole Blood. *J.L. Maron[1], K.L. Johnson[1], C.Q. Lai[1], D. Slonim[2], D.W. Bianchi[1].* 1) Division of Genetics, Tufts Univ. School of Med., Boston, MA; 2) Department of Computer Science, Tufts Univ., Medford, MA.

Background: The rapid clearance of fetal nucleic acids from the maternal circulation following delivery presents an opportunity to identify unique, gender-independent markers. We used expression microarrays to study differences between peripartum women and their newborns. Methods: Paired sample sets were obtained from pregnant women immediately prior to term delivery and 24 hours postpartum, along with their newborns umbilical cord blood. Controls were non-pregnant women. Total RNA was extracted from whole blood samples in accordance with the PAXgene blood RNA kit protocol. Successful RNA extraction was confirmed using real-time RT-PCR for the housekeeping gene GAPDH. RNA was amplified in accordance with the Affymetrix One-step Amplification Protocol. Samples were hybridized to the Affymetrix HGU133a microarrays, scanned with the GeneArray Scanner and analyzed using the GeneChip Microarray Suite 5.0 (Affymetrix). Results: We successfully isolated, amplified and hybridized mRNA from maternal and newborn whole blood to oligonucleotide microarrays. Umbilical cord blood consistently had greater amounts of extracted and amplified mRNA. Comparative analysis between genes expressed in both the antepartum and the corresponding umbilical samples, but absent in both the postpartum and the control samples, identified a subset of genes that are presumably fetal in nature. Conclusions: Preliminary results suggest that comparison expression microarray analysis between a peripartum pregnant woman and her infants umbilical cord blood can be utilized to identify unique fetal markers, to monitor fetal-maternal RNA trafficking, and to potentially develop predictive models of pregnancy-related disease.

Joubert syndrome: a paradigm for prenatal diagnosis of specific hindbrain malformations by ultrasound and MRI. *D. Doherty[1], D. Nyberg[2], J.R. Siebert[3], M.A. Parisi[1], D.W.W. Shaw[1], P.J. Strouse[3], P.F. Chance[1], M. Barr, Jr[3], B. Maria[4], I.A. Glass[1].* 1) University of Washington, Seattle, WA; 2) The Fetal and Women's Center of Arizona, Phoenix AZ; 3) University of Michigan, Ann Arbor, MI; 4) Medical University of South Carolina, Charleston, SC.

Malformations of the hindbrain (cerebellum, pons and medulla) affect approximately 1/5000 births (Metropolitan Atlanta Congenital Defects Program, personal communication). Although advances in brain imaging technology have facilitated identification of hindbrain malformations, difficulty in assigning precise diagnoses has created significant challenges for counseling patients and families regarding etiology, prognosis and recurrence risk. Disorders with cerebellar vermis hypoplasia (often labeled Dandy-Walker variant) represent a particularly challenging diagnostic group due to the many underlying causes and broad spectrum of outcomes. One of these disorders, Joubert syndrome (JS), is an autosomal recessive hindbrain malformation disorder characterized by cerebellar vermis hypoplasia, thick superior cerebellar peduncles and a deep interpeduncular fossa (the molar tooth sign (MTS)). Clinical signs include congenital hypotonia, ataxia, developmental delay, disordered respiratory control and abnormal eye movements. While the recurrence risk for JS is 25%, prenatal diagnosis using DNA testing is not clinically available for the vast majority of families, and the MTS has yet to be described using fetal MRI. We report our ultrasound and MRI results on fetuses with JS at 22-34 weeks, demonstrating that cerebellar vermis hypoplasia is present from early in gestation, and that the MTS can be identified well before birth. While we have not yet observed the MTS before 24 weeks gestation, we have accurately diagnosed JS before 22 weeks in one at-risk fetus and excluded JS in five other at-risk fetuses. In addition, we present correlation with fetal neuropathology and postnatal imaging. We propose an imaging strategy for the accurate in utero diagnosis of JS as an initial step toward differentiating between diverse hindbrain malformations to provide more accurate information regarding prognosis and medical management.

Prenatal diagnosis of acute promyelocytic leukemia in a fetus at 28 weeks gestation. *E. Kolomietz[1], EJT. Winsor[1], G. Ryan[2,3], G. Seaward[2,3], S. Keating[1], C. Wang[1], D. Chitayat[2,4].* 1) Pathology/Laboratory Medicine, Mount Sinai Hosp/Univ Toronto, Toronto, Ontario, Canada; 2) Dept. of Ob&Gyn, Mount Sinai Hosp/Univ Toronto, Toronto, Ontario, Canada; 3) Fetal Medicine Unit, Mount Sinai Hosp/Univ Toronto, Toronto, Ontario, Canada; 4) Prenatal Diagnosis and Medical Genetics Program; Mount Sinai Hosp/Univ Toronto, Toronto, Ontario, Canada.

Fetal leukemia is an extremely rare disease and in almost all reported cases the fetus had Down syndrome. We report a fetus that presented with hydrops fetalis due to promyelocytic leukemia. The mother was a healthy 30 year-old G1P0. Ultrasound examination at 27 weeks gestation revealed hydrops fetalis including pleural effusions, ascites and skin edema. Attempts to karyotype the fetus by amniocentesis and cordocentesis failed since neither specimen produced metaphases in culture. Cytogenetic analysis was successful on pleural effusion and repeat amniotic fluid obtained at 28 weeks gestation. There were multiple single cell chromosome aberrations in both specimens. The most consistent aberration was an unbalanced derivative of chromosome 16 which resulted from a translocation between chromosomes 16 and 17 [der(16)t(16;17)(p13.3;q21)]. This was found in the amniotic fluid, but not in the pleural fluid. Spontaneous demise occurred at 33 weeks gestation. At delivery, the fetus was macerated with severe hydrops. The full blood count on a suboptimal specimen collected about 24 hours after birth revealed extreme leukocytosis with a white cell count 110 x 109 /L. The peripheral blood film showed immature granulocytes with features of promyelocytes. The morphological findings resembled those in acute promyelocytic leukemia. Molecular and FISH studies to check for involvement of the RAR-alpha gene on chromosome 17 are in progress.

Prenatal diagnosis of dysmorphic syndromes. *C. Stoll, Y. Alembik, B. Dott, MP. Roth.* Genetique Medicale, Faculte de Medecine, Strasbourg, France.

Some dysmorphic syndromes can be detected prenatally(DPN) by ultrasound examination(US).The objectives of this study was to evaluate the prenatal diagnosis of dysmorphic syndromes by routine US. The material for this study came from our population based registry of congenital anomalies.The study period was 1992 to 2003. Results :we report the dysmorphic syndromes in categories of congenital anomalies. There were 564 cases with congenital heart diseases and 110 of them had recognized syndromes :86 chromosomal anomalies(23 % of them were diagnosed prenatally) and 24 non chromosomal syndromes,including 6 22q11microdeletions(3 DPN) ;4 situs inversus(3 DPN) ;3 VATER association(2 DPN) ;and 11 others :one each FAS,Ellis-Van Creveld,Greig,OFD, Chondrodysplasia punctata and Roberts detected prenatally and one each CHARGE,Aarskog, OAVS,Robinow,and SLO not detected prenatally.Theprenatal detection rate for the chromosomal syndromes and for the non chromosomal syndromes were 86 % and 80% for renal malformations,50% and 62% for limb reduction defects,71% and 83% for abdominal wall defects,80% and 100% for diaphragmatic hernia,37% and 43% for intestinal atresias,82% and 82% for cleft lip/palate,and 100% and 83% for neural tube defects respectively.Among the non chromosomal syndromes non detected were 3 VA(C)TER(L),3 osteochondrodysplasias,3 FAS,and one each amniotic band, Hanhart,Fanconi,Aarskog,De Lange,Di George,TAR,osteogenesis imperfecta, Goldenhar,OFD,Pierre Robin,Meckel-Gruber,caudal regression,OEIS,and Fryns. Detection rate varies with the type of syndrome and increases with increasing numbers of abnormalities in the fetus.For all categories of congenital anomalies apart from renal ones,the detection rate is much higher for associated anomalies than it is for isolated anomalies. However,prenatal ultrasound screening allows diagnosis of a large proportion of chromosomal syndromes and recognized dysmorphic syndromes without chromosomal anomalies.

Perinatal outcome in women with combined neural tube defects and Down syndrome screening positivities. *S. Kim, S. Bai.* OB/GYN, Col Med, Seodaemun Ku, Yonsei Univ, Seoul, Korea.

To evaluate the perinatal outcome of patients with serum screen-positive for both neural tube defects(NTD) and Down syndrome(DS). Alpha-fetoprotein(AFP),unconjugated estriol(uE3) and intact human chorionic gonadotropin(hCG) levels were determined with RIA kits at 15-20 weeks of pregnancy.Estimates of individual DS risk were made using the concentrations of these analytes and maternal age.We have selected cases with both an AFP value 2.5 multiples of median(MoM) and a DS risk more than 1:270 at second trimester (dual positivity). We have analyzed all data about the perinatal outcomes.Dual positivity was found in six cases.There were one anencephaly and 1 open spina bifida.Karyotypes were not performed and pregnancies were terminated.In four remaining cases the fetal karyotypes was normal.Among these 4 cases,one showed severe preeclampsia associated with fetal growth restriction and delivered at 29 weeks.In the other 3 cases,the perinatal outcomes was uneventful.Our findings suggest that patients with dual positivity at NTD/DS serum screening may have an increased risk of adverse perinatal outcome.

Maternal steroids and the non-invasive diagnosis of low-estriol disorders. *J. Marcos[1], W.Y. Craig[2], C. Shackleton[1].*
1) Children's Hospital Oakland, Oakland, CA; 2) Foundation for Blood Research, Scarborough, ME.

Introduction: Unconjugated estriol (uE3) is measured during second trimester prenatal screening. While estriol itself has little physiological importance, low values can indicate the presence of a disorder in feto-placental synthesis with potential health implications for the baby. Since fetal steroids pass through the maternal circulation and into the urine, analysis of maternal fluids can be used for diagnosing individual causes of low estriol. **Methods**: Samples of urine and serum were obtained from >1,000 pregnant women who exhibited low uE3 (<0.3 MoM), and most were collected as part of a multicenter study to evaluate potential screening for Smith-Lemli-Opitz syndrome (SLOS). The sample (1ml) was hydrolyzed, extracted, derivatized and analyzed by GC/MS for compounds diagnostic of SLOS, STS and other disorders. Key analytes for SLOS detection were dehydropregnanetriols and dehydroestriol, and the key parameter for STS was excessive excretion of 16-hydroxy-DHEA sulfate. **Results**: Quantitative ratios between diagnostic steroids (*precursor metabolite/product metabolite*) have been evaluated. Cut-off values for these in urine and serum were established to optimize the sensitivity and specificity. The false positive rate for SLOS was 0%, and for STS was 3.2%. The false negative rate for both SLOS and STS was 0%. From these selected ratios 5 pregnancies positive for SLOS, and 182 positive for STS were detected. Confirmatory diagnostic data were available through independent testing and/or postnatal clinical examination for all SLOS cases and 50% of STS cases. Independent of above study, we also present data on another low-estriol condition, fetal P450 oxidoreductase deficiency (ORD).**Conclusions**: For STS and SLOS, non-invasive second trimester diagnosis is readily attainable through GC/MS analysis. In contrast to FISH testing, the method detects STS caused by point mutations. Analytes have also been included in the panel that should allow detection of OR, 17-hydroxylase and aromatase deficiencies.**Acknowledgements**: Funding was from the NIH (R01 HD38940). The contribution of multiple investigators in participating institutions is acknowledged.

PLACENTAL mRNA IN MATERNAL PLASMA AND ITS CLINICAL APPLICATION TO THE EVALUATION OF PLACENTAL STATUS IN A PREGNANT WOMEN WITH PLACENTA PREVIA-PERCRETA. *S. Miura, H. Masuzaki, K. Miura, T. Ishimaru.* Dept OB/GYN, Nagasaki Univ Biomed Sci, Nagasaki, Japan.

Objective: We applied placental mRNA measurement in maternal plasma to the evaluation of residual placenta condition in a pregnant woman with placenta previa-percreta (PPP) and bladder invasion. Material and Methods: Although a supra-vaginal hysterectomy just after the cesarean section (the first surgery) was done at 37 weeks of gestation, a 16-cm placental mass close to the internal os of the uterus could not be removed. Therefore, therapy with methotrexate (MTX) was initiated four times after the first surgery to aid resorption of the placental residue, and then a second surgery was performed to complete the hysterectomy. Blood samples were collected at intervals, and before/after surgeries. Human chorionic gonadotropin (hCG) and human placental lactogen (hPL) were selected as representative placental mRNAs, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA was measured as a housekeeping gene. A one-step real-time RT-PCR assay was performed to measure the concentration of mRNA in maternal plasma. Result: The hCG mRNA showed a decreasing tendency similar to the pattern for hCG protein levels measured by an immunoradiometric assay , but exhibited a transient increase after the first MTX therapy and then decreased again to <10 copies/ml after the second surgery. Interestingly, plasma hPL mRNA levels showed a similar pattern but rose again after the second MTX therapy, while the hCG mRNA level decreased. The GAPDH mRNA concentrations in plasma also increased after both surgeries and after the first MTX therapy. Conclusion: Real-time quantitative RT-PCR adopted in the present study is a sensitive method to monitor changing mRNA levels resulting from apoptotic effects in the placenta, and to evaluate invading conditions of the trophoblastic villus.

Uncommon Mutations Have Been Found During Prenatal Diagnosis of More Than 1200 Iranian Families Using DNA Sequencing. *B. Azimifar[1, 3], M. Eram[1], M. Masrouri[1], V. Lotfi[1], P. Foulady[1], M. Hosseini[1], A. Abdolhosseini[1], S. Zeinali[1, 2].* 1) Medical Genetics Lab of Dr. Zeinali, Tehran, Iran; 2) Department of Biotechnology, Pasteur Institute, Tehran, Iran; 3) Department of Biology, Shahid Beheshti University, Tehran, Iran.

Beta thalassemia is the most common hereditary severe blood disorder in Iran. Prenatal diagnostic (PND) strategies for Î²-thalassemia by now are one of the most effective means for preventing the birth of affected children. More than 1117 prenatal diagnosis had been completed by our lab since mid 2000. Besides routine ARMS-PCR methods were used for screening the most common Iranian Î²-globin gene mutations, more rigorous molecular analyses were performed for the 58 unresolved cases (5% or 58/1117) using DNA sequencing. The total of 22 rare Î²-globin gene mutations has been found by us yet. There were 4 new mutations [i.e. codon 37/39 (-GACCCAG), codon 37 (GA), codon 44 (-C) and IVSII nt 850 (GC)] which had not been reported in Iran, previously. The knowledge of mutation types, their frequencies and hematological data of the carrier individuals could be useful for developing Î²-thalassemia molecular screening plan in Iran and other neighbor's countries.

Decrease in mitochondrial cytochrome c oxidase III and ATPase 6 levels and mutations in the promoter region in preeclamptic pregnancies. *D. Cha, S.H. Lee, C.N. Lee, K.J. Lee, S.W. Cho, J.B. Chang.* Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea.

Objectives: The placenta transports nutrients and oxygen to the fetus. In active transport, energy is expended to transport material against a gradient. Preeclamptic pregnancies are often associated with an undernourished fetus, suggestive of a reduction in placental transport. To clarify the possible relation between mitochondrial gene expression and the placental dysfuction in preeclampsia, we examined the expression of cytochrome c oxidase III and ATPase 6. The promotor region was also investigated to detect any mutation in H-strand and L-strand. Materials and Methods: Placental tissues were obtained from preeclampsia and control group(each 5 cases) between 22 and 41 gestational weeks. The expression of cytochrome c oxidase III and ATPase 6 were analyzed by RT-PCR and quantified by the densitometry. The H-strand and L-strand of promotor region were analyzed by ABI prism 377 DNA analyzer after PCR. Results: The expression of cytochrome c oxidase III and ATPase 6 levels were reduced in the preeclampsia than in the control group. The mutation of L-strand promotor region was not detected in both group. In H-strand, some mutations including T insertions(553, 557, and 560), substitution(C567T), and mutated AAA(563-565). Conclusions: The decreased level of the mitochondrial gene(cytochrome c oxidase III and ATPase 6) is involved in placental dysfunction in preeclampsia. The reduced expression of these genes suggests malfunctioned transcription in the promotor region. The verified mutations in the promotor region may support this suggestion.

Evaluation of the fetus with multiple skeletal anomalies. *E. Severin, D.F. Albu, C. Albu.* Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania.

Background.Skeletal anomalies are bone and cartilage disorders and most of these are genetic conditons.With early detection, antenatal screening, patients can avoid or minimize the complications associated with this disorders.Objective.To specify the role of 3D ultrasonography as a screening tool for prenatal identification of specific skeletal anomalies in skeletal dysplasias. Patients and Methods. A 34-year-old Caucasian female was referred at 19 weeks' gestation for a routine prenatal ultrasound. The patient was examined with Color Doppler and 3D system.We also collected information about family medical history. Amniotic fluid samples were taken to perform prenatal molecular diagnosis.Parental studies were made for recurrence risk counseling. Results. The patient's obstetrics history revealed three previous miscarriages, all in the second trimester (unknown causes). Her third pregnancy ended at 24-week with stillborn fetus (thanatophoric dysplasia morphology appearance but no radiologic examination or molecular confirmation were made). A 3D ultrasound examination of fourth pregnancy identified a single fetus with skeletal findings suggestive of thanatophoric dysplasia type II: micromelia with straight femurs and cloverleaf skull deformity. More associated anomalies were detected.Clinical suspicion was confirmed by molecular diagnosis. The couple chose to terminate the pregnancy. Conclusions.Multiple skeletal anomalies were detected by ultrasound in the prenatal period. The pattern of skeletal anomalies suggested thanatophoric dysplasia. Molecular confirmation was possible. Evaluation and genetic counseling based on both 3D ultrasonography and molecular genetic testing should be considered for the next pregnancy.

Prenatal diagnosis of a fetus with lip-jaw-palatal cleft. *D.F. Albu, E. Severin, C. Albu.* Human Genetics, Carol Davila Univ. Med and Pharm, Bucharest, Romania.

BackgroundVisualization of the fetal face has acquired a special importance because noticeable features in the phenotype facilitate the diagnosis of syndrome-like or chromosomally induced clinical conditions. Prenatal screening offer the possibility of preventing the birth of infants with serious congenital abnormalities. **Objective**. To specify the most appropiate safety method of trisomy 13 prenatal screening. **Patient**. A 27-year-old Caucasian female, pregnant for the second time, underwent to routine ultrasound examination at 16 weeks of pregnancy. The woman and her husband had normal general health and were not genetically related. There was no history of abnormal children in their families. **Methods**: routine ultrasonography at 16 weeks of pregnancy; selective ultrasonography for the detection of fetal abnormalities; triple test; amniocentesis(amniotic fluid samples were taken at 17 weeks); chromosome analysis in cultured fetal cells was performed following the standard protocols. **Results**. Ultrasound examination revealed a single prenancy with an abnormal foetal facial development: lip-jaw-palatal cleft. This sonographic marker indicated the possibility of a chromosomal anomaly, such as trisomy 13 or trisomy 18. Lip-jaw-palatal cleft is typical, but not specific for trisomy 13. Triple test was not sensitive to the presence of trisomy 13. Chromosome analysis was recommended and fetal karyotype demonstrated 47,xy,+13. After an extensive counseling the parents decided to terminate the pregnancy with trisomy 13. **Conclusions**. In this case report, the lip-jaw-palatal cleft was a strong and useful screening tool for the prenatal detection of trisomy; chromosomal analysis is recommended in all cases with similar types of facial cleft diagnosed prenatally because many of the features of trisomy 13 and trisomy 18 overlap.

Perinatal and neurodevelopmental outcome with isolated fetal ventriculomegaly: A systematic review. *M.D. Laskin[1], J. Kingdom[1], A. Toi[2], D. Chitayat[3], A. Ohlsson[4].* 1) Department of Obstetrics and Gynecology , Mount Sinai Hospital; 2) Department of Medical Imaging, Mount Sinai Hospital; 3) The Prenaal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; 4) Department of Pediatrics, Mount Sinai Hospital, Toronto, Ontario, Canada.

Objective: To establish the perinatal and neurodevelopmental outcomes of fetuses diagnosed with isolated ventriculomegaly (IVM). Methods: A systematic review of cohort, case/control studies, case series and case reports of IVM [unilateral or bilateral enlargement of the lateral ventricle (>10 mm) with no additional diagnosis at the time of the initial ultrasound], identified by searching without language restrictions The Cochrane Library, MEDLINE and Embase databases in June 2004. Results: No cohort study was retrieved but 518 cases were identified in one case/control study and 29 case series/case reports. Of 206 cases with follow-up and known gestational age at diagnosis, normal developmental outcomes were found in 82%, mild impairments in 9% and moderate/severe impairments in 10%. Prenatal diagnosis could have reduced the risk of moderate/severe impairments to 7%. In 83 cases followed to at least 20 months of age, 74 % had normal neurodevelopment, 11% were mildly delayed and 16% had moderate/severe developmental delays. Conclusions: Outcome was favorable in 82% of IVM cases, decreasing to 74% when cases are followed to at least 20 months of age. We recommend prospective cohort studies with new diagnostic modalities to better identify the underlying conditions relating to moderate/severe impairments in the remaining cases.

Prenatal Diagnosis of Steatocystoma Multiplex of the scalp using fetal ultrasound and MRI. *R. Teitelbaum[1], S. Blazer[4], A. Toi[3], K. Fong[3], N. Okun[2], D. Chitayat[1,2].* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto ON, Canada; 2) Department of Obstetrics and Gynecology, MSH, Toronto ON, Canada; 3) Department of Medical Imaging, MSH, Toronto ON, Canada; 4) Division of Neuroradiology, Department of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto ON, Canada.

Steatocystoma multiplex (OMIM184500) is an AD condition associated with benign round/oval dermal cysts widely distributed on the body. It is caused by a mutation in the keratin 17 gene(KRT17). We report the diagnosis of these scalp lesions, which can resemble encephalocele, in two fetuses using ultrasound and MRI. (1) The couple was healthy, non-consanguineous and of Caucasian descent. The 31yr-old G1P0 mother reported a history of two subcutaneous lesions on her scalp. Her father and identical twin sister also had subcutaneous cysts. In this pregnancy detailed fetal ultrasound revealed a 2x1.5cm cystic lesion protruding from the right frontal bone. The cystic lesion appeared to be separate from the bone and had no solid elements. A fetal MRI utilizing the HASTE sequence at 22weeks gestation revealed a 1.6x0.8x2.1cm midline encapsulated cystic structure within the scalp without continuity with the intracranial structures. The findings were consistent with a subcutaneous cyst. A male child was delivered at term by an uncomplicated SVD. On initial examination, a subcutaneous scalp cyst was palpated and regressed substantially since birth. His growth and development are normal. (2) The parents were healthy and non-consanguineous and of Caucasian descent. In this pregnancy, amniocentesis showed a normal female karyotype. A detailed fetal ultrasound at 19 weeks gestation showed a cystic mass overlying the left frontal bone near the coronal suture raising the possibility of an encephalocele. No distinct connection has been demonstrated to the subarachnoid space. The underlying brain and the rest of the fetal anatomy appeared normal. Fetal MRI showed a well defined T2 hyperintense 7mm lesion in the left scalp. There was no intracranial connection and no cranial abnormalities were detected. The findings were consistent with a dermoid cyst.

Renal Tubular Dysgenesis (RTD. Report of Three Cases. *M. Thomas.* Dept Medical Genetics, Mount Sinai Hosp, Toronto, ON, Canada.

Renal Tubular Dysgenesis (RTD). Report of Three Cases. M. Thomas1, S. Keating2, A. Toi3, G. Ryan4, D. Chitayat1 Mount Sinai Hospital, Dep. Of Obstet&Gyn, 1) The Prenatal Diagnosis and Medical Genetics Program, 2)Fetal Medicine Unit, 3)Dept. of Pathology and 4) Dept. of Diagnostic Imaging, University of Toronto, Toronto, Ontario, Canada. RTD is a lethal autosomal recessive condition caused by a defect in differentiation of the proximal and distal convoluted tubules. It is associated with oligohydramnios in later pregnancy. Most cases are associated with calvarial hypoplasia, which may provide a tool for early prenatal diagnosis. Case 1: The parents were of Sri Lankan descent and non-consanguineous. Their pregnancy was uncomplicated until 22.6 weeks gestation when fetal U/S showed enlarged and echogenic kidneys. U/S at 26.7GA showed 24W size fetus with anhydramnios. The pregnancy was terminated and autopsy showed RTD, Potter sequence, and hypoplastic calvarium with prominent sutures. Case 2: The parents were of French-Canadian origin and non-consanguineous. A fetal U/S at 19W gestation was normal. At 24GA the U/S showed severe oligohydramnios with normal-looking kidneys. The pregnancy was terminated and the autopsy showed RTD, collapsed hypoplastic calvarium with prominent fontanels Case 3: A sib of case 2. The pregnancy was uncomplicated until 23 weeks gestation when the U/S showed severe oligohydramnios. The pregnancy was terminated and the autopsy showed RTD, hypoplastic calvarium with prominent fontanels and sutures. The possibility of RTD should be raised in late onset oligohydramnios. The finding of calvarial hypoplasia and large fontanels can help in making the diagnosis and in earlier PND in couples at risk.

The prenatal diagnosis of femoral facial syndrome. *A.F. Wagner[1], L.M. Hill[2], E. McPherson[3], W.A. Hogge[1].* 1) Dept. of OB/GYN/RS, Div. of Reprod. Genetics, Magee-Womens Hosp., Pittsburgh, PA; 2) Dept. of OB/GYN/RS, Div. of Ultrasound, Magee-Womens Hosp., Pittsburgh, PA; 3) Medical Genetics, Marshfield Clinic, Marshfield, WI.

We report a case of a prenatally-diagnosed skeletal dysplasia. A 39yo G_5P_4 was referred for a targeted ultrasound at 26.9wks after an outside scan demonstrated short bowed femurs, micrognathia and clubbed feet. She had insulin-requiring diabetes. Amniocentesis showed a 46,XX karyotype. The long bones except the humerus were short. Both femurs were short and bowed(19.4wks). Micrognathia and the clubbed feet were confirmed. At 32.3wks, the femurs were consistent with 22.7wks. All other long bones except the humerus were shortened (27-29wks). A small right pelvic kidney was seen. The diagnoses of femoral facial syndrome and bilateral proximal femoral focal deficiency were entertained. At 35.9wks, the femur and tibia now measured 10 and 6 weeks behind. Due to placenta previa, she had a C/S at 37.1wks. The weight and HC were within normal limits. There was right microtia with abnormal folding of cartilage on the left. She failed the hearing screen. There was a cleft palate consistent with Pierre-Robin sequence. Thumbs were digitalized. Lower arms were shorter than the upper. There was excess skin at the elbows. Feet were clubbed bilaterally. Femurs were extremely short. Hips were fixed and externally rotated with dimpling. Her skin along the femurs and groin was smooth without any creases. Knees could flex but not extend past 40. On renal U/S, the right kidney was small. An echocardiogram and head U/S were normal. Neonatal evaluation considered femoral facial and Roberts syndrome. Peripheral blood karyotype was 46,XX with no evidence of premature centromere separation. Femoral facial syndrome was diagnosed. She was discharged to a step-down unit from the NICU and then home. She has been evaluated by plastic surgery and speech therapy and had a heel cord lengthening. This case demonstrates the successful prenatal diagnosis of femoral facial syndrome. The appearance of femoral hypoplasia with micrognathia, cleft palate, malformed ears, and maternal diabetes is consistent with this diagnosis.

Power to detect genotype × environment interaction in continuous environments. *V.P. Diego, T.D. Dyer, L. Almasy, J.W. MacCluer, J. Blangero.* Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

There is growing interest in the possible role of genotype × environment interaction in human variation. We carried out power analyses of genotype × environment interaction along a continuous environment by analytically deriving the Fisher information (FI) matrix under our model and numerically computing this FI matrix for a specific data set, namely the San Antonio Family Heart Study (SAFHS), at a fixed sample size, N = 690. In general, the null hypothesis of no genotype × environment interaction corresponds to two hypotheses on the genetic effects across the environmental continuum: 1) the additive genetic variance is homoscedastic, and 2) the genetic correlation is not different from 1. Under our model, heteroscedasticity in the additive genetic variance is indicated by a slope parameter in the additive genetic variance that is significantly different from 0. Similarly, a genetic correlation different from 1 is indicated by a slope parameter in the genetic correlation that is significantly different from 0. As an example, we examined an empirical case of genotype × age interaction using data on the insulin-like growth factor I (IGF-I) axis in Mexican American families participating in the SAFHS. We found significant genotype × age interaction for IGF-I due to heteroscedasticity in the additive genetic variance and to a genetic correlation different from 1. Given the observed parameter estimates, we computed the FI matrix, the Wald statistic and power for a range of parameters. We found that the Wald statistic is unbiased and the power functions are monotonic, thus indicating a well-behaved test statistic. The power to detect the slope parameter in the additive genetic variance at the observed effect size was 0.9976 and the power to detect the slope parameter at the observed effect size in the genetic correlation was 0.9334. Thus, there was adequate power to detect genotype × age interaction for IGF-I in our study.

An admixture model to identify genotyping errors via Hardy Weinberg disequilibrium. *H. Seltman.* Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA.

Detection of markers for which errors in the determination of allele status are systematically present is an important pre-processing step in linkage and association analysis. Problematic markers often lead to an excess of homozygotes in the sample genotypes and hence are typically identified by conducting tests for Hardy Weinberg (HW) equilibrium. This approach is complicated by the presence of population substructure. With large samples even minor substructure and misclassification of ancestry of subjects can lead to numerous violations of HW. To circumvent these difficulties we develop a Bayesian hierarchical model that simultaneously models recent populations as a mixture of ancient continental populations and models population/marker HW disequilibrium as deviation from the HW homozygosity rate. The output of this model is a matrix of estimates of disequilibrium by recent population group and by marker that can be used for exploratory data analysis to detect problematic markers that have high disequilibrium or markedly different levels of disequilibrium across populations.

PANCPRO: a Mendelian Risk Prediction Model for Pancreatic Cancer. *W. Wang[1], A.P. Klein[2,3,4], S. Chen[1,5], G. Parmigiani[1,2,3].* 1) Biostatistics, Johns Hopkins School of Public Health; 2) Oncology, Johns Hopkins School of Medicine; 3) Pathology, Johns Hopkins School of Medicine; 4) Epidemiology, Johns Hopkins School of Public Health; 5) Environmetal Health Science, Johns Hopkins School of Public Health.

Pancreatic cancer is the 4th leading cause of cancer death in the United States. Given that the 5-year survival rate is 5% and surgical resection of early lesions offers the best chance for survival, early detection is critical to reducing the disease burden. Numerous studies demonstrate that individuals with a family history of pancreatic cancer are at an increased risk. While segregation analysis showed evidence of genetic effects, the genetic basis of the majority of this familial aggregation has yet to be identified. However, even in the absence of precise genetic testing, identification of individuals who are at high risk of developing pancreatic cancer and who may benefit from screening is of great importance. To this end we developed PANCPRO, a Mendelian risk prediction tool for pancreatic cancer. Mendelian models use estimates of genetic effects (gene frequency, penetrance etc) and apply well-established Bayesian prediction techniques to obtain carrier probabilities. PANCPRO is built upon MARGENE, a C routine implemented in BayesMendel(available in R), a generic tool for building Mendelian risk prediction models. The underlying model for PANCPRO is based on the segregation model by Klein et al. 2002. PANCPRO gives the probability an individual carries a mutation at the major locus and the probability the individual will develop pancreatic cancer during a particular age interval. To validate this model we compared the predicted incidence of pancreatic cancer in about 900 families enrolled in the National Familial Pancreas Tumor Registry, to the actual number of prospective pancreatic cancers in the registry. Results indicate no significant difference between the observed and predicated number of cases, supporting the utility of this model. In conclusion, PANCPRO is a powerful tool for health care providers to help identify individuals who may carry a major gene that increases risk of pancreatic cancer.

Twin Study Heritability Estimates of Central Auditory Processing Functions. *D. Drayna[1], C. Brewer[1], H. Snieder[2], C. Zalewski[1], T. Friedman[1], R. Morell[1].* 1) NIDCD/NIH, Rockville, MD; 2) Georgia Prevention Institute, Augusta, GA.

Sound is transduced by the cochlea to nerve impulses that are processed in the central auditory pathway. Skills and behaviors that comprise auditory processing include sound localization and lateralization, auditory performance in the presence of competing and/or degraded signals, and temporal resolution, masking, integration and ordering. Auditory processing disorders (APD) can arise due to central nervous system (CNS) disease and trauma, age-related changes in the CNS, and peripheral hearing loss. In children, APD is often comorbid with disorders that can be heritable, including dyslexia, stuttering, autism, and specific language impairment. The extent to which APD may contribute to, or share etiology with, these heritable disorders is controversial, and little is known about the heritability of auditory processing abilities in the general population. We administered several tests of auditory processing to healthy, same-sex identical and fraternal twins. We found variation in test performance, and significant differences between MZ and DZ correlations for performance on three tests of dichotic listening. In these tests, two different stimuli are presented simultaneously, one to each ear, and subjects are asked to identify both stimuli. While the stimuli differed in the three tests, the dichotic presentation was the same. We estimate heritability to be 0.74 (0.63-0.81, 95% CI), 0.71 (0.53-0.82) and 0.43 (0.16-0.64) for performance on these three tests, using multiple regression analyses within a Generalized Estimating Equation (GEE). These results that genetic approaches may be useful for understanding Auditory Processing Disorders.

Estimation of the fraction of Usher syndrome families due to unidentified genes. *W.J. Kimberling, D. Orten.* Dept Genetics, Boys Town Natl Research Hosp, Omaha, NE.

Usher syndrome is the most common form of combined hearing and vision loss. There are 3 clinical types (1, 2, and 3) and 11 different genes responsible. Only 8 of these 11 genes have been identified. A modification of a novel method for the statistical analysis (Kimberling, in press, Hum Mut) of a genetically heterogeneous recessive disorder was used to estimate the fraction of different molecular subtypes of Usher syndrome as a function of the referring diagnosis. This methodology takes into account the fraction of cases remaining undiagnosed because no mutation was detected in any of the Usher genes. The analysis involved 304 Usher type I and 560 Usher type II families. Usher type II was excluded because the numbers were insufficient. For the Usher type I phenotype, the proportions were: 40% MYO7A, 17.7% CDH23, 10.6% PCDH15, 3.6% USH1C, with 3.3% due to the 4 other subtypes. By subtraction, 24.8% of the Usher I families were due to unidentified genes. For the Usher type II phenotype, the proportions are 78.4% USH2A, 7.3% MYO7A, 1.2% CDH23, 3.6% VLGR1, and 3.3% USH3. By subtraction, 6.2% of the families were due to unidentified genes. These results were then used to estimate the rates of false positive and negative molecular diagnoses conditioned on whether 0, 1, or 2 mutations were observed in one of the Usher genes. This data will have impact in the assessment of recurrence risk for genetic counseling of Usher syndrome families and on estimates of the reliability of the identification of cases for upcoming clinical trials. Further, the results show that a substantial number of Usher cases are due to as yet unidentified etiologies, which may or may not be genetic and recessive. So, in a related study, segregation analysis of families for whom no mutation has yet been observed showed no deviation away from that expected for an autosomal recessive trait. Thus, there is a compelling reason to believe that further investigation will reveal new recessively inherited genes involved in this disorder. This analysis also showed no evidence of digenic inheritance for Usher syndrome.

Exclusion probability in a DNA mixture from a substructured population. *W. Niu, H.S. Lee, X. Sheng, R. Chakraborty.* Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Interpretation of data gathered for DNA-based human identification problems is also relevant for identifying contamination of foreign cells in samples of biological samples collected for tissue typing. DNA mixture, which provides signature of the presence of DNA from multiple sources, constitutes one such category of applications. Although likelihood-ratio based statistics provide relative supports of different alternative scenarios of mixture origin, when the mixture DNA profile is analyzed along with DNA profiles of suspected contributors, the concept of exclusion probability has also been used in this context. Probability of exclusion (PE) describes the chance of excluding a random individual (or cell type) as a part contributor of the mixed sample. Consequently, the PE computation uses data on the alleles present in the mixture sample alone, irrespective of the DNA profiles of the known subjects analyzed. In analogy of the PE computations in parentage analysis, the first suggestion of exclusion probability computations in DNA mixture analysis, used the assumption of Hardy Weinberg Equilibrium of genotype frequencies, which lead to the conclusion that the combined frequencies of all alleles in the mixture is the only determinant of PE. Later work in this area extended the computation of PE for substructured populations, again leading to the conclusion that the number of contributors in the DNA mixture does not affect the exclusion probability. With the use of the sampling theory of Dirichlet distribution of allele frequencies in a substructured population, we conclude that the exclusion probability is not independent of the number of contributors in the mixture. The chance that a random person would be excluded as a part contributor is in fact a composite function of the summed allele frequency, together with the presumed number of contributors, and the coefficient of coancestry in the substructured population. Numerical computations suggest that PE can be different depending on the number of contributors, even when the summed allele frequency remains the same. (Research supported by a grant from the Department of Development, State of Ohio).

PEDMerge - A program for merging extended pedigrees: The CANHR Study. *Y. Wang, B.B. Boyer, A. Goropashnaya, G.V. Mohatt, R. Plaetke.* CANHR, Institute of Arctic Biology, University of Alaska Fairbanks, Fairbanks, AK.

At the Center for Alaska Native Health Research, we ascertain extended pedigrees for a genetic study of obesity and type 2 diabetes mellitus. In the field, we collect pedigree information using a pedigree drawing program. Pedigrees often become large. Therefore we often collect the information in sub-pedigrees that constitute one pedigree and finally need to be merged for data analyses. Merging these sub-pedigrees can be tedious and error prone even when using pedigree drawing programs. For example, in our study we have been repeatedly merging 26 sub-pedigrees to obtain one pedigree consisting of 986 individuals (recruited: 507) for genetic statistical analyses, since ascertainment is ongoing. In order to solve this problem, a Perl program PEDMerge - running across all platforms - was developed that merges multiple sub-pedigrees to one pedigree based on key individuals that are occurring in (multiple) sub-pedigrees and function as connecting points between sub-pedigrees. The size and number of sub-pedigrees to be merged are unlimited. Thus, each sub-pedigree may have multiple key individuals.

PEDMerge takes two input ASCII files: (1) pedin.txt, a standard pedigree file consisting of pedigree ID, ego ID, father ID, mother ID, sex and (2) keys.txt, a file that provides information about the key individuals specific IDs in each sub-pedigree. PEDMerge generates two output files: (1) pedout.txt, a file containing all merged pedigrees and unmerged pedigrees and (2) master.txt, a candidate Master file for the database PEDSYS developed by the Southwest Foundation for Biomedical Research (San Antonio, TX).

We will show (1) our approach to collect pedigree data in the field and (2) the application of PEDMerge.

Genomic data mining to narrow down candidate disease genes for T1D. *X. Wang, Y. Xie, V. Magnuson, S. Ghosh.*
Max McGee Center for Juvenile Diabetes, Medical College Wisconsin, Milwaukee, WI.

Type 1 diabetes (T1D) is a complex genetic disease. It has become one of the most common chronic disorders for children. Identifying all the genetic factors contributing to the disease risk has been a challenge. We lack efficient means to identify all functional candidates beyond the HLA region and the insulin gene, as the exact disease etiology is still unclear; on the other hand genome scan studies offer too many positional candidates, with most of them bear no relationship to the disease. Here we describe a new approach that utilizes bioinformatics and data mining to narrow down the candidate genes. It identifies the genetic pathways that have enhanced representation among the positional candidates, and then identifies the key genes within these pathways that are also positional candidates. We apply it to a set of T1D genome scan data that we have, and the significance of the results is evaluated through Bootstrapping. Beside the expected findings such as pathways of antigen presentation, we found several new themes that are surprising, yet meaningful, including pathways highly relevant to normal beta-cell functioning, stress and cell death. These findings lead to protocols to prioritize positional candidates.

Large scale analysis of gene-gene interactions. *W.S. Bush, S.M. Dudek, K.K Ryckman, M.D. Ritchie.* Center for Human Genetics, Vanderbilt University, Nashville, TN.

The development of high-throughput genotyping technologies has dramatically increased the number of polymorphisms considered in a typical genetic association study. These new technologies will dramatically change the state-of-the-art in studies of human disease. Detecting and characterizing interactions between these polymorphisms may be important in discovering genetic contributions to common complex diseases. Here, we present parallel multifactor dimensionality reduction (pMDR), a tool for extending the scale and scope of analyses of gene-gene and gene-environment interactions. MDR is a nonparametric, model-free approach developed for the detection of gene-gene and gene-environment interactions in the presence and absence of statistically detectable main effects. However, the previous implementation of MDR could not handle the computational scale of genome-wide association data. Thus, an extension utilizing the benefits of parallel computing was in order. To determine the power of pMDR to detect gene-gene interactions, we simulated 10 two-locus disease models with varying epistatic heritabilities (5% to 25%) and allele frequencies (.2/.8 and .4/.6). These models were used to simulate case-control datasets for each disease model with 50,000 SNPs. pMDR had 100% power to detect the disease loci for models with greater than 5% heritability. In the 5% heritability models, the disease loci typically appeared in at least one of the five cross-validation intervals. By assigning statistical significance with a post-analysis Bonferroni corrected chi-square statistic, only the disease loci were found significant. Each analysis was conducted on 24 pentium-4 processors of a computing cluster, and completed in 40 hours, demonstrating that the analysis of gene-gene and gene-environment interactions on this scale is computationally tractable with modest computing resources. This is a crucial step in facilitating our understanding of the genetic architecture of common, complex disease.

Haplotype Inference for Tightly Linked SNPs in General Pedigrees. *K. Zhang[1], H. Zhao[2].* 1) Department of Biostatistics, Univ Alabama at Birmingham, Birmingham, AL; 2) Deparment Epidemiology & Public Health, Yale University School of Medicine, New Haven, CT.

Haplotype reconstruction for tight linked markers in general pedigrees remains a challenging problem. Not only just a few methods are available to efficiently estimate haplotype frequencies and accurately infer haplotype configurations for general pedigrees, especially in the presence of missing data, but also performances of them have not been carefully evaluated. We have developed an efficient computer program, HAPLORE, for haplotype reconstruction and frequency estimation in general pedigrees with tightly linked SNP markers. Here, we compare and contrast HAPLORE with other two previously published methods (GENEHUNTER and PedPhase). We review the methods and point out the differences between them in terms of the models and computational strategies they use. Their performances are assessed through simulated haplotypes based on a real pedigree. Our results in the following table indicate HAPLORE outperforms the other methods. In the table, SAD is the sum of absolute difference between the true and estimated haplotype frequencies, IE (individual error) is the portion of individuals whose estimated haplotypes are not completely correct, and SE (similarity error) is the Hamming distance between the true and estimated haplotypes of an individual.

	Data Sets without Missing			Data Sets with Missing		
	HAPLORE	GENEHUNTER	PedPhase	HAPLORE	GENEHUNTER	PedPhase
SAD	0.0014	0.0401	0.0164	0.0297	0.1289	0.2953
IE	0.0015	0.0167	0.0079	0.0866	0.1054	0.1728
SE	0.0083	0.0801	0.0249	0.6236	0.5464	0.7248

Open-source multifactor dimensionality reduction (MDR) software for detecting, characterizing, and interpreting gene-gene interactions. *N. Barney[1], W. Holden[1], B.C. White[1], L.W. Hahn[2], W. Bush[2], M.D. Ritchie[2], J.H. Moore[1].* 1) Computational Genetics Laboratory, Department of Genetics, Dartmouth Medical School, Lebanon, NH; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Multifactor dimensionality reduction (MDR) is a computational approach to detecting epistasis or gene-gene interactions. MDR has good power for detecting epistasis and has been successfully applied to genetic studies of amyloid polyneuropathy, atrial fibrillation, bladder cancer, breast cancer, coronary artery calcification, hypertension, myocardial infarction, prostate cancer, schizophrenia, and type II diabetes, for example. We describe here a comprehensive MDR software package with a user-friendly GUI that is programmed in JAVA and provided for free as open-source to the research community. Open-source MDR is distributed in three modules for 1) analysis, 2) permutation testing, and 3) data processing. The MDR analysis module carries out a combinatorial search for the best epistasis model as determined by n-fold cross-validation. Output includes statistics such as accuracy, sensitivity, specificity, odds ratios, and IF-THEN rules that facilitate interpretation. In addition to a text report of results, MDR provides publication quality graphical output of the distribution of cases and controls for each genotype combination. In addition, the fitness landscape of all evaluated models is provided in the form of line graphs and histograms that can be explored interactively through zoom and model identification features. The software can be run from a command line interface and will automatically run in parallel on multiprocessor computers with threading. The permutation testing module provides empirical p-values while the data processing module facilitates imputation of missing genotypes and resampling. Open-source MDR is platform independent and is freely available for download from Sourceforge.net which can be accessed from www.epistasis.org. Future features will include filter and wrapper methods to facilitate MDR analysis in genome-wide association studies.

Kinship Estimation with an M-dependent Markov Model. *J. Ge[1], G. Zhang[2], R. Chakraborty[1,2].* 1) Dept Biomed Engineering, Univ Cincinnati, Cincinnati, OH; 2) Center for Genome Information, Dept. Environmental Health, Univ Cincinnati, Cincinnati, OH.

Kinship estimation, alternatively described as determination of biological relationships between individuals, is relevant in many research areas (e.g., biomedical sciences), forensic case-work, paternity testing, and victim identification in mass disaster cases. With genotype data from individuals, kinship can be estimated by using the maximum likelihood method. Assuming recombination between markers are independent (no genetic interference), identity-by-descent (IBD) states at an ordered map of markers represent a hidden Markov Chain. Although the precision of this model for estimating close relationships (e.g., full-sib) is satisfactory, its accuracy for second-degree relationships (e.g. avuncular) estimation is poor and unacceptable. We relax the assumption to allow genetic interference, and extend the simple Markov Model to OLE_LINK1an M-dependent Markov Model, in which IBD states of one marker are dependent on IBD states of multiple previous markers instead of only one previous marker. The computational complexity of this Model is large due to the need of calculating joint distributions of multiple IBD states for different kinships. Symbolic computing is a way to reduce the complexity. In addition, genotyping errors can reduce the precision of likelihood estimation, and population substructure increases the proportion of homozygous loci in individual's genome. These two factors are also incorporated to determine their effects on kinship estimation. Better performance of the M-dependent Markov Model has been achieved compared to a simple Markov Model for real datasets. This new model is also applied to simulation data to evaluate its performance with genotyping error and population substructure. (Research supported by a grant from the Department of Development, State of Ohio).

A Novel Statistic for Testing Association of Pathway with Disease. *Z. Yu[1], W. Wang[2], L. Jin[3], M. Xiong[4].* 1) Probability and Statistics, Beijing, China; 2) Chinese National Human Genome Center at Shanghai; 3) School of Life Science, Fudan University, Shanghai; 4) Human Genetics Center, University of Texas Health Scince Center at Houston.

The new concept concerning complex disease is to assume that development of disease should be considered as a dynamic process with gene-gene and gene-environment interaction within a complex biological system, which is hierarchically, organized into complex gene interaction networks. . Traditional analytical methods for investigating the contribution of genetic variation to disease risk focus on the locus-by-locus paradigm, studying one locus, one haplotype, or one gene at a time. The locus-by-locus approaches are inadequate and inappropriate for addressing questions of the relationship between biological networks and phenotypes. Although the variation each gene contributes to disease risk is unidentifiable, the contribution of the set of genes in the network as a whole may be significant. Therefore, association of the biological networks with the disease will play an important role not only for understanding the mechanism of the diseases, but also for the development of efficient drugs. Study design and statistical methods for testing association of biological networks with disease will be difficult, but essential. New non-traditional analytical methods for testing association of biological networks with the disease and the biological interpretation of test results are desperately required. In this report, we will develop a general framework and statistics for testing association of biological networks with the disease The distribution of the statistics will be studied by simulation and analytic methods. The relationship between the association of biological networks and gene-gene interactions within and between pathways will be investigated. The proposed methods will be applied to atherosclerosis study to test association of inflammatory and antioxidant pathways with the disease.

Effectiveness of maximization algorithm of area under the ROC curve for partitioning quantitative phenotypic value into genotypic value and environmental value. *S. Kamitsuji[1], N. Kamatani[2].* 1) JBIRC, JBiC, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Algorithm for partitioning quantitative phenotypic value into genotypic value and environmental value is proposed. An aim of Quantitative Trait Locus (QTL) analysis is to find a locus or haplotype contributed to an observed quantitative phenotye. Quantitative phenotype is the result of genetic factors, environmental factors, and the environmental factors that interact with the genetic factors, and it is natural to consider that the sum of these factors contributes to a variation in a population. For finding such a locus or haplotype, it is important to extract only genetic variation from the observed quantitative phenotypic value. Linear model, one of traditional statistical models, is frequently used for this implementation. However, it may be complicated to understand the result of linear model since estimated coefficients change by selecting coding method for genotype data. Such a burden is resolved by an introduction of notion of area under the Receiver Operating Characteristic (ROC) curve. ROC curve is a plot to show the trade-off between sensitivity and specificity. Accuracy of diagnostic test can be evaluated by the area under the ROC curve (AUC), which takes the value from 0 to 1. If diagnostic test has high accuracy, then AUC is closed to 1. In our study, it is assumed that genotypic value can be represented as the difference between quantitative phenotypic value and the value of linear combination of environmental factors. Under this assumption, the coefficients in linear combination above are estimated so as to maximize the AUC when the quantitative phenotypic value is divided into two parts in terms of genotypes on a target locus, and the modified quantitative phenotypic value can be calculated as subtracting the sum of product between each estimator and environmental value from the original value. The advantages of using the modified value over the original value or the value modified by a linear model are shown by giving a numerical example of predicting the haplotype contributed to quantitative phenotypic value using the computer algorithm QTLhaplo.

Haplotype Tag SNPs Selection Using Support Vector Machines. *J. Li.* Computer Science, Case Western Reserve Univ, Cleveland, OH.

Tag SNPs selection is an extremely important problem for whole genome association studies with two important implications. First, genotyping efforts can be greatly reduced by only typing the tag SNPs for large scale whole genome association studies. Second, by removing redundant SNPs, statistical power of association analyses can be improved since the number of tests, which is usually proportional to the total number of SNPs, will be greatly reduced. Although the tag SNPs selection problem has been investigated intensively recently, challenges are remain. Most methods select the minimum SNPs that could capture the haplotype diversity. Other methods assess the predictive power of a SNP (or a set of SNPs) to other SNPs. But none of the above formulations have directly addressed the discriminative power of the subset of tag SNPs with respect to phenotypes. We argue that, for whole genome association studies of complex diseases, the redundancy of all the SNPs should be evaluated based on their relevance to the disease of interest. And we formulate the SNP selection problem as the feature selection problem under the supervised learning framework. More specifically, we employ a state-of-the-art learning algorithm called support vector machine (SVM) to rank SNPs. We take the case-control study design and assume that haplotypes of each individual are known. Polynomial kernels based on Hamming similarity of haplotypes are used to train the data. SNPs are ranked based on their contributions to the discriminate function. We evaluate the approach on simulated data as well as real datasets. The results show that for each dataset, a compact subset of SNPs with high discriminative power was retained for further association analysis.

Complex Segregation Analyses of Bipolar Affective Disorder: Evidence for a Single Major Predisposing Locus.

M.C.M Oliveira[1], R. Ferreira[2], I. Lopes-Cendes[1], H. Kriger[2], M. Bittar[1], P. Dalgalarrondo[1], C. Banzato[1]. 1) Genetics, UNICAMP, Campinas, SP, Brazil; 2) Department of Parasitology3, Institute of Biomedical Sciences, São Paulo University, Brazil.

Background: The etiology of bipolar affective disorder (BP) is to still unknown. Genetic factors are known to contribute to the etiology of BP. Family studies have shown that the lifetime prevalence of BP in families of BP probands is higher that in families of psychiatrically healthy controls. We aimed to investigate the most likely mode of inheritance in a large sample of BP patients seen at the psychiatric clinic of a large university hospital. Subject and Method: Complex analysis segregation was carried out using 656 individuals distributed within 92 nuclear families from a sample of 99 unrelated BP probands. Each family member was seen by a single psychiatrist and interview using the Mini International Neuropsychiatric Interview Plus. Segregation analysis was conducted using the unified mixed model implemented in the computer program POINTER. Results and conclusion: Compared to the mixed Mendelian model the sporadic model was rejected (4GL, $p < 0.000$). The hypothesis of no major effect also was rejected (3GL., $p < 0.000$); whereas the hypothesis of no multifactorial component was not rejected (1GL., $p = 0.824$). The results indicate the presence of a major gene that influences BP. However, when recessive, dominant and additive models were compared with multifactorial transmission, none was accepted. The dominant mode was proved to be more suitable according to Akaike criterion (AIC = 527,816). In conclusion, our data supports the existence of a major predisposing gene to PB in our large sample of patients making it suitable for linkage and/or association studies.

Mapping Tumor Suppressor Genes using Multipoint Statistics from Copy-Number Variation Data. *I. Ionita, B. Mishra.* NYU, New York, NY.

Microarray-based comparative genomic hybridization (array-CGH) approach now provides rapid genome-wide assays and indicates copy-number variations of chromosomal segments in a tumor genome. Specifically, chromosomal segments, deleted in a single or both copies of the diploid genomes of a group of cancer patients, point to location of tumor suppressor genes (TSGs) implicated in a cancer. We present a novel multipoint statistical method that is capable of estimating the location of TSGs by analyzing array-CGH data characterizing segmental deletions (hemi- or homozygous) in cancer genomes. Our approach is based on computing a multipoint score for intervals of consecutive probes that measures how likely it is for that genomic interval to be the TSG, sought after. A significance is given to the maximum scoring interval in a region using results from scan statistics. Based on these scores we can estimate the most likely left margin and right margin of the TSG interval. We assess the power of the method by examining how well it uncovers the true location of the TSG; we compute the Jaccard's measure of the overlap between the true location of the TSG and the estimated one. We applied our method to datasets simulated under different scenarios; each dataset contains 100 samples and the genomic region under investigation is of length 100 Mb with a probe every 5 kb; each dataset contains some samples that are sporadic and the rest are split between those with homozygous deletion and hemizygous deletion respectively of the TSG. In the table below we illustrate results on some of the important scenarios. For each scenario, we simulate 50 datasets and report the average overlap as given by the Jaccard's measure.

1-hit rate/sporadic rate	0%	50%
0%	0.72	0.48
50%	0.66	0.46

Removing Ceiling Effect related Type II Errors in Two-locus Variance Component Linkage Analysis Identifies New QTLs for Serum Lipid Levels in Sib-pair Data. *M. Falchi[1,4], T. Andrew[1], H. Snieder[1,2], R. Swaminathan[3], G. Surdulescu[1], T.D. Spector[1].* 1) Twin Res & Gen Epidem Unit, St Thomas Hosp, London, United Kingdom; 2) Georgia Prevention Institute Department of Pediatrics, Medical College of Georgia, Augusta GA; 3) Dept of Chemical Pathology, Guys & St Thomas NHS Foundation Trust; 4) Medical Genetics Unit, Dept. Mother and Child, University of Modena and Reggio Emilia, Modena, Italy.

Given the underpowered sample sizes commonly used in human genetics linkage studies, minor quantitative trait loci (QTLs) effects often go undetected and those that are detected will be upwardly biased. We show that the discrepancy between the real biological and the estimated QTL effects are likely to often generate an unpredictable source of false-negative errors, reducing the power to detect multiple QTLs through linkage analysis. We apply a heterogeneity method to offset this problem in a two-locus setting, showing a greatly increased power to detect multiple QTLs both via simulations. The practical use of the new approach is illustrated by a genome-wide search (GWS) for serum lipid QTLs using a 10cM marker map for 961 female sib-pairs. Three genome-wide significant QTLs were identified for apolipoprotein A1 on chromosomes 8p21.1-q13.1 (LOD score 3.71), 9q21.32-33.1 (LOD score 3.28) and 10p15.1-p13 (LOD score 5.51), two for lipoprotein (a) on chromosomes 6q25.2-q27 (LOD score 10.18) and 21q21.1-q21.3 (LOD score 4.57) and two for triglycerides on chromosomes 4q28.3-32.1 (LOD score 3.71) and 5q23.1-q32 (LOD score 3.60). This approach has led to the identification of known and novel regions linked to serum lipid levels. The successful simultaneous QTL modeling method provides compelling evidence that the novel QTLs detected are likely to be reliable.

The mannose binding lectin Arg52Cys gene coding variant uniquely predicts angiographic coronary artery disease. *M.J. Kolek[1], J.L. Anderson[1,2], J.F. Carlquist[1,2], B.D. Horne[1,3], T.L. Bair[1], J.L. Clarke[1], J.B. Muhlestein[1,2].* 1) Cardiovascular Department, LDS Hospital, Salt Lake City, UT; 2) Cardiology Division, University of Utah School of Medicine, Salt Lake City, UT; 3) Division of Genetic Epidemiology, University of Utah, Salt Lake City, UT.

The mannose binding lectin (MBL) gene encodes a soluble protein that binds potentially atherogenic *Chlamydia pneumoniae* and other bacteria, marking them for opsonization via complement. Several single nucleotide polymorphisms (SNPs) in the MBL gene are reportedly associated with lower plasma MBL levels and elevated coronary artery disease (CAD) risk. Patients entered into the Intermountain Heart Collaborative Study registry (1994-1998) who underwent coronary angiography were studied to assess the association of MBL SNPs with CAD prevalence (N=2,327). Plasma MBL was measured in a subset (n=302) and compared by genotype. Three coding (Arg52Cys, Gly54Asp, Gly57Glu), two promoter (G-550C and G-221C), and one 5' UTR SNPs (G+4A) were studied. Adjustments were made for CAD risk factors using logistic regression. Principal component analysis assessed the linkage disequilibrium (LD) between each SNP. Average age was 6412 years, 70% were male, and 77% had CAD. All 6 SNPs were associated with differences in plasma MBL (p0.03). The G-550C variant was in high LD with two other SNPs (G-221C and G+4A) that accounted for its variation, thus it was excluded from further analysis. G-221C and G+4A were not associated with CAD. Minor allele carriage in any one of the three exonic SNPs was confirmed to be associated with CAD (OR=1.32, p=0.020), as previously reported. However, only Arg52Cys was independently associated with CAD (adjusted OR=1.54, CI=1.07-2.21, p=0.019). Further, the dilution of risk that was found when all three exonic SNPs were jointly considered suggests that Arg52Cys may be the risk-related variant. Although all 6 SNPs were associated with plasma MBL, the Arg52Cys findings encourage exploration of the mechanisms underlying this SNPs effect on the MBL protein, including potential pro-atherogenic host response to infection.

Subclinical Atherosclerotic Traits are Heritable: the Framingham Heart Study. *L.A. Cupples[1], C.Y. Liu[1,2], U. Hoffman[3], J.M. Massaro[1], S.J. Hwang[2], M.G. Larson[4], E. Manders[2], C.S. Fox[2], C.J. O'Donnell[2,3].* 1) Department of Biostatistics,Boston Univ Sch Public Health, Boston, MA; 2) National Heart, Lung and Blood Institutes Framingham Heart Study, Framingham, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Department of Mathematics and Statistics, Boston University, Boston, MA.

Coronary heart disease and other atherosclerotic cardiovascular diseases (CVD) comprise the leading causes of death for men and women in the U.S. Using noninvasive high resolution imaging modalities, subclinical atherosclerosis can be detected as quantitative levels of calcific deposits in major arterial beds such as the coronary arteries and aorta in large cohorts of men and women. Such traits have been reported to have genetic etiology. We studied coronary artery calcific deposits [CAC] and abdominal aortic calcification [AAC] measured between 2002 and 2005 by multidetector computed tomography in 2946 subjects from the second and third generations of 676 pedigrees of the Framingham Heart Study. The subjects ranged in age from 35 to 83 years (with the mean age at 51). We used variance component models in SOLAR to assess the heritability of the Agatston scores for both CAC and AAC. Each score was adjusted for gender, age, systolic blood pressure, smoking, total and HDL cholesterol, diabetes, body mass index, anti-hypertensive treatment, lipid treatment and prevalent CHD and CVD status using regression methods on traits derived from a logarithmic transformation after adding 1 to each value. The age-adjusted heritability of CAC is 304 percent and multivariable-adjusted heritability is 274 percent. For AAC, these estimates are 354 and 284 percent, respectively. Given these findings, genomewide linkage and association studies are warranted in order to identify important genomic regions in the pursuit of QTLs associated with the development of coronary heart disease.

Phylogeny-Based Haplotype Association Analysis for Coronary Artery Disease and the Cholesteryl Ester Transfer Protein Gene. *B.D. Horne, J.F. Carlquist, J.L. Anderson, C.P. Mower, N.J. Camp.* Cardiology/Genetic Epidemiology, LDS Hospital, U Utah, SLC, UT.

Disease associations of candidate gene single nucleotide polymorphisms (SNPs) are notoriously difficult to replicate. Evaluation of haplotype groups based on phylogenetic SNP relationships is a novel approach that may increase study resolution. We evaluated the association to coronary artery disease (CAD) of haplotypes constructed from tagging SNPs (tSNPs) in non-recombinant regions of the cholesteryl ester transfer protein (CETP) gene. Non-diabetic, non-smoking patients (N=4811) with angiographically-significant CAD (70% stenosis) or normal coronaries (<10% stenosis) were genotyped for 11 tSNPs previously selected to represent 32 SNPs in the promoter, exons, and 3¢ UTR. Phylogenetic relationships were evaluated using PAUP and all CAD association analyses were multivariable-adjusted in logistic regression. Patient age averaged 6313 years and 63% were male. In the non-recombinant intron 8-3¢ UTR region, six terminal haplotype groups were found for 8 tSNPs, and association to CAD was found for haplotypes containing ATG (T+1086A, C+878T, G+2389A) with patients having 68%, 65%, and 60% CAD for carriage of 0, 1, and 2 haplotypes (for 2 vs 0 haplotypes: adjusted OR=0.58, 95% CI=0.34-0.99, p=0.046), for haplotypes containing AGGT (MspI, G+2389A, A373P, C+408T) with 67%, 67%, 63% CAD (2 vs 0: OR=0.76, CI=0.56-1.04, p=0.087), and for GGCT haplotypes in those 4 tSNPs with 67%, 70%, 70% CAD (1 or 2 vs 0: OR=1.34, CI=1.03-1.74, p=0.030). In the promoter-intron 8 region, 4 haplotype groups were found for 3 tSNPs (C-631A, Taq1B, and MspI), and for AAA haplotypes patients had 69%, 67%, 65% CAD (OR=0.78, CI=0.64-0.95, p=0.012). Evaluation of phylogeny-based haplotype groups in the CETP gene showed significant associations to CAD. For the ATG and AAA haplotype groups, the relative risks were similar to previous findings for T+1086A alone and for C-631A alone, respectively. However, for two other groups this phylogenetic grouping strategy extracted associations where single tSNPs did not. This suggests that phylogenic haplotype grouping may be used to guide and improve association analysis.

Pleiotropic relationships between lipoproteins and two biomarkers of oxidative stress and inflammation in the San Antonio Family Heart Study. *D.A. Winnier[1], D.L. Rainwater[1], X-L. Wang[2], J.W. MacCluer[1], M.C. Mahaney[1].* 1) Southwest Foundation for Biomedical Research, San Antonio,TX; 2) Baylor College of Medicine, Houston, TX.

Recent research suggests that the association between variation in plasma lipoproteins and risk of cardiovascular disease is attributable in large part to the processes of oxidative stress and inflammation. We conducted statistical genetic analyses to characterize the relationships between circulating lipoproteins and two biomarkers of oxidative stress and inflammation: platelet activating factor acetylhydrolase(PAF-AH) and paraoxonase-1(PON1). From stored plasma samples for 1,406 San Antonio Family Heart Study participants, we measured PAF-AH (an LDL-associated phospholipase A_2 that degrades PAF); PON1 (an HDL-associated molecule that may inhibit LDL oxidation); and LDL, HDL, and their apolipoprotein (apo) components. We used a multivariate maximum-likelihood based, variance decomposition approach implemented in SOLAR to estimate the phenotypic, genetic, and environmental correlations between these traits. All traits had significant heritabilities (h^2= 0.23-0.77). As expected, each biomarker was more correlated to traits from its own lipoprotein moiety; thus PAF-AH exhibited significant correlations with LDL, its subfractions, and related apolipoproteins, the strongest of which was between PAF-AH and apoB ($_P$=0.53, $_G$=0.61, $_E$=0.47; P<0.02). We also observed significant correlations between PAF-AH and total LDL ($_P$=0.44, $_G$=0.43, $_E$=0.43). Between 20% and 36% of the additive genetic effects on PAF-AH and the LDL-related traits was due to pleiotropy. By contrast, PON1 exhibited weaker relationships with HDL and its related traits. We observed marginally significant correlations(P0.05) between PON1 and apoA-II ($_P$=0.28, $_G$=0.18, $_E$=0.47) and HDL-3 ($_P$=0.18, $_G$=0.17, $_E$=0.23),with shared genetic effects accounting for 18% or less of the genetic variance in these trait pairs. The actual genes responsible for these shared genetic effects on variation in lipoproteins and biomarkers of oxidative stress and inflammation-all recognized risk factors for CVD-may underlie variation in CVD risk as well.

Stress-Induced Sodium Excretion, a New Heritable Intermediate Phenotype to Study the Genetics of Salt Sensitive Hypertension? *D. Ge, H. Zhu, Y. Dong, X. Wang, G.A. Harshfield, F.A. Treiber, H. Snieder.* Georgia Prevention Institute, Department of Pediatrics, Medical College of Georgia, Bldg HS-1640, Augusta GA 30912, USA.

We have recently proposed that impaired stress-induced pressure natriuresis, measured by urinary sodium excretion ($U_{Na}V$), is an indication of salt sensitivity. However, it is unknown whether and to what extent genetic factors contribute to stress-induced $U_{Na}V$. To assess the heritability of stress-induced $U_{Na}V$, we studied 199 African- (AAs) and 245 European-American (EAs) twin pairs from the South-Eastern US, including monozygotic and dizygotic of same- as well as opposite-sex (mean age: 17.6 3.3; range: 11.9-30.0). We used a combination of an overnight and a pre-stress $U_{Na}V$ as the baseline $U_{Na}V$, while the stress $U_{Na}V$ was measured after a protocol that included an echocardiographic examination and exposure to three stress tasks: a social stressor interview, a virtual reality car driving test and a competitive video game. All univariate and multivariate genetic model fitting was performed using Mx software. No significant sex effects on genetic and environmental contributions to $U_{Na}V$ were detected. The best fitting univariate model showed that the heritabilities [h^2 (95% confidence interval)] for stress $U_{Na}V$ were 0.41 (0.23-0.56) in EAs and 0.53 (0.35-0.66) in AAs, but the difference between the two ethnic groups was not statistically significant. A multivariate model was then used to estimate the genetic and environmental influences shared with baseline $U_{Na}V$, showing only 23% (14-32%) and 13% (6-29%) of the total variance could be attributed to shared factors in EAs and AAs, respectively. The specific heritabilities for stress-induced $U_{Na}V$ were 0.30 (0.09-0.47) in EAs and 0.53 (0.33-0.67) in AAs after the adjustment for the shared influences with baseline $U_{Na}V$. In summary, this study shows stress-induced $U_{Na}V$ is a heritable phenotype that can be used to study the genetic etiology of salt sensitivity in relation to hypertension in both AA and EA populations.

Seeing the Forest for the Trees in Genome-wide Association Studies. *J. Witte, E. Jorgenson.* Epidemiology & Biostatistics, Univ California,San Francisco, San Francisco, CA.

Advances in genotyping and greater knowledge about human genetic variation have led to an escalating interest in genome-wide association studies. Undertaking these studies requires large SNP sets with comprehensive coverage of either the entire genome or at least all known genes (i.e., positional cloning or candidate gene based sets). We first consider the rationale for developing such SNP sets, and the resulting implications for genome-wide association studies. We then compare the sample sizes needed forand relative cost ofpositional cloning versus candidate gene studies. The positional cloning approach requires substantially more SNPs, slightly larger sample sizes, and thus is considerably more expensive to perform than the candidate gene approach. However, the candidate gene approach may miss a limited number of causal variants outside of genes, specifically variants in *cis*-regulatory regions which may be located far away from coding regions. The expected ratio of causal variants in genes versus outside of genes helps distinguish which approach is most appropriate.

A realistic power estimation for genome-wide association tests using the Phase I HapMap data set. *K. Nakazaki[1], Y. Nannya[1], M. Kurokawa[1], S. Chiba[1, 2], S. Ogawa[1, 3, 4].* 1) Departments of Hematology/Oncology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Cell Therapy/Transplantation Medicine, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Regeneration Medicine for Hematopoiesis, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Japan science and technology agency, Basic research programs,'@CREST, Saitama, Japan.

With recent advances in high-throughput SNP typing technologies, genome-wide association studies involving a large number of SNP markers have become a more feasible approach to identify causative genes for common diseases of complex genetic traits. It is of particular importance to evaluate the expected genetic power before conducting such studies requiring costly large-scale genotyping. However, it is still unclear how much power could be obtained with a particular set of SNP markers used. While several estimations have been made for power of association studies, they do not take into account the strength of association of the target SNP with SNPs included in a given marker set. It is of particular importance to evaluate the expected genetic power before conducting such studies requiring costly large-scale genotyping. The recent publication of the phase I data from the international HapMap project, allows us to more accurately calculate parameters of linkage disequilibrium between a given marker within the subset of these HapMap SNPs and a randomly selected candidate for the disease SNP, thus enabling us to better estimate the probability of finding possible association for a particular marker set. Here we applied this method of power calculation to the Affymetrix 100K mapping set and provide a gross estimation of the power that could be obtained when the 100K set is used for association analysis. We also show the effects of SNP marker selection on the power of association tests. Our method, which is implemented in the PowerSNP program, will provide a useful tool for evaluating the performance of a given subset of the HapMap SNPs and also for constructing an optimized marker set for genome-wide association studies.

Simulation study of empirical NULL distribution of LODPAL's LOD scores. *N. Mukhopadhyay[1], B.H. Reck[1], D.E. Weeks[1,2].* 1) Dept Human Genetics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA; 2) Dept of Biostatisics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA.

Several studies have noted that the logistic regression model used by LODPAL produced LOD scores with higher false-positive rates than expected. However, no methodical study has been made of this inflation. Covariate-based methods are becoming increasingly popular in mapping complex diseases, hence, such a study is of great interest.Our simulation study is designed to systematically characterize this inflation.Here, we examine the empirical null distributions of LODPALâs LOD-scores by vary ing the following study parameters: (a) number of affected sibling-pairs in a pedigree, (b) marker densities, (c) number of covariates, and (d) degree of inter-sibling as well as trait-covariate correlation. Our aim is to study the effects of varying these parameters on (i) thresholds for suggestive and significant linkage, and (ii) tails of empirical null distributions as sample size increases.Phenotypes for sibships of size 5 were created as follows. A binary trait and 4 covariates were created for each sibling. The binary trait was simulated using a continuous underlying liability phenotype from a multivariate normal distribution, and taking the upper 75th percentile to be affected. Then we applied an ascertainment step, selecting samples of 50, 100, 150, and 200 sibships with 2,3,4 and 5 affected siblings respectively. Similarly, each of the 4 covariates for the 5 siblings were drawn from a multivariate normal distribution.There is no correlation among the covariates. We used a low value (0.2) and a high value (0.7) for inter-sibling and trait-covariate correlations. We studied all four combinations of these correlation values. Genotypic data consists of 11 markers with realistic frequencies, and with map spacings of approximately 1, 5 and 10 cM. Genotype data were simulated under the assumption of no linkage to either the trait or any of the covariates. 10,000 replicates of genotype data were simulated for each sibship-types(2,3,4,5 affecteds), map spacing (1,5,10 cM), and sample size (50,100,150, 200). LODPAL was run on each simulated set with 0,1,2,3,and 4 covariates.

Breaking very large complex pedigrees and the impact on genetic analysis. *D. Brocklebank, J. Gayan, L. Cardon.*
Bioinformatics and Statistical Genetics, Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.

Linkage based analyses employing large extended pedigrees represent an invaluable tool for localizing and identifying human quantatitive trait loci. However, even with the substantial advances in statistical modelling, incorporated in packages such as Simwalk and LOKI, pedigrees of large size and high levels of complexity are often beyond current constraints. This generally requires breaking such pedigrees into smaller discrete subpedigrees and losing potentially valuable information. We have developed novel methods to efficiently encode and process arbitrarily large and complex pedigree structures employing concepts from graph theory. Algorithms are implemented for pedigree management, pruning, clustering subpedigrees, quantifying pedigree relationships and performing variance components analysis. With the aim of maximising extraction of pedigree information for analysis, we present systematic pedigree partitioning techniques to identify subpedigrees of computationally manageable sizes. Different and complimentary techniques are suggested for pedigrees of varying sizes, including a method based on kinship information for very large structures, and methods based on sampling connecting individuals for removal. We have developed automated tools to identify the approach optimal for a given pedigree structure. We apply methods to real extended pedigrees, including the Tristan de Cunha pedigree, a highly inbred connected pedigree comprising 363 individuals and containing more than 100 loops. Through simulation of phenotypic and genotypic data to reflect the true data patterns, we investigate the impact of varying degrees of pedigree breakage on the accuracy of Identity By Descent (IBD) computations, and the effect of resulting bias in IBD estimates on the power to detect linkage under various genetic models. IBD estimates are obtained using both Markov Chain Monte Carlo (MCMC) methods and deterministic methods where computationally feasible. For larger sub pedigrees, the MCMC estimates are compared with true IBDs, and the effect of incorporating increasingly distant ancestral information on the accuracy and convergence of MCMC estimates is explored.

Computing power in genetic case-control association studies in the presence of phenotype and genotype misclassification errors. *F. Ji[1], Y. Yang[2], C. Haynes[1], D. Gordon[1].* 1) Laboratory of Statistical Genetics, Rockefeller University, New York, NY; 2) University of Science and Technology of China, Hefei, China.

It is well established that phenotype and genotype misclassification errors reduce the power to detect genetic association. Resampling a subset of phenotype and/or genotype data (i.e., double-sampling) with a gold standard measurement is one method to address this issue. We derive the non-centrality parameter (NCP) for the recently published Likelihood Ratio Test Allowing for Error (LRTae) in the presence of random phenotype and genotype errors. With the NCP, power and sample size can be analytically determined at any significance level. We verify analytic power with simulations using a 2^k factorial design given high and low settings of: case and control genotype frequencies, phenotype and genotype misclassification probabilities, total sample size, ratio of cases to controls, and proportions of phenotype and/or genotype double-samples, at significance level settings of 0.05, 0.01, 0.001, and 0.0001. For 0.05 and 0.01 significance levels, the absolute difference in power between computer simulation and theoretically determined results is at most 0.016. For the 0.001 and 0.0001 significance levels, 2% (respectively, 5%) of the settings have a difference larger than 0.02. ANOVA analysis indicates that differences are mainly affected (in order of F-statistic) by the minor allele frequency, ratio of cases to controls, and total sample size. Our method enables researchers to perform power and sample size calculations in the presence of phenotype and genotype errors and also to perform cost/benefits analysis using different experiment designs (e.g., larger sample sizes with no double-samples vs. smaller sample sizes with some double-samples) without the need for time-consuming computer simulation.

Mutual Information Relevance Networks for Modeling Gene-Gene. *L. Luo[1], Y. Wang[1], L. Jin[1,2], M. Xiong[1,3].* 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Center for Genome Information, University of Cincinnati, Cincinnati, OH, USA; 3) Human Genetics Center, University of Texas - Houston Health Science Center, Houston, TX, USA.

Shannon entropy, originally defined in information theory (Shannon 1948), is used to measure the uncertainty removed or the information gained by performing an experiment and to measures the uncertainty of random variables or the degree of nonstructure of a system. When it is applied to characterize DNA variation, entropy measures genetic diversity and extracts the maximal amount of information on a set of SNP markers. The entropy can quantify the level of the linkage disequilibrium (LD) between two marker loci. It is known that gene-gene interaction will create LD between two interacted genes. Intuitively, we can test interaction between two genes by comparing the difference in the levels of the LD between two genes in the cases and controls. In this report, we propose to use entropy and mutual information to model interactions between genes. A higher mutual information between two genes indicates that one gene is more likely to be non-randomly associated with another gene. By comparing mutual information for a pair of genes in cases and controls we can measure the strength of interaction between genes. Therefore, by calculating pair-wise mutual information, we can link interacted genes and remove uninteracted genes to generate mutual information relevance networks, which can be used to model genetic interaction networks.

Estimate Genotyping Error from Multi-locus Genotype Data of Unrelated Individuals. *G. Zhang[1], R. Chakraborty[1], L. Jin[1,2].* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Institute of Genetics, Fudan University, Shanghai, China.

Haplotype analyses and linkage disequilibrium (LD) mapping of complex diseases depend crucially on the accuracy of genotype data. Even moderate genotyping error rates can have serious affects on haplotype or LD measure inferences. Unlike pedigree data, in which genotyping error can be detected through Mendelian incompatibilities or close double recombinants, in unrelated individuals, genotyping error of single marker can only be partially inferred from deviation of Hardy-Weinberg equilibrium. In this presentation, we describe an expectation-maximization (EM) algorithm to detect genotyping errors by jointly analyzing genotype data of multiple markers in close linkage disequilibrium. Specifically, the algorithm estimates the haplotype frequencies conditional on multi-locus genotype data and an assumed (priori) model of genotyping error probabilities, and calculates the posterior genotyping error probabilities based on the observed genotype data and the estimated haplotype frequencies. Through simulation study, we examine the accuracies of our proposed method on genotyping error detection and haplotype frequency inference, and explore the effects of marker density, genotyping error rate and sample size on this method. The results show that our method performs well in estimating genotyping errors and haplotype frequencies, especially for multiple markers in high LD.

Power to detect imprinting using linkage data: Parent-of-origin penetrance vs. independent male-female recombination fractions. *D.A. Greenberg[1], C. Monti[1,2], B. Feenstra[1,3].* 1) Div Stat Genet, Dept Biostat, Columbia Univ, NY, NY; 2) Dept. Applied Health Sci, Pavia Univ, Italy; 3) Royal Vet & Agricult Univ, Dept Natural Sci, Denmark.

There are an increasing number of genes known whose expression depends on the sex of the parent contributing the gene, i.e., imprinting. For brain-related traits, this may be particularly important; in mice, there is region-specific imprinting of some genes. We tested two methods for detecting imprinting: A) lod score maximization w.r.t. parent-of-origin-based penetrances; and B) lod score maximization w.r.t independent male-female recombination fractions.

We simulated family data with imprinting, which we defined as existing when the penetrance in offspring depended on the parent of origin of the allele. We maximized the two-point lod score: a) over parent-of-origin penetrances (PP) and b) over combinations male-female recombination fraction (RF). In both cases, we compared the max score assuming equal parameter values from mothers and fathers to the global max over all combinations. Only data sets in which evidence for linkage was significant were used to calculate power to detect imprinting. For both approaches, we calculated the chi-squared value based on lod score differences to determine the significance for imprinting. We calculated the power over a range of data set sizes. We also tested the confounding effects of 1) reduced penetrance, 2) heterogeneity, 3) differential male-female penetrance, and 4) biased ascertainment.

If neither heterogeneity nor reduced penetrance is present, the PP method has more power to detect imprinting than the RF. Imprinting detection power actually increases for the PP method if reduced penetrance exists, given linkage is detectable. However, the power to detect imprinting increased for the RF method and decreased for the PP method when heterogeneity existed. If one sex had higher penetrance than the other, the PP method could falsely indicate imprinting, while the RF method was not fooled. Neither method gave biased results because of parent-specific ascertainment bias.

An S-Plus/R library for Quantitative Trait Linkage Analysis. *M. de Andrade[1], E. Lunde[1], E.J. Atkinson[1], J. Chen[2], C.I. Amos[2].* 1) Div Biostatistics, Mayo Clinic, Rochester, MN; 2) Dep Epidemiology, UT M.D. Anderson Cancer Center, Houston, TX.

We have implemented the Multic program from the ACT software in an S-Plus/R library called multic. Multic estimates variance components for quantitative linkage analysis using maximum likelihood method (scoring algorithm) for multivariate traits and longitudinal data. Additionally, we have created tools to import SIMWALK2 and Solar IBD data to be used by multic. The S-Plus/R library provides tools to easily run the main analysis, summarize the results for polygenic and major gene models, and plot the overall results. Diagnostic tools are also provided to detect influential families or individuals. The integration of multic in S-Plus and R provides the users with all the niceties already available in these software packages such as the usage of modeling language to create transformations and interactions, the ability to use results from other models (like factor analysis) as potential traits or covariates, and a suite of sophisticated graphics tools. We will present examples of the proposed features and will include runtime comparisons of SOLAR with Multic in its former format and with Multic embedded in S-Plus/R. The software will be publicly available by the time of the meeting, with user-friendly documentation.

SimPed: A Simulation Program to Generate Haplotype and Genotype Data for Pedigree Structures. *S.M. Leal[1], K. Yan[1], B. Müller-Myhsok[2].* 1) Department of Molecular and Human Genetic, Baylor College of Medicine, Houston Texas, USA; 2) Computational Genetics Group, Max-Planck-Institute of Psychiatry, Munich, Germany.

With the widespread availability of SNP genotype data, there is greater interest in analyzing pedigree haplotype data. For microsatellite markers due to their physical distance, intermarker linkage disequilibrium is usually low; however, for dense maps of SNP markers, there can be strong linkage disequilibrium between marker loci. Linkage analysis (parametric and nonparametric) and family-based association studies are currently being carried out using dense maps of SNP marker loci. Given the widespread use of dense maps of marker loci, it is important to be able to generate a large number of marker loci in linkage disequilibrium or a mixture of markers with some loci in linkage disequilibrium and others in linkage equilibrium for pedigree data. In order simulate this type of data the SimPed program which is written in C was developed. It can quickly generate haplotype and/or genotype data for pedigrees of virtually any size and complexity. Marker data either in linkage disequilibrium or equilibrium can be generated for > 10,000 diallelic or multiallelic marker loci. Haplotypes and/or genotypes are generated for pedigree structures using specified genetic map distances and haplotype and/or allele frequencies. SimPed quickly generates data, for example, genotypes for 50 marker loci defining a total of 20 haplotypes were generated for a three-generational pedigree with 16 family members. For this study, 1,000 replicates were generated in 0.73 seconds on a computer with a Xeon 3.0 GHz processor and 4 GB of RAM running under Red Hat (v9.0) Linux operating system. Additionally, for the same pedigree structure the genotypes for 50 SNP marker loci were generated for 1,000 replicates in 0.75 seconds. The data which SimPed generates is useful for a variety of analysis purposes, including evaluating methods that estimate haplotype frequencies for pedigree data, evaluating type I error and estimating empirical p-values for linkage and family-based association studies.

Simulation and analysis of complex multifactorial diseases. *M.A. Schmidt, E.R. Hauser, E.R. Martin, S. Schmidt.*
Center for Human Genetics, Duke University, Durham, NC.

Identifying genes contributing to complex multifactor diseases of genetic and environmental origin is one of the biggest challenges in genetics. Statistical software is available to address some of these complexities, however simulation studies of new software often focus on only a few selected data generation mechanisms. Thus it is important to give investigators the tools to test new software under a variety of conditions. We have developed a general simulation package called SIMLA, which can simulate a great variety of complex multifactorial disease models and provides many input file formats for commonly used analysis programs. SIMLA can simulate up to two disease loci on either X-linked or autosomal chromosomes, distinct relative risk parameters for males and females, up to two environmental covariates, each of which may be correlated within families, and linkage disequilibrium of marker and disease loci. Various ascertainment criteria for the data set can be specified. Genes and environmental covariates may interact in a number of ways, as specified by highly flexible penetrance functions. SIMLA provides the user with a number of summary statistics for the simulated data, such as observed IBD-sharing, allele and environmental exposure frequencies in selected individuals, sibling recurrence risk and penetrance values for all exposure combinations. With these statistics, the user may evaluate different data generation mechanisms with standard measures of genetic effect sizes. The number of markers, print options, disease prevalence and ascertainment criteria impact the performance of SIMLA, but it can typically generate more than 100 pedigrees per second with a 100-marker map on common hardware. This immediate feedback about the impact of various factors on the generated data sets, prior to analyzing them with any particular statistical-genetic software, makes SIMLA particularly useful. Several plausible disease models and associated analysis methods have been introduced in the literature (Marchini et al. 2005; Ritchie et al. 2001). We will refer to these models and illustrate how to implement them using the SIMLA software.

Independent population based studies support the role of Upstream Stimulatory Factor 1 (*USF1*) -gene variants in coronary heart disease. *M. Perola[1], K. Komulainen[1], K. Ahonen[1], M. Alanne[1], J. Saarela[1], S. Kulathinal[2], K. Kuulasmaa[2], K. Silander[1], V. Salomaa[2], L. Peltonen[1].* 1) Dept. of Molecular Medicine, KTL, Biomedicum, Helsinki, Finland; 2) Dept. of Epidemiology and Health Promotion, KTL, Mannerheimintie 166, 00300, Helsinki, Finland.

The *USF1* gene, encoding a transcription factor regulating several genes of lipid metabolism, has been associated with familial combined hyperlipidemia (FCHL), and various other trait components predisposing to coronary heart disease (CHD). We studied here the allelic variants of the *USF1* gene in two independent population-based cohorts, FINRISK 92 of 5999 Finns and FINRISK 97 of 8141 Finns, to assess the significance of the gene as a risk factor for CHD at the population level. Five haplotype-tagging SNPs across the 5.7 kb *USF1* gene were genotyped in a case cohort setting for a total of 2222 individuals including 843 CHD cases. Importantly, the gene was found to be associated with the risk of CHD in both cohorts.

We initially explored for association between the *USF1* gene and the prospective risk of CHD in FINRISK 92 cohort with a follow-up time of 10 years using the Cox proportional hazards analysis. We established an association between the risk of CHD in females and *USF1* risk allele defined by five SNPs (HR 5.8, 95% Cl 1.7-19.3, P=0.005). We also identified a putative protective role of another five SNP allelic haplotype (HR 0.13, 95% Cl 0.03-0.50, P=0.003). Comparable evidence of the effect of the *USF1* gene was obtained from the analysis of FINRISK 97 females (HR 4.3, 95% Cl 1.2-15.6, P=0.024 and HR 0.47, 95% Cl 0.16-1.45, P=0.19 for a risk and protective allele, respectively). Combined analysis of the two cohorts further supported the findings (HR 3.7, 95% Cl 1.7-8.0, P=0.001 and HR 0.34, 95% Cl 0.16-0.72, P=0.005 for the risk and protective allele, respectively). These results underline the importance of the *USF1* gene variants as a CHD risk factor at the population level. The critical function of *USF1* in the lipid metabolism well agrees with its important role in the pathogenesis of CHD.

Genetic variations in thrombosis cascade predispose to cardiovascular events in a prospective follow-up study. *K. Ahonen[1], K. Komulainen[1], M. Alanne[1], K. Silander[1], K. Kulathinal[2], V. Salomaa[2], L. Peltonen[1,3], M. Perola[1,3].* 1) Dept. of Molecular Medicine, KTL, Haartmaninkatu 8, Helsinki, Finland; 2) Dept. of Epidemiology and Health Promotion, KTL, Mannerheimintie 166, Helsinki, Finland; 3) 3Dept. of Medical Genetics, University of Helsinki, Haartmaninkatu 8, Helsinki, Finland.

Thrombomodulin (TM), intercellular adhesion molecule -1 (ICAM1), protein C (PROC) and factor V (F5) are critical elements of a natural clotting cascade, where TM activates PROC, which leads to inactivation of F5. Previous studies of single polymorphisms of these four genes have suggested association to cardiovascular diseases (CVD). To address the details of genetic variation of this physiological cascade and its role in pathogenesis of CVD, we analyzed altogether 23 single nucleotide polymorphisms (SNPs) of these four genes in a prospective follow-up study. FINRISK92 is a stratified random sample of men and women aged 25-64 years examined in 1992. The follow-up time for CVD events was ten years (1992-2001). From the total sample of 5,999 individuals, 999 were chosen for genotyping using case-cohort study design. 222 persons had a history of cardiovascular events at the baseline. During the follow-up, 195 incident coronary events (CHD) and 68 ischemic stroke events (CI) were observed. The SNPs were selected to monitor the allelic diversity by capturing the major haplotypes. All the SNPs were tested in Cox proportional hazards model using CHD, CI and all CVD events as endpoints. Of the five PROC SNPs analyzed, two showed association to CI in the whole genotypic sample (HR 3.43, CI 95% 1.43-8.21, p=0.0057 and HR 3.18, CI 95% 1.31-7.64, p=0.011). For all CVD events, an association was observed with one SNP of PROC in men (HR 2.25, CI 95% 1.15-5.50, p=0.020) and one ICAM1 SNP in women (HR3.98, 95% CI 1.19-13.36, p=0.025). Several F5 SNPs showed association to CHD in females, whereas TM SNPs showed no association. Our results imply that genetic variation in this cascade contribute to the risk of cardiovascular events. Future analyses focus to define the epistatic character of the genes.

The Burden of genetic disease in a hospitalized pediatric population in Colombia. *I. Zarante, P. Paez, N. Garcia, F. Suarez.* Inst de Genetics Humana, Pontificia Univ Javeriana, Bogota, Colombia.

The important role of genetics in pediatric illness has been increasingly recognized. There is not information about the genetic burden in disease affecting children in developing countries like Colombia. The purpose of this research is to establish the frequencies of diseases with clearly established genetic etiology and those with predisposition or susceptibility in a hospitalized pediatric population at a Universitary Hospital in 2003. The diagnosis database of all hospitalized children during 2003 from one to eighteen years old from the Hospital Statistic Department was recorded. With the objective of determine the genetic basis of the diseases affecting children, the diagnosis were assigned to the following categories: Monogenic disease with clearly monogenic inheritance (I), chromosomal diseases (II), complex disease conditions including multifactorial diseases and malformations (III), unknown etiology disease but with probably genetic basis (IV), diseases without genetic cause including infections and trauma (V), unclassified diagnosis (VI). Delivery, pregnancy, related pregnancy disease and related neonatal diagnosis were excluded. A total of 3901 records were analyzed. 1796 were excluded. A diagnosis category assignment was reached in a total of 2105 records. Sex ratio male: female were 1,5:1. The age range was 1 to 18 years with an average of 6.7 (5,3). The major percentage of diagnosis were in category III (27%) and V (13,2 %) which are similar percentages reported in other similar works performed in developed countries. Other major causes of hospitalization were category IV (13.1%) which included diseases like leukemia, malignat long bone tumors, depressive episodes and epilepsy. The commonest diagnoses were respiratory tract infections in category V (55.3%). The commonest malformation were congenital heart defects. This work indicates that 30% of the disease in this hospitalized pediatric population has a strong genetic etiology similar to the reported in developed countries, Colombia has achieved a significant epidemiological transition but still a lower resource country that need to develop a complete medical genetic service.

Identification of Genetic Interaction Networks. *Y. Wang[1], J. Zhao[2], X. Zhou[3], W. Wang[4], J. Li[1], M. Xiong[2].* 1) Genetics, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas Health Scinece Center at Houston; 3) Medical School, University of Texas Health Science Center at Houston; 4) Chinese National Human Genome Center at Shanghai.

Current research demonstrates that only a small proportion of the disease risk is due to the influences of variations in a single gene with large genetic effects. In the real world, complex diseases develop as a consequence of interactions between multiple DNA variants and exposures to environmental agents varying over time and space, which are organized into networks. Actions of genes through networks are a consequence of complex molecular interactions occurring during biological processes such as metabolism, transcription, signal transduction and translations. The phenotypic variations depend on the genetic interaction networks. Dissecting genetic architecture of complex diseases requires uncovering hierarchically organized gene interaction networks. Unfortunately, the statistical methods for reconstruction of genetic interaction networks have not been well developed. Therefore, developing statistical methods for studies of genetic interaction networks is urgently needed. In this report, we present a general statistical framework for identifying genetic interaction networks and computational algorithms for discovering structure of genetic interaction networks. The identified genetic interaction networks will be compared with regulatory networks, protein-protein interaction networks and metabolic networks. . The proposed statistical methods and computational algorithms will be applied to atherosclerosis disease study.

Differential Prediction of Coronary Artery Disease among Diabetics by CETP Tagging SNPs. *C.P. Mower[1], N.J. Camp[2], B.D. Horne[1,2], J.L. Anderson[1,2], J.L. Clarke[1], M.J. Kolek[1], J.T. McKinney[3], J.F. Carlquist[1,2].* 1) CV Research, LDS Hospital, SLC, UT; 2) Genetic Epidemiology and Cardiology Divisions, U of U, SLC, UT; 3) Idaho Technology, SLC, UT.

The cholesteryl ester transfer protein gene (CETP) regulates plasma lipid fractions and HDL cholesterol, but its effect on coronary artery disease (CAD) in the presence of diabetes mellitus (DM) may differ. The use of tagging single nucleotide polymorphisms (tSNPs) allows for better replications of SNP analyses. We evaluated the association between CETP tSNPs (C-631A, Taq1B, MspI, F287F, T+1086A, C+878T, G+2389A, A373P, C+408T, NlaIII, A+1825C) and CAD in the context of DM. DM (n=1273) and non-DM patients (n=4812) undergoing coronary angiography and free of any smoking history were included. Significant CAD (70% stenosis) was compared to non-CAD (10% stenosis) for the 11 tSNPs previously chosen for CETP. Genotyping was performed by quantitative PCR with probe hybridization. Logistic regression adjusted for traditional risk factors. CAD was present among 85% of DM and 66% of non-DM. DM patients averaged 6412 years of age and 40% were female, and only G+2389A (intron 10) had $p<0.25$ for association to CAD (86%, 85%, and 79% CAD for GG, GA, and AA). With full adjustment, AA vs. GG had OR=0.59 (95% CI: 0.36,0.97, p=0.036). To confirm this finding, a quasi-validation analysis predicted the presence of DM among CAD patients (age: 6612 years, female: 28%) and separately among those with no CAD (age: 5614 years, female: 45%). DM was less prevalent for the +2389 AA genotype among CAD patients (DM: 27%, 24%, 23% for GG, GA, AA), but was more prevalent for non-CAD patients (10%, 11%, 14% for GG, GA, AA), validating the CAD prediction results among DM (AA vs. GG: p-interaction with CAD= 0.022). CETP tSNP G+2389A (tagging the intron 8-exon 16 region) predicts CAD in DM, although it was found previously to not predict CAD among non-DM. This was validated, predicting differences in DM when stratified by CAD status. This study suggests that genetic risk for CAD among DM may involve similar pathways as in non-DM, but that the specific mechanisms may differ, and this hypothesis requires further testing.

Extended Family Investigation of Nephropathy and Diabetes (E-FIND): Design and conduct of genetic studies. *N. Arar, R. Duggirala, H. Abboud.* Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX.

The Family Investigation of Nephropathy and Diabetes (FIND) study is designed to localize susceptibility genes for diabetic nephropathy (DN) by performing full genome scan in DN probands, their diabetic siblings with and without DN. As one participating center in FIND we recruited 300 DN probands and 900 siblings. The Extended Family Investigation of Nephropathy and Diabetes (E-FIND) is a subproject of the FIND. The goal of the E-FIND is to establish a pedigree-based genetic study by enrolling 50 multiplex Mexican American families of FIND probands 1st, 2nd, and 3rd degree relatives in order to assess susceptibility genes for DN using a variance components linkage approach. Another goal is to identify strategies to improve informed and voluntary participation in genetic family studies (GFS) among minority populations. Method: Structured interviews with enrolled subjects were conducted to (1)gather information about the family history of diabetes and DN, and (2)collect clinical data related to diabetes and DN using the FIND medical questionnaires. A separate set of questions assessed subjects informed and voluntary participation in GFS using the Contextual Assessment Questionnaire developed and validated in our center. Urine and blood samples were collected from all enrolled subjects for phenotype assessment regarding diabetes and DN. Additionally, buffy coat will be isolated from all blood samples for future DNA analysis. Results: We contacted 137 individuals representing 21 FIND families. Of those, 114 subjects were willing to participate in the E-FIND study, while 23 refused. Enrollment rate of 83.2% is appropriate to build pedigree-based FIND families and achieve the required sample size to perform linkage analysis. Based on our experience in the FIND and E-FIND studies, we will discuss the: (1) rationale for complex pedigree-based design as compared to sib pair linkage approach to search for DN genes, (2) methods for screening, contacting and enrolling subjects in GFS, (3) ethical issues associated with subjects participation in GFS and effective strategies to address them. Support/NIH/NIDDK; George M. O' Brien Kidney Research Center.

Comparison of Methods for Stratified Analysis of Association Studies in Fine-Mapping Type 2 Diabetes in Multiple Populations for Chromosome 1q. *R. Hanson[1], E. Zeggini[2], W. Rayner[2], B. Mitchell[3], J. O'Connell[3], A. Shuldiner[3], S. Elbein[4], M.C.Y. Ng[5], K. Xiang[6], P. Froguel[7], P. Deloukas[8], M. McCarthy[2], W. Knowler[1], International Type 2 Diabetes 1q Consortium.* 1) NIDDK, Phoenix, AZ; 2) Oxford University, Oxford, UK; 3) University of Maryland, Baltimore, MD; 4) University of Arkansas, Little Rock, AR; 5) Chinese University of Hong Kong, Hong Kong, China; 6) Shanghai Diabetes Inst, Shangai, China; 7) CNRS UMR 8090, Lille, France; 8) Wellcome Trust Sanger Inst, Hinxton, UK.

Methods for pooling results for genetic association studies include the Mantel method, which estimates a common effect across populations, and Fishers method, which does not. We compared these methods in a large fine-mapping study of type 2 diabetes in a 13.5 Mb region on chromosome 1q. Data include 2331 SNPs from a total of 1617 diabetic cases and 1640 nondiabetic controls from 7 different populations. The Mantel extension test (^2_M) was applied to estimate the common effect of genotype on diabetes across all populations, under an additive model, and to assess its statistical significance. P-values from the test for trend in each population were also combined using Fishers method and the 1 df equivalent ^{2} for the resultant p-value was taken (^2_F). For each SNP, a permutation procedure was used to assess whether the difference (^2_M-^2_F) departed from that expected under no association. The rank correlation between p-values for the two methods was 0.37. 42 SNPS from 8 regional clusters were associated with diabetes at $p<0.001$ by at least 1 method. For 36 of these, ^2_M gave stronger evidence for association than did ^2_F ($p<0.0001$ by sign test). However, in 1 region, where different alleles were associated in different populations, ^2_F gave much stronger evidence and ^2_M-^2_F was lower than expected by chance ($p=0.0004$). The Mantel and Fisher methods, although correlated, provide complementary information. The Mantel method gives stronger results in most significant SNPs, suggesting effects are homogeneous across populations. Regions where Fishers method gives stronger results may reflect allelic heterogeneity or different linkage disequilibrium across populations.

Variants in the HNF4A gene associated with diabetes and related traits in Hispanic Americans: The IRAS Family Study. *T.E. Fingerlin[1], C.D. Langefeld[2], A.B. Lehtinen[2], S.S. Rich[2], R.N. Bergman[3], S.M. Haffner[4], M. Bryer-Ash[5], D.W. Bowden[2], J.M. Norris[1].* 1) University of Colorado at Denver and Health Sciences Center; 2) Wake Forest University School of Medicine; 3) University of Southern California; 4) University of Texas Health Sciences Center; 5) University of California Los Angeles.

Variation in the HNF4A gene has recently been associated with type 2 diabetes (T2D) in Finnish, Ashkenazi Jewish and several other populations. We typed 23 SNPs spanning the HNF4A gene in 842 Hispanic American (HA) individuals in 45 families and 310 African American (AA) individuals in 21 families in the IRAS Family Study (IRASFS). We tested for association between these SNPs and T2D using the pedigree disequilibrium test. We identified several SNPs in and near the P2 promoter significantly associated with T2D in the HA sample (rs4810424 [p=.007], rs1884613 [.009], rs1884614 [.008], rs2144908 [.008], rs6073418 [.03]). We did not detect association with any SNPs in the AA sample; SNPs rs1884614, rs2144908 and rs6073418 had p=.09 for the putative at-risk alleles, suggesting that power in the smaller AA sample may be an issue. Minor allele frequencies for SNPs rs1884614 and rs2144908 were more common in our HA pedigrees (.47 and .46) and less common in our AA pedigrees (.12 and .12) compared to published Caucasian (C) samples (.17-.20). Thus, haplotypes with the at-risk allele at each of the SNPs are more (less) common in our HA (AA) sample than in published C samples. We also tested for association between these markers and glucose homeostasis measures from an FSIGT. Using a GEE1 approach, we found modest association between P2 promoter SNPs and SI in AA (p=.02-.03), but no evidence for association with acute insulin response or disposition index. In summary, we observed associations between markers in the P2 promoter region of HNF4A and T2D in an HA sample. Preliminary results suggest that these SNPs may contribute to variation in insulin resistance, but not disruption of insulin secretion. We are currently testing these results in a second set of independent families from the IRASFS in an attempt to corroborate these findings.

Genetic architecture of the APM1 gene and its influence on adiponectin plasma levels and parameters of the metabolic syndrome in 1727 healthy Caucasians. *I.M. Heid[1], S.A. Wagner[1,2], H. Gohlke[1], B. Iglseder[2], J. Mueller[3], P. Cip[2], G. Ladurner[2], R. Reiter[2], A. Stadlmayr[2], T. Illig[1], F. Kronenberg[4], B. Paulweber[2].* 1) GSF-National Research Center, Neuherberg, Germany; 2) Paracelsus Private Medical University Salzburg, Austria; 3) Technical University, Munich, Germany; 4) Innsbruck Medical University, Innsbruck, Austria.

Reports on variants of the adiponectin (APM1) gene showed numerous, but inconsistent associations with parameters of the metabolic syndrome. We performed a systematic investigation of APM1 and its role in modulating adiponectin plasma concentrations in a particularly healthy population of 1727 well-phenotyped Caucasians. Genotyping 53 SNPs (average spacing of 0.7 kb) in the APM1 gene region in 81 Caucasians revealed a two-block LD structure and enabled comprehensive tagSNP selection. We found particularly strong association with circulating adiponectin for 11 out of the 18 tagSNPs genotyped subsequently in the 1727 subjects up to a difference of 3 g/ml adiponectin concentration (increased levels: 14811, p<0.000001; -11388 p<0.000001; 45, p=0.0006; 276, p=0.00007; 712, p<0.000001; Y111H, p=0.04; 3639, p=0.001; 4545, p=0.01; decreased levels: 10066, p<0.000001; 8564, p=0.00002; and -450, p=0.0003). Haplotype analysis provided a thorough differentiation of adiponectin levels with 9 out of 17 showing significant association (5 with p-values<0.0001) also supported by a minimal spanning net. No significant association was found for any of the parameters of the metabolic syndrome. We thus present the first study based on fine-mapped APM1 SNPs in combination with a haplotype tagging SNP approach showing strong associations of APM1 variants with adiponectin concentrations in healthy subjects. The revealed two-block structure may point towards two causal regions, one including the promoter SNPs and a second the relevant exons. Our data on healthy subjects further suggests that modulation of adiponectin concentrations by variants in APM1 is not merely a concomitant effect in the course of disease but most apparent already in a healthy status.

Comparison of direct versus indirect measures of insulin resistance in genetic studies using a novel compartmental modeling-based approach. *R.M. Watanabe, Z. Guan, D.V. Conti.* Dept Preventive Medicine, Keck School of Medicine at USC, Los Angeles, CA.

Insulin resistance (IR) is a hallmark of type 2 diabetes. Direct assessment of IR can be impractical for large genetic studies, resulting in use of easily obtained indirect indices of IR based on fasting concentrations or oral glucose tolerance test (OGTT). Indirect indices correlate with direct IR measures, but data suggests the correlation is largely due to environmental, rather than genetic factors. The aim of this study is to use computer simulation to compare the ability of direct vs. indirect IR measures to accurately detect and characterize genetic variation underlying IR. We developed a compartmental model-based system that simulates the effect of genetic variation on glucoregulation. The model is physiologically-based, takes into account the feedback regulation between glucose and insulin, and is capable of simulating clinical research protocols, e.g., OGTT and intravenous glucose tolerance test (IVGTT). Genetic variation is introduced by assigning genes to specific model parameters to simulate specific genetic defects. For each gene, genotype specific parameter values are derived from a population distribution, constrained by gene frequencies and assuming an additive genetic model. A sample of OGTTs/IVGTTs are simulated assuming one gene affecting IR and another gene affecting -cell function. A common indirect index of IR, Stumvoll index (St_I), is computed from the simulated OGTT. Simulated IVGTT data are analyzed by minimal model to derive the insulin sensitivity index (S_I), a direct measure of IR. St_I and S_I are used as phenotypes to test for association with the two genes introduced in the simulation. Initial results show both St_I and S_I have good power (47% and 63%, respectively) to detect genetic variation underlying IR. However, St_I lacks IR specificity and detects variation underlying -cell function (41%), while S_I does not (17%). Additional simulations are under way. We conclude that while both indices allow detection of genetic variation underlying IR, St_I also incorrectly detects association with genes underlying -cell function.

Insulin VNTR is a determinant of over-mortality associated with severe obesity. *D. Meyre[1], F. Degraeve[1], B. Heude[2], V. Vatin[1], M. Ghoussaini[1], E. Durand[1], P. Boutin[1], C. Dina[1], M.A. Charles[2], P. Froguel[1, 3].* 1) CNRS UMR8090, Lille, France; 2) INSERM U258, Villejuif, France; 3) Imperial College, London, UK.

We analyzed INS VNTR-linked -23 Hph1 polymorphism in 2 French family samples: 286 population-based pedigrees (484 children, 434 parents) and 449 selected pedigrees (633 obese children, 804 parents and 517 grandparents). We observed a borderline over transmission of the VNTR class I allele (transmission rate: 55%, p=0.07) from parents to children in the whole population-based cohort, whereas the class I allele was associated with childhood overweight (p=0.0005) and childhood obesity (p=0.009). In the obese children cohort, class I allele was associated with higher % of fat mass (p=0.04), higher insulin secretion (p=0.004) and higher % of binge-eating (p=0.05). In parents from the general population, class I allele was associated with severe obesity (p=0.007) and glucose intolerance/type 2 diabetes (p=0.05). In parents from childhood obesity families, class I allele was associated with morbid obesity (p=0.05), higher food disinhibition score (p=0.07), lower HDL cholesterol/total cholesterol ratio (HDL/TOT) (p=0.06) and higher triglycerides level (TG) (p=0.03). In grandparents, class I allele was associated with obesity (p=0.02), lower HDL/TOT (p=0.005) and higher TG (p=0.03). Morbid obesity prevalence was 2-fold higher in obese children parents (9.5%) compared to their grandparent (4.4%, p=0.0005). When comparing genotype distribution between the 3 generations in childhood obesity pedigrees, we observed an over-representation of III/III genotypes in grandparents in comparison with parents and obese children (OR=1.45 and OR=1.58, p=0.06 and p=0.06) inducing modest Hardy-Weinberg disequilibrium (p=0.01). Our results suggest that the VNTR class I allele 1) promotes better survival in the first stages of life (as suggested by its over transmission in children) 2) leads to a chronic severe obesity phenotype later in life through enhanced insulin secretion and possibly abnormal food intake 3) leads to reduced life span probably due to metabolic complications associated with severe chronic obesity. We propose that the INS VNTR could be a key determinant of the thrifty genotype.

Demographic factors associated with participation in genetic studies as part of the National Birth Defects Prevention Study. *K. Crider[1], A. Woomert[2], J. Reefhuis[1], M. Honein[1].* 1) NCBDDD, CDC, Atlanta, GA; 2) Battelle, Durham, NC.

The National Birth Defects Prevention Study is a multicenter case-control study designed to examine both environmental and genetic risk factors for birth defects. We assessed demographic characteristics associated with completion of a mailed buccal cell collection kit after a telephone interview about prenatal exposures. The analysis was limited to participants from Atlanta with an estimated delivery date on or before 12/31/2001 who completed an interview (interview participation rate=74%). A total of 1,222 interviewed mothers were eligible to receive a buccal kit (946 case mothers, 276 control mothers). In this group 47% (n=572) were non-Hispanic White (White), 34% (n=413) were non-Hispanic Black (Black), 14% (n=165) were Hispanic, and 6% (n=72) were other or missing race information. The buccal kit was completed by 46% of the interviewed mothers and participation rates were highest among Whites (60%), followed by other (40%), Hispanics (38%) and Blacks (30%). In a multiple logistic regression model, Black race (OR 0.3; CI 0.2-0.4) and Spanish interview (OR 0.3; CI 0.2-0.5) were associated with decreased participation, while wanting to become pregnant at the time of conception (OR 1.5; CI 1.1-1.9) was associated with increased participation. Among White mothers, over 12 years education (OR 2.1; CI 1.1-2.5), wanting to become pregnant at the time of conception (OR 1.7; CI 1.1-2.5) and having a child with a birth defect (OR 1.7; CI 1.1-2.7) were associated with increased participation. Among Black mothers, over 12 years education (OR 0.58; CI 0.3-0.95) and household income under $20K a year (OR 0.57; CI 0.34-0.96) were associated with decreased participation. Among Hispanic mothers, Spanish interview (OR 0.3; CI 0.1-0.5) was associated with decreased participation, while folic acid or multivitamin use before pregnancy (OR 2.53; CI 1.17-5.45) increased participation. Although women were willing to participate in an extensive interview, low participation in the genetic component limits both the power for analysis and the generalizability of results. Evaluations and interventions to increase participation might need to be tailored to individual groups.

Evidence of gene-gene interaction of DRD4 and DAT1 loci for increased susceptibility to attention-deficit/hyperactivity disorder in Chilean families. *X. Carrasco[1], P. Rothhammer[2], M. Moraga[2], H. Henriquez[2], F. Aboitiz[2], F. Rothhammer[2], R. Chakraborty[3].* 1) Hospital Calvo Mackenna, Santiago, Chile; 2) Human Genetics Program, Faculty of Medicine, University of Chile, Santiago, Chile; 3) Center for Genome Information, Dept. Environmental Health, University of Cincinnati, Cincinnati, OH 45267.

Attention-deficit/hyperactivity disorder, ADHD (MIM 126452), is a common, highly heritable neurological disorder of childhood onset, characterized by hyperactivity, impulsiveness, and/or inattentiveness. We carried out a family-based discordant sib-pair analysis (with 26 cases and 25 controls) to detect possible associations between dopamine receptor D4 (DRD4) and dopamine transporter 1 (DAT1) polymorphisms and ADHD in Chilean families. Classified as homozygote or heterozygote for the DRD4 7 repeat and DAT1 10 repeat alleles, both loci, individually did not exhibit genotype frequency differences between affected children and their healthy siblings (Fishers exact test $p > 0.25$ in both cases). However, simultaneous presence of DRD4 7 repeat heterozygosity and DAT1 10 allele homozygosity was significantly higher (34.6%) in cases, compared with their unaffected siblings (4%; Fishers exact test $p = 0.0096$; odds-ratio, OR = 12.71). Increased density of dopamine transporter in ADHD brains, along with abundance of 7 repeat D4 receptors in prefrontal cortex, which is impaired in ADHD patients, make the observed gene-gene interaction worthy of further studies. (Data analysis of this research is supported by NIH grant GM 41399 to RC).

Hereditary hemochromatosis of type I: influence of body mass index on biological expressivity. *V. Scotet[1], G. Le Gac[2], F. Boisbras[1], C. Ka[2], MC. Mérour[2], C. Férec[1,2].* 1) INSERM U613, Brest, France; 2) Etablissement Français du Sang - Bretagne, Site de Brest, France.

Hereditary hemochromatosis is a disorder of iron metabolism, whose main form is usually associated with missense mutations in the HFE gene. The phenotypic expression of the most common HFE genotype (C282Y/C282Y) is heterogeneous and its expressivity is influenced by environmental and genetic factors. The aim of this study was to assess the influence of body mass index (BMI) on the disease expressivity in a cohort of patients homozygous C282Y/C282Y. The study included the C282Y homozygous patients enrolled in a phlebotomy program at the blood centre of Brest (western Brittany, France). A clinical questionnaire was completed at the time of diagnosis. The body mass index (BMI) was assessed and divided in three classes (normal: BMI25 kg/m², overweight: BMI25 and 30, obesity: BMI30). A multiple logistic regression was used to determine the effect of BMI (coded as two dummy variables) on elevated serum ferritin (cut-off of 1000 g/L), after adjustment on potential confounders. This study included 381 patients, among whom 51.2% were males (n=195). The BMI was documented for 346 patients (90.8%). Among them, 18 were obese (5.2% i.e. 3.4% of males and 6.9% of females) and 104 overweight (30.6% i.e. 36.6% of males and 23.6% of females). Serum iron parameters were significantly higher in the group of obese and of overweight patients than in the other group (p0.001). The risk for patients with overweight to have a ferritin level greater than 1000 g/L was 1.7 times higher than in patients with normal BMI (OR=1.7 [1.0; 3.0], p=0.043). This risk was 3.2 times higher for obese patients (OR=3.2 [1.2; 8.8], p=0.019). After adjustment on potential confounders such as gender, age at diagnosis and alcohol consumption, only the risk associated with obese patients remained significant. This study highlights the influence of BMI on the biological expression of hereditary hemochromatosis. This contributes to explain a part of the heterogeneity observed in the phenotypic expression of the C282Y/C282Y genotype.

Meta-analysis of genome-wide linkage studies for quantitative lipid traits in African Americans. *A. Malhotra[1], H. Coon[2], M.F. Feitosa[3], W. Li[4], K.E. North[5], R.A. Price[4], C. Bouchard[6], S.C. Hunt[7], J.K. Wolford[1].* 1) Diabetes & Obesity Unit, TGen, Phoenix, AZ; 2) Psychiatry Dept, U of Utah, Salt Lake City, UT; 3) Div of Biostatistics, Washington U, St. Louis, MO; 4) Dept of Psychiatry, U of Pennsylvania, Philadelphia, PA; 5) Dept of Epidemiology, U of North Carolina, Chapel Hill, NC; 6) Pennington Biomedical Center, Louisiana State U, Baton Rouge, LA; 7) Cardiovascular Genetics Div, U of Utah, Salt Lake City, UT.

To date, five genome scans, including two independent analyses using the same population, have been performed to identify loci underlying quantitative lipid levels in African Americans, but with results that have been largely inconclusive. Linkage analyses are often limited by both sample size and heterogeneity, which may lead to nominal LOD scores or lack of evidence for linkage; the use of meta-analysis to combine linkage results from populations with similar ethnic backgrounds has been proposed as a method to overcome these issues. Thus, we performed a meta-analysis using data from lipid studies conducted in African American families to identify genetic regions showing evidence for linkage across studies. The genome scans were performed using data from: 1) the HyperGen study, 2) obesity-ascertained families, 3) the GENNID study, and 4) the HERITAGE study. We used the Genome Scan Meta-Analysis program to assess evidence for linkage for the following traits: total cholesterol, triglycerides (TG), LDL-C, and HDL-C. In the meta-analysis, p-values were estimated when combining the linkage results for a given lipid trait and were weighted by study size. In addition, a Bonferroni correction was applied to assess genome-wide significance. Significant evidence (i.e., $p<0.00042$) for linkage was found for LDL-C on chromosome 1q32.1-q41 ($p=0.00014$) and 1q41-q44 ($p=0.00017$). We also found suggestive evidence (i.e., $p<0.00847$) for TG on 16p12.1-q11.2 and for HDL-C on 4p15.1-p11. These results indicate that meta-analysis can be a valuable tool for increasing power to detect linkage. Importantly, statistically significant evidence for linkage on chromosome 1q suggests that this region may harbor a gene underlying the inheritance of LDL-C in African Americans.

Identification of two regions predisposing to HTLV-1 infection in childhood by a model-based genome-wide linkage analysis. *S. Plancoulaine[1], A. Gessain[2], P. Tortevoye[2], A. Boland[3], L. Abel[1].* 1) INSERM U550 - HGID, Necker Medical Sch, Paris, France; 2) EPVO, Pasteur Institute, Paris, France; 3) Centre National de Genotypage, Evry, France.

Background Human T-cell leukemia/lymphoma virus type 1 (HTLV-1), is a human oncoretrovirus which causes an adult T-cell leukemia/lymphoma and a chronic neuromyelopathy. We previously showed by segregation analysis that a major gene controlled HTLV-1 infection in children of African origin living in a high endemic area. The aim of the present study was to map this major gene by means of a genome-wide scan.

Methods A total of 52 subjects belonging to 5 families were genotyped for 382 microsatellites markers spanning the entire genome. Linkage analysis was performed using a dominant model of transmission with parameters estimated by our previous segregation analysis. We conducted two kind of analyses. The first one, denoted as affected only, considered only the HTLV-1 seropositive subjects. In addition to seropositive subjects, the second strategy, denoted as intermediate, also considered seronegative offsprings born of seropositive mothers. Refined mapping was performed within regions with at least suggestive evidence for linkage (lod score = 2).

Results Two regions provided evidence for linkage. The first region was identified on chromosome 2 (lod score = 2.94) using the intermediate analysis. Evidence for linkage to this region was even stronger (lod score = 3.04) when considering only the larger pedigree of the sample. The second region was identifed on chromosome 6 (lod score = 2.89 in the whole sample) by the affected only analysis. The investigation of one candidate gene within each region is ongoing.

Conclusions Genome-wide linkage studies confirm the existence of at least one major locus controlling susceptibility to HTLV-1 infection in children (i.e. acquired through breast-feeding) of African origin.

Asso-Link : association with the evidence of linkage when parents are not typed. *C. DINA[1], C. LECOEUR[1], P. FROGUEL[1,2].* 1) Lille Biology Institute , CNRS, Lille, Nord-PdC, France; 2) Genomic Medicine and Genome Center, Hammersmith Campus, Imperial College London, UK.

When genetic linkage has been identified, association analysis of single-nucleotide polymorphisms (SNPs) is carried out within the linkage region. If a SNP shows evidence of association, it is useful to know whether it can explain the linkage result. We have developed a method, Asso-Link, that evaluates the lod-scores for affected sib-pairs Identical By State (Boutin, et al., 2003). We here evaluate the properties of our method when the parents are not typed, which is common for complex diseases and propose an extension to general pedigree structure and quantitative traits. Asso-Link evaluates the relation of the candidate SNP genotype vector (Gj) with the linkage statistic. This method uses all the possible inheritance vectors Sj, for a family, together with all the possible Founder Genotypes Labels (FGL) combinations, which defines the distribution of all Gi. The probabilities of the different FGL states, when the parents are untyped, depends on allele frequencies (F) and non-founders genotypes (NFG). The relation between the lod-score and Gj is compared to its expected value under several H0 hypotheses. To investigate the methods properties, we simulated familial data under a model including single gene, polygenic and environmental effects. From simulated data, we extracted families with homozyguous parents to estimate the confounding between association with trait and association with the linkage. Our method yields correct p-values under the hypothesis of no association, with 5 percent of replicates displaying a nominal p-value of 0.05. However, when parents are not genotyped, the choice of F influences the p-value for association with linkage. When we use the population allele frequency, our Asso-Link test is a simple test of association whereas using the allele frequency estimated in the sample and the NFG data assesses the real impact on linkage. Although a significant association result is important, we need to distinguish this result with the association with the evidence of linkage. In terms of power, our method performs as well as similar tests like GIST.

Indication for a pleiotropic effect of a quantitative trait locus (QTL)on two asthma-related phenotypes in 295 French EGEA families. *A. Ulgen[1], E. Bouzigon[1], M.H. Dizier[2], J. Maccario[3], C. Krähenbühl[1], A. Lemainque[4], M.P. Oryszczyn[3], F. Kauffmann[3], M. Lathrop[4], F. Demenais[1].* 1) INSERM EMI0006, Evry; 2) INSERM U535, Villejuif; 3) INSERM U472, Villejuif; 4) Centre National de Génotypage, Evry, France.

A genome-wide screen for asthma and seven asthma-related phenotypes was recently conducted in 295 EGEA families ascertained through asthmatic probands. This scan showed potential evidence for linkage of 21q22 region to two asthma-related phenotypes: %predicted FEV1 (forced expiratory volume in 1 second, a quantitative measure of lung function) and SPTQ (number of positive skin test responses to 11 allergens, a measure of allergen polysensitization). Moreover, principal components of genome-wide lod scores indicated that these phenotypes may share genetic determinants. To investigate whether the 21q22 region may contain a QTL with a pleiotropic effect on %FEV1 and SPTQ, we conducted a multivariate linkage analysis based on Haseman-Elston regression method, using a fine map of 13 microsatellites (average spacing of 3 cM). This multivariate analysis indicated linkage in the same region as univariate analyses with a p-value of 0.0001 (at 35 cM), this p-value being lower than the p-values previously obtained when analyzing %FEV1 and SPTQ separately (p=0.002 for %FEV1 and p=0.004 for SPTQ). This result suggests that the 21q22 region may contain a QTL underlying these two phenotypes. Further analysis based on bivariate variance component method will be carried out to further investigate this finding.

Comorbidities in ADHD: Pleiotropy and New Susceptibility Loci. *M. Jain[1], L.G. Palacio[1], F.X. Castellanos[2], J.D. Palacio[3], D. Pineda[3], M.I. Restrepo[3], J.F. Muñoz[3], F. Lopera[3], D. Wallis[1], K. Berg[1], J.E. Baily-Wilson[1], M. Arcos-Burgos[1], M. Muenke[1].* 1) Natl Human Genome Research, Natl Inst of Health, Bethesda, MD; 2) New York University Child study Center, New York, NY, USA; 3) Neurosciences Group, University of Antioquia, Medellin, Colombia.

Attention deficit/hyperactivity disorder (ADHD) that is comorbid with Oppositional Defiant Disorders (ODD), Conduct Disorder (CD) and Substance Abuse/Dependence appears to be a subset of the phenotypic ADHD spectrum. Because of its high heritability this combination of behavioral disorders has been particularly suited for molecular genetic studies. We applied segregation and linkage analyses in a set of extended and multigenerational families of a genetic isolate densely segregating ADHD comorbid with disruptive behaviors such as ODD, CD, Alcohol Abuse/Dependence, and Nicotine Dependence and found evidence for the presence of pleitropy. Our data suggest that ADHD plus comorbid disruptive behaviors are monogenic cosegregating as a discrete unit as evidenced by the highly significant linkage among these traits: ADHD and ODD (LOD = 14.19), ADHD and CD (LOD = 5.34), ODD and CD (LOD = 6.68) and CD and Alcohol Abuse/Dependence (LOD = 3.98). In addition to previously reported ADHD susceptibility loci, 4q13.2, 5q33.3, 8q11.23, 11q22, and 17p11, we found significant evidence of linkage for this severe ADHD phenotype to a locus at 8q24, and suggestive evidence of linkage for loci at 2p21-22.3, 5p13.1-p13.3, 12p11.23-13.3, 8q15, and 14q21.1-21.2, 1. These results were replicated using as affected status a phenotype constituted by latent classes clustering individuals with ADHD plus disruptive behaviors symptoms. Based on our data we conclude that patterns of cosegregation of ADHD with comorbidities are crucial for understanding the inheritance patterns not only for ADHD, but also of other behavioral disorders in general. Furthermore, a refined description of the severe ADHD phenotype involving the cosegregation profile of comorbidities will be a powerful tool to define significant regions of linkage in the human genome.

Evaluating power and false positive rates using Gaw 14 data. *R. Li[1], Y. Yao[2].* 1) Life Science, Fudan University, shanghai, China; 2) Epidemiology, Johns Hopkins Bloomberg School of Public Health.

FBAT is a unified approach based on the classical TDT method. The basic idea underlying this method is to compute the distribution of FBAT statistic under the null hypothesis, conditional on the observed phenotypes, and compare the statistic distribution deriving from observed genotype to it. It allows the use of different genetic models and tests of different null hypotheses. The aim of our project is to investigate the effect of different options in FBAT on power and false positive rate. In order to test type-I error we used all purchased packets, and the ones that involving the chromosomes 1 and 3 where disease loci locate were excluded. And all the 100 replicates were analyzed. False positive rate (FPR) is defined as proportion of markers of which test statistic gets significant p-value (0.05). We performed multiple FBAT analyses to compare the FPR using different inheritance models, different sets of offset and different null hypothesis. We evaluated the power to detect association using the SNP marker B03T3067. It situated on top of the disease locus involved in P1. The power for association analysis is defined as the number of replicates gave a p-value less than 0.05. Power under different genetic model, different use of offset and different null hypothesis was calculated. We used Haploview to perform association analysis on marker B03T3067 for the purpose of comparison. Under dominant model the false positive rate is 0.09, which is much higher than empirical type-I error. To calculate power, we performed FBAT analysis using B03T3067. It was carried out under different model of inheritance, diffent offsets. Power under dominant model is higher than additive one if we chose to use a general FBAT statistic. However there is insignificant difference between two models if we used the -e option. For incorporating offset in construction of test statistic -o option did not improve power. In conclusion, we found that false positive rate is inflated under a dominant model.

Comparisons of mining methods for gene mapping using family-based and population-based SNP data. *C.H. Chen[1], L.Y. Wei[1, 2], C.L. Huang[2, 3].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Information Management, Huafan University, Taipei, Taiwan; 3) Department of Information Management, National Kaohsiung First University of Science and Technology, Kaohsiung, Taiwan.

Data mining methods have been widely applied to deal with complicated data. Several studies had demonstrated the use of data miming skills in genetic research. However, some of the methods were developed under specific genetic models or for data with restricted properties. Improper use of these methods might result in false positives. This study aims to symmetrically assess the application of four data mining methods for detecting genes susceptible to diseases. Family-based and population-based data are simulated under a grid of genetic models. Genetic factors considered in the disease locus are inheritance mode, disease allele frequency, and penetrances. Two-locus Heterogeneity is also incorporated in the data. Qualitative traits are generated based on disease locus. Linked SNP markers in candidate regions are simulated with various recombination fractions and first order linkage disequilibrium measurements. In this study, four data mining methods are inspected, including Decision Trees (C4.5 and RTREE), Johnson Algorithms combined with Rough Set Theory, and Genetic Algorithms combined with Rough Set Theory. Power or the probability of correctly identifying the susceptibility genes is calculated for comparison. Our results show that, in general, high penetrances lead to higher powers under all models for all methods. However, the four methods fail when the perentrance is lower than 0.25. The combining of genetic algorithms and Rough set theory produces the highest power in family-based data under single gene models, while, under two-locus heterogeneity models, Decision trees C.5 and RTREE has the highest power in population- and family-based data respectively. The four methods have similar performance in population-based data under single gene models. In summary, the use of data mining methods should base on the characters of data in order to reduce false positives.

Using conditional linkage to detect epistasis or heterogeneity. *D. Shmulewitz[1,2], J. Zhang[2], L.J. Strug[2], D.A. Greenberg[1,2,3].* 1) Department of Psychiatry; 2) Division of Statistical Genetics, Department of Biostatistics, Columbia University, New York, NY; 3) New York State Psychiatric Institute, New York, NY.

Introduction: Complex diseases are most likely caused by a number of genes. Each may act alone (heterogeneity, H), or interact (epistasis, E), or a combination of both. We are often able to identify such genes singly, using linkage analysis. But we need to determine if these genes act alone or interact to cause disease. One suggestion is to condition on the linkage at one locus to determine if a second locus is involved. In this scheme, to detect E, families with positive npl scores at the first locus are used to calculate an adjusted npl score for locus 2 (2-adj). To detect H, families with negative npl scores for the first locus are used to calculate 2-adj. Depending on the above weighting scheme, if 2-adj is greater than the original locus 2 score (2-orig), that is evidence for either E or H. **Method:** We tested this method by simulating 100 datasets of 100 families for a number of genetic models, with E, H, or both. By design, linkage existed and was detectable at the two loci being tested. E or H were detected if 2-adj was greater than 2-orig. **Results:** H was detectable for two genetic models, R-R (recessive at both loci) and R-D (recessive at locus 1, dominant at locus 2), but only when the original evidence for linkage was much greater at the first locus. The empirical power to detect H (% datasets with 2-adj > 2-orig) was 51.1% and 58.8% for the R-R/R-D models. E was detectable only for the RR (recessive at both loci) model, but only when data were simulated such that a third locus independently caused disease. The power to detect E was 61% when the third locus was recessive, and 52% when it was dominant. **Discussion:** Thus only in certain cases will conditioning on linkage at one locus indicate evidence for a more complex genetic model. Even in these experiments with ideal data the power is low. Therefore, conditioning on linkage at one locus may be of limited utility in determining the underlying genetic models.

Random forest analysis: a novel approach for exploring the genetic component in multiple sclerosis (MS). *E. Madden[1], A. Cutler[2], S. Sawcer[3], A. Compston[3], J.R. Oksenberg[1], S.L. Hauser[1], M.A. Pericak-Vance[1], J.L. Haines[1], G. Stewart[4], L. Peltonen[5], L. Massacesi[6], T. Masterman[7], J. Hillert[7], M.G. Marrosu[8], M. Eraksoy[9], L.F. Barcellos[1].* 1) US MS Genetics Group, UCSF; 2) Utah State Univ; 3) Univ of Cambridge, UK; 4) Univ of Sydney, AU; 5) Univ of CA, Los Angeles; 6) Univ of Florence, IT; 7) Karolinska Inst, SE; 8) Univ of Cagliari, IT; 9) Univ of Istanbul, TR.

Despite strong evidence for polygenic inheritance in MS, only the MHC (ch. 6p21) region has consistently demonstrated linkage and association. It appears that the HLA-DRB1*15 association largely explains this linkage signal; however, the exact mechanism(s) by which MHC gene(s) operate in MS are not known. Genome screens have been performed in MS, but results suggest the existence of genes with strong individual effects in MS is not likely. Novel non-parametric approaches such as tree-based classification methods that accommodate large marker datasets and allow for genetic heterogeneity may be useful for MS studies. Recent theoretical work has also shown that the prediction accuracy of classification trees is significantly improved by building a collection of trees, or a so-called Random Forest(RF). Whole genome screen data for 824 MS ASPs from 8 populations was pooled and analyzed using a RF approach, to identify evidence for loci potentially interacting with the MHC region. Genetic sharing (mean IBD) at other regions of the genome (3 cM map intervals), country and gender distribution for each MS sib pair (total of 1176 predictors) were used to predict sharing at HLA-DRB1 (outcome). The no. of variables considered at each node was 400; the final error rate was 2.3 % (based on 10,000 trees). As expected, the genomic regions where sharing was most important in predicting DRB1 sharing were in close proximity to this locus (+/-3 cM on each side); however, no evidence for country, gender or sharing at loci outside of the MHC as predictors of DRB1 sharing was observed. Using this novel approach, our results strongly suggest that loci outside the MHC are not contributing substantially to influence risk in patients stratified by sharing at DRB1.

Recruitment strategies and DNA marker selection for maximizing power of linkage analysis. *A.L. Maes[1,2], S.R. Diehl[2].* 1) Merck Research Laboratories, Rahway, NJ; 2) Center for Pharmacogenomics & Complex Disease Research, New Jersey Dental School, UMDNJ, Newark, NJ.

A common ascertainment strategy is the affected sibpair design. Previous studies suggest that recruitment of parents of affected sibs is highly desirable, but this is difficult for diseases with late age of onset. DNA may be unavailable from deceased parents, and its often not possible to confidently assign disease phenotypes for parents. Less attention has been paid to unaffected sibs of affected sib pairs. We used computer simulation to evaluate the relative contributions to linkage mapping power of parental disease phenotypes and availability of marker genotypes for parents and/or for 1 to 3 unaffected sibs. Penetrance of 25%, 50% and 75% under dominant and recessive transmission were evaluated. Several recent studies have examined the power of high density SNP maps as alternatives to microsatellites. We simulated a high density SNP map with markers spaced at 0.1 cM intervals and a map of SNP islands (3 SNPs located 0.1 cM apart with islands at 2 cM intervals). We compared these to microsatellites (8 alleles) spaced at 2-, 5- and 10-cM distances. Lastly, we introduced genotype errors of 1% or 5% to compare loss of power for our various pedigree structures, genetic maps, and disease models. Simulated data were analyzed using GENEHUNTER (GH, v2.1r5). HLOD scores under the true (generating) model and maximized over disease models with correction (MMLS-C), and the Information Content (IC) measure were calculated by GH. Results demonstrate that i.) parental disease phenotypes increase power more than parental marker genotypes; ii.) adding a single unaffected sib often adds as much or more power as both parents, even at low penetrance; iii.) SNP islands perform substantially better than 10 cM microsatellite maps, equivalent to 2 cM microsatellite maps or SNPs at 0.1 cM intervals; iv.) 1% SNP genotyping error causes > 50% loss of power in data sets of affected sibs only, but even 5% error is compensated by genotyping either both parents or 2 unaffected sibs (deleting markers in families with inconsistencies); the IC statistic fails to reflect these differences in power.

Gene dropping vs. empirical variance estimation: A comparative study of standardization methods for allele-sharing statistics. *J. Jung, D.E. Weeks, E. Feingold.* Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

In this study, we compare the statistical properties of a number of methods to find p-values for allele-sharing statistics in nonparametric linkage analysis. Some of the methods are based on the normality assumption, using different variance estimation methods, and others use simulation (gene-dropping) to find empirical distributions of the test statistics. For variance estimation methods, we consider the perfect variance approximation and two empirical variance estimates. The simulation-based methods are gene-dropping with and without conditioning on the observed founder alleles. We also consider a Monte Carlo method proposed by Lin and Zou (2005). We discuss the analytical properties of these various p-value estimation methods, and then present simulation results comparing them. Assuming that the sample sizes are large enough to justify a normality assumption for the linkage statistic, the best p-value estimation method depends to some extent on the (unknown) genetic model and on the types of pedigrees in the sample. If the sample sizes are not large enough to justify a normality assumption, then gene-dropping is the best choice. We discuss the differences between conditional and unconditional gene dropping.

Importance of allowing for dominance in variance components linkage analysis: Examples using dyslexia and cardiovascular disease. *N.H. Chapman[1], R.P. Igo Jr.[1,2], E.M. Wijsman[1,2].* 1) Department of Medicine, Division of Medical Genetics; 2) Department of Biostatistics; University of Washington, Seattle, WA.

Variance component (VC) methods are a popular approach to linkage analysis, in part because they are generally believed to be model-free. The model implicitly assumed in most software includes an additive major gene, and a polygenic component in which the individual loci are all additive. In fact, any locus may act in a way that is not exactly additive; in this case a non-zero dominance VC exists. If only sib-pairs are available, the additive and dominance VCs cannot be separately estimated. However, when extended families are available, dominance VCs can be estimated.

Models including dominance VCs can be fit using Genehunter (for small pedigrees) and SOLAR. In recent work involving a quantitative trait related to dyslexia in non-randomly ascertained families, we used a model that included a dominance VC for the major gene, but not in the polygenic part of the model. The results were difficult to interpret, due to a high background lod score in regions of the genome where no signal was apparent. Including a dominance VC in the polygenic part of the model solved this problem, demonstrating the importance of including dominance VCs in both parts of the model.

The question remains as to whether including dominance VCs will yield results that are qualitatively different from using a model with additive variance alone. The answer is dependent on the data set and trait in question. We give an example of HDL-cholesterol levels in 4 pedigrees of between 48 and 88 individuals where the inclusion of dominance VCs results in a substantial increase in the lod score (from 0.4 to 1.7). These pedigrees are extended families with multiple large sibships, which is exactly the situation where one would expect to get good estimates of both additive and dominance variance components.

Analysis of continuous covariates in affected sib-pair linkage studies: Am I finding susceptibility or quantitative trait loci? *S. Schmidt, M. Schmidt, E.R. Martin, E.R. Hauser.* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Data sets ascertained for the genetic analysis of complex human diseases often include a number of continuous covariates, which may be risk factors for a dichotomous disease phenotype, endophenotypes, quantitative biomarkers, or other disease-related phenotypic features. These covariates may influence the disease trait in two different ways: (A) They may be truly environmental, but may define a more genetically homogeneous subset of families with increased linkage evidence for a disease susceptibility locus, compared to the entire data set. (B) They may themselves have a genetic basis, causing the underlying quantitative trait locus (QTL) to contribute indirectly to disease risk. We performed a simulation study with the software SIMLA in order to evaluate whether the application of two distinct analysis methods to the same data set, the ordered subsets analysis (OSA) and a QTL analysis (MERLIN-REGRESS), would be informative for distinguishing between (A) and (B). Our results can be summarized as follows: (i) When the covariate is a risk factor for disease and its distribution in the population is influenced by a QTL, both OSA and MERLIN-REGRESS are very likely to detect the QTL. (ii) When the covariate is not a risk factor but does have a genetic basis, OSA is much less likely than MERLIN-REGRESS to detect the QTL. (iii) When the covariate distribution is not influenced by a QTL but confers a greatly increased disease risk only in the presence of a disease susceptibility genotype (gene-environment interaction), OSA is much more likely than MERLIN-REGRESS to detect linkage to the disease susceptibility locus. These findings assist in the interpretation of analysis results in real data sets. They suggest that concordance or discordance of OSA and QTL results may be indicative of underlying genetic mechanisms related to disease risk.

Comparison of two binning strategies for linkage genotypes on blood and archival tissue samples: the PACGENE experience. *G. Petersen[1], S. Grimes[2], K. Rabe[2], C. Olswold[2], M. Goggins[3], M. de Andrade[2].* 1) Health Sci Research, Mayo Clinic, Rochester, MN; 2) Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) Johns Hopkins University.

The Pancreatic Cancer Genetic Epidemiology (PACGENE) consortium comprises seven institutions with ongoing efforts to rapidly ascertain and recruit familial pancreatic cancer patients and relatives, including accrual of biospecimens, tumor tissue, and risk factor data, with the goal of susceptibility gene discovery by linkage analysis. To date, 50 families with 412 blood samples and 31 archival tissues have been genotyped for 405 microsatellite markers at the Center for Inherited Disease Research (CIDR). Feasibility of genotyping DNA from archival tissues and combining these data with blood DNA genotypes on pedigrees from the Center for Inherited Disease Research has been demonstrated by the Genetic Epidemiology of Lung Cancer Consortium. However, our study is the first to use the same platform to generate genotypes from both lymphocytes DNA and DNA from archival tissues. We have developed an allele calling algorithm that accommodates the two sources of genotypes. To assess the efficiency of our algorithm, we compared it to the conventional CIDR allele binning algorithm. . Concordance rates on alleles called by the two algorithms were performed for all autosomal chromosomes. The average rate was 88%, with minimum and maximum rates of 66.7% and 100% in 2 and 3 chromosomes, respectively. To evaluate the efficiency of these two strategies, we compared the Mendelian errors in these chromosomes. These preliminary results suggest the important role played by the type of markers and the length repeats in defining the allele calls.

A novel method for linkage disequilibrium mapping of quantitative trait loci. *H.H.H. Goring[1], S. Nair[1], D. Sudimack[1], F. Nosten[2], J.T. Williams[1], T.J.C. Anderson[1].* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Shoklo Malaria Research Unit, Maesot, Thailand.

Some investigators view genome-wide linkage disequilibrium (LD) analysis as the most promising strategy for deciphering the genetic etiologies of complex traits in humans. This belief is spurred by vast improvements in genotyping technology and by the potential existence of haplotype blocks. Most applied genome-wide association studies, as well as related research on statistical methodology, have focused on dichotomous disease phenotypes in a case-control study design framework. The emphasis on clinical disease endpoints may be suboptimal, and quantitative endophenotypes correlated with disease may be more suitable targets---for linkage analysis and for LD analysis alike---because of their likely simpler etiology and larger information content. When multi-allelic data are used (such as microsatellites or SNP haplotypes), the power of association analysis may be greatly reduced because of the multitude of degrees of freedom (df). We have therefore adapted the approach developed by Terwilliger for LD analysis of multi-allelic data and discrete traits (AJHG 56:777) for use with quantitative traits. The key benefit of our approach is the reduction in number of df to 1, rather than the usual n - 1 (with n being the number of observed alleles or haplotypes). The reduction in df is achieved by making the critical assumption of a single ancestral functional site. The approach does not assume knowledge of which marker allele/haplotype is on the ancestral chromosome, and instead weights over all possibilities. The approach can be powerful even if the assumption of a single origin is not correct. We have applied our method by performing genome-wide association analysis for drug resistance loci in the genome of the malaria parasite *Plasmodium falciparum*. Using the approach, we were able to successfully detect association between mefloquine resistance and a known multi-drug resistance locus on chromosome 5 and have located a number of other potentially interesting candidate regions. Details of the statistical methodology and its application will be presented.

Bias-Reduced QTL Effect Size Estimation Via Statistical Resampling. *L. Wu[1], L. Sun[2,3], S.B. Bull[1,2].* 1) Samuel Lunenfeld Research Institute,Toronto,Canada; 2) Department of Public Health Sciences, University of Toronto, Toronto,Canada; 3) Hospital for Sick Children, Toronto, Canada.

In genome-wide linkage analysis the locus-specific effect estimate is subject to upward selection bias because of the genome-wide maximization of the test statistic and the adoption of stringent significance criteria. Göring et al. (2001)demonstrated inflation in genetic effect estimation in a variance-components linkage analysis of quantitative-trait-loci (QTL). We employed Görrings simulation scheme and investigated the resampling techniques proposed by Sun and Bull (2005) to reduce the selection bias.We performed the linkage scan and locus-specific QTL-heritability estimation with an extension of Haseman-Elston regression procedure (Sham et al., 2002) implemented in Merlin (Abecasis et al. 2002). We constructed three bootstrap-based estimators: the shrinkage estimator, the out-of-sample estimator and the weighted estimator. We investigated each of six simulation settings (0 to 5 QTLs) with true locus-specific QTL-heritability of 0.1. In each of 500 replications we estimated the QTL-heritability at the locus with the maximum test statistic in the genome scan. All three estimators effectively reduced the upward bias in estimation of locus-specific QTL-heritability and the shrinkage estimator provided the best bias reduction overall. We also extended this method to jointly estimate the genetic effects of multiple loci for the case where there are several loci meeting genome-wide significance.

QTLs	True and False peaks		True Peaks		False Peaks	
	Naive	Shrinkage	Naive	Shrinkage	Naive	Shrinkage
1	.226	.035	.143	-.044	.242	.050
5	.250	.005	.211	-.033	.303	.058

Mixed effects logistic approach for association following linkage scan for complex disorders. *H. Xu, S. Shete.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

Large scale population-based association studies at genomic level hold substantial promises for unravelling the genetic basis of complex disorders, in which the etiology usually involves both genetic and environmental factors. Family-based association procedures such as transmission disequilibrium test (TDT) has less power in detecting association than the properly controlled population-based procedures. Because of the relatedness of family members, using affected family members and unrelated normal control directly leads to false positive results in association studies. In this study, we propose a new approach using mixed model logistic regression in which associations were performed using family members and unrelated controls. Thus, the information contained in family members can be fully explored while retaining the high power. To examine the properties of the new approach, we developed an efficient algorithm to simulate environmental risk factors and the genotypes at both the disease locus and a marker locus with/without linkage disequilibrium (LD) in families. Extensive simulation study showed that our approach can effectively control the Type-I error rate. Our approach is better than family based designs such as TDT because it allows the use of unrelated cases and/or controls and it uses all the affected members in the study for whom DNA is possibly already available. Our approach also allows the inclusion of covariates such as age and smoking status. Our method can be further extended to accommodate more complex pedigree structures.

On the use of maximal segmental score to estimate regional specific p-value in gene mapping studies. *C.S.J. Fann[1,2], I.B. Lian[3], C.L. Kuo[2].* 1) Epidemiology & Public Health, Inst Biomed Sci, Acad Sinica, Taipei, Taiwan; 2) Institute of Public Health, Yang-Ming University, Taipei, Taiwan; 3) Department of Mathematics, National Chang-Hua University of Education, Chang-Hua, Taiwan.

Identifying the susceptible disease gene is an important issue in biomedical research. To do this, one of the popular tools is to use highly-dense SNP markers to perform large scale association tests. In these studies, multiple test correction for type I error is needed. Conventional methods, such as Bonferroni¡¦s method, are conservative with low statistical power. Previously, we proposed using the distribution of the ¡§longest significant run¡¨ to attain ¡§region-specific p-value¡¨, in which a sequence of p-values from single marker tests were firstly converted into binary indices of zero and one according to a preset cutoff (e.g. p = 0.05). In this project, to reduce the loss of information due to a simple cutoff, we extended the idea of the run of dichotomous index to a more flexible ¡§maximal segmental score¡¨ of polychotomous weight according to the range of p-values. A few weighting strategies were considered. Simulations were carried out to choose the best strategy according to the statistical power and type I error rate under various assumptions on the penetrance, sample size, and disease allele frequency. The results show that weighting strategy using the function of log10 scale of p-value performed best. We also applied the best strategy to three authentic datasets that were available in the public domain and were able to confirm the previous findings.

Excess homozygosity of haplotypes in the presence of population substructure and genetic admixture. *R. Chakraborty, X. Sheng.* Ctr Genome Infor/Env Hlth, 108, Univ Cincinnati, Cincinnati, OH.

Linkage disequilibrium (LD) is generally inferred from deviations of haplotype frequencies from the product of respective allele frequencies. For a pair of biallelic markers, a single LD parameter explains the non-random association of alleles between loci. When one or both loci are multiallelic, the overall non-random association of alleles between loci is a composite function of several allele-specific disequilibria measures. Further, since the observed data generally are in the form of genotypes, and not haplotypes, LD estimation has also been attempted by computing the deviation of multilocus homozygosity from the product of homozygosity values at the respective individual loci (the resultant statistic is called excess homozygosity, or identity excess, IE). Though this formulation does not contrast frequencies of each individual genotype with their expectations under the assumption of independence, IE has some interesting population genetic properties and it is easily computed and directly estimated from observed data. Like LD, IE is also affected by population substructure and genetic admixture. We provide a quantitative evaluation of enhancement of IE by the effects of population substructure and genetic admixture. We show that in the presence of genetic admixture, enhancement of IE by the process of admixture provides provides a better power of conducting a trend analysis of monatomic decay of LD with recombination distance between loci. Consequently, the use of IE-based inference may add power of disease gene mapping by using admixture linkage disequilibrium (MALD) in populations of mixed ancestry where the ancestral populations differ by disease prevalence as well as allele frequencies at the marker loci. Availability of genome-wide MALD SNP markers and their genotype data from the different SNP databases provide opportunity for evaluate the increased power of IE in relation to the traditional LD measure to study variation of LD in admixed versus non-admixed populations.(Research supported by a NIH grant GM41399).

Is localization for complex disease genes via linkage analysis really that bad? *C.W. Bartlett, V.J. Vieland.* Ctr Statistical Genetics Res, Univ Iowa, Iowa City, IA.

It is frequently said that linkage analysis cannot accurately localize genes for complex disorders, and that localization only becomes accurate when linkage evidence is very strong. We set out to test these assumptions, using as our measure of location the position of the maximum 2-pt linkage statistic on a simulated map (for full information and no errors, this is equivalent to localization based peak multipoint lod). We simulated a two-marker map, and varied (1) marker informativeness, (2) pedigree structure, (3) the position of the disease gene relative to each marker, (4) the degree of complexity in the generating trait model, and (5) the degree of misspecification in the analysis model. Our outcome measure was P[M0], the probability that the marker closest to the trait locus (M0) yields the largest statistic. We found that P[M0] appears to be largely independent of both the observed lod score and also the assumed mode of inheritance. Moreover, complicating the generating trait model by introducing locus heterogeneity actually increased the accuracy of localization. What does appear to drive P[M0] is the sample size N, independently of the ELOD associated with given N. E.g., under a simple recessive generating model, a recessive lod yields P[M0] = 52%-92% as N increases from 2 to 50 nuclear families; while analyzing the same pedigrees under a (wrong) dominant model yields P[M0] = 51% - 90% for the same values of N; but ELODs are essentially half as large under the dominant model at each value of N. Thus in these simulations, accurate localization does not depend on large lod scores, trait model misspecification does not adversely affect localization, and heterogeneity can actually improve localization - although *linkage detection* is affected by these things. Across all generating conditions considered thus far, at N = 50 nuclear families P[M0] ? 72.5%. In short, localization based on the 2-pt linkage peak appears to be reliable and robust. Current extensions of this work include consideration of sampling variability across a marker map and effects of marker density.

Genome-wide variation in rates of gene conversion and crossover. *G. Hellenthal, M. Stephens.* Statistics, University of Washington, Seattle, WA.

Recombination is an important biological process that results in the "mixing-up" of human genetic material during cellular meiosis. There are two known kinds of recombination: crossover and gene conversion. There has been considerable recent progress in the development of statistical methods to infer fine-scale rates of crossover from population genetic data (i.e. genetic data on random samples of individuals from a population). Application of these methods to data from human populations suggests that average rates of crossover vary considerably among genes, and that within many genes a large proportion of crossover events occur within very restricted regions ("recombination hotspots"). In contrast, estimating rates of gene conversion has proved more difficult, and little is known about how such rates vary either among or within genes.

Here we aim to gain insight into the extent at which rates of gene conversion vary among genes. To do so, we have developed a statistical method (a modification of the "Product of Approximate Conditionals" (PAC) model of Li and Stephens (2003)) to jointly estimate rates of crossover and gene conversion. We use this within a hierarchical modeling framework to estimate the distribution among genes of the relative rate of gene conversion to crossover. By borrowing strength across genes, we attempt to estimate the parameters of this distribution, with an emphasis on estimating its variance. We applied this method to two datasets on human variation. Our studies thus far suggest that the relative rate of gene conversion to crossover, which researchers have previously assumed to be constant across the genome, may in fact vary by more than an order of magnitude.

$_2$-Adrenergic Receptor Gene (*ADRB2*) Polymorphisms and Asthma in African Americans. *E.G. Burchard[1,2], N. Shaikh[1,2], H.J. Tsai[1,2], J. Kho[1,2], S. Choudhry[1,2], M. Naqvi[1,2], D. Navarro[1,2], H. Matallana[1,2], R. Castro[1,2], C. Lilly[3], H.G. Watson[4], K. Meade[5], M.L. Noir[6], S. Thyne[1], E. Ziv[1].* 1) University of California, San Francisco, CA; 2) Lung Biology Center, San Francisco General Hospital, SF, CA; 3) Brigham and Womens Hospital, Boston, MA; 4) The James A. Watson Wellness Center, Oakland, CA; 5) Children's Hospital and Research Institute, Oakland, CA; 6) Bay Area Pediatrics, Oakland, CA.

Ethnic-specific differences in genetic risk for diseases and drug response are well documented. $_2$-Adrenergic receptor gene (*ADRB2*) variants have been associated with asthma-related traits in different studies. However, association results have been inconsistent across various populations. Also, there is very limited information regarding genetic association between the *ADRB2* and asthma-related traits in African Americans. The biggest limitation for studying genetic association in African Americans is the confounding effect due to population stratification. We genotyped six known and recently identified SNPs, which were selected based on potential biological function and the haplotype structure. Thirty ancestry informative markers were genotyped and used to adjust the confounding effect due to population stratification in our analyses. We compared allele frequencies of the SNP +46 (*Gly^{16}Arg*) in our cohort (264 cases and 176 controls) with the ones reported in various populations including Caucasians, Chinese, Mexicans and Puerto Ricans. Significant genotype associations of bronchodilator response (FEF_{25-75} reversibility and FEV_1 /FVC reversibility) were found with the SNPs -468 and -47 (p=0.017 and 0.001 for FEF_{25-75} reversibility; p=0.037 and 0.012 for FEV_1 /FVC reversibility, separately). Significant haplotype association was shown between the haplotype combination (SNPs -47, +46 and 3'UTR) and asthma disease status. We did not observe association of asthma-related traits with the SNP +46 (*Gly^{16}Arg*), which has been associated in various populations. Our results underscore the importance of investigating genetic associations of the *ADRB2* and other asthma disease genes across different ethnic groups in asthma morbidity and bronchodilator drug responsiveness.

Power Implications of the Dichotomized Continuous Trait FBAT. *D. Fardo, C. Lange.* Biostatistics, Harvard School of Public Health, Boston, MA.

Family-based association tests (FBATs) are used to test associations between a genetic marker and a disease susceptibility locus for many different scenarios. Here we examine the effects of using a binary affectation status based on a continuous phenotype. Based on simulation studies and analytical considerations, we propose a rule for this dichotomization that minimizes power loss under fairly general circumstances. The proposed approach is illustrated using a genetic asthma study.

Linkage Analyses of Diabetic Nephropathy Phenotypes: The Family Investigation of Nephropathy and Diabetes (FIND). *S.R. Quade, K.A. Goddard, for the FIND Consortium.* Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH.

The FIND consortium was established to investigate genetic factors associated with diabetic nephropathy (DN) using both family-based and case control approaches. Genotyping was performed on 1227 individuals at 404 microsatellite markers from 378 families of African American (AA), American Indian (AI), European American (EA), and Mexican American (MA) descent. Model-free linkage analyses were conducted separately for each ethnicity using sib pairs concordant or discordant for DN, and p-values were pooled across ethnicities. We applied the Haseman-Elston (HE) procedure to quantitative intermediate phenotypes for DN including proteinuria and glomerular filtration rate (eGFR) estimated using the Modification of Diet in Renal Disease equation. Under the HE test we observed evidence of linkage for DN on chromosomes 7q, 10p and 15q (empirical p-values=5.99x10-4, 2.0x10-5 and 4.80x10-4, respectively). The AA families contributed to peaks on 7 at 102cM and 15 at 84 cM and the AI families contributed to the peak on 10 at 0 cM. We observed significantly decreased sharing among the discordant AA and AI sib pairs at locations on chromosomes 7 and 10 respectively, and slight evidence for decreased sharing on 15. Locations on 7 and 10 also show evidence of increased allele sharing among the AA and AI affected sib pairs respectively, consistent with the expected pattern of allele sharing for true susceptibility loci. Linkage signals for proteinuria were observed on 14q (94 cM, p=1.71x10-3) and 17q (82 cM, p=1.30x10-2) in MA families and 6q (80cM, p=2.65x10-3) in EA families, after adjusting for sex and age at diabetes onset. Suggestive linkage signals for eGFR were observed on 1q (266 cM, p=8.99x10-5) and 8p (52 cM, p=9.20x10-5) for the MA families, 6q (158 cM, p=4.48x10-4) and 15q (60cM, p=1.41x10-5) for the AI families, and 14q (55cM, p=2.69x10-3) for the EA families. In 2006, a complete genome scan will be performed using single nucleotide polymorphism markers. This scan will provide better power to detect our weaker signals and will hopefully replicate our significant signals.

Study design and analysis issues in whole genome association studies. *J.C. Barrett[1], I. Pe'er[2], M.J. Daly[2], L. Cardon[1].* 1) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, United Kingdom; 2) Broad Institute of Harvard and MIT, Cambridge, MA.

Falling SNP genotype costs and the recent availability of genome-wide surveys of genetic variation have made whole genome association (WGA) studies imminent. Despite such advances these studies are still expensive and present significant analytical hurdles. It is important, therefore, to consider what the goal of a WGA study is, how well newly developed SNP panels address that goal and how downstream analysis choices influence the interplay of those two questions.

One crucial choice is deciding upon a set of "target variants" that we wish to test for association to disease. Alternative strategies have proposed focusing on coding variants, SNPs in genes or conserved regions, or all known variants. An orthogonal axis to this choice concerns the desired allele frequency spectrum. Further complicating these issues is the relationship between the set of genotyped SNPs and subsequent association tests and analysis.

Recent data from the HapMap project and Perlegen have made it possible to examine how well current and soon-to-be-available SNP genotyping products can capture "target sets", and to explore the consequences of initial marker selection on subsequent analyses. Using the available data, we compare different gene-based SNP panels with LD-derived and LD-agnostic panels of 100,000, 250,000 and 500,000 SNPs. We show how the initial genotyping strategy strongly influences later analysis choices and the eventual chances for identifying specific trait loci. Our results emphasize the importance of considering the entire study from SNP selection to final analysis in order to maximize power.

Genotype-by-smoking interaction and burden of aortic atherosclerosis: The NHLBI Family Heart Study. *K.E. North[1], L.A. Lange[2], J.J. Carr[3], I.B. Borecki[4], A. Kraja[4], M. Province[4], J.S. Pankow[5], J.B. Wilk[6], J.E. Hixson[7], G. Heiss[1].* 1) Epidemiology, UNC, Chapel Hill, NC; 2) Genetics, UNC, Chapel Hill, NC; 3) Radiol Sci, Wake Forest Med, Winston-Salem, NC; 4) Biostat, Wash U Med, St. Louis, MO; 5) Epidemiology, U of Minn, Minneapolis, MN; 6) Neurology, BU Med, Boston, MA; 7) Hum Genetics, UTHSC, Houston, TX.

There is growing evidence that complex interactions among genetic and environmental factors influence the pathogenesis of atherosclerosis. In previous work in the NHLBI Family Heart Study (FHS), two QTLs for calcified aortic plaque, (CAP) on chromosomes 7p and 13q were localized. In this study, these analyses were extended to incorporate additive and QTL specific genotype-by-smoking interaction. Families in FHS were recruited from five US study centers. During standardized clinical exams smoking habits were ascertained and CAP was quantified with helical CT. MGS typed a total of 398 microsatellite markers. Among 2,133 Caucasians comprising 4,703 relationship pairs variance component linkage analysis in both in the full sample and samples stratified by smoking exposure dichotomized as ever/never, current/non-current, and, 15 or 20 pack-years/ 15 or 20 pack-years of smoking was performed in SOLAR. Marker allele frequencies derived from pedigree founders were used to estimate multipoint identity-by-descent sharing using GeneHunter. The mean value of CAP was 3246 in men and 1923 in women. Ever smoking was reported by 907 participants, whereas only 194 reported that they currently smoked. Adjusting rank transformed CAP for age, sex, and center, significant additive genotype-by-smoking interaction was detected for all measures of smoking exposure (all p 0.05). QTL specific genotype-by-smoking interaction was detected in smokers with 15 pack-years smoking exposure (maximum adjusted LOD = 4.3) on chromosome 4 at 102 cM and in smokers with 20 pack-years of smoking exposure on chromosome 2 at 264 cM (adjusted LOD = 3.1). These findings will be further tested in the African American FHS sample, upon completion of genotyping. Accounting for genotype-by-smoking interaction in the pathogenesis of CAP improves our ability to detect QTLs.

Reliability of high throughput genotyping of whole genome amplified DNA in large-scale genotyping studies. *Y. Berthier-Schaad[1], W. Kao[1], L. Zhang[1], N. Fink[1], J. Coresh[1], M. Smith[2].* 1) Department of Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD.

Whole genome amplification (WGA) of DNA has been proposed as the solution for limited DNA in human studies. Previous studies have examined the reliability of genotyping of WGA DNA samples, but they have focused on small number of SNPs or individual samples (N<5) or on samples derived from cell lines. We determined the reliability of WGA DNA genotypes in two sets of replicated samples: (1) WGA-original: 33 pairs of original DNA vs. WGA DNA and (2) WGA-WGA: 32 split samples of WGA DNA. WGA DNA samples were amplified using the multiple displacement amplification method (MDA). Genotyping was successful for 1362 of 1536 SNPs from 164 cardiovascular candidate genes in a single Illumina panel. Percent of successful SNP calls and kappa statistics () were calculated for all SNPs and by Illumina SNP assay score and gen_call score. In the 33 WGA-original pairs, mean call rate for original DNA samples was significantly higher than that of WGA samples (99% vs 93%). Approximately 5% of assays that were successfully typed in original samples were not in WGA samples. A total of 41,428 pairs of WGA-original genotype data were available for genotype concordance analysis. Mean for WGA-original pairs was 0.98. Concordance between WGA-original pairs was high irrespective of either SNP assay score or gen_call score. Reproducibility was lower amongst WGA-WGA pairs (mean for the 32 WGA-WGA pairs was 0.89; inter-quartile range: 0.84-1.00). However, the lower concordance was largely driven by 18 WGA-WGA pairs where the original DNA was not of sufficient quality or quantity for the Illumina platform. In summary, the MDA method produces WGA DNA samples that can be genotyped using high-throughput technology with slightly lower call rates but very high reproducibility to the original DNA. These results also indicate that variability in the original DNA quality plays a role in WGA reproducibility. This method of DNA amplification will be useful for future large-scale genetic analyses in studies with limited DNA.

Can genes act as mediators describing the gene-environment interaction effects on obesity? *B.M. Chakraborty[1], M.B. Rao[2], R. Chakraborty[2].* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Center for Genome Information, Univ. Cincinnati, OH.

Gene-environment interaction (GxE) effect on phenotypes is described by heterogeneity of environmental (E) effects across different genotypes, or by genotypes (G) having different phenotypes under different environments. GxE effects may be significant even in the absence of main effects of G and/or E. Distinctions of different forms of GxE effects have been used in psychological and nursing studies by utilizing the concepts of mediators and moderators. Statistical methodologies (structural equation models and path diagrams) have been used to distinguish these two forms of interactions, but in the genetic context the explicit distinction of different forms of GxE effects has been limited. For example, in obesity research, twin/adoption studies suggest that 30-70% of the inter-individual variation of obesity may be due to underlying genetic variation, and more than 70 possible candidate gene loci have been implicated. These include genes involved in central nervous regulation systems (e.g., leptin, the leptinreceptor, POMC, MCR-4), and energy expenditure and adipocyte differentiation (e.g., beta-adrenergic receptors, UCPs, and the nuclear receptor PPARy). Many of these genes regulate food intake and energy expenditure. However, the three-way link between gene polymorphism, food intake/exercise habit, and obesity has not been rigorously studied to document the precise nature of GxE effects on obesity. Consequently, data on absence of obesity-causing mutations or sequence variation at the Ob-Rb, PYY, and Y2R genes, without considering the caloric ingestion and physical exercise characteristics of the subjects, cannot be properly interpreted. We provide a theoretical framework for testing the significant role of such gene polymorphisms using a model of mediating type of GxE interaction effects on obesity in which the main effect of genes may remain undetected without data on physical activity and/or caloric intake of subjects. Study designs for testing such interaction effects are illustrated with their relevant power computations. (Research supported by a NIH grant GM41399).

Genomic screening and replication in one data set in family-based association testing. *C. Lange[1,3], K. van Steen[1], M. McQueen[1], A. Herbert[2], B. Raby[3], H. Lyon[5], D. DeMeo[3], A. Murphy[1], J. Su[1], S. Datta[3], C. Rosenow[4], M. Christman[2], E. Silverman[3], N. Laird[1], S. Weiss[3].* 1) Dept Biostatistics, Harvard Sch Public Health, Boston, MA; 2) Department of Genetics and Genomics, Boston University School of Medicine, Boston, Massachusetts 02115, USA; 3) Channing Laboratory, Harvard Medical School, Boston, Massachusetts 02115, USA; 4) Genomics Collaboration Genotyping, Affymetrix, Inc., Santa Clara, California 95051, USA; 5) Division of Genetics, Childrens Hospital, Boston, Massachusetts 02115.

The Human Genome Project and its spin-offs are making it increasingly feasible to determine the genetic basis of complex traits using genome-wide association studies. The statistical challenge of analyzing such studies stems from the severe multiplecomparison problem resulting from the analysis of thousands of SNPs. Our methodology for genome-wide family-based association studies, using single SNPs or haplotypes, can identify associations that achieve genome-wide significance. In relation to developing guidelines for our screening tools, we determined lower bounds for the estimated power to detect the gene underlying the disease-susceptibility locus, which hold regardless of the linkage disequilibrium structure present in the data. We also assessed the power of our approach in the presence of multiple disease-susceptibility loci. Our screening tools accommodate genomic control and use the concept of haplotype-tagging SNPs. Our methods use the entire sample and do not require separate screening and validation samples, as population-based designs do. We will illustrate the practical relevance of the proposed screening tools by an application to a genome-wide association study (100K-scan) of the Framingham Heart Study.

Evaluation of analysis methods for whole genome association studies with 100K SNPs. *M.G. Ehm[1], S.-A. Bacanu[1], M.R. Barnes[2], C.Z. Bowman[1], L.P. Briley[1], J. Charnecki[1], O. Delrieu[4], R.A. Gibson[4], M.L. Jones[5], K. Long[3], M.R. Nelson[1], K.L. Nangle[3], M.V. Plumpton[2], S. Shouse[1], Z. Xue[1], D.P. Yarnall[1], E.H. Lai[1].* 1) Discovery & Pipeline Genetics, GlaxoSmithKline, Res Triangle Pk, NC; 2) Bioinformatics, GlaxoSmithKline, Harlow, UK; 3) Bioinformatics, GlaxoSmithKline, Res Triangle Pk, NC; 4) Translational Medicine & Genetics, GlaxoSmithKline, UK; 5) Bioinformatics Research Center, North Carolina State University, Raleigh, NC.

The commercial availability of Affymetrix Genechip technology (100K and 500K SNP arrays) has made it possible for whole genome association scans to be completed in research laboratories. To develop a capacity to efficiently complete the genotyping for whole genome scans, test the capacities of our bioinformatics systems, investigate analysis techniques, and interpret the results, we genotyped 126 unrelated Caucasian subjects including 63 patients and 63 controls using the 100K mapping set. We tested for association between this complex disease and SNPs on this chip using a variety of analysis methods, including Fishers exact allelic and genotypic tests. Interpretation of results was aided by clustering results using linkage disequilibrium. We also used visualization of gene and pathway determinants of disease using a novel application of empirically derived log Bayes Factors. We compared the results identified by these techniques and interpretation for whole genome association screens, in general. While this study was underpowered to identify modest effects, the information learned from this experiment will guide the further development of statistical methods for appropriately powered studies using the 500K mapping set.

Single SNP vs haplotype block based association studies. *Z. Yu[1], R. Guerra[1], J.C. Cohen[2,3], H.H. Hobbs[2,3].* 1) Dept Statistics, Rice Univ, Houston, TX; 2) Donald W. Reynolds Cardiovascular Clinical Research Center and the Department of Internal Medicine, Dallas, TX; 3) Howard Hughes Medical Institute, University of Texas Southwestern Medical Center, Dallas, TX.

Recently, a lot of articles have discussed the power of single SNP and haplotype based association studies. Much of the discussion has been based on theoretical considerations or simulations. In this study we analyzed the association between several phenotypes and regions where SNPs were fully genotyped using both single-SNP and haplotype block based analyses. The data set is a stratified probability sample from Dallas County and represents three ethnic groups. The comparison between the two approaches was based on physical length, number SNPs and marker density of haplotype blocks. Advantages and disadvantages of each approach exist and described in this presenation.

A quantitative genetic paradox of association studies involving quantitative trait and a genetic polymorphism.
M.B. Rao, X. Sheng, R. Chakraborty. Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Association of genetic polymorphism with quantitative phenotypes is traditionally established by analysis of variance (ANOVA) of the quantitative trait with subjects classified by genotypes. Trait values are sometimes transformed to conform to the assumption of normality when the sampled subjects are biologically unrelated. With the other implicit assumptions satisfied (e.g., there is no deviation of Hardy-Weinberg expectation of genotype frequencies, and covariate of phenotypes are adjusted for), the most likely interpretation of genotypic association with phenotype variation is that the locus studied is at linkage disequilibrium (LD) with a putative major gene explaining a significant proportion of the phenotypic variation in the sampled subjects. Using the quantitative genetic model of major genes, we show that this method of analysis poses a quantitative genetic paradox. Analytical derivations suggest that the critical assumption of ANOVA, namely, homogeneity of the variance of phenotypic values across genotypes, is inherently violated in this model, unless the locus itself is the causative locus. The differences of within genotype variance of the trait are composite functions of LD, allele frequencies, and allelic affects on the phenotype. In fact, the homoscedasticity assumption of ANOVA is satisfied only when the LD is complete, or the null hypothesis of no major gene effect is true. In other words, the paradox arises from the fact that the critical assumption of ANOVA is always violated when the null hypothesis is not true, but the causative locus is not the one examined. With parameter estimates from some phenotype-gene association studies (e.g., APOE gene effect on lipid variation), we provide a numerical strength of the violation of the assumption. We propose a mixture analysis methodology to handle such quantitative genetic paradox of association studies of quantitative traits with gene polymorphism. The A1298C and C677T polymorphisms of the methylenetetrahydrofolate reductase (MTHFR) gene in Mexican patients with rheumatoid artritis (RA). *J. Mena[1], I. Davalos[1], J.I. Gamez[2], L. Gonzalez[2,3], F. Muñoz-Valle[4], M. Vasquez del M[4], G. Martinez[4], L. Sandoval[1], H. Rangel[5], M. Casillas[1], L.E. Figuera[1], M. Salazar-Paramo[2,4].* 1) Division de Genetica, CIBO, IMSS, y Doctorado en Genetica, U de G; 2) UIMEC, UMAE, HE, CMNO, IMSS; 3) HGZ 110, IMSS; 4) Departamento de Fisiologia,U de G; 5) CUCienega, Universidad de Guadalajara, Jalisco, Mexico.

Introduction. The enzyme methylenetetrahydrofolate reductase plays a critical role in homocysteine metabolism, catalyzing the conversion of 5,10- methylenetetrahidrofolate to 5-methylenetetrahydrofolate, the methil group donor in the B12 - dependent remethylation of homocysteine to methionine. Two common variants in the MTHFR gene (C677T and A1298C) are associated with reduced MTHFR specific activity. Moderate hyperhomocysteinaemia and folate deficiency has been described in patients with autoimmune diseases including RA. Objective. To determine the genotype frequency (GF) and allelic frequency (AF) of MTHFR C677T and A1298C polymorphisms in Mexican patients with RA. Methods. Group RA consisted in 119 RA patients diagnosed according to the American College of Rheumatology (ACR) and group M consisted in 140 normal individuals. Both groups were typed for the MTHFR C677T and A1298C by PCR/RFLP method. Results. MTHFR C677T GF (n) in the RA group were: CC 26 (31), CT 59 (70), TT 15 (18) ; AF (n): C 56 (132) and T 44 (106). The GF In the group M were: CC 31 (44), CT 52 (72), TT 17 (24); AF: C 57(160) and T 43(120). MTHFR A1298C GF in the RA (n=79) group were, AA 61 (48), AC 34 (27), CC 5 (4); and the AF: A 78 (123) C 22 (35). For group M (n=43) AA 49 (21), AC 46(20), CC 5(2); AF: A 72(62) C 28(24). Genotype frequencies were in agreement with the HWE. Conclusion. There were similar MTHFR C677T and A1298C AF between the two groups.

Quantitative Analysis of the CYP2A6 gene deletion using pyrosequencing. *D. Koontz, A. Spencer, S. Nikolova, J. Huckins, M. Gallagher.* CDC, DLS, NCEH, Molecular Biology Branch, Atlanta, GA.

CYP2A6 plays a major role in the metabolism of drugs and precarcinogens, in particular nicotine and coumarin. Numerous polymorphisms in this gene have been characterized and contribute to much of the interindividual variability in CYP2A6 activity. One such variant is a total deletion of the gene (CYP2A6*4) and is found at a high frequency in the Japanese population. This gene deletion has been associated with lowered risk for tobacco-related cancers due to impaired ability to activate tobacco smoke precarcinogens. To date, the method for genotyping CYP2A6*4 has been by PCR-RFLP which involves enzyme digestion of a CYP2A6-specific gene fragment to generate banding patterns specific for the presence or absence of the gene. This method is laborious and not easily adapted for studying large numbers of samples. The proposed mechanism for this gene deletion involves an unequal crossover event between homologous regions of CYP2A6 and the CYP2A7 pseudogene. We exploited resulting sequence differences between the downstream region of CYP2A6 and CYP2A7 in order to design a pyrosequencing assay that would easily genotype homozygous normal, heterozygous, and homozygous gene deletion. Genotype calls were derived from informative raw peak height ratios that give unique values for each genotype. We genotyped a Japanese panel (N=10) and a multi-ethnic panel of 90 individuals (N=24 European American, N=24 African American, N=12 Mexican American, N=6 Native American, N=24 Asian American) both from the Coriell Human Variation Collection; results showed a CYP2A6*4 allele frequency of 15% [one homozygote and one heterozygote(3/20)] and 4% [eight heterozygotes (8/180)], respectively. This striking inter-ethnic difference in the distribution of the CYP2A*4 allele is consistent with previous reports of a much higher prevalence in Japanese populations. All results were 100% concordant with conventional PCR-RFLP. Here we present a rapid and reliable assay to assess CYP2A6*4 that lends itself to large-scale studies needed to accurately assess the prevalence of this gene deletion in populations and to generate informative genotype-phenotype correlations.

Genomic Variation in Transforming Growth Factor Beta 1 Induced Transcript 1 (TGFB1I1) is Associated with Multiple Measures of Body Composition in Afro-Caribbean Men. *A.L. Kuipers[1], S.P. Moffett[1], C.S. Nestlerode[1], V.W. Wheeler[2], A.L. Patrick[2], C.H. Bunker[1], J.A. Cauley[1], R.E. Ferrell[1], J.M. Zmuda[1].* 1) Epidemiology, University of Pittsburgh, Pittsburgh, PA; 2) The Tobago Health Studies Office, Scarborough, Tobago, West Indies.

Transforming growth factor beta 1 induced transcript 1 (TGFB1I1) is a coactivator of nuclear receptors such as the androgen receptor and PPARgamma. We performed genetic association analyses of TGFB1I1 and body composition related phenotypes by genotyping a C-to-G substitution in the 3 untranslated region of TGFB1I1 (rs10596) in 925 Afro-Caribbean men aged 40 years and older. Body composition was measured with dual-energy X-ray absoprtiometry (Hologic QDR 4500). The frequency of the minor G allele was 0.101. Genotype frequencies were: CC, 89.84 %; CG, 9.95 %; and GG, 0.22% and did not depart from Hardy Weinberg Equilibrium. Presence of the G allele was associated with increased body weight (CC: 82.20 0.51 kg; CG+GG: 86.84 1.52 kg; p = 0.004) and height (CC: 174.1 0.2 cm; CG+GG: 175.6 0.6 cm; p = 0.019). The increased body weight associated with the G allele was due to increased lean mass (CC: 63.08 0.28 kg; CG+GG: 65.55 0.84 kg; p = 0.006) and fat mass (CC: 16.85 0.24 kg; CG+GG: 18.74 0.72 kg; p = 0.013). Carriers of the G allele also had significantly increased femoral neck bone mass (CC: 0.971 0.005 g/cm2; CG+GG: 1.003 0.015 g/cm2; p = 0.0384). The association with bone mass was no longer statistically significant after adjusting for the increased body weight and height among carriers of the G allele. Our preliminary analyses suggest that genomic variation at the TGFB1I1 locus may contribute to phenotypic variation in body size and body composition related traits. Studies with additional markers spanning the locus and in other samples are required to confirm and extend this hypothesis.

Nuclear Receptor Coactivator-3 Alleles are Associated with increased bone mass in Afro-Caribbean men. *Y. Sheu[1], J. Zmuda[1], S. Moffett[1], C. Bunker[1], J. Cauley[1], A. Patrick[2], C. Ishwad[3], R. Ferrell[3].* 1) Epidemiology, University of Pittsburgh, Pittsburgh, PA; 2) Tobago Health Studies Office, Scarborough, Tobago, West Indies; 3) Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Sex steroid hormones are an important determinant of bone health in men. Nuclear receptor coactivator-3(NCOA3) is a steroid hormone receptor coactivator that facilitates steroid hormone receptor transcriptional activation of target genes. NCOA3 may affect bone mineral density(BMD) by modulating inter-individual differences in skeletal sensitivity to sex steroid hormones. To test this hypothesis, we conducted genetic association analyses between potentially functional alleles at this locus, body composition, and whole body and hip BMD(Hologic QDR450) in 814 Afro-Caribbean men(age 6110 yrs, mean SD; range 40-84 yr). Men were genotyped for a CAG repeat polymorphism in NCOA3, which encodes a polyglutamine tract of variable length in the C-terminal transcriptional activation domain of the protein. We found a significant increase in both hip and whole body BMD with increasing copies of the most common allele(224bp, 43.2%) before and after adjusting for age, weight and height. For example, men without the 224bp allele had 5% lower femoral neck BMD than men who were homozygous for this allele(Table). Similar results were observed for whole body BMD. No significant differences were found for whole body fat mass and lean mass across genotypes. We conclude that allelic variation at the NCOA3 locus may contribute to the genetic control of bone mass among older men.

Table:BMD(g/cm2) by number of copy of NCOA3 Allele.

	0(n=204)	1(n=516)	2(n=94)	p-value
Whole Body	1.23(.12)	1.27(.11)	1.28(.12)	.0005
Femoral Neck	.94(.15)	98(.14)	.99(.15)	.0013

Values are means (SD) and adjusted for age, weight and height.

The ATGL gene is associated with free fatty acids, glucose and trigylceride concentrations. *F. Kronenberg[1], V. Schönborn[1], I.M. Heid[2], C. Vollmert[2], A. Lingenhel[1], T.D. Adams[3], P.N. Hopkins[3], T. Illig[2], R. Zimmermann[4], R. Zechner[4], S.C. Hunt[3].* 1) Div. of Genetic Epidemioloy, Innsbruck Medical University, Innsbruck, Austria; 2) GSF-National Research Center for Environment and Health, Insitute of Epidemiology, Neuherberg, Germany; 3) Cardiovascular Genetics, University of Utah, Salt Lake City, UT; 4) Institute of Molecular Biosciences, Karl-Franzens-University, Graz, Austria.

Adipose triglyceride lipase (ATGL) was recently described to predominantly perform the initial step in triglyceride hydrolysis (Science 306:1383, 2004) and therefore seems to play a pivotal role in the lipolytic catabolism of stored fat in adipose tissue. This is the first study which investigates genetic variations within the ATGL gene in humans. We investigated in a large epidemiological study involving 2434 Caucasians from Utah, USA, twelve polymorphisms in the ATGL gene identified via sequencing and data base search. These polymorphisms and their statistically reconstructed haplotypes were analysed for association with plasma free fatty acids (FFA) and other phenotypes related to lipoprotein metabolism, obesity, and type 2 diabetes. FFA concentrations were significantly associated with several SNPs and haplotypes of the ATGL gene (decreased FFA levels: SNPs 3,6,8,10,11,12, p-values from 0.016 to 0.00007), consistent with additive inheritance. Three rare SNPs (SNPs 5,7,9) showed a tendency towards significance. Furthermore, SNP5 (and similarly SNP9) showed associations with glucose levels (p=0.00017, +19 mg/mL), risk of type 2 diabetes (OR=2.6, p=0.025) and nonsignificant but consistent differences in BMI and HOMA. Triglyceride levels showed a nonsignificant tendency for an association with ATGL in accordance with the FFA associations. The associations of triglycerides and glucose became stronger when restricting the analysis to subjects without diabetic medication. Haplotype analysis supported and extended the shown SNP association analyses. In summary, genetic variation within the ATGL gene shows strong associations with FFA, and less pronounced but still detectable associations with parameters of the metabolic syndrome and type 2 diabetes.

A regression-based association approach using haplotype similarity for genome scans. *J.Y. Tzeng[1], M. Davidian[1], D.C. Thomas[2].* 1) Department of Statistics, North Carolina State Univ, Raleigh, NC; 2) Division of Biostatistics, Department of Preventive Medicine, University of Southern California, Los Angeles, CA.

The prospect of genome-wide association scans is being enhanced by the progress in human genome research and the advance in the large-scale genotyping technique. In genome screening, chromosomal regions are divided into hundreds or thousands of small segments by forming a moving window, and association test are performed within each window to detect susceptibility locations. Commonly used approaches to test for association include using likelihood ratio tests or chi-squared tests of homogeneity, or regressing trait values on haplotypes. As the power of a single haplotype-based association test can be limited by its large degrees of freedom, the overall performance of an association scan can be further diminished by the multiple testing adjustment. To tackle this problem, we propose a regression-based approach for testing association using haplotype similarity; specifically we extend the haplotype test based on pair-wise similarity measures to a model based framework. We detect association by looking for the unusual sharing of chromosomal segments within homogeneous trait groups using a much fewer parameters, and extra degrees of freedom are spared by not modeling individual haplotypes. We use regression framework to accommodate environmental covariates, polygenic effects and corresponding interactions, and also gain flexibility in modelling different trait types. The method is connected with the ordinary regression that treats individual haplotypes as covariates under a hierarchical modeling framework. Through simulation studies we assess the performance of the proposed method, and demonstrate its validity in testing for genetic association.

Association of SNP haplotypes of interleukin-1 beta with persistent sciatica following lumbar diskectomy. *T. Wu[1], A. Kingman[1], A. Bollettino[1,2], H. Hipp[1,2], M. Scully[1], I. Belfer[1,2], S. Atlas[3], B. Buzas[1,2], C. McKnight[1,2], R. Keller[4], D. Goldman[2], M. Max[1].* 1) National Institute of Dental and Craniofacial Research, Bethesda, MD; 2) National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD; 3) Massachusetts General Hospital, Harvard Medical School, Boston, MA; 4) Maine Spine and Rehabilitation Center, Scarborough, ME.

Interleukin-1 (IL-1) is a cytokine that is produced in response to infection, injury, or antigenic challenge. It mediates neuropathic pain behaviors in animal models. Solovieva et al.(2004) reported that IL-1 C3954T and disc degeneration and low back pain were likely associated. We examined association of 10 single nucleotide polymorphisms (SNPs) in IL-1 gene with leg pain (z-score) in 107 Caucasian patients, who had been followed for 10 years after lumbar diskectomy for sciatica in Maine Lumber Spine Study (Atlas et al., 2001) . A Z-score was calculated for each patient based on the four leg pain scores (7-point questionnaires about frequency and post-surgical improvement in leg pain and leg pain after walking) at baseline, 3, 6, 12 and 24 months. Strong linkage disequilibrium among the 10 SNPs was observed, the pair-wise D ranging from 0.82 to 1.00. Five haplotypes were inferred from the population by EM algorithm (SAS/Genetics). Analysis of individual SNPs indicated that none of the ten SNPs showed significant association with the leg pain z-score. Haplotype-based analysis revealed that the haplotype CGCGAAGCGT(with frequency 13.7%) had the highest adjusted mean of z-score among the five haplotypes. A multilocus diplotype-based analysis found patients with the haplotype had significantly higher pain z-scores than those without the haplotype (p=0.018). The result suggests that polymorphisms in the IL-1 gene may affect the risk of chronic sciatica after lumbar diskectomy. 1 Solovieva, et al., Pain, 2004. 2 Atlas, et al., Spine, 2001.

Estimation and testing of genotype and haplotype effects in case/control studies: comparison of weighted regression and multiple imputation procedures. *H.J. Cordell.* Dept of Medical Genetics, University of Cambridge, UK.

A popular approach for testing and estimating genotype and haplotype effects associated with a disease outcome is to conduct a population-based case/control study, in which haplotypes are not directly observed but may be inferred probabilistically from unphased genotype data. A variety of methods exist to analyse the resulting data while accounting for the uncertainty in haplotype assignment, but most focus on the issue of testing the global null hypothesis that no genotype or haplotype effects exist. A more interesting question, once a region of disease association has been identified, is to estimate the relevant genotypic or haplotypic effects and to perform tests of complex null hypotheses such as the hypothesis that some loci, but not others, are associated with disease. Here I examine the performance of two classes of methods for addressing this question. The first is a weighted regression approach in which posterior probabilities of haplotype assignments are used as weights in a logistic regression analysis, generating a test based on either a weighted pseudo-likelihood, or a weighted log-likelihood. The second is a multiple imputation approach using either an improper procedure in which the posterior probabilities are used to generate replicate imputed data sets, or a proper data augmentation procedure. In simulations, all methods were unbiased but the weighted pseudo-likelihood and multiple imputation methods had superior confidence interval coverage. Multiple imputation was easier to implement in standard statistical software and to extend to more complex models of gene-gene or gene-environment interaction.

Normalized logistic-based rank transformation for QTL mapping methods. *K. Shibata[1], R. Takemura[2], N. Kamatani[2,3].* 1) Integrated Database Group, Japan Biological Informatics Consortium, Tokyo, Japan; 2) Algorithm Team, Japan Biological Informatics Consortium, Tokyo, Japan; 3) Tokyo Women's Medical University, Tokyo, Japan.

QTL mapping is generally based on the assumption that the quantitative phenotypes follow normal distributions. However, many real phenotypes are not normally distributed. One approach is to attempt to find a mathematical transformation that will convert the trait into a normal distribution for genetic mapping of quantitative trait loci. However, given a particular transformation such as Box-Cox transformation, we need to estimate the optimal value of the transformation parameter. Also, the effect of outliers may be too great and an appropriate transformation may be difficult to find. Here, we introduce the logistic-based rank transformation for QTL mapping, which does not involve the optimal choice of parameters. We define the ranks of the observed quantitative phenotypes, where the ranks are 1 for the smallest observation, 2 for the next, preserving the order of the data. Our strategy is to transform the order of the data into an approximate normal distirbution using logistic function, which is implemented in the latest version of QTLHAPLO (Shibata et al. 2004). We conduct the simulations based on real data and the phenotypic effect for multivariate phenotypes can be estimated. We discuss the effect of logistic-based rank transformation on power and type I error rates of parametric association test where the phenotype has a Cauchy distribution, uniform distribution and exponential. We have compared the power of the association study under different modes of inheritance. The logistic-based rank transformation represents an important initial step in QTL analysis under a variety of distributions.

An Algorithm for Constructing Associated Haplotypes from High Density SNP Genotype Data. *J.M. Laramie[1], J.B. Wilks[2], A.L. DeStefano[3], R.H. Myers[2].* 1) Bioinformatics, Boston University, Boston, MA; 2) Departments of Neurology, Boston University School of Medicine, Boston, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Introduction We present an algorithm called *HaploBuild* that, in conjunction with the program haplotype FBAT (Family Based Association Tests)[1], can construct nonconsecutive haplotypes of any length that are statistically associated, through a family based association test, with a quantitative or qualitative phenotype from a set of high density single nucleotide polymorphism (SNP) and microsatellite genetic markers.

Methods In essence, the *HaploBuild* algorithm defines a function for choosing markers that are combined as a haplotype and tested for association with a disease phenotype. Given a set of genotyped markers our algorithm works in two steps. The first step tests for association all two marker haplotypes within a given distance of each other. The second step builds an *n-ary* tree from each of the two marker haplotypes that reached a specified level of significance in Step 1. The goal of tree building is to greedily add markers one at a time to a haplotype increasing the overall haplotype association significance and pruning those nodes that do not increase significance. In this context, the leaf nodes of the trees built represent the maximal number of markers that can be combined into an significantly associated haplotype.

Discussion In a simulation study, *HaploBuild* correctly finds the haplotypes containing the SNP causing the phenotypic effect. If the SNP causing the phenotypic effect is removed prior to analaysis *HaploBuild* finds haplotypes in strong LD with the removed SNP. In our simulation study we were able to narrow the canidate gene region from 18Mb down to ~400kb.

Haplotype analysis in the presence of missing data. *N. Liu[1], I. Beerman[2], R. Lifton[2], H. Zhao[1,2].* 1) Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT; 2) Department of Genetics, Yale University School of Medicine, New Haven, CT.

It is common to have missing genotypes in practical genetic studies, and the exact underlying missing data mechanism is generally unknown to the investigators. Although some statistical methods can handle missing data, they all assume that genotypes are missing at random, that is, at a given marker, different genotypes and different alleles are missing with the same probability. These include those focusing on haplotype frequency estimation and haplotype association analysis. However, it is likely that this simple assumption does not hold in practice, yet no study to date has examined the magnitude of the effects when this simplifying assumption is violated. In this study, we demonstrate that the violation of this assumption can lead to serious bias in haplotype frequency estimates, and haplotype association analysis based on this assumption can induce both false-positive and false-negative evidence of association. To address this limitation in the current methods, we propose a general missing data model to characterize missing data patterns across a set of two or more markers simultaneously. We prove that haplotype frequencies and missing data probabilities are identifiable if and only if there is linkage disequilibrium between these markers under our general missing data model. Simulation studies on the analysis of haplotypes consisting of two single nucleotide polymorphisms illustrate that our proposed model can reduce the bias both for haplotype frequency estimates and association analysis due to incorrect assumption on the missing data mechanism. Finally, we illustrate the utilities of our method through its application to a real data set.

New correction method for association study using SNPs in linkage disequilibrium with each other. *A. Takahashi[1], S. Fujii[2], J. Takasaki[1], T. Nakamura[1], M. Yanagisawa[2], Y. Nakamura[1], N. Kamatani[1,3].* 1) SNP Research Center, RIKEN, Yokohama, Kanagawa, Japan; 2) Department of Computer Science, Waseda University, Japan; 3) Institute of Rheumatology, Tokyo Woman's Medical University, Japan.

Single nucleotide polymorphisms(SNPs) have been effective markers to discover genes associated with diseases. If association studies using SNPs are performed over the whole genome, the number of association tests will be too large. Then the problem of multiple tests will emerge. Several methods have been proposed till now to overcome this problem including the standard Bonferroni's correction. It is well known, however, that Bonferroni's correction gives too conservative conclusions especially when SNPs are in linkage disequilibrium with each other. We propose a new correction method for case-control association studies using SNPs in linkage disequilibrium with each other. The equation of probability of exact type I error was derived given population haplotype frequencies. Exact type I error rate could be calculated numerically when sample sizes were small; however, it was difficult when the sample sizes were large. Here, we developed a Markov chain Monte Carlo method to calculate asymptotic type I error rate for large samples sizes.

fastPHASE: an efficient method for haplotype reconstruction and missing genotype imputation using a flexible cluster-based model for population genetic data. *P. Scheet, M. Stephens.* Statistics, University of Washington, Seattle, WA.

Various methods exist for the analysis of haplotype data from unrelated individuals; however, studies of human genetic variation generally consist of unphased genotypes, where the haplotypes are not observed. With the advent of technologies for cheaply and quickly producing large amounts of genetic data, there is a coming need for models that are computationally tractable for genotype data from thousands of individuals at thousands of loci. Here we present such a model for genetic variation based on clustering the latent haplotypes over short regions. Existing approaches divide the data into discrete windows, but we take a more flexible approach that allows the clustering to change continuously along the chromosome according to a hidden Markov model for cluster membership. Parameter estimation is accomplished via an expectation maximization algorithm, and quantities of interest are estimated by averaging over multiple modes of the likelihood surface. We apply the model to dense SNP genotype data from real populations for the tasks of imputing missing genotypes and inferring haplotypes, and compare it against several existing methods. For imputing missing genotype data, performance is superior to the best available methods. And for haplotype reconstruction, our model performs almost as well as the best existing method but at a fraction of the computational cost. Our new methods for these tasks have been implemented in a software program called fastPHASE.

Type I error and power for statistical association tests in the presence of haplotype misclassification. *M. Levenstien, J. Ott, D. Gordon.* Laboratory of Statistical Genetics, Rockefeller University, New York, NY.

Haplotype association studies are gaining popularity as a method for fine mapping susceptibility genes for human disease. Because current molecular haplotyping methods are expensive and not amenable to automation, many researchers rely on statistical methods to infer haplotype pairs from multilocus genotypes and subsequently treat these inferred haplotype pairs as observations. Although these methods provide an efficient alternative to molecular haplotyping, some haplotype pairs can be misclassified. We examine the effect of these misclassification errors on the type I error and power for a variety of association tests. These tests include the standard likelihood ratio test (standard LRT), a likelihood ratio test which weights the inferred haplotype pairs by the posterior probability associated with them (weighted LRT), and a likelihood ratio test that employs a double sampling approach to allow for the misclassification inherent in the haplotype inference procedure (LRTae). In addition, we aim to determine the cost-benefit relationship of increasing the double sample proportion (the proportion of individuals with molecular haplotype measurements in addition to genotypes) to raise the power gain of the LRTae over the standard LRT. This analysis should provide a guideline for determining the minimum number of molecular haplotypes required for desired power. Our simulations with two SNP markers indicate that 1) for each statistic permutation methods maintain the correct type I error; 2) complete misclassification occurs in the vast majority of situations; and 3) asymptotic p-values for the standard LRT appear to fluctuate between conservative and anti-conservative values.

Dissecting the relationship beetween C-reactive protein and metabolic syndrome. Common *CRP* haplotypes: application of Medelian ranomisation. *N. Timpson[1], D. Lawlor[1], R. Harbord[1], T. Gaunt[3], I. Day[1, 3], L. Palmer[1, 2], et al[1, 4, 5].* 1) Dept of Social Medicine, Bristol University; 2) Western Australia Inst of Medical Research, UWA; 3) Human Genetics Research Division, University of Southampton; 4) Peninsular Medical School, Exeter University; 5) Medical Department, Haemostasis and Thrombosis Unit, Glasgow University.

CRP is associated with components of metabolic syndrome, but the nature of this relationship remains unclear. With common *CRP* haplotypes associated with plasma CRP, Mendelian randomisation was used to generate estimates of association between plasma CRP and metabolic syndrome phenotypes(MSPs) free from confounding/reverse causation. CRP associated SNPs were genotyped in 3218 British women and associations of *CRP* haplotypes with MSPs were assessed. Comparison was made between estimates of association between plasma CRP and MSPs derived from basic regression analysis and those from a Mendelian randomisation framework implemented via instrumental variables(IV) techniques. There were strong linear associations between log plasma CRP concentrations and MSPs (all p*0.001). Differences existed between mean circulating CRP for observed haplotypes (p=*0.001). Haplotypes CAC and GGT (rs1800947/rs1130864/rs1205) showed strongest association with higher and lower plasma CRP levels respectively (geometric means for plasma CRP: CAC 2.03[2.02, 2.04]; GGT 1.39[1.38, 1.40]). Potential confounders, e.g. smoking, were associated with plasma CRP concentration (all p=*0.003), but don't show evidence for association with *CRP* haplotypes. There was strong evidence that the two methods of estimating the CRP/MSPassociations gave conflicting results for the CRP-BMI association (p=0.0002) and evidence of conflicting results for associations of CRP with HOMA-R (p=0.014), Triglycerides (p=0.03) and HDLc (p=0.07). We observed disparity in estimates of the relationship between plasma CRP and MSP derived from conventional analyses and an IV approach, This suggests no association between the component of CRP directly related to *CRP* variation and MSPs. Analyses are analogous to an RCT of plasma CRP levels and do not suggest a causal role for CRP in the aetiology of MSPs.

Haplotype reconstruction in population individuals using coalescent trees. *D. Qian[1], L. Beckmann[2].* 1) Department of Biostatistics, City of Hope National Medical Center, Duarte, CA, USA; 2) Division of Clinical Epidemiology, German Cancer Research Center, Heidelberg, Germany.

We present a two-stage algorithm to reconstruct haplotypes in population individuals using hierarchical clustering and coalescent tree analysis. First, haplotypes are grouped into clusters, and each cluster contains similar haplotypes that are likely descended from a common ancestor. Second, haplotypes within each cluster are fitted to a coalescent tree structure. Each tree is then quantified with a tree distance, and the haplotype configuration with the minimum sum of tree distances is defined as the optimal one under the identified trees. The similarity between haplotypes as well as the tree distances are calculated based on haplotype sharing, i.e. the number of shared markers identical by state. The approach allows for multiple origins of haplotypes within a population. The plausibility of a haplotype is quantified using similar haplotypes within the same cluster, and the effect of random similarities between clusters has been excluded. The algorithm is applicable for both SNPs and multiallelic microsatellites.

We analyzed three real data sets with known molecular haplotypes. The impact of missing data was analyzed in a simulation study by imputing randomly 3% and 6% missings into the data sets. For comparison, we used three commonly used algorithms (PHASE, HAPLOTYPER, SNPHAP). Preliminary results indicate similar performance as the Bayesian approach implemented in PHASE. Our approach outperformed HAPLOTYPER and SNPHAP in the presence of missing data in two data sets.

Associations of the apolipoprotein A1/C3/A4/A5 gene cluster with triglyceride and HDL levels in women with type 2 diabetes. *L. Qi[1,2,4], S. Liu[1,2,4], N. Rifai[3], D. Hunter[1,2,4], F. Hu[1,2,4].* 1) Department of Nutrition, Harvard School of Public Healt, Boston, MA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 3) Department of Laboratory Medicine, Childrens Hospital and Harvard Medical School, Boston, MA; 4) Channing Laboratory, Department of Medicine, Brigham and Womens Hospital and Harvard Medical School, Boston, MA.

Recent studies have shown that the apolipoprotein gene cluster (APOA1/C3/A4/A5) contributes to the homeostasis of triglycerides (TG) and high-density lipoprotein cholesterol (HDL-C) and may affect the risk of coronary heart disease (CHD) in non-diabetic populations. Patients with type 2 diabetes are prone to accelerated atherogenesis. However, no study has investigated the association of the genetic variability in APOA1/C3/A4/A5 cluster and the levels of TG and HDL-C among diabetic patients. We examined the effects of ten polymorphisms at APOA1/C3/A4/A5 gene cluster in 902 women with type 2 diabetes. A linkage disequilibrium (LD) breakdown was observed between APOA5 and other genes. Two common haplotypes encompassing four APOA5 polymorphisms (SNP1, SNP2, S19W, and SNP3) were significantly associated with 37% (haplotype 2212, APOA5*2, P=0.016) and 60% (haplotype 1121, APOA5*3, P=0.0002) higher fasting TG levels as compared with the most common haplotype (1111, APOA5*1) respectively. Adjustment for age, BMI, and other covariates did not appreciably change such associations. The homozygosity of APOC3 promoter polymorphism, -455T/C, was also associated with significantly increased fasting TG levels (P=0.012). The effects of APOA5 and APOC3 were independent of each other. In addition, APOA4 347T/A was associated with significantly lower levels of HDL-C under a dominant inheritance model (P=0.009). Our results indicate that the variability of APOA5 and APOC3 gene may independently affect fasting TG levels, and, variants at APOA4 locus may affect HDL-C levels in women with type 2 diabetes.

Disease gene location estimation using admixture population. *S. Zhang[1], Q. Sha[1], X. Zhu[2].* 1) Dept Mathematical Sci, Michigan Tech Univ, Houghton, MI; 2) Department of Preventive Medicine and Epidemiology, Loyola University Medical Center, Maywood, IL.

Admixture mapping is an efficient approach to localizing disease-causing variants that differ in frequency between two historically separated populations. It may be more powerful than linkage studies and, for a genome search, it typically require only ~1%; genotyping effort as many as required by a genome-wide association study. Recently, several methods have been proposed to test linkage between a susceptibility gene and a disease locus by using admixture-generated linkage disequilibrium (LD) for each of the typed markers. In this report, we propose a likelihood based method to estimate the location of disease genes which include point estimation and interval estimation. The method is applicable to a candidate region or a genome-wide search under either a case-control design or a case-only design. We use simulation studies to evaluate the performance of the method. In simulation studies, we generate admixture population under different population models by using a dense ancestry-informative marker penal for African-American. The simulation results show that the proposed method approximately gives an unbiased location estimation and the coverage of 95%; confidence interval is approximately 95%.

Nonparametric Bayesian models for family-based association tests with multi-allelic markers and gene-gene interactions. *B. Shahbaba[1], S. Malik[2], E. Schurr[2], C.M.T. Greenwood[3].* 1) Public Health Sciences, University of Toronto, Toronto, Canada; 2) Research Institute of the McGill University Health Centre, Montreal, Canada; 3) Genetics & Genomic Biology, Hospital for Sick Children, Department of Public Health Sciences, University of Toronto, Toronto, Canada.

Genetic association studies, particularly for the family-based control design, are plagued by small sample sizes and sparse data. In particular, when examining gene-gene interactions, the number of informative parents may be extremely small. Here we propose a nonparametric Bayesian model for analyzing genetic associations in trios of an affected child and two parents. We use continuous latent variables for modeling multivariate categorical data. By transforming the categorical variables into a continuous space, we overcome some problems associated with estimating numerous parameters in a sparse contingency table. Our approach is based on finding a set of latent variables which, when conditioned upon, the categorical variables (genotypes or haplotypes) can be regarded as independent. In this way, any dependency between the observed categorical variables can be induced based on dependency between the latent variables. We model the joint distribution of the latent variables as a mixture of simple multivariate normal distributions. The mixing distribution is given a Dirichlet process prior. Markov chain Monte Carlo methods are used for estimation. Missing information is a ubiquitous problem in statistics. Here, we model the joint distribution of response and all predictors. As a result, we avoid direct imputation of missing values by assuming they occur at random. This approach is illustrated using data collected on three candidate genes among 110 families ascertained to have a child with tuberculosis. Genetic markers are measured in parents and their affected child(ren). Our results show that one of the genes (Vitamin D Receptor) may have a small effect on risk; no interactions were identified. Using standard methods, however, testing for interactions is difficult.

A unified multilocus association test. *H.C. Yang[1], C.Y. Lin[2], C.S.J. Fann[1,2].* 1) Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Public Health, Yang-Ming University, Taipei, Taiwan.

Multilocus association tests using information of inter-marker linkage disequilibrium is more powerful than single locus tests when disease etiology is contributed by a simultaneous work of several linked genetic loci related to each other. However, reduction of testing power or inflation of type 1 error may be caused by noisy interference due to the use of non-informative markers, demonstrating the importance of marker selection for multilocus association mapping. In this study, we proposed a unified association test based on a convenient marker-selection procedure (sliding window) combined with an adjustment approach (SNP weighting) to diminish the impact of non-informative markers on association tests. The new procedure includes several conventional p-value combination methods as its special cases, where sampling distributions of the test statistics were discussed. Comprehensive simulation studies based on different evolutionary and disease models were performed to investigate the impact of nuisance markers and evaluate the performance of the suggested procedure. Simulation results show that testing power was inversely proportional to the quantity of nuisance markers. Among a class of p-value combination methods, the product p-value method had the highest testing power. Compared with conventional unweighted approach, the proposed weighted strategy not only improved testing power, but also reduced type 1 error. Two authentic data sets of disease gene mapping studies, psoriasis and Alzheimer disease, were analyzed. The results using the proposed method were consistent with the previous findings; more importantly, the proposed method is able to identify novel disease genes.

A comparison of methods for evaluating the relative effects of neighbouring polymorphisms associated with a disease. *J.M. Biernacka, H.J. Cordell.* Dept. of Medical Genetics, Univ. of Cambridge, Cambridge, United Kingdom.

In a small region several marker loci may be associated with a trait. Some of these may be associated because they directly influence the trait, while others are associated because they are in linkage disequilibrium (LD) with a causal variant. Several methods have been proposed to assist in distinguishing potentially causal polymorphisms from those that show association due to LD. Given a postulated effect at a primary variant, we may ask if any other variants in the region appear to further contribute to the trait. Evidence of such further effects indicates that the additional variant is causal or is in LD with another causal locus. Subsequent conditioning on several markers may identify additional causal polymorphisms. Various methods of approaching this problem using case-parent trio data have been proposed, among those the stepwise conditional logistic method described by Cordell and Clayton (2002), and a permutation-based method recently proposed by Spijker et al. (2005). The test statistic proposed by Spijker et al. (2005) is a marginal test of association that does not in itself take into account previously identified polymorphisms. However, significance of this statistic is evaluated using a permutation procedure that does take into account previously identified loci. We compared these methods and other related approaches by simulation. Under the conditions investigated, no advantage was found using the permutation procedure over asymptotic conditional logistic regression. The procedure described by Spijker et al. (2005) and unconditional logistic regression can lead to inflated type 1 errors in situations when haplotypes are not inferable for all trios. Because these procedures rely on AFBAC (affected family-based) controls, they are prone to bias and therefore increased type 1 error when haplotypes cannot be inferred for all families, as illustrated in our simulations. We propose an alternative to the permutation method of Spijker et al. (2005), which does not rely on haplotyping, and thus avoids the bias inherent in procedures that use AFBAC controls. Our results show that this alternative procedure leads to good type 1 errors and power.

Matching Cases and Controls Using Genotype Data from a Whole Genome Association Study. *W. Guan, L. Liang, M. Boehnke, G.R. Abecasis.* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Whole genome case-control association studies are now being undertaken for many complex diseases such as hypertension, diabetes, and bipolar disorder. Such studies typically require that thousands of samples be genotyped for hundreds of thousands of genetic markers. Interesting markers are those that show substantial allele or haplotype frequency differences between cases and controls. However, population substructure may result in heterogeneity between cases and controls, and can result in spurious disease-marker associations. Approaches exist to match cases and controls prior to genotyping, or based on genotype data for a few genetic markers; such approaches certainly can be useful. However, once genotyping for a whole genome association study is completed, much better case-control matching is possible by using all available genotype data. We propose a strategy for matching cases and controls after whole genome association genotyping is completed based on similarity scores calculated from all available marker genotype data. Through analysis of data from and inspired by the International HapMap project, we demonstrate that our strategy improves case-control matching beyond what is possible prior to whole genome analysis, decreasing false positives and improving power to detect true disease predisposing variants. We further show that our strategy can handle large numbers of samples and markers efficiently. We suggest that initial matching of cases and controls prior to whole genome genotyping combined with careful re-matching after whole genome genotyping is the method of choice for whole genome association studies.

Calpain 10 and Interleukin 6 variants are associated with polycystic ovary syndrome. *C. Lamina[1], S. Hahn[2], C. Vollmert[1], M. Kolz[1], A. Schöpfer-Wendels[1], K. Mann[2], F. Bongardt[1], J.C. Müller[1], F. Kronenberg[1,3], H.-E. Wichmann[1], C. Herder[4], R. Holle[1], W. König[5], H. Löwel[1], T. Illig[1], O.E. Janssen[2], the KORA group.* 1) GSF-National Research Center, Neuherberg, Germany; 2) University of Duisburg-Essen, Dept. of Medicine, Essen, Germany; 3) Innsbruck Medical University, Innsbruck, Austria; 4) German Diabetes Center, Düsseldorf, Germany; 5) University of Ulm, Medical Center, Ulm, Germany.

Polycystic ovary syndrome (PCOS) is known to be associated with an increased risk of type 2 diabetes mellitus (T2DM) and was proposed to share a common genetic background. Recent studies suggest that Calpain 10 gene (CAPN 10) and Interleukin 6 gene (IL6) variants contribute to genetic predisposition to T2DM and therefore represent strong candidate genes for a role in PCOS susceptibility. We genotyped the CAPN 10 UCSNPs: 44, 43, 56, Ins/Del19, 110, 58, 63, and 22 as well as the IL6 Promotor-SNPs: -598, -573, -174 in 146 German PCOS women (mean age 27 years, BMI 30.2 kg/m2) with 606 age-matched healthy controls (BMI 24.7 kg/m2) taken from a large population based study (KORA study, Augsburg, Germany) using MALDI-TOF MS technique. Genotype distributions were in Hardy-Weinberg equilibrium. Statistical analysis was corrected for age and BMI. An association between CAPN10 and the susceptibility to PCOS was found for UCSNP56 with an odds ratio of 2.91 (CI=1.5-5.6) for genotype AA compared to GG. The 22-allele of the Ins/Del19 variant was also associated with an increased odds ratio for PCOS (2.98, CI=1.55-5.73). For both SNPs, a dose-dependent allele-effect was detected. Eleven CAPN10 haplotypes with frequencies >1% were identified, of which the haplotype TGG3AGCA (frequency 21%, p=0.0057) and the TGA2AGCA haplotype (frequency 4.9%, p=0.0011) were significantly associated with PCOS. For the genotyped IL6 SNPs a significant PCOS predisposition was found in -598_GA/-174_GC-carriers (p=0.0004) compared to -598_AA/-174_CC-allele-carriers. In conclusion, CAPN10 UCSNPs 56 and 19, as well as IL6 SNPs -598 and -174 showed a genotype-dependent association with PCOS, which was confirmed by results of haplotype analysis.

Association of MAOB Polymorphism and Parkinson's Disease. *S.J. Kang, W.K. Scott, Y. Li, M. Hauser, J.M. van der Walt, K. Fujiwara, J.M. Vance, E.R. Martin.* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Parkinson's disease (PD) is a genetically complex disorder that affects more than one million Americans. The inability to control movement in PD patients results from severe loss of dopaminergic neurons within the substantia nigra. The mechanism causing dopaminergic cell death in PD has not been defined although it is generally accepted that environmental and genetic sources both contribute to risk. Monoamine oxidase (MAO) is one of the primary enzymes regulating metabolism of neurotransmitters such as dopamine. Two distinct forms of the enzyme, encoded by genes MAOA and MAOB located on the X chromosome, have been considered as possible factors in the pathogenesis of PD. Previous association studies of PD and MAO genes reported inconsistent results. In this study, we used a large family-based data set to test associations between MAO genes and a risk of PD. The data set includes 298 female discordant sibpairs and 348 male discordant sibpairs. Mean $\pm$ SD age of onset in affected individuals in the sample is 57.85 $\pm$ 13.20 (58.13 $\pm$ 12.70 for males and 57.41 $\pm$13.95 for females). For this study, all subjects analyzed were white and families with known parkin mutations were removed. We analyzed 15 single nucleotide polymorphisms (SNPs) in the MAO genes.

We used the pedigree disequilibrium test (PDT) to test association of the SNPs with PD risk among female discordant sibpairs and male discordant sibpairs separately. We performed the PDT analysis on the sex-specific data sets. Significant association was found with the intron 13 SNP of MAOB in overall female subset (p-value 0.02). No significant association was found in overall male subset. Though only marginally significant, the result is compelling since the same SNP has been found to be associated with PD in previous studies. Our results add to the evidence of involvement of MAOB in PD, and suggest that the effect may be stronger in females.

Familial Aggregation of Hyperemesis Gravidarum. *M. Schoenberg-Fejzo[1], M. Wilson[1], L. Yedigarova[1], K. Mac Gibbon[2], S. Ingles[1], T.M. Goodwin[1].* 1) USC, Los Angeles, CA; 2) HER Foundation.

Nausea and vomiting or morning sickness during the first trimester of pregnancy affects between 70-90% of gravidas. Pernicious vomiting of pregnancy, or Hyperemesis Gravidarum (HG), is less common, occurring in approximately 0.3-2% of all pregnant women, and is the second leading indicator for antenatal hospitalization. Hyperemesis gravidarum may persist throughout gestation, and the characteristic weight loss of at least 5% in the expectant mother is often considered a defining feature distinguishing HG from typical nausea and vomiting. In addition, the disease can be associated with ketonemia, ketonuria, electrolyte imbalance, dehydration, hepatic and renal damage, and even death. The cause of HG is unknown, however, it is a disease that bridges multiple races, cultures, and species. Significant ethnic differences in the incidence of HG have been reported for multiple populations including higher prevalence in New Zealand pacific island women, United Kingdom Indian and Pakistani women, and African-American women compared with ethnic European women. It is perplexing that nausea and vomiting in pregnancy, a condition that appears to have an ill effect on the health and well-being of the mother and fetus, has not been selected out in nature, nor is it unique to humans. Our analysis of a HER Foundation Survey suggests familial aggregation of HG. 110/628 (18%) sisters with a pregnancy history reportedly share HG. 88/1064 (8%) reported sharing HG with their mothers, and 107/1064 (10%) reported having at least one secondary relative with HG, with 20 reporting a paternal relative, and 22 reporting a maternal relative. 5 sets of twins reportedly shared HG. This provides evidence for a genetic component to HG, making it a disease amenable to genetic studies.

Complex Segregation Analysis of 1919 Pedigrees with Ovarian Cancer from the Gilda Radner Familial Ovarian Cancer Registry. *B.O. Tayo[1], R.A. DiCioccio[2], Y. Liang[1], M. Trevisan[1], M.S. Piver[3], K. Odunsi[2].* 1) University at Buffalo, Buffalo, NY; 2) Roswell Park Cancer Institute, Buffalo, NY; 3) Sisters of Charity Hospital, Buffalo, NY.

Familial component is estimated to account for up to 10% of ovarian cancer. However, the mode of inheritance of ovarian cancer still remains poorly understood. The goal of this study was to investigate the inheritance model that best fits the observed transmission pattern of ovarian cancer among the 7424 members of 1919 pedigrees ascertained through probands from the Gilda Radner Familial Ovarian Cancer Registry of Roswell Park Cancer Institute, Buffalo, New York. Criteria for proband selection included a family history of two or more cases of ovarian cancer. Using the SEGREG program of the Statistical Analysis for Genetic Epidemiology (S.A.G.E.), we fitted different regressive multivariate logistic models (Mendelian, sporadic, environmental and general) to the data on ovarian cancer status of the 7424 pedigree members. Covariate on affection status for other related cancer sites such as breast, pancreas, uterus/endometrium and prostate, was included in each fitted model. Parameters estimated include the frequency of susceptibility allele, logarithm of the odds of being affected versus unaffected, transmission and transition probabilities for the different models. Our analysis results indicate that Mendelian codominant model provides a significantly better fits than the other models for ovarian cancer.

An empirical evaluation of tagging SNP strategies for candidate gene association studies. *M. Weale[1], B. Browning[2], K. Ahmadi[3], D.B. Goldstein[4].* 1) Inst. Human Genetics & Health, University College London, London, United Kingdom; 2) GlaxoSmithKline, Research Triangle Park, NC, USA; 3) Department of Biology, UCL, London, UK; 4) Institute of Genome Sciences and Policy, Duke University, NC, USA.

There is currently no consensus on an optimal method for tagging SNP selection (identifying SNPs from a reference sample such as HapMap to be used in a larger association study). Three popular methods are based on different measures of association between the tags and other SNPs in the region: pairwise r2, haplotype r2, and allelic (or locus-scoring) r2. We describe a novel procedure for the empirical evaluation of these methods, and apply it to representative candidate gene regions using HapMap data. In terms of average power, all three methods perform equally well. In terms of genotyping efficiency however (i.e. the number of tagging SNPs required), the two multimarker methods perform considerably better than the pairwise r2 method. We explore the properties of a given genetic region that may predispose it to one or other SNP tagging method.

An evaluation of power and type I error of single SNP transmission disequilibrium tests under locus heterogeneity. *K.K. Nicodemus, Y. Yao.* Dept Genetic Epidemiology, Johns Hopkins SPH, Baltimore, MD.

The testing of preferential transmission of alleles from parents to affected offspring has become a common method to assess association between genetic markers and disease. The number of variations on the original TDT are a testament to its continued popularity. However, no guidelines exist to assist researchers to decide which method is the most powerful to use, especially under locus heterogeneity. Since TDT-like methods are most often applied to complex disease data, locus heterogeneity may have a strong impact on power to detect association. We evaluated the power and type I error of FBAT, PDT, and TDTPHASE under conditions of 25%, 50%, and 75% of families associated with an observed SNP. Using simulated data with approximately 100 parent-affect child trios, a disease allele frequency of 0.20, and penetrances representing 3 different genetic models (additive: penetrance 1/2=0.25, 2/2=0.5; recessive 2/2=0.50; dominant 1/2 and 2/2=0.50) and 1000 replicates, we found that the association tests gave moderate power to detect association at the presence of locus heterogeneity; power, calculated holding type I error constant at 0.05, for FBAT was superior to TDTPHASE and PDT under all conditions, and the increase in power was from 1.3%-4.0% for TDTPHASE and 1.5%-5.1% for PDT. PDT was more powerful than TDTPHASE in 5 out of 9 simulated conditions. As expected, power increased under the dominant and recessive models versus the additive models. Data was simulated using the same number of families and the same family structure; we also calculated type I error rates. FBAT had a slightly inflated marker-wise type I error of 0.064, whereas both TDTPHASE and PDT showed an almost exactly expected type I error of 0.0498(TDTPHASE) and 0.0499(PDT). All methods showed acceptable levels of type I error although one method (FBAT) was more powerful than the other two methods. We are currently testing the same methods on replicates of 500 families, which is closer to a realistic family-based association study; further, we intend to test other single SNP association methods.

The determinant of haplotype frequency matrix can evaluate the Linkage Disequilibrium between multi-allelic loci. *R. Takemura[1], S. Kamitsuji[1], N. Kamatani[2].* 1) Japan Biological Information Research Center, JBiC, Tokyo, Japan; 2) Department of Advanced Biomedical Engineering and Science Tokyo Womens Medical University, Tokyo, Japan.

The need for the methods of genome wide linkage disequilibrium (LD) analysis has emerged in order to map common disease genes or the genes associated with drug responses. There are a lot of studies about LD in which pair-wise bi-allelic loci are involved. Thus, D or r2 and other measures reflect the deviation of haplotype frequencies from the state of linkage equilibrium (LE), and thereby indicate the strength of LD. There are few studies about LD in which multi-allelic loci are involved. Zapata et al. (2001) proposed the measure D for LD between multi-allelic loci. However the use of D gives too conservative conclusions, and does not fit the method to discover genes using LD. Then we now propose a new measure for the strength of LD. Imagine that the first locus is composed of m alleles while the second locus is composed of n alleles. The entire haplotype frequencies can be expressed by a m x n matrix whose elements are haplotype frequencies. Our aim is to determine how much the observed haplotype frequencies deviate from expected haplotype frequencies under the assumption of LE. As a simple resolution, we introduce the determinant of matrix. When m=n, Multi Allelic linkage Disequilibrium (MAD) is defined by the determinant of the haplotype frequency matrix. It is noted that MAD can be written as only the determinant of the deviation matrix which is obtained by subtracting haplotype frequency matrix under the assumption of LE from the observed haplotype frequency matrix. Since, however, the range of value of MAD changes by variation of allele frequencies, it may be difficult to evaluate the magnitude of LD by using MAD directly. Then we also propose MAD which standardize MAD so as to take the value from 0 to 1, and the validity of the above method is shown by giving a numerical simulation. In case of mn, MAD is calculated as the square root of determinant of the product between the haplotype frequency matrix and its transpose, and its validity is also shown by giving a numerical simulation.

Nonlinear tests for genomewide association studies. *J.Y. Zhao[1], L. Jin[3], M.M. Xiong[1, 2].* 1) Human Genetics Ctr, Univ Texas HSC at Houston, Houston, TX; 2) School of Life Science, Fudan University, Shanghai, China; 3) Center for Genome Information, Department of Environmental Health, University of Cincinnati, OH.

As millions of single-nucleotide polymorphisms (SNPs) have been confirmed and high throughput genotyping technologies have been rapidly developed, large-scale genomewide association studies are feasible in practice. Genomewide association studies require performing a large number of multiple tests. After accounting for multiple comparisons, each independent test needs very small p-values to ensure a genomewide significance level of 0.05. Unfortunately, almost no current statistical methods can provide very small p-value for genetic association tests. In this report, we introduce nonlinear tests, which are based on nonlinear transformation of allele or haplotype frequencies, to amplify the differences in allele or haplotype frequencies. We show that a class of similarity measure-based test statistics is based on the quadratic function of allele or haplotype frequencies, thus they belong to nonlinear tests. The type I error rates of the nonlinear tests are validated using extensive simulation studies. Power of the nonlinear test statistics are studies by analytical methods. Power study shows that, in most cases, nonlinear test statistics have higher power than the standard chi-square test statistic. The difference between the power of the nonlinear test statistics and the standard chi-square test statistic depends on the measure of nonlinearity of the nonlinear transformation of allele or haplotype frequencies. To further evaluate the performance of the nonlinear test statistics, they are also applied to three real examples.

Multipoint linkage analysis for a very dense set of markers. *S. Bacanu.* Genetic Research, GlaxoSmithKline, Research Tr, NC.

Multipoint linkage methods are powerful tools that are often employed as the first means to discover alleles affecting liability to diseases. With the advent of dense marker maps, linkage disequilibrium (LD) between markers is inevitable and it comes at the cost of bias and increased rate of false-positive findings for linkage analyses that assume alleles of different markers are independent. I propose a multipoint on subsets method that avoids this issue by partitioning the markers into interlaced and non-overlapping subsets. Each subset is analyzed separately, their statistics are then averaged, and the resulting average is standardized by its estimated standard deviation. In addition to being robust to the challenges induced by dependent marker alleles, data simulated under linkage equilibrium show that the proposed method does not suffer any detectable loss of power when compared to traditional methods.

Theoretical comparison of P-value for a disease variant and P-value for the adjacent biallelic marker in case-control association test. *J. Ohashi, K. Tokunaga.* Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

Although common disease variants are expected to be identified by fine-scale mapping using case-control association test, a disease variant does not always show smaller P-value than the adjacent polymorphic markers if linkage disequilibrium (LD) between them is strong. It is therefore generally difficult to detect a true disease variant based solely on the P-values for the tested markers being in LD each other. To find a condition that a primary variant associated with the disease can be determined based on P-values from case-control association test, we compared P-value for a disease variant with that for the adjacent biallelic marker being in LD, using a computer simulation analysis where two-locus two-allele model (i.e., one disease variant and one biallelic marker) was assumed. In the simulation, we estimated the probability that P-value for the marker being in LD with the variant is smaller than that for the disease variant for a variety of parameter sets (haplotype frequency, penetrance, sample size). The estimated probability was not so small for small penetrance and strong LD when the sample size is small (e.g., 300 cases and 300 controls). However, P-value for the marker became hardly a one-tenth following of P-value for the disease variant. These results suggest that a single variant primarily associated with the disease can be inferred by case-control association test only when P-value for the variant is markedly smaller than those of all other polymorphisms being in LD with the variant.

The Khatri Sikh Diabetes Study (SDS): Study Design, Methodology, Sample Collection and Initial Results. *D.K. Sanghera[1], J.S. Bhatti[2], G.K. Bhatti[3], S.K. Ralhan[2], G.S. Wander[2], J.R. Singh[4], C.H. Bunker[5], D.E. Weeks[1], M.I. Kamboh[1], R.E. Ferrell[1].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA; 2) Hero DMC Heart Institute, Ludhiana, Punjab, India; 3) 560-B, Sector 32-A, Chandigarh, India; 4) Guru Nanak Dev University, Amritsar, Punjab, India; 5) Department of Epidemiology, University of Pittsburgh, PA.

Type 2 diabetes (T2DM) has become a major public health problem in India. The pilot or Phase I of the Sikh Diabetes Study (SDS) was launched to build resources to initiate a large scale genetic epidemiological program with an aim to identify the genomic regions responsible for diabetes susceptibility in Khatri Sikhs from North India. With full informed consents and following stringent selection criteria, 1892 subjects were enrolled to participate in this family-based linkage study. Of these, 1623 subjects were recruited from 324 families including 1288 T2DM patients (siblings, parents or relatives) and 335 unaffected siblings, parents or relatives. The remaining 269 subjects were enrolled as unrelated non-diabetic controls. Each one of these families had at least two siblings affected with T2DM with a current total of 515 affected sibling pairs (ASPs). Buffy coats were harvested from EDTA whole blood and DNA was extracted and stored at -80oC. This population has several novel features which are ideal for performing genetic studies. This vegetarian, non-smoking endogamous caste group presents unusual clinical spectrum with relatively younger age of onset and possesses a unique physiology of obesity that remains unexplained by BMI. It is important to study the underlying molecular mechanisms responsible for increased prevalence of T2DM especially in the populations adapted to survival under nutritional thriftiness and physically demanding work. The SDS has created a comprehensive genetic and epidemiological resource. Ours will be the first systematically conducted study to be undertaken in this North Indian population and will facilitate a genome-wide search to map Asian Indian susceptibility genes.

Incorporation of sex-specific recombination information fails to improve PPL performance. *M.W. Logue, V.J. Vieland.* Center for Statistical Genetics Research, University of Iowa, Iowa City, IA.

The 2-point posterior probability of linkage, or PPL, is a Bayesian statistic which directly measures the probability that a marker is linked to a disease gene. It removes the need to specify the genetic model *a priori* by integrating over the genetic model space. The Bayesian nature of the PPL allows incorporation of prior information, such as the sex-specific recombination ratio ($R=_F/_M$) in the region of the marker in question. In a series of simulations, we explore the effects of assuming a single *sex-averaged* in PPL computation (denoted PPL_{SA}), and compare it to a PPL computed from a *sex-specific* likelihood (as a function of $_M$ and $_F$), denoted PPL_{SS}. We evaluate the PPL_{SS} with two different forms of the prior distribution on ($_M$, $_F$). The first is fixed (independent of R), while the second places additional prior weight based on knowledge of R. We denote the PPLs computed with these priors as the *non-adaptive* (PPL_{SS-NA}), and the *adaptive* (PPL_{SS-A}) sex-specific PPLs. We find that the PPL_{SS-NA} performed almost identically to the PPL_{SA} replicate by replicate, across a large number of generating models. However, the PPL_{SS-A} varied widely from the PPL_{SA} (and PPL_{SS-NA}), being as much as 21% lower, and performed worse, on average, than the PPL_{SA} and PPL_{SS-NA}, when R was large. This is due to considerable variability in the observed likelihood, in that, while maximum likelihood estimates of $_M$ and $_F$ perform well "on average", in any particular replicate peak $_M$, $_F$ locations bear little relation to the true generating value of R, even in very large samples. Thus, even under ideal circumstances, MLEs of $_M$ and $_F$ are not reliable indicators of the true values; and as a result, incorporating prior genomic information is not necessarily helpful in real applications.

Mixed inheritance model-based method to implement linkage analysis for multiple genetic loci responsible for the complex diseases under threshold model. *A. Narita, A. Tajima, I. Inoue.* Div Genetic Diagnosis, Inst Medical Science, Tokyo, Japan.

As multiple factors, either genetic or environmental, are involved in complex diseases, difficulties in the elucidation of the complicated architecture underlying these diseases are confronting. By incorporating the concept of quantitative trait, we developed an effective tool to detect multiple genetic loci responsible for the complex diseases under the threshold model, in which a discrete trait is actually determined by a normally distributed variable, called liability, that depends on multiple genetic effects (*liability* = + *G* + *e*). In addition, genetic factors affecting predisposition of these diseases are, in many cases, biallelic SNPs (at which one allele increases the risk of affection, whereas the other might reduce). Therefore, instead of the commonly-used variance component model which treats genetic effects as random effects, the mixed inheritance model is adopted. The model considers three possible genotypes at the causative loci as fixed effects and the unobservable genotypes at the loci can be estimated for each individual. At the same time, as the method is based on the Bayesian approach via the Markov chain Monte Carlo (MCMC) algorithm, genotypic effects at each locus and its chromosomal location can be also estimated. Moreover, the reversible jump MCMC algorithm, which is a specialized version of the MCMC algorithm for the determination of the most likely genetic model through iterative additions and deletions of variables, enables estimation of the number of loci responsible for the diseases as an unknown parameter. Effectiveness and flexibility of the method were demonstrated by using simulated data. The results indicate that some potential causative loci, which have an important role in predispositions of these complex diseases but have not been detected previously, would be additionally identified. In the future, loci which have epistatic effects (gene-to-gene interactions) will also be approached.

A cluster-based SNP linkage mapping set based on genetic distances and on haplotype heterozygosity. *J. Ziegle, F.C.L. Hyland, J. Day, C. Scafe, R. Koehler, N. Peyret, C. Larry, M. Rhodes, T. Woodage, X. You, L. Xu, E. Spier, F.M. de la Vega.* Applied Biosystems, 850 Lincoln Centre Dr., Foster City, CA 94404, USA.

A SNP linkage mapping set that combines the heterozygosity of microsatellite loci and the efficiency, accuracy, cost advantages and automation potential of SNP genotyping is described. To enable high-throughput and cost-effective genotyping, the platform for this human linkage mapping set is the SNPlex Genotyping System, a multiplexed high throughput genotyping platform based on the oligonucleotide ligation assay that utilizes capillary electrophoresis as the readout. A 3.9 cM resolution SNP map for linkage mapping previously developed by The SNP Consortium (TSC) (Matise et al. 2003) was used as the framework. The set is composed of SNP clusters, with spacing between clusters based on genetic rather than physical distance. In the first phase, SNPlex assays for markers in the TSC linkage mapping set were tested. In the second phase, validated SNPs from the TaqMan SNP genotyping assays were chosen to fill gaps between clusters larger than 5 cM. To select new candidate SNPs, NCBI physical coordinates were transformed to genetic distances using the TSC genetic map. The transform was refined using the metric linkage disequilibrium map (expressed in LD Units) derived from the TaqMan assay validation. 10 candidate SNPs were selected for each cluster. Haplotypes were computed for every possible combination of 4 of these 10 SNPs, and the 4 SNPs that maximized haplotype heterozygosity across four populations (Caucasian, African American, Japanese, Chinese) were converted into SNPlex assays using the OLA Probe Designer (OPD) pipeline, and extensively validated to select only highly robust SNPs. A genetic map was calculated using genotypes of 574 samples from 43 CEPH families. Genetic distances proved to be highly correlated with LDU: the average correlation between LDU and observed cM was 0.99. The linkage mapping set is composed of clusters spaced 1.9 cM apart, with the mean distance between SNPs being 1.04 cM. No gaps larger than 10cM are present. The average information content of the set is 0.95.

A Multimarker Regression-Based Test of Linkage for Affected-Sib-Pairs at Two Linked Loci. *M.J Barber, J.A. Todd, H.J. Cordell.* Juvenile Diabetes Research Foundation/Wellcome Trust Diabetes and Inflammation Laboratory, Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, UK.

We address the analytical problem of evaluating the evidence for linkage at a test locus while taking into account the effect of a known linked disease locus. The method we propose is a multimarker regression approach that models the identity-by-descent states for affected-sib-pairs at a series of linked markers in terms of the identity-by-descent state at the known disease locus. Our method allows analysis to be performed at a test location (or a series of locations) without the requirement that identity-by-descent be directly observed at either the test or the known conditioning locus. An advantage of our method is that identity-by-descent states from multiple markers are included simultaneously in the test of linkage, without recourse to multipoint imputation. The properties and power of the method are examined under various null and alternative hypotheses. The method is applied to data from a type 1 diabetes study to examine the evidence for an additional locus (IDDM15) on chromosome 6, linked to IDDM1 in the HLA region. Analysis in this region is complicated by the strong effect of IDDM1 in type 1 diabetes, and by differing rates of male and female recombination in the region.

Transmission recoding: a powerful multipoint likelihood algorithm for linkage and linkage disequilibrium mapping. *J.R. O'Connell.* Div Endo/Diabetes/Nutrition, Univ Maryland, Baltimore, MD.

Multipoint likelihood calculations are the core of pedigree-based gene mapping methods. Algorithmic advances continue to extend the range of computationally feasible exact likelihood calculations with regard to both the number of markers and size of pedigrees. Allele consolidation methods such as set recoding as implemented into VITESSE are the most powerful methods to date to speed up the Elston-Stewart algorithm. We introduce a new recoding method called *transmission recoding* based on the simple biological principle that at meiosis only one of two alleles in a parental diploid genotype is transmitted to the offspring while the other allele is lost to genetic drift. When an individual is untyped the allelic state of the non-transmitted allele is unconstrained and only enters the likelihood through its population frequency. Thus, by introducing a universal non-transmitted allele X with unit frequency to represent all alleles at a locus, we can recode genotypes as T/T, T/X and X/X, where T represents a transmitted allele. In addition we introduce a new parent-offspring inheritance rule: a parent genotype T_1/T_2 is consistent with its offspring if and only if *both* alleles T_1 and T_2 are transmitted. Thus, in particular, the only consistent parental genotypes in matings with a single genotyped offspring are of the form T/X, where T is an observed allele in the offspring. Transmission recoding is most powerful in the computationally difficult components of the pedigree containing consecutive generations of missing data where the number of founder alleles lost to genetic drift tends to be large compared to the number of observed non-founder alleles. Timing results show that transmission recoding can speed up the likelihood calculation 2-3 orders of magnitude over set recoding. Moreover, transmission recoding also eliminates biases in maximum likelihood estimates of allele and haplotype frequencies due to imputing unobserved founder alleles and haplotypes, therefore preserving linkage disequilibrium patterns between densely spaced markers. Transmission recoding is a powerful method to improve linkage and association mapping in pedigrees.

Consequences of exhaustive haplotype association analysis. *B.A. Salisbury, R.S. Judson, M. Pungliya, Y. Zhao, B. Dain.* Genaissance Pharmaceuticals, New Haven, CT.

Purpose: In searching for associations between a phenotype and a genetic locus with multiple polymorphisms, it is possible to test every individual polymorphism and every genetic marker formed by alleles from two or more of those polymorphisms (i.e., haplotypes). We have investigated trade-offs inherent in exhaustively testing markers of ever greater complexity. **Methods:** From each of 11 genes sequenced on 200 subjects we designated two SNPs, one common and one rare, as causal in dominant mode. For each of these 22 SNPs independently, we modeled four continuous phenotypes, two each with raw p-values equal to 0.005 and 0.00005. Associations were sought between each gene and its corresponding phenotypes, with limits of 1 to 5 SNPs per marker. Analyses were run with and without the model SNPs. For each gene-phenotype test, the most significant marker was recorded along with its adjusted p-value, which is the fraction of permuted data sets for which the best marker had a p-value at least as good as the original best. **Results:** Allowing more complex markers decreases raw p-values greatly. When causative SNPs are included in analyses, adjusted p-values get worse with an increasing complexity limit, as one would predict. In contrast, when the causative SNPs are excluded, adjusted p-values improve, on average, as more complex markers are allowed, in some cases rescuing associations that would be lost if testing only single SNPs. Another consequence of allowing more complex markers is that the number of SNPs in the most significant markers goes up, regardless whether the causative SNP is tested. Surprisingly, the number of SNPs in a gene had a negligible effect on adjusted p-values. **Conclusions:** These findings argue for testing multi-SNP markers whenever the true causal sites may not have been included, a possibility that can rarely be excluded. However, resulting associations must be treated cautiously, as the complex markers giving the lowest p-values are likely to be overfit. That larger loci are not inherently more challenging is encouraging and suggests that it may be unnecessary to break them down into small haplotype blocks for analysis.

Allelic structure of human disease, a simulation study. *M. Kimmel, B. Peng.* Dept Statistics, Rice Univ, Houston, TX.

The success of mapping genes involved in complex diseases using association or linkage disequilibrium based methods depends heavily on the number and frequency of susceptibility alleles of these genes. These methods would be economical and statistical feasible if common diseases are usually influenced by one or a few susceptibility alleles at each locus (CDCV hypothesis), but not so if there is a high degree of allelic heterogeneity. Here, we use population simulations to investigate the impact of various genetic and demographic factors on the allelic spectra of common diseases, and estimate the effective number of alleles of common diseases with in the general human population as well as in isolated populations.

Sexual dimorphism and large QTL on chromosome 2p influencing serum uric acid levels in hypertensive families from a relative isolate population. *F. Gagnon[1], J. Pintos[2], D. Gaudet[2], J. Tremblay[2], A.W. Cowley[3], P. Hamet[2].* 1) Epidemiology and Comm Med,Univ of Ottawa,Ottawa,Canada; 2) CHUM,Montreal,Canada; 3) Medical College of Wisconsin,Milwaukee,USA.

Epidemiological and experimental data have long suggested a relationship between serum uric acid levels (SUA) and essential hypertension (HT). SUA is ignored in clinical practice because it is believed not to have a causal role in HT. Recently, a biological mechanism by which SUA could cause HT in humans was identified. We completed a genome scan for SUA in 93 families (n=1116), from a French-Canadian relative isolate, ascertained through hypertensive dyslipidemic probands. Using covariated-adjusted (age and sex) joint linkage and segregation analysis based on Bayesian Markov chain Monte Carlo methods, we localized a quantitative trait locus (QTL) with an individual contribution of ~ 13% of total SUA variance. We estimated a strong sexual dimorphism for SUA with an effect of ~22% of the total variance due to being female; age had an effect of ~4%. Multiple regression analysis supported an interaction of age and sex. The SUA QTL is located on chromosome (chr) 2p at the HT locus (OMIM 607329) identified by Angius et al. (2002). We re-analyzed chr 2 adding an interaction term for age and sex to the covariates, which increased by ~2.4 fold the linkage signal, with intensity ratio (IR) for linkage of ~ 26. The IR is the posterior acceptance rate of QTL positions, calculated here for 2 cM intervals, to the prior such rate. We assessed the empirical significance for this QTL using the LOP score (log of the ratio of the posterior probabilities of linkage to the chr 2 QTL and ten simulated chr without QTL)(Daw et al. 2003): LOP 3.13 with an estimated gene effect on the squared-root variance of ~ 31 mol/L. Variance-component analysis of chr 2 provided some additional evidence for this QTL (Lod 1.52). In view of the sexual dimorphism observed for SUA, including our report for higher uric acid heritability estimates in females (Am.J.Hum.Genet 76:815-832, 2005), a model-free linkage analysis adapted for genomic imprinting is under way, as well as genotype by sex interaction variance-component analysis.

Dissecting Heritabilities for 98 Quantitative Traits in a Large Cohort Study with 6,148 Participants. *W-M. Chen[1], G. Pilia[2], A. Scuteri[3,4], M. Orru[2], G. Albai[2], M. Dei[2], S. Lai[2], L. Usala[2], C. Mameli[2], L. Vacca[2], M. Deiana[2], M. Masala[2], S.S. Najjar[4], A. Terracciano[4], T. Nedorezov[4], A. Sharov[4], A.B. Zonderman[4], P. Costa[4], E.G. Lakatta[4], D. Schlessinger[4], the Progenia Team.* 1) Dept. of Biostatistics, U. of Michigan, Ann arbor; 2) INN-Consiglio Nazionale delle Ricerche, Cagliari, Italy; 3) Unita' Operativa Geriatria, Rome, Italy; 4) Gerontology Research Center, NIA, Baltimore.

Large pedigrees from founder populations offer a powerful setting for genetic studies because of their greater genetic and phenotypic homogeneity. In a cluster of 4 towns in a Sardinian founder population, we recruited a cohort of 6148 participants, comprising over 60% of those aged 14-102. In all participants born within the 4 towns, at least 95% have all grandparents born in the same region. The group includes 4933 sib pairs, 4256 parent-child pairs, 4014 cousin pairs, and 6400 avuncular pairs. Quantitative traits (98) were scored, including cardiovascular risk factors and facets of personality as well as blood tests and anthropometric measurements. Analysis of this large dataset posed novel analytical and computational challenges. Data were fitted under a variety of variance components models incorporating genetic and environmental effects and their interactions. To obtain maximum likelihood estimates of heritabilities of all traits, we implemented a computationally efficient scoring method. Estimates of narrow genetic heritability for cardiovascular and personality traits ranged from about 0.09 to 0.45, while estimates of broad heritability which includes genetic dominance were up to 2-fold higher. For 25 traits, heritability differences were seen between the sexes, with 19 of them more heritable in females. In addition, 48 traits showed differences in heritability between those above and below mean age, with 36 traits more heritable in young individuals. Nevertheless, variance component analyses showed that for nearly every trait, the same QTLs contribute to variation for male and female, young and old. Prospective linkage analyses are predicted to have the power to detect loci that contribute about 10% of genetic variance for single or multiple traits.

Genome-wide scan of a delayed skin granulomatous reaction in leprosy sibships. *B. Ranque[1], A. Alcaïs[1], N.V. Thuc[2], V.H. Thai[2], E. Schurr[3], L. Abel[1].* 1) unité INSERM 550, faculté Necker, PARIS,France; 2) hospital for Dermato-Venerology, Ho Chi Minh City, Vietnam; 3) Mac Gill university, Montréal, Canada.

Leprosy is a chronic infectious disease caused by Mycobacterium leprae affecting 600,000 people each year. The Mitsuda reaction is a delayed skin granulomatous reaction elicited by intradermal injection of heat killed *M.leprae* that reflects cellular immune response to *M.leprae*. While epidemiological studies have provided evidence for a genetic control of the Mitsuda response, the exact nature of this genetic component remains unknown.

We first conducted a segregation analysis of quantitative Mitsuda reaction in 168 nuclear Vietnamese families ascertained through leprosy patients. Different strategies of analysis provided strong evidence for a recessive major gene controlling the Mitsuda reaction, independently of the leprosy status. Under this genetic model, 12% of the population was homozygous for the recessive allele and predicted to display high values of Mitsuda reaction. Noteworthy, strong residual familial correlations persisted after accounting for the major gene effect.

Subsequently, a genome-wide scan of the quantitative Mitsuda reaction was performed in a subsample of 19 families (110 children), using both model-based (the genetic model being estimated by the segregation analysis), and model-free (quantitative Maximum Likelihood Binomial) approaches. Multipoint analyses provided some evidence for linkage (lod score>1.1) to 5 chromosomal regions, which were further saturated by 30 markers. The model-free fine mapping found a suggestive linkage to the NRAMP1 gene (lod score=2.1), confirming the results of a former candidate gene linkage study. In addition, both model-based and model-free analyses identified a novel chromosomal region. Interestingly, we found a negative correlation between the family-specific lod scores at the two regions, suggesting a negative interaction between them.

So far, this study is the most complete dissection of the genetic control of the Mitsuda reaction, and is expected to cast novel lights into the mechanisms of granuloma formation in leprosy.

Genomic screening in family-based association testing: a new screening methodology. *A. Murphy[1], C. Lange[1,2].* 1) Biostatistics, Harvard School of Public Hlth, Boston, MA; 2) Channing Laboratory, Harvard Medical School, USA.

Recently, Van Steen et al (2005) introduced a two stage-testing strategy for family-based designs that substantially outperforms standard methodology, e.g. false-discovery rate (FDR, Benjamini and Hochberg 1995), which made genome-wide association testing feasible, even for relatively moderate sample sizes. Their approach is built upon the conditional mean model (Lange et al 2003), and therefore requires variation in the phenotype or trait to be tested for association. However, in most family-based studies, affection status is the primary phenotype of interest. Typically, only affected probands are recruited, making an application of the testing strategy by Van Steen et al (2005) impossible. Here, we propose a completely novel approach that can be applied in such situations to circumvent the multiple testing problem. Our method has the same advantages as the approach by Van Steen et al (2005), but does not require any variation in the phenotype or specification of a phenotypic mean model. We assess power of our screening method by analytical power calculations and simulation studies. Its practical importance is illustrated by an application to a 100K-scan of the Framingham Heart Study.

Assessing genotyping error rates using test-retest data. *A.D. Anderson.* Department of Statistics and Bioinformatics Research Center North Carolina State Univ, NC.

Estimating genotyping error rates is an important component of quality control when genotypes are to be used in scientific studies (e.g. using phenotype-genotype associations to map complex traits). One common method for assessing the error rate is to evaluate a single genotype many times and calculate the proportion of reported genotypes that were in error. The data we dealt with had an alternate form: A number of genotypes were run twice and we were asked to use the concordance/discordance status of each pair of reported genotypes to estimate the error rate. In this work, we assume a simple model for genotyping error rates and use it to derive a maximum likelihood estimator and associated Wald and score confidence intervals for estimating genotyping error rates from such test-retest data. We then compare the behavior of the two proposed confidence intervals for various sample sizes, genotyping error rates, and types of markers. Our results show that, for small error rates such as might be typically expected in human genetic studies, the score confidence interval is to be preferred. However, when error rates are expected to be high, as might be the case when genotypes are run using degraded DNA (e.g. some forensic analyses), the Wald confidence interval shows better behavior. We conclude with simulation results that demonstrate that our estimator performs well even when our model assumptions are violated.

Disease association in case-control studies - a latent variable approach. *T. Wang[1,2], H.J. Jacob[2], Z.B. Zeng[3].* 1) Division of Biostatistics, Medical College of Wisconsin, Milwaukee, WI; 2) Human Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 3) Bioinformatics Research Center & Department of Statistics, North Carolina State University, Raleigh, NC.

There is a growing utilization of high-resolution genetic markers of single nucleotide polymorphisms (SNPs) in characterization of sequence variants in regions harboring genes that influence common complex traits such as hypertension and diabetes. In this study, we present a method for testing disease association in the case-control based design with multiple tightly linked SNPs. First, an EM algorithm is used to estimate haplotype frequencies in cases and controls separately. Following this, the association between multiple SNPs and a disease is assessed through the existence of a latent trait locus. A likelihood-based statistic provides a comprehensive test for various relevant hypotheses. In case-control association studies, ascertainment of individuals that exhibit a disease phenotype may enrich the underlying disease mutant alleles. Various evolutionary factors may also influence the association pattern in our current sampled populations. Simulation studies are implemented via random coalescent process to evaluate influence of sample ascertainment and various evolutionary factors on the power and asymptotic behavior of the test statistic.

Likelihood association tests. *T.M. Teslovich, D.J. Cutler.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Conventional genetic disease association test statistics use a relatively small proportion of the available genetic information. Often the test statistic compares the frequency of an allele in Case versus Control individuals, or compares the frequency of transmission of an allele from heterozygous parents to affected offspring (TDT). While these simplified approaches lead to easy-to-calculate test statistics, and are sometimes highly powered, they ignore all the complexity of real disease, such as dominance relationships between alleles, differences in effect in males versus females, and epigenetic (parent of origin) effects. Worse still, these simplified approaches often lead to substantial false positive rates from such real world complicating factors as population stratification in the Case-Control studies and genotyping error in TDT studies. Combining data from these two types of study designs is often impossible in a conventional framework.

Here we describe a new analytical framework, Likelihood Association Tests (LATs) that explicitly accounts for all these real world complications: arbitrary dominance, gender specific effects, epigenetic effects, population stratification, and genotyping error. We demonstrate how to use LATs with either Case-Control or Trio Data, or both simultaneously. We show that in the simplest of situations, LATs are at least as powerful as conventional test statistics (such as TDTs). However, in most situations, particularly involving complex genetic models (gender specific or epigenetic affects), LATs are substantially more powerful than conventional tests. We also show that LATs correctly account for population stratification and genotyping error, and are not subject to false positives from these sources.

Analysis of the protein polymorphism Tyr402His in the Complement Factor H (CFH) gene in extremely discordant sibpairs with neovascular Age-related Macular Degeneration. *M. DeAngelis[1], I. Kim[1], F. Ji[2], S. Adams[1], A. Harring[1], T. Osentoski[3], A. Capone[3], J. Ott[2], J. Miller[1], T. Dryja[1].* 1) The Ocular Molecular Genetics Institute and the Retina Service, Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 2) The Laboratory of Statistical Genetics, Rockefeller University, New York, NYInfirmary, Boston, MA; 3) Associated Retinal Consultants, PC., William Beaumont Hospital, Royal Oak, MI.

We studied the Tyr402His protein polymorphism in the CFH gene recently reported by several other groups to be associated with increased risk for all subtypes of age-related macular degeneration (AMD). We ascertained 55 extremely discordant sibpairs in which one member (the index patient) had neovascular AMD and another member (the unaffected sib) had no sign of AMD at the same age or older. Alleles for this variant were detected through direct sequencing. McNemars test was used to determine statistical significance between the His alleles and disease risk. We found a statistically significant association between the Tyr402His protein polymorphism in the CFH gene in the homozygous state only and the neovascular form of AMD (p=.0001 for 2 His alleles vs.presence of 0 or 1 His alleles, 16 informative pairs or p =.03 for 2 His alleles vs. presence of 0 His alleles only for 6 informative pairs). We found no statistically significant deviation from Hardy-Weinberg equilibrium for both affected and unaffected individuals. In calculating an IBS score for this variant, with a heterozygosity of 0.47, observed data revealed that 6 sibpairs shared 0 alleles (expected=3 sibpairs); 22 sibpairs shared 1 one allele(expected=20 sibpairs) and 27 sib pairs were observed to have 2 alleles in common (expected=32 sibpairs). The difference between the observed and expected for 55 sibpairs yielded an 2=1.52, df=2, P =.47. An observed IBS resulted in a score of 1.38 and the expected score was 1.16. Since the expected IBS of 1.16 is lower than the observed IBS score of 1.38 this may suggest that the presence of 1 His allele exerts a modest affect on disease susceptibility to the neovascular form of AMD.

Association of 3 vitamin D genes with insulin secretion in Hispanic and African Americans: the IRAS Family Study. *C.D. Engelman[1], T.E. Fingerlin[1], C.D. Langefeld[2], A.S. Bagwell[2], S.S Rich[2], R.N. Bergman[3], S.M. Haffner[4], M. Bryer-Ash[5], D.W. Bowden[2], J.M. Norris[1].* 1) University of Colorado at Denver and Health Sciences Center; 2) Wake Forest University School of Medicine; 3) University of Southern California; 4) University of Texas Health Sciences Center; 5) University of California Los Angeles.

Vitamin D is associated with type 2 diabetes and related quantitative traits such as insulin secretion. The vitamin D receptor (VDR) gene, the vitamin D-binding protein (GC) gene, and the vitamin D 1-alpha-hydroxylase (CYP27B1) gene have been implicated, though not consistently, in insulin secretion. All 3 genes are expressed in pancreatic beta cells, which secrete insulin. We genotyped 32 SNPs in the 3 genes (average spacing of 4.5 kb) in 1424 Hispanic American and 604 African American individuals from 90 and 42 extended families, respectively, recruited in the Insulin Resistance Atherosclerosis (IRAS) Family Study. We used the family based association test (FBAT) program to investigate the association of SNPs in the 3 genes and insulin secretion, as measured by acute insulin response (AIR) calculated by minimal model analysis of samples from a frequently-sampled intravenous glucose tolerance test. SNPs were tested individually and in haplotypes containing SNPs associated with AIR and in strong LD with each other (D>.9). In African Americans, 3 contiguous SNPs in the VDR gene, rs9729, rs1544410 and rs2239185, were associated or marginally associated with AIR (p=0.03, 0.07, 0.09, respectively). The AGT haplotype formed by these SNPs was associated with higher AIR (p=0.02). Two contiguous SNPs in the GC gene, rs1491709 and rs4588, were associated or marginally associated with AIR (p=0.03 and 0.06, respectively). The TC haplotype formed by these SNPs was associated with higher AIR (p=0.05). In Hispanics, one SNP in the GC gene, rs222003, was associated with AIR (p=0.02). The CYP27B1 gene was not associated with AIR in either ethnic group. This is the first report of evidence that the VDR and GC genes may play a role in insulin secretion in Hispanic and African Americans, as has been reported in other ethnic groups.

Case-control statistical comparison of LD patterns for genetic association studies. *D.V. Zaykin*[1], *Z. Meng*[2]. 1) Biostatistics, NIEHS/NIH, Res Triang Prk, NC; 2) Clinical Biostatistics, Merck Research Laboratories.

Characterization of LD as a part of the analysis of haplotypic variation is an important step during association studies. It has been observed that in a region of genetic association the extent of LD is likely to differ between the case and the control groups. Color plots of standardized measures of LD are reported increasingly often. Such plots allow to visually assess the difference in LD between phenotype subgroups and researchers might claim higher LD in the cases based on such assessment. We present approaches for statistical comparison of such pairwise matrices of LD. Our methods avoid the HWE assumption, allow efficient computation, graphical display and statistical characterization of pairwise matrices of LD. Case-control comparison of LD facilitates statistical analysis aimed for identification and description of genetic variation underlying disease susceptibility, efficacy and adverse reactions to drugs.

Estimation and testing of genotype and haplotype effects in family-based analyses of quantitative traits: comparison of prospective and retrospective approaches. *E. Wheeler, H.J. Cordell.* Department of Medical Genetics, University of Cambridge, UK.

The case/pseudocontrol approach is a convenient framework for family-based association analysis of case-parent trios, incorporating several previously-proposed methods such as the transmission/disequilibrium test and log-linear modelling of parent-of-origin effects. The method allows genotype and haplotype analysis at an arbitrary number of linked and unlinked multiallelic loci, as well as modelling of more complex effects such as epistasis, parent-of-origin effects, maternal genotype and mother-child interaction effects, and gene-environment interactions. Here we extend the method to perform analysis of quantitative as opposed to dichotomous (disease) traits. The resulting method can be thought of as a retrospective approach, modelling genotype given trait value. Application of this method to quantitative traits involves several complications not encountered when analysing disease traits, such as issues related to selected sampling and unmodelled population stratification. Through simulations and analytical derivations, we examine the power and properties of our proposed approach, and compare it to several related methods for single-locus quantitative trait association analysis. All methods are found to give correct type 1 error rates and unbiased parameter estimates when applied to randomly ascertained trios from a single homogeneous population. With randomly ascertained families, in the presence of population stratification, a prospective approach (modelling trait value given genotype) is generally more efficient and interpretable than our retrospective approach. However, our method is found to have some advantages with regard to estimation and interpretability of parameter estimates when applied to selected samples.

Testing for association based on excess allele sharing in a sample of related cases and controls. *L. Klei, K. Roeder.* Carnegie Mellon Univ, Pittsburgh, PA.

We compare a new matching statistic (MS) to two available methods in which a sample of related cases and controls can be used to determine association signals. MS is based on detecting excess allele matching between all pairs of cases by using the difference between observed and expected IBS for each pair. Expected IBS is determined from the population allele frequencies and the kinship of the pairs. We also explored the Hellinger distance (HD), which is determined by taking the sum of the squared differences of the square root of allele frequencies in cases and controls. These methods were compared to the case control quasi-likelihood score (CC-QLS), which is based on the difference between allele counts in cases and controls, properly adjusted for relatedness (Bourgain et al. 2003). To obtain the estimates for the allele frequencies for these three methods we used BLUE for estimating allele frequencies in complex pedigrees (McPeek et al. 2004). We simulated datasets for a disease with low prevalence (0.02) and moderate to high disease allele frequencies under an additive genetic model. The disease allele was linked to an STR allele using different levels of LD. STRs were simulated using a linkage dataset to mimic naturally occurring markers. We created complex pedigrees with at least 2 related cases. Controls were also drawn from these pedigrees. Our results suggest that HD is more powerful than CC-QLS. We also observe a tendency for HD to be more powerful for low frequency STR alleles, while MS is more powerful for high frequency STR alleles. Our results also suggest that the highest power for HD is found in situations where the allele frequency of the disease matches the frequency of the STR allele. In contrast maximum power of MS is always highest for intermediate STR allele frequency irregardless of the disease allele frequency. Low correlations between MS and HD indicate that the two statistics key in on different characteristics of the linked allele. Therefore, these methods should not be seen as complementary in finding possible association between a disease and a marker for many different situations. We also apply these methods to complex schizophrenia pedigrees.

Missing Phenotype Data Imputation in Pedigree Data Analysis. *B. Fridley[1], M. de Andrade[2].* 1) Statistics, University of Wiscosin, LaCrosse, WI; 2) Div Biostatistics, Mayo Clinic College of Medicine, Rochester, MN.

Methods to handle missing data have been a statistical area of research for many years. However, little research has been done in the area of missing phenotype information within a pedigree analysis. Recently, Fridley et al (2003) proposed a data augmentation approach within a Markov chain Monte Carlo for imputing missing phenotype information for polygenic models using family data. The imputation for the missing data takes into account the familial relationships and uses the observed familial information. We propose extending the use of data augmentation as a means to impute values for the missing phenotype information, from which a pedigree data analysis using a major gene model could be fit. Using a polygenic model, data augmentation will produce a set of k complete-augmentation data from which a major gene model can be fit. By producing a set of k complete datasets, the total variance associated with an estimate can be partitioned into a within-imputation and a between-imputation component. Data augmentation for missing phenotype information was completed using the Genetic Analysis Workshop (GAW13) data.

A method for singlepoint qualitative trait mapping in arbitrarily large and complex pedigrees. *M. Abney.* Dept Human Genetics, Univ Chicago, Chicago, IL.

Linkage mapping on large pedigrees is typically more powerful than mapping on smaller pedigrees, given a fixed sample size, yet there are few methods for performing such analyses. Methods that can analyze large pedigrees have been oriented towards either quantitative traits or based on model-dependent, parametric methods. Here, I present a nonparametric method for singlepoint linkage analysis on pedigrees of virtually arbitrary size and complexity. The method is able to compute the allele sharing statistic S-pairs as well as assess significance even in the case of only a single pedigree. The method is fast enough to analyze typical genome screen data. I demonstrate the validity of the test by presenting the results of simulations on a 3,028 person pedigree comprising 13 generations with 50 affected individuals (1,275 pairs). I also examine the consequences of performing an analysis with the pedigree divided into separate subpedigrees.

A comparison of multilocus mapping approaches in the presence of epistasis and heterogeneity. *J. Tzenova, M. Farrall.* Dept Cardiovascular Medicine, Wellcome Trust Centre for Human Genetics, Univ Oxford, Oxford, United Kingdom.

Several linkage methods have been proposed to assess the evidence that multiple regions contribute to a complex trait. We investigated the performance of five different approaches under two-locus genetic models of epistasis and heterogeneity in samples of affected-sib-pairs (ASP). Two-locus genetic models were specified in terms of the two-locus penetrances, resulting in 9 models of epistasis - four of which fit a multiplicative model, 2 models of heterogeneity, and 2 additive models. Data were also generated under the null hypothesis of neither gene contributing to the trait or a single gene acting under a recessive, dominant, or interference model. Marker genotypes were simulated in samples of 100 ASPs assuming a population prevalence of 10%, sibling recurrence risk ratio of 2, and equal disease allele frequencies at both disease loci. We analyzed each replicate with 1/ Genehunter-two-locus using the two-locus parametric Lod score (Strauch et al., Am J Hum Genet, 2000, 66:1945-1957), 2/ Genehunter-Plus using the epistatic and heterogeneity discrete weighting scheme at each locus (Cox et al., Nat Genet, 1999 21:213-215), 3/ Twoloc - a simultaneous two-locus mapping approach in ASP (Farrall, Genet Epi, 1997, 14:103-117), 4/ GeneFinder - a generalized estimating equation approach (Liang et al., Genet Epi, 2001, 21:105-122), and 5/ simplified logistic regression (Holmans, Hum Hered, 2002, 53:92-102). Significance thresholds were obtained for each method under the four null models and false-positive rates were compared to previously published results where applicable. We evaluated power for each method under the different two-locus models and examined the effect of missing data on power. The results vary according to the two-locus method applied, but overall models of strong epistasis fare well regardless of the mapping approach. Methods which stratify the sample appear to have less power than methods which analyze the unstratified sample across all models. We also investigate parameter estimates obtained from three of the methods under each genetic model in an attempt to obtain a range of parameter values specific to the genetic model simulated.

Sample Size needed to detect gene-gene interaction with association designs in the presence of genotyping errors.
S. Wang. Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY.

The needs of searching for gene-gene interactions and accounting for gene-gene interactions in mapping complex diseases have been well acknowledged by researchers. Gauderman (2002) and Wang and Zhao (2003) have reported extensive studies on the statistical power to detect gene-gene interaction through association studies, but without considering the possibility of genotyping errors. As interest in using single-nucleotide polymorphisms (SNPs) as the markers of choices in gene-mapping studies grows, genotyping errors will unfortunately more and more become an issue, especially for high-throughput genotyping methods. Many researches have been done in mapping genes accounting for genotyping error and have suggested the great impact genotyping error might bring, but no work in detecting gene-gene interaction considering genotyping error has been carried out. Therefore, account for genotyping errors in the detection of gene-gene interactions seems to be a necessary when doing complex disease mapping. In this study, we investigate the sample size needed to detect gene-gene interactions at two disease loci with the presence of genotyping errors for association designs. Logistic regression models for disease risks are applied and different genotyping error models are considered. Our results indicate that the required sample size to detect gene-gene interaction increases as genotyping error rate increases, but the amount increased differs with different error models. The increase for case-control design is much greater than that for case-parent design. With error rate varying from 1% to 5%, the increase in the required sample size can be up to 50% for case-parent design, and 100% for case-control design.

A Bayesian approach to the analysis of candidate genes association studies. *B. Servin, M. Stephens.* Statistics, University of Washington, Seattle, WA.

We present a new method for the analysis of data on association studies of candidate genes. The experimental design we focus on is as follows: first, a small panel of individuals is resequenced for the candidate genes, to identify SNPs in the gene and to investigate the patterns of Linkage Disequilibrium (LD). Then, based on the panel information, a subset of SNPs (Tag SNPs) that summarize the variation in the gene is selected. Finally a large cohort of individuals (for whom phenotype data and relevant covariates are available) are genotyped at the Tag SNPs only. Current typical analysis of data from this kind of study focus on the Tag SNPs genotype data and phenotype data for the large cohort, and largely ignore the panel data once Tag SNPs have been selected. In particular, many methods focus on haplotype at Tag SNPs to capture indirectly the effect of untyped variants. The method we propose uses the information on the panel and avoid relying on indirect associations with Tag SNPs. In order to achieve this we proceed in two steps. First, using models for LD in the gene, we estimate the rates of recombination within the gene, the haplotypic phase, and the genotype data at all untyped (ie non-Tag) SNPs. In doing this, we aim to exploit the fact that Tag SNPs are usually selected in such a way that their genotypes are good predictors of the genotypes at non-Tag SNPs. Second, we use a Bayesian regression model to estimate the posterior probability that each SNP is responsible for phenotypic variation. We do this in a Bayesian framework by iterating the two steps outlined above. The first advantage of this setting is that it provides a natural framework within which to account for the fact that the imputed genotypes are only estimates of the actual genotypes. The second advantage is that, in our view, Bayesian approaches to regression can be designed to cope much more satisfactorily with highly correlated covariates (SNP genotypes) than a standard regression approach. We illustrate our method for a simulated case / control study and for a real study on a quantitative trait.

Tagging strategies for the design of complex disease association studies: evidence from large-scale empirical and simulated datasets. *E. Zeggini[1], W. Rayner[1], A. Morris[1], G.A. Hitman[2], M. Walker[3], A.T. Hattersley[4], P. Deloukas[5], L. Cardon[1], M.I. McCarthy[1], on behalf of the International Type 2 Diabetes 1q Consortium.* 1) WTCHG, University of Oxford, Oxford, UK; 2) Centre of Diabetes and Metabolic Medicine, Barts and The London Queen Marys School of Medicine and Dentistry, London, UK; 3) School of Clinical Medical Sciences, University of Newcastle, Newcastle, UK; 4) Centre for Molecular Genetics, Peninsular Medical School, Exeter, UK; 5) Wellcome Trust Sanger Institute, Hinxton, UK.

To evaluate the performance of alternative strategies for defining sets of tag-SNPs on the capacity to capture common and rare variation, we examined large-scale empirical and simulated datasets. As part of the International T2D 1q Consortiums efforts to positionally clone T2D susceptibility variant(s) on 1q, a dense map of SNPs (3000 over 13.5 Mb, the majority from the HapMap but with a proportion of SNPs with MAF<5%) has been genotyped in over 4000 individuals from 7 populations. To ensure that findings were not compromised by the inevitable biases in SNP ascertainment, we repeated studies in simulated datasets generated under the neutral coalescent model. In both datasets, we assessed the effects of training set sample size, MAF distribution and tag-SNP selection method on the proportion of common (MAF>5%) and rare (MAF 1-5%) variation captured in test data. We find that >80% of common SNPs are captured (r^2>0.8) with training-set sample sizes over 45 individuals, irrespective of the tag-SNP selection method used: performance does not improve substantially with larger samples. Tagging of rare SNPs is consistently poor irrespective of training set sample size when tag-SNPs are restricted to common SNPs only (though aggressive analyses outperform pairwise methods). The power to tag rare variants improves when the tag-set is allowed to include SNPs of any MAF, showing a linear increase with training set sample size and reaching 80% of rare variants for training-set sample sizes over 100. This increase in performance, however, necessitates that most of the rare variants be included in the tag-set, at the price of a substantial increase in the number of tags that have to be genotyped.

A full pedigree based method to detect genetic anticipation with application to Huntington's Disease and Li-Fraumeni Syndrome. *T.J. Costello[1], G.E. Bonney[2], L.C. Strong[3], C.I. Amos[1].* 1) Epidemiology, MD Anderson Cancer Center, Houston, TX; 2) Statistical Genetics and Bioinformatics, Howard University, Washington, DC; 3) Clinical Cancer Genetics, MD Anderson Cancer Center, Houston, TX.

Genetic anticipation is defined as a decrease in age of onset or increase in severity as a disease is passed through subsequent generations. Anticipation affects several diseases including Huntington's Disease, Myotonic Dystrophy and Fragile X Syndrome. Additionally, it is suspected in numerous mental disorders (e.g. Schizophrenia, Bipolar Disorder), cancers (Li-Fraumeni Syndrome, Leukemia) and other complex diseases. Several statistical methods have been applied to determine whether anticipation affects a particular disorder, beginning with standard statistical tests and continuing through the development of an affected parent/affected child pair method by Huang and Vieland (1997). These methods have severe limitations for assessing anticipation for a variety of reasons, including familial correlation and low power. Tsai et al (2005) describes a new parent-child pair method that accounts for correlated data in nuclear families, but the authors note that some parent-child pairs may still have to be discarded. Therefore, we have developed a likelihood-based method to assess anticipation in families that appropriately models the underlying transmission of the disease gene and penetrance function. We will present results from simulation studies comparing data sets with differing levels of anticipation versus no anticipation, genetic heterogeneity and missing data along with type I error rates of the method. Preliminary results from simulations suggest this method has good power to detect anticipation and the application of this method to Huntington's Disease and Li-Fraumeni Syndrome data sets revealed evidence for a generation effect in both cases.

Joint analysis of false discovery rate and non-discovery rate. *L. Sun*[1,2,3], *R.V. Craiu*[2]. 1) Department of Public Health Sciences, Univerity of Toronto; 2) Department of Statistics, University of Toronto; 3) Hospital for Sick Children Research Institute, Toronto.

The multiplicity problem has become increasingly important in genetic studies. The seminal work of Benjamini and Hochberg (1995) on the control of the false discovery rate (FDR) has brought forth a way of thinking about multiple hypothesis testing that is often more relevant than the one based on controlling the family-wise error rate (FWER). In the context of FDR, we propose and study a new quantity, the fraction of non-rejections among the cases in which the null hypotheses are false, which we call non-discovery rate (NDR). We argue that, when a large number of hypotheses are tested simultaneously, NDR could be naturally interpreted as type II error rate if FDR is considered as type I error rate, and we show that much can be gained from a clear understanding and representation of the dependence between FDR and NDR. In particular, we are concerned with the trade off between FDR and NDR and its impact on the choice of FDR and sample-size calculation for a desired NDR. The ideas are illustrated using a series of real-data examples, including microarray data and pedigree data.

Association analysis with phenotypic covariates using MDR-Phenomics. *H. Mei[1], ML. Cuccaro[2], MA. Pericak-Vance[2], ER. Martin[2].* 1) Bioinformatics Research Center, North Carolina State Univ, Raleigh, NC; 2) Center for Human Genetics, Duke Univ, Durham, NC.

Mapping genes for complex diseases is hindered by genetic heterogeneity. Many common complex disorders are characterized by phenotypic variation, which can be used to harness genetic heterogeneity. Traditional approaches for incorporating phenotypic covariates rely on stratified analysis, which can lose power when there are many possible strata with no a priori knowledge of optimal groupings. We present a novel statistical approach, MDR-Phenomics (MDR-P), developed to jointly integrate discrete phenotypic covariates with genetic data to identify associations with disease. MDR-P is based on multifactor dimensionality reduction (MDR). It uses the genotype-pedigree disequilibrium test statistic and a modified permutation test (Extended-MDR; Mei et al 2005) to look for significant association in family triads. MDR-P classifies genotypes into high-risk and low-risk groups based on combinations of levels of phenotypic covariates and genotypes. To evaluate MDR-P, we used the simulation program SIMLA to model different levels of heterogeneity and phenotypic covariates. We compared power and type I error for three methods: analysis of the overall dataset without stratification by the phenotypic covariate (NS); stratification by phenotypic covariate with the Bonferroni adjustment (SBA); and MDR-P analysis. We found that all methods have similar type I error with estimates equal to or below the nominal level. In general when the phenotypic covariate was restricted to two levels, SBA was more powerful than MDR-P; both exceeded NS. As the number of phenotypic levels increase, MDR-P becomes more powerful than the SBA approach. This study shows that MDR-P is a valid approach and better able to detect disease genes in the presence of heterogeneity than stratified analysis. Like the MDR, MDR-P is an efficient procedure for dealing with large numbers of phenotypic covariates and genetic loci without substantial loss of power. Further, the patterns of association identified through MDR-P can give clues regarding phenotypic attributes important in defining more homogeneous subgroups.

A 2-locus TDT: properties in the presence of epistasis and population stratification. *S. Kotti, M. Bourgey, F. Clerget-Darpoux.* Inserm U535, Paris, France.

Over the last few years, there has been great interest in assessing the interactive effects of genes because of the important role they may play in the etiology of most human diseases. Until now, several gene-gene interactions have been reported in multifactorial diseases but mainly when one gene effect has already been evidenced. Methods, such as the Conditional TDT, have been proposed to test conditionally to the first gene, the effect of a second one and their interaction. However, it is important to note that this method cannot be applied anymore in the case of epistatic models with weak or no marginal effect at each of the susceptibility loci.

As an alternative, we developed a new method: the 2-locus TDT which has the advantage to be used under such a situation. Our approach is applicable to nuclear family data genotyped for two candidate genes and compares the conditional genotype of the offspring (case genotype) formed by the transmitted gametes given parental genotypes versus the genotype (internal control genotype) formed by the non transmitted gametes.

Using formal computation, we compare our method with the Conditional TDT in terms of:

(i) robustness to population stratification,

(ii) power under different epistatic models.

We show that, unlike the Conditional TDT, the 2-locus TDT is robust to population stratification. In addition, even under no population stratification, the 2-locus TDT may be more powerful than the Conditional TDT.

REGENERATOR: an analysis tool for genetic association testing in extended pedigrees and genealogies of arbitrary size. *K. Allen-Brady, J. Wong, N.J. Camp.* Genetic Epidemiology, Department of Medical Informatics, University of Utah, Salt Lake City, UT.

We present a general approach to testing for association and transmission-disequilibrium of genetic markers and qualitative or quantitative traits in pedigrees and genealogies of arbitrary size and structure. Our approach uses Monte Carlo significance testing to provide a valid test for related individuals that can be applied to any test statistic, and is not limited to statistics with a known distribution. The REGENERATOR software we introduce incorporates several standard statistical tests for association, including chi-square, trend test, odds ratio, means test, ANOVA, as well as several transmission disequilibrium statistics for qualitative and quantitative data. We illustrate the method and software by analyzing breast cancer and age-at-diagnosis data for associations with a tagging-single nucleotide polymorphism (tSNP) in the ATM gene in high-risk Utah breast cancer families. No association with breast cancer was observed. However, a significant difference (p=0.038) was seen for age-at-diagnosis of breast cancer (mean age SD) between heterozygous carriers of the rare allele (54.2 12.3 yrs) compared to the wild type genotype (57.2 13.7 yrs). This reduction in diagnosis age was due mostly to an increase in the percentage of individuals classified as heterozygous being diagnosed < 50 years old compared to individuals with the wild type genotype, and more individuals with the wild type genotype being diagnosed at > 70 years. We conclude that this tSNP has a small but significant effect on age-at-diagnosis of breast cancer.

Population-based Methods For Association Mapping Of Quantitative Traits: Model-Free Approaches. *S. Ghosh, A. Mondal.* Human Genetics Unit, Indian Statistical Inst, Kolkata, India.

Although statistical methods for association mapping of binary traits have been extensively proposed and compared, development of such methods for quantitative traits is currently an active area of interest. The paradigm of association for quantitative traits is not very obvious and methods have generally considered the intuitive concept of differences in allele frequencies between individuals with high values of the quantitative trait and those with low values of the trait as evidence of linkage disequilibrium. While some novel methods of association (Allison 1997, George et al. 1999, Abecassis et al. 2000) for quantitative traits in family-based studies have been developed, population-based quantitative data have usually been analyzed using classical analysis of variance (ANOVA) methods. However, ANOVA is valid in a strict statistical sense only under the assumption of equality of variances in each underlying group. On the other hand, the assumption of equality of variances of the quantitative traits at the different QTL genotypes is genetically unrealistic. Thus, it is of interest to explore for model-free alternatives which would circumvent this problem. We propose two methods: (i) a quantile-based regression and (ii) a goodness of fit chi-square to test for allelic association. The basic paradigm of both the methods is that a marker allele in linkage disequibrium with an allele at the QTL would have a non-uniform frequency distribution across the range of quantitative trait values. We perform Monte-Carlo simulations for different genetic parameters to assess the powers of our proposed methods and find that the two methods give comparable powers.

Statistical Methods for Detecting Microdeletions. *C.C. Wu, S. Shete, C.I. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

Small chromosomal deletions, which have been demonstrated as a fairly common cause for several Mendelian diseases such as Prader-Willi syndrome and Velo-Cardio-Facial syndrome, are commonly observed in children with mental retardation and have been implicated as causally related to some complex diseases, such as autism and schizophrenia. Microdeletions range in size from < 1kb to 4Mb. The density of available microsatellites is only sufficient to detect large deletions. By using single nucleotide polymorphisms (SNPs), the high density of genetic maps would, in principle, be sufficient to identify small deletions. However, microdeletions at microsatellites are more readily detectable than identified from SNPs because of higher information content. We have developed methods for detecting microdeletions using a case-control approach to identifying regions showing an excess of homozygous marker strings in affected individuals. At microsatellite markers, we proposed statistical tests based on binomial distributions and combinatorial models. We suggested to apply the scan statistic to SNP markers. We are evaluating our methods on the data from studies of rheumatoid arthritis and also on simulated data.

The Restricted Partition Method used to screen for genetic interactions. *R. Culverhouse, B. Steinmeyer, W. Shannon.* Washington University School of Medicine, St. Louis, MO.

Epistatic interactions play an important role in complex diseases: a few loci with little or no main effects can nonetheless control phenotype to a large degree. The Restricted Partition Method (RPM) was developed to examine multi-locus genotypes as predictors of quantitative traits in unrelated individuals. Earlier work verified three important properties: (1) the RPM is robust to allele frequency variations in both contributing loci and null loci, (2) the RPM is computationally feasible and has good power for the analysis of 3-locus models, and (3) two-locus analyses of 3-locus models can have good power to identify contributing loci.

Data from the Pharmacogenetics Research Network Analysis Workshop II consists of real genotypes from which phenotypes were simulated. This data provided an opportunity to test the RPM in three ways: (1) qualitative as well as quantitative phenotypes, (2) a greater number of markers than the RPM was originally intended to handle, and (3) a realistic pattern of linkage disequilibrium.

The RPM was used to scan for univariate effects and 2-way interactions among 4 environmental covariates and 133 candidate SNPs from a sample of 557 unrelated individuals. Phenotype and covariate information was complete, but a sizable number of genotypes were missing. The RPM correctly detected a significant gene-environment interaction related to a qualitative phenotype. In addition, a region of high linkage disequilibrium where multiple SNPs were significantly associated with a quantitative phenotype was identified. The causative SNP could clearly be identified from the analysis. The use of a single replicate data set was sufficient to eliminate the false positives from both of these initial analyses.

Key Results: Designed to detect interactions contributing to a quantitative trait, the RPM performed well in an analysis of a qualitative trait. Further, when faced with a single causative locus in LD with surrounding loci, the RPM correctly identified a univariate model over an interaction model.

Investigating gene-gene interactions in breast cancer suscpetibility. *P. Pharoah[1], J. Tyrer[1], M. Ostergaard[2], A. Cebrian[1], A. Dunning[1], D. Easton[2], B. Ponder[1].* 1) Oncology, Univ Cambridge, Cambridge, United Kingdom; 2) Public Health and Primary Care, Univ Cambridge, Cambridge, UK.

Much research has been aimed at finding common genetic variants associated with disease, mostly concentrating on the role of individual variants (SNPs). There is a large body of research into theoretical approaches to the study of gene-gene interactions, but the few studies using real data have been limited to data sets with a small number of SNPs. We have previously genotyped 52 tagging SNPs in 10 candidate genes from the antioxidant defence pathway in ~2,200 breast cancer cases and 2,200 controls. The data showed borderline evidence for a main effect for two SNPs. The aim of this analysis is to identify interactions between any of these SNPs in the presence or absence of a measurable main effect. If the form of the interaction were predictable, methods could be tailored to maximise power to detect them. However, the likely models for important interactions are not known, and so we have implemented four different analytic approaches. These are: A) Hierarchical clustering which groups the study subjects independent of case-control status using all the data for classification. Case control frequency in the groups is then compared. The remaining methods search for important combinations of two, three or possibly four SNPs. B) Multifactor dimensionality reduction (MDR) searches for SNP subsets which best discriminate between cases and controls. C) Full interaction models use a saturated logistic likelihood model to search for SNP subsets which give the largest significance value when compared with a null hypothesis of no interaction. D) A single cell search which identifies the most significant combinations of SNP genotypes that vary in frequeny between cases and controls. These methods have been applied to the data described above. As the number of possible interactions is very large the significance of any positive findings will be assessed using permutation testing. We shall present the results and discuss their implications particularly in the context of the possibility of searching for interactions between larger number of SNPs e.g. in a whole genome association study.

Risk Factor interactions and genetic effects associated with post-operative atrial fibrillation. *A.A Motsinger[1], B.S. Donahue[2], N.J. Brown[3], D.M Roden[3], M.D. Ritchie[1].* 1) Center Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Anesthesiology, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

Postoperative Atrial Fibrillation (PoAF) is the most common arrhythmia after heart surgery, and continues to be a major cause of morbidity. Due to the complexity of this condition, many genes and/or environmental factors may play a role in susceptibility. Previous finding have shown several clinical and genetic risk factors for the development of PoAF. The goal of this study was to determine whether interactions among candidate genes and a variety of clinical factors are associated with PoAF. We applied the Multifactor Dimensionality Reduction (MDR) method to detect interactions in a sample of 940 adult subjects undergoing elective procedures of the heart or great vessels, requiring general anesthesia and sternotomy or thoracotomy, where 255 developed PoAF. We took a random sample of controls matched to the 255 AF cases for a total sample size of 510 individuals. MDR is a powerful new statistical approach used to detect gene-gene or gene-environment interactions in the absence of main effects. We chose polymorphisms in 6 candidate genes, all previously indicated in PoAF risk, and a variety of environmental factors to analyze. We detected an interesting single locus effect of IL-6 which is able to correctly predict disease status with 59.8% ($p<0.001$) accuracy. We also detected an interaction between history of AF and length of hospital stay that predicted disease status with 68.34% ($p<0.001$) accuracy. These findings demonstrate the utility of novel computational approaches for the detection of disease susceptibility genes. While each of these results looks interesting, they only explain part of the PoAF story. It will be important to collect a larger set of candidate genes and environmental factors to better characterize the development of PoAF. Applying this powerful new approach, we were able to elucidate potential associations with postoperative atrial fibrillation.

MC4R variant is associated with measures of adiposity in the general population. *M.R. Lee[1], S.B. Manuck[2], R.E. Ferrell[1].* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Psychology, Univ Pittsburgh, Pittsburgh, PA.

Background: Rare missense and nonsense mutations in the melanocortin-4 receptor (MC4R) gene are a cause of genetic forms of severe obesity, and targeted disruption of the mouse MC4R leads to obesity. The role of variation at the MC4R locus in influencing interindividual variation in body size and composition in the general population is controversial. **Objective**: To test the hypothesis that polymorphic variation at the MC4R locus is significantly associated with measures of adiposity in the general population. **Methods**: A single nucleotide polymorphism, -4599 G>T, in the 5-flanking region of MC4R was verified by resequencing in 16 individuals and genotyped in the larger sample by fluorescence polarization. 810 healthy, non-Hispanic white volunteers, age 30-54 years, were recruited from the Pittsburgh community. A medical and demographic history was collected and anthropomorphic measures, fasting lipoproteins, glucose and insulin and resting metabolic rate were measured. ANOVA was used to assess the relationship between genotype and metabolic parameters. **Results**: BMI was greater in participants having a G allele (GG + GT genotypes) than among TT homozygotes ($p < 0.02$), and this association was of similar magnitude in both men (BMI 28.2 vs. 27.5) and women (BMI 26.9 vs. 25.8). Nominally defined overweight (BMI 27) also varied significantly (Chi-sqare = 7.289, $p < 0.03$) across MC4R genotypes (GG: 53.9%; GT: 47.3%, TT: 39.9%). Finally, subjects with any G allele had significantly higher percent of body fat (29.9% vs. 28.8%; $p < 0.05$) and greater waist circumference (36.4 vs. 35.6; $p < 0.03$). Total, LDL-, HDL-cholesterol, fasting insulin, glucose and HOMA and resting metabolic rate were not associated with MC4R genotype. **Conclusion**: Common variation in the 5-flanking region of the MC4R gene is significantly associated with measures of adiposity in men and women in the general population, but is not associated with other indicators of the metabolic syndrome.

Functional Polymorphisms of the CYP1B1 Gene Predict the Onset of Natural Menopause in Chinese Females.

J.R. Long[1], X.O. Shu[1], Q. Cai[1], Y.T. Gao[2], F. Jin[2], W. Zheng[1]. 1) Department of Medicine and Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN 37232; 2) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, 200032, China.

Menarche and menopause are among the significant milestones in a female's life. Ages of menarche and menopause and overall menstruation years may influence the health in later life. The Cytochrome P450 1B1 (CYP1B1) plays an important role in mediating estrogen metabolizing. Relatively little is known, however, about the impact of this gene on the onset and cessation of menstruation. In this study, three functional SNPs, including Arg48Gly, Ala119Ser, and Leu432Val, were genotyped in 1227 healthy Chinese females. Among them, 387 women experienced natural menopause. There was no evidence of relationship between the CYP1B1 gene and menarcheal age; however, we did find significant associations for menopausal age and overall menstruation years among natural menopause women, with P values of 0.015 and 0.017 for Arg48Gly, 0.013 and 0.010 for Ala119Ser, and 0.002 and 0.006 for Leu432Val, respectively. The Gly and Ser alleles of Arg48Gly and Ala119Ser were associated with later menopause and longer menstruation years, while, women with allele Val at Leu432Val had a 1.6 yrs earlier menopause and 1.6 yrs shorter reproductive span. Similar significant associations were observed in the haplotype analyses, with P values of 0.026 and 0.022 for menopausal age and menstruation years, respectively. Furthermore, we ascertained the correlations of several personal parameters with menopausal age, such as education level (P=0.010), physical activity (P<0.001), number of live birth (P=0.048) and history of miscarriage (P=0.050). In conclusion, the functional CYP1B1 SNPs and some lifestyle and reproductive parameters may predict natural menopausal age in Chinese females.

Associations of repair gene polymorphisms and genotoxicity of pregnant women exposed to smoking hazard. *C.J. Chan[1], T.C. Lai[3], C.C. Lee[4], L.Y. Lin[5], T.H. Chiu[4], J.C. Ying[6], H.L. Yang[2], H.D. Wu[1], F.Y. Wu[1].* 1) Institute of Environmental Health, China Medical University, Taichung, Taiwan; 2) Institute of Nutrition, China Medical University, Taichung, Taiwan; 3) Department of Medical Technology, Chungtai Institute of Health Sciences and Technology, Taichung, Taiwan; 4) Department of Obstetric and Gynecology, China Medical University Hospital, Taichung, Taiwan; 5) Institute of Medical Science, Chung Shan Medical University, Taichung, Taiwan; 6) Department of Healthcare Administration, I-Shou University,Kaohsiung, Taiwan.

The purposes of this study were to examine the possible effect of cigarette smoking or environmental tobacco smoke (ETS) on the health of pregnant women, by measuring cotinine concentrations and comet assay, and to analyze the correlations of repair gene polymorphisms and genotoxicity of gestation women. With consented, pregnant women participated prenatal care at two medical centers and one regional hospital in central Taiwan were recruited in this study. The subjects were asked to complete a structured questionnaire. Urine and serum cotinine level were measured using HPLC/UV. PCR-RFLP method was utilized to determine XRCC1, XRCC3, XPD and hMLH1 genotypes. DNA damage was measured by comet assay. The 237 pregnant participants included 102 (43%) non-smokers, 118 (49.8%) passive smokers, and 17 (7.2%) smokers. The findings indicated that the cotinine levels in serum and urine collected at deliver elevated significantly as the exposure to ETS and smoking increased. Our data suggest that the comet assay is a useful tool for detecting DNA damage, and the level of DNA damage among the smoking and ETS groups were significantly higher than that of non-smoking group. The value of DNA damage among women with hMLH1 A/A or G/A genotypes was significantly higher than in subjects with G/G genotype. (aOR=3.49; 95%CI: 1.32-9.24). Genotypic variants of these polymorphisms did elevate DNA damage for women exposed to smoking hazard, especially in ETS group (p=0.021). In conclusion, hMLH1 A/A or G/A genotypes may modify the correlations between Smoking or ETS-exposed and DNA damage.

The relationship among birth outcome, cotinine level and CYP2A6 polymorphism of neonates in ETS-exposed pregnancy maternity. *H.C. Tsui[1], R.Y. Wang[1], C.C. Lee[2], L.Y. Lin[3], T.H. Chiu[2], H.D. Wu[1], H.W. Kuo[1], F.Y. Wu[1], J.S. Lai[1].* 1) Institute of Environmental Health, China Medical University, Taichung, Taiwan; 2) Department of Obstetric and Gynecology, China Medical University Hospital, Taichung, Taiwan; 3) Institute of Medical Science, Chung Shan Medical University, Taichung, Taiwan.

Previous studies have shown that cigarette smoking contributed to various harmful effects for pregnancy maternity and neonates, and cotinine level may be an important indicator of the metabolic process. On the other hand, CYP2A6 is a metabolic enzyme for nicotine to cotinine. The purpose of this study was to evaluate the correlations among infants CYP2A6 genetic variants, cotinine levels and birth outcomes (including height, weight, head circumference etc.) for environmental tobacco smoke (ETS) exposed and non-exposed. We recruited 227 paired samples of pregnancy maternity and newborns from gynecology outpatient department of three hospitals in central Taiwan. The blood specimens, neonatal birth outcomes, and structured questionnaire data were collected. Serum cotinine level was determined and CYP2A6 was genotyped. The 227 participants included 121 (53.3%) ETS-exposed and 106 (46.7%) non-ETS exposed individuals. Maternal occupation (P=0.0009) and education level (P=0.0005) were significant variables between the two groups. There was significant difference between two groups in infants head circumference (HC) (p=0.0167). The cotinine levels between maternal and neonatal showed highly significant correlation (r=0.88, p<0.0001). Our data revealed that infants with CYP2A6*4C/4C genotype had low cotinine levels compared with those of CYP2A6*1A/4C and CYP2A6*1B/4C (p=0.0365 and p=0.0399, respectively). The HC of neonates with CYP2A6 *4C/4C genotype were smaller in ETS than Non-ETS group (33.81.28 cm vs 32.91.65 cm, p=0.0396). In conclusion, our results suggested that CYP2A6*4C/4C variant in neonates born from ETS-exposure maternities correlated to HC of neonates. In the future, extensive studies to identify the effects of other related genes and environmental factors in neonatal birth outcomes will be warranted.

Environmental tobacco smoke, metabolic gene polymorphisms, genotoxicity and pregnancy outcome. *F.Y. Wu[1], H.D. Wu[1], H.L. Yang[2], L.Y. Lin[5], C.C. Lee[4], C.J. Lin[3], T.H. Chiu[4], H.W. Kuo[1], J.S. Lai[1].* 1) Institute of Environmental Health, China Medical University, Taichung, Taiwan; 2) Institute of Nutrition, China Medical University, Taichung, Taiwan; 3) Department of Nursing, China Medical University, Taichung, Taiwan; 4) Department of Obstetric and Gynecology, China Medical University Hospital, Taichung, Taiwan; 5) Institute of Medical Science, Chung Shan Medical University, Taichung, Taiwan.

The purposes of this study were to examine the effects of cigarette smoking or environmental tobacco smoke (ETS) on the health of pregnant women and their neonates, and to investigate the inter-relationship among metabolic gene polymorphisms, genotoxicity and pregnancy outcome of gestation women exposed to smoking hazard. Pregnant women sought prenatal care at two medical centers and one regional hospital in central Taiwan were invited to participate in the research as study subjects voluntarily. Six hundred and eighty-five subjects completed the initial questionnaire survey. Metabolic gene polymorphisms of 421 mothers were analyzed. Eventually, 398 subjects remained at labor, and all of them delivered live birth singleton (384 newborns). Comet assay was measured from lymphocytes 291 mothers. Our finding indicated that the levels of DNA damage among the smoking and ETS groups were significantly higher than that of non-smoking group, especially for the ETS group. However, it was not related to metabolic polymorphisms genes. In addition, the results revealed that the average birth weight of neonates born to subjects with severe DNA damage (within 90th percentile, DNA damage score greater than 129.5) was 141g lighter than that of their counterparts (p=0.09). The risk of DNA damage for participants who exposed to EST at home was 4.35 times greater than their counterparts (aOR =4.35). In conclusion, Our study verified the negative relationship between high level of DNA damage among pregnant women and low birth weight (LBW). Pregnant women exposed to ETS were at higher risk of DNA damage than smokers, but they did not aware of the hazard.

Prostate Cancer, sun expsoure and genes modifying risk. *J. Dickinson[1], T. Dwyer[2,1], L. Blizzard[1], J. Fryer[1], B. Patterson[1], A. Pollanowski[1], J. Stankovich[1,3], J. McKay[1,4].* 1) Menzies Research Institute, Univ Tasmania, Hobart, Tasmania, Australia; 2) Murdoch Children's Research Institute, Melbourne, Victoria; 3) Walter and Eliza Hall Institute, Melbourne, Victoria; 4) International Agency for Research on Cancer, Lyon, France.

UVR exposure may have a protective effect in a number of diseases including prostate cancer. Furthermore, circumstantial evidence exists suggesting that this effect may be mediated by vitamin D status and/or vitamin D receptor polymorphisms, although results to date are unclear. Evidence is also mounting that the selected genes playing pivotal roles in the physiological response to the UVR exposure also have a role in modifying cancer risk. The Tasmanian Prostate Cancer Case Control Study is currently being conducted in Tasmania, Australia. Cases under the age of 70 years identified from the Tasmanian Cancer Registry and age-matched disease free controls selected at random from the Tasmanian Electoral Roll are currently being recruited to the study, recruitment target 400 cases and 400 controls. Comprehensive data comprising family history, dietary factors, physical activity, current and past history of sun exposure is being collected together with vitamin D levels. In data to hand, odds of low (50 mmol/L) vitamin D were 4.66 (95% confidence interval 1.70-12.74) times higher for cases than controls among those with vitamin D measured in higher-UVR months, and 1.22 (0.58-2.56) times higher among those with vitamin D measured in lower-UVR months.The odds of low (50 mmol/L) vitamin D were 2.14 (1.21-3.78) times higher for cases than controls when adjusted for season. Furthermore, preliminary analysis of skin pigmentation measures has revealed that risk of prostate cancer was associated with measures of skin pigmentation (P=0.02), and this effect is modified by sun exposure. We are examining polymorphisms in genes involved in the physiological response to UVR, these include VDR and genes involved in determining skin type, MC1R and tyrosinase. Preliminary analysis of genotyping data is currently underway and UVR exposure and skin type together with MC1R and VDR genotyping data will be presented.

The Trp64Arg polymorphism of the beta 3-adrenergic receptor gene is associated with weight loss by health promotion intervention in obese Japanese men. *M. Yamakita, S. Tang, D. Ando, Z. Yamagata.* Health Sci, Univ. Yamanashi, Yamanashi, Japan.

It has been reported that the Trp64Arg gene polymorphism of the beta 3-adrenergic receptor gene was associated with impairment of its lipolytic function, a lower resting metabolic rate, and tendency to gain weight in obese individuals. Several studies have suggested that obese subjects with this polymorphism have difficulty in losing weight, but other studies have not supported this. Thus, it is unclear whether this gene polymorphism is associated with difficulties of weight loss. In this study, we investigated the relationship between the Trp64Arg gene polymorphism and weight loss by health promotion intervention in obese Japanese men. The subjects were 615 Japanese men aged 20-56 years who received general health check-ups in a company. In the company, health promotion intervention such as dietary intervention programs and exercise promotion campaigns conducted from 1999. The dietary intervention will affect health-related dietary knowledge, provide practical skills with which to change the diet, and facilitate or maintain behavioral changes through environmental programs. The plan for a cafeteria was to provide leaflets, to leave advertising menus at point of purchase and on tables in the cafeteria, and to put up posters on the walls. Genomic DNA was extracted from peripheral blood leukocytes. Trp64Arg genotype was determined by denaturing high-performance liquid chromatography (DHPLC) and PCR-RFLP. The subjects with BMI>25 kg/m^2 classified as obese. At the baseline of BMI, body weight, systolic blood pressure, diastolic blood pressure, there was no significant difference in participants with/without Trp64Arg polymorphism of the beta 3 adrenergic receptor gene. In analysis of covariance, significant difference was found in BMI change in Trp64Trp group (-0.30 kg/m^2), but not in Trp64Arg group (+0.54 kg/m^2) after adjusted for age, baseline BMI. We concluded that the Trp64Arg polymorphism of the beta 3-adrenergic receptor gene is difficult to weight loss by health promotion intervention in obese Japanese men.

Heritability and Pleiotropy of Muscle and Bone Related Traits in Afro-Caribbean Families. *X. Wang[1], C.M. Kammerer[1], V.W. Wheeler[3], A.L. Patrick[3], C.H. Bunker[2], J.A. Cauley[2], J.M. Zmuda[2].* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Epidemiology, Univ Pittsburgh, Pittsburgh, PA; 3) The Tobago Health Studies Office, Scarborough, Tobago, West Indies.

The loss of bone and muscle with aging is a major contributor to increased morbidity and mortality. Bone and muscle mass are heritable polygenic traits, and muscle forces on the skeleton are among the strongest signals to stimulate bone growth. Despite the close relationship between muscle and bone, studies examining the potential pleiotropic effects of genes on muscle and bone related traits have yielded conflicting results. To address this issue further, we conducted quantitative genetic analyses to partition the phenotypic variance of muscle mass and bone size into their additive genetic and environmental components using maximum likelihood variance decomposition methods. State-of-the-art peripheral quantitative computed tomography (pQCT) was used to measure muscle cross-sectional area (mCSA) and periosteal circumference (PC) of the proximal tibia in 404 individuals aged 18 and older (mean, 43 years) from 8 large, multigenerational Afro-Caribbean families with a mean family size of >50 individuals (range from 21 to 112). Measured covariates (age, gender, height, weight) explained 50% of the variance in both mCSA and PC. The residual heritabilities of mCSA and PC were also moderately high: 0.40 0.10 and 0.67 0.10, respectively ($P<0.01$ for both traits). Besides, there was a strong positive genetic correlation between mCSA and PC (rhoG = 0.75 0.12; $P<0.001$) that was also significantly different from 1.0. Our results suggest that as much as 56% of the joint phenotypic variation in muscle mass and bone size may be influenced by a common set of genes. Bivariate genetic analysis of these pQCT related phenotypes should lead to the identification of genes for bone growth and osteoporotic risk.

Macrophage scavenger receptor 1 (MSR1) haplotypes and prostate cancer (PC) risk in African Americans and Caucasians. *H. Rennert, C.M. Zeigler-Johnson, S.B. Malkowicz, T.R. Rebbeck.* University of Pennsylvania, Philadelphia, PA.

MSR1 plays a major role in inflammation, and was proposed as a candidate gene for hereditary PC. Germline mutations and sequence variants in MSR1 have been reported to be associated with PC risk and disease severity. Though several SNP-disease association studies have been reported for MSR1, very little is known about the association of MSR1 haplotypes with PC risk. We characterized MSR1 haplotypes using 5 SNPs (-14,742A>G, 520G>T, 876C>T, IVS5-59C>A, IVS7delinsTTA) with frequencies >1%. We examined the relationship between these haplotypes and PC risk in a case-control sample of 769 African American (AA) and European American (EA) men, using the EM algorithm as implemented by hapipf in STATA 8. Over ten haplotypes were observed in each race, with frequencies that varied significantly by race:

Haplotype	EA Cont (N=243)	EA Cases (N=382)	AA Cont (N=88)	AA Cases (N=55)
A.G.C.C.delTTA	0.84	0.85	0.59	0.60
A.G.C.C.insTTA	0.04	0.04	0.14	0.15
G.G.C.C.delTTA	0.05	0.05	0.15	0.18

Five haplotypes occurring at a frequency >1% accounted for >98% of all haplotypes in EA and AA. No overall difference in the distribution of MSR1 haplotypes by case status, grade, or by stage was observed in either race. This is in agreement with the negative association between PC risk and these sequence variants observed in the single SNP-based analyses. In contrast, in single-SNP based analyses IVS7delTTA had an elevated risk for low-stage and low-grade disease, while 876C>T was associated with high-grade PC. Because the SNP-based effects were by disease severity, future haplotype studies should employ larger sample-size, considering analysis by PC severity.

Gene-environment Interaction between Asthma, Socioeconomic Status and Ancestry in Latino and African American Populations. *S. Choudhry[1], M. Naqvi[1], J. Kho[1], N. Ung[1], H.J. Tsai[1], S. Nazario[2], M. LeNoir[3], H.G. Watson[4], S. Thyne[1], K. Meade[5], W. Rodriguez-Cintron[2], N. Risch[1], E. Ziv[1], E.G. Burchard[1].* 1) University of California, San Francisco; 2) San Juan VAMC, Puerto Rico; 3) Bay Area Pediatrics, Oakland; 4) The James A. Watson Wellness Center, Oakland; 5) Children's Hospital and Research Institute, Oakland.

Asthma is a common respiratory disease caused by an interaction of genetic and environmental factors. Among U.S. children, asthma has been shown to be most prevalent in low income and minority groups. In the U.S., Puerto Ricans have the highest (11.2%), African Americans have an intermediate (5.9%), and Whites and Mexican Americans have the lowest asthma prevalence rates, 3.3% and 2.7%, respectively. Puerto Rican, Mexican American and African American are admixed populations and share varying proportions of African, European and Native American ancestries. We hypothesized that socioeconomic status (SES) may mediate the relationship between asthma and ancestry in admixed populations. We analyzed 360 Puerto Rican, 362 Mexican American and 352 African American asthma cases and controls. Individual admixture for each subject was estimated using up to 44 ancestry informative markers and the program STRUCTURE. SES was assigned using the FFIEC Geocoding/Mapping System based on median family income. Multivariate regressions were performed to test for an association between asthma, SES and ancestry and to look for an interaction between ancestry and SES. We found an interaction between SES and ancestry that was significantly associated with asthma in Puerto Ricans ($p= 0.003$), a trend for Mexican Americans ($p= 0.16$) and nothing significant for African Americans ($p= 0.85$). Most interestingly among Puerto Ricans, there was a significant trend towards higher European and lower African ancestry in cases with moderate and middle SES categories and lower European and higher African ancestry in cases with upper SES category ($p= 0.0005$ and 0.003). These results suggest that there may be a gene-environment interaction between asthma, SES and ancestry that may help explain part of the racial/ethnic variation in asthma prevalence.

Admixture and Breast Cancer Risk Among Latinas in the San Francisco Bay Area. *E. Ziv[1], E. John[2], S. Choudhry[1], J. Kho[1], W. Lorizio[1], S. Huntsman[1], H. Matallana[1], E. Gonzalez-Burchard[1].* 1) Center for Human Genetics & Dept Medicine, Univ California, San Francisco, San Francisco, CA; 2) Northern California Cancer Center, Union City, CA.

Breast cancer rates vary substantially among different ethnic groups in the U.S. Latinas are known to be an admixed population with European, Native American and African ancestry. We examined genetic ancestry among Latina breast cancer cases and controls to determine if individual genetic ancestry is associated with risk. The study included 244 Latina women diagnosed with breast cancer between 1999 and 2001 and reported to the Northern California Cancer Center and 333 Latina controls, age-matched and obtained from a population based sample in the same geographic region. 44 ancestry informative markers were used to estimate ancestry among cases and controls. We used a maximum likelihood approach to combine information across markers to estimate individual ancestry. To compare distribution of ancestry among cases and controls were performed using a non-parametric rank sum test. In the combined sample we estimated European ancestry as 52.8%, Native American ancestry as 41.1% and African ancestry as 5.6%. There was a non-significant trend towards higher European ancestry among cases (53.7%) compared with controls (52.9%). However, among pre-menopausal women there was significantly higher Native American ancestry among cases (45.3%) compared with controls (39.3%) (p=0.039). Among post-menopausal women there was a trend towards higher European ancestry among cases (55%) compared with controls (51.7%) (p=0.16). Adjustment for known reproductive and lifestyle factors attenuated the difference in post-menopausal women but did not attenuate the difference in ancestry among pre-menopausal women. Higher Native American ancestry and lower European ancestry is associated with breast cancer among younger, pre-menopausal Latina women. These results may be due to unmeasured environmental risk factors or to difference in genetic risk factors that increase a particular subtype of breast cancer among younger Latinas with higher Native American ancestry.

An empirical Bayesian procedure to assess population substructure using single nucleotide polymorphisms. *Q. Zhang, J. Luo, R. Chakraborty, L. Jin, R. Deka.* Center for Genome Information, Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

To assess the population substructure, hierarchical Bayesian approaches have been widely applied to estimate F_{ST}. However, subjective priors are often used in these approaches. To avoid dependence on priors, we have implemented an empirical Bayesian method to estimate F_{ST}. A Monte Carlo EM algorithm is adopted to estimate the hyperparameters. In this approach, three levels of hierarchy are implemented. At the first level, the data denoted by x_{ik}, the number of chosen alleles at i^{th} locus in k^{th} population, is distributed as a binomial distribution with the allele frequency as the parameter. The second level specifies beta distribution for allele frequencies with F_{ST} and ancestral allele frequency as parameters. The ancestral allele frequency is drawn from a distribution consistent with the expected allele frequency spectrum of neutral alleles under mutation-drift equilibrium (infinite sites model). The third level denotes beta distribution with hyperparameters (,) for F_{ST}. The posterior distribution for F_{ST} can be generated through hybrid form of Gibbs sampling and Metropolis Hasting (MH) algorithm while hyperparameters are updated by Monte Carlo EM algorithm. To save computing time, an importance sampling approximation is adopted, so instead to rerun the Gibbs and MH sampler at each update of the EM sequence, the hyperparameters (,) can be updated through reusing the first generated sampler. Simulation studies with different numbers of unlinked single nucleotide polymorphism markers and different numbers of populations are ongoing now to check the deviation of the estimated F_{ST} from the true F_{ST} and compare with general Bayesian methods. Supported by NIH grant ES06096.

Natural history of HFE-related hemochromatosis in the Atherosclerosis Risk in Communities (ARIC) Study. *J.S. Pankow[1], E. Boerwinkle[2], P.C. Adams[3], E. Guallar[4], J. Rogowski[1], J.H. Eckfeldt[1].* 1) Univ Minnesota, Minneapolis, MN; 2) Univ Texas Health Science Center, Houston, TX; 3) London Health Sciences Centre, London, Ontario, Canada; 4) Johns Hopkins Medical Institutions, Baltimore, MD.

The C282Y mutation of the HFE gene is a frequent cause of hemochromatosis, a disorder characterized by excess iron deposition in multiple tissues and organs that may result in clinical disease. We examined morbidity and mortality among C282Y homozygotes (C282Y/C282Y) in the ARIC Study, a population-based cohort study conducted in four U.S. communities that featured four examinations (visits 1-4) approximately 3 years apart. Subjects were 45-64 years old at visit 1 (1987-89) and were followed through 2002 for death, incident coronary heart disease (CHD), and stroke, through 1996-98 for incident diabetes, and through 2000 for incident cancer. Cox proportional hazards regression was used to model time to event for each outcome. The prevalence of homozygosity for the C282Y mutation was 0.41%; (45/10,999) in Caucasians, similar to other North American population-based studies. By contrast, the prevalence in African Americans (0.03%; 1/3,926) was too low to permit further analysis. No C282Y homozygotes were hospitalized with a discharge diagnosis of liver disease during the follow-up period. Rates of all-cause mortality, and incident CHD, stroke, and diabetes among Caucasians were similar in C282Y homozygotes and wild-type subjects. Although differences were not statistically significant, there was a modest excess of incident cancer among C282Y homozygotes (HR: 1.79; 95%CI: 0.93-3.44), particularly for breast cancer in women (HR: 3.05; 95%CI: 0.99-9.52) and prostate cancer for men (HR: 3.10; 95%CI: 0.99-9.68). At visit 1, LDL cholesterol levels were 15 mg/dl lower in C282Y homozygotes compared to wild-type subjects (p=0.009), a difference that remained statistically significant at later exams (11, 13, and 16 mg/dl at visits 2, 3, and 4, respectively). These population-based data suggest that the penetrance of any clinical disease in C282Y homozygotes is relatively low. Further investigation of possible HFE-related differences in cancer incidence and LDL cholesterol levels appears warranted.

Optimum two-stage designs in case-control genetic association studies using false discovery rate. *A. Kuchiba[1], N.Y. Tanaka[2], Y. Ohashi[1].* 1) Dept Biostatistics, Univ Tokyo, Tokyo, Japan; 2) Dept Clinical Bioinformatics, Univ Tokyo, Japan.

Genetic association studies using case-control designs are often carried out to identify disease-susceptibility loci. In such studies, a large number of genetic markers can be used, and therefore result in increase of genotyping cost. Several types of two-stage designs are proposed and used from the point of cost-effectiveness. We propose the utilization of false discovery rate (FDR) with multiple-testing correction in two-stage designs, and show optimal sample sizes and criteria for selecting markers associated with the disease in each stage that minimize the cost of genotyping. The sample sizes and selection criteria is defined as a function of a prior probability that marker-disease association is true. In addition, the efficiency of the following confirmatory study can be considered by the definition of FDR. We compare the expected power and the expected cost of two-stage designs with those of one-stage designs under the assumptions that the genetic markers are independent and total sample size is fixed. The results show that the proposed two-stage procedure usually reduces the cost of genotyping by 40-60% with similar power of the one-stage designs. Also, we examine the effect of the correlation between markers if those exist, and the misspecification of a prior probability on the efficiency by using computer simulations.

Novel screening method for whole genome candidate gene association studies. *N. Tanaka[1], T. Miki[2], T. Tokunaga[3].*
1) Dept Clinical Bioinformatics, Grad Sch of Medicine, Univ of Tokyo,Tokyo, Japan; 2) Dept of Geriatric Medicine, Ehime Univ Sch of Medicine,Matsuyama, Japan; 3) Dept of Human Genetics, Grad Sch of Medicine, Univ of Tokyo,Tokyo,Japan.

With the development of high-resolution mapping of microsatellites and single nucleotide polymorphisms (SNPs) in the human genome, enormous amounts of gene polymorphism data with various diseases have become available. Then a large number of candidate genes can be subjected to whole genome candidate gene association studies with various diseases. Based on such extensive association analyses, the candidate regions are selected for further analysis. Many statistically methods, which have been proposed for association screening, are mostly based on the methods of statistical hypothesis testing so that the candidate regions are often selected based on the adjusted significance level. However, the statistical power is depended on the marker allele frequencies, which might be varying among genetic region, so infrequent and modest risk alleles are easy to be failed to detect. Furthermore, not only p-values but also odds ratios might be important measures for selecting the candidate regions. We propose here novel screening method for case-control association studies to select candidate genes based on smoothed odds ratios, which consider variance-covariance structures of the odds ratios estimated in each genetic region. Simulation studies were performed to compare the present method with other standard methods, having data from an extensive multi-institutional case-control association study on hypertension in Japanese. The present method provided better performance than the other methods in the situations that susceptibility-associated alleles are infrequent and exhibit only moderate risks to the disease.

The Effect of Clinical and Brain White Matter Before and After Treatment in Patients with Tetrahydrobiopterin Deficiency. *Z. Zhang, W. Yu, Z. Zhou, X. Zhang.* Department of Pediatric, China-Japan Friendship Hospital, Beijing, China.

Objective To present MRI evidence on the effect of treatment by comparing the brain abnormalities of the white matter and myelination before and after treatment for one year in patients with BH4 deficiency using 0.5T MRI examination. Method Eleven patients with BH4 deficiency aged 17 weeks to 4 years were observed. Among the 11 cases , 9 were males and 3 were females .All cases were diagnosed as BH4 deficiency by analysis of urinary pterins, BH4 loading test and determination of dihydropteridine reductase in RBC. The patients undertook MRI examination before treatment with BH4, L-Dopa and 5-HTP, 8 cases were revaluated with the Gesell developmental scale. Results The result showed that the DQ of 8 cases have been developed after treatment. At the beginning, Eleven cases (100%) presented delayed myelination in frontal lobe, 8cases (72.7%) having delayed myelination in occipital lobe , 4 cases (36.4%) in temporal lobe and 3 cases(27.3%) in parietallobe. Delayed myelination of corpus callosum can be found in 6 cases(54.5%). There were abnormal diffuse high signal in white matter shown by T2W1 in all cases. Of the 9 patients reevaluated after one year treatment, delayed myelination were still present in 5 cases(45.5%) in frontal lobe, in 5 cases (45.5%) in occipital lobe, in 2 cases (18.2%) in temporal lobe, in 2 cases(18.2%) in parietal lobe. in 3 cases(27.3%) in corpus callosum. Abnormal diffuse high signal in white matter shown by T2W1 in 5 cases(45.5%). Conclusion All patients(100%) with BH4 deficiency present brain abnormalities in white matter, which is higher than the occurrence of patients with PKU. A possible explanation is that the impairment of decreased synthesis of neurotransmitters precipitate the brain abnormalities in white matter. Great improvement was seen in the white matter after one year treatment, which is consistent with the improvement in clinical manifestations.

Development of a therapeutic bone-targeting system for mucopolysaccharidoses. *S. Tomatsu[1], M. Gutierrez[1], T. Nishioka[1], J. Grubb[2], W. Sly[2].* 1) Dept Pediatrics, Ped Res Inst, St Louis Univ, St Louis, MO; 2) Dept Biochem, St Louis Univ, St Louis, MO.

Current approaches for the treatment of mucopolysaccharidoses (MPS) have little impact correcting the bone pathology. Deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GALNS) and -glucuronidase (GUS) responsible for MPS IVA and VII leads to the systemic skeletal dysplasia. Modifying the drug to be delivered to the bone more specifically is noteworthy to enhance the drug effectiveness. The aims of this study were to compare efficiency of delivery of GALNS and GUS enzymes to the bone between untagged and tagged enzymes(the small acidic peptide-six glutamines was tagged to N-terminus of mature protein), and to assess pathological improvements by using enzyme replacement on established MPS IVA and VII mouse models immunotolerant to human enzymes. Methods: 1. Purified GALNS and GUS derived from CHO cell lines were administered intravenously to respective mouse model at a single dose of 250 units/g of body weight. Treated mice were examined by assaying the enzyme activity at 0, 2, 5, 10, 20, 30, 60, 120, and 240 min to assess clearance of the enzyme in the blood stream. The mice were sacrificed 2, 24, 72, 168 hr after infusion of the enzyme for studies of the tissue distribution pattern of the enzymes. 2. To see the effectiveness of clearance of storage and reversal of phenotype, the 250 units/g dose was given through tail veins weekly for 12 weeks on mouse models. Mice were sacrificed seven days after the last infusion. Results: 1. The tagged enzymes had 5-10 times more prolonged clearance of half life time in blood and 10% of GUS enzyme activity retained in blood even after 6hr of injection. Tagged enzymes retained longer in bone and bone marrow, keeping 3 times higher enzyme activity in bone in 24hr compared to the untagged enzyme. 2. The pathological findings in mice treated with tagged enzymes showed the more clearance of the storage materials in bone and interestingly, cornea as well, compared to those with untagged enzymes. Conclusion: The results of pre-clinical trials on the MPS IVA and VII mouse models indicate the effectiveness of this bone-targeting strategy.

Animal Study of Direct Central Nervous System Administration of Copper Histidine: Prelude to Clinical Trial in Menkes Disease. *K. Lem[1], L.R. Brinster[2], O. Tjurmina[3], S.G. Kaler[1].* 1) Unit on Pediatric Genetics, NICHD/NIH; 2) Division of Veterinary Resources, NIH, Bethesda, MD; 3) Center for Scientific Review, NIH, Bethesda, MD.

BACKGROUND: Classical Menkes disease (MD) is a fatal neurogenetic disorder of infancy caused by mutations in a copper transporter gene (ATP7A) associated with brain copper (Cu) deficiency. Subcutaneous Cu injections (500 mcg q.d.) from early infancy can prevent neurodegeneration in some MD infants. Success of this treatment is mutation-dependent; patients with null defects do not respond favorably. Post-mortem tissue analyses in such treatment failures indicated that copper failed to traverse the blood-brain barrier. OBJECTIVE: To assess the safety of copper administration to the CNS as a therapeutic approach for MD infants with null ATP7A mutations, we performed toxicologic studies of intraventricular copper histidine (CuHis) in healthy adult rats. DESIGN/METHODS: We used stereotaxic brain surgery to implant cannulae into the R lateral ventricles of 36 adult male rats, and infused 20 microliters of CuHis or normal saline over 10 minutes. To determine maximum tolerated dose (MTD), 0.5,1.0, 2.5, 5.0, 7.5, 10 or 100 mcg of CuHis was administered; brains were harvested and examined after 6 hrs. To assess longer term effects, 10 rats received 5 mcg CuHis and were euthanized after 14 days. RESULTS: Surgeries and infusions were well tolerated. On clinical grounds, the MTD for intraventricular CuHis was 5 mcg. Compared to saline-treated controls, rats receiving the MTD showed mild periventricular inflammatory changes after 6 hrs. After 14 days, ventricular dilatation, neuronal cell loss, spongiform changes, and dense periventricular inflammatory cell infiltrates were evident. In contrast, with a dose of 0.5 mcg CuHis, histologic findings were much less severe and, in some instances, indistinguishable from saline-infused controls. CONCLUSIONS: We established a MTD (5 mcg) of intraventricular CuHis in adult rats. Histopathological analyses suggested that a 0.5 mcg dose is safer and better tolerated. These results provide guidance concerning intrathecal copper therapy for classical MD.

Towards therapy of Smith-Lemli-Opitz syndrome with combination high cholesterol diet and simvastatin. *A. Pappu[1], W. Connor[1], L. Merkens[2], J. Penfield[2], J. Jordon[1], R. Steiner[2, 3].* 1) Dept of Med, OHSU, Portland, OR; 2) Dept of Ped,OHSU, Portland, OR; 3) Dept of Mol & Med Gen, OHSU, Portland, OR.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive condition, with a deficiency of 7-dehydrocholesterol reductase, which converts 7-dehydrocholesterol (7DHC) to cholesterol (chol). The resultant low chol and high 7DHC levels in plasma and tissues may be responsible for the phenotypes. One treatment objective of SLOS is to raise plasma chol levels by increasing dietary chol intake and simultaneously lower 7DHC levels. A frequently used measure of disease severity and response to therapy in SLOS is the 7DHC/chol ratio, a low ratio being desirable. Statins inhibit HMG CoA reductase (HMG CoAR), a key regulatory enzyme in the chol biosynthetic pathway, and can be monitored by measuring the enzyme product, mevalonate, in urine (UMVA). We selected the lipophyllic simvastatin (simv) as the statin of choice to study in SLOS because of its potency in inhibiting HMG CoAR, its ability to pass the blood brain barrier. Five subjects with SLOS were studied on three different dietary regimens: a very low chol diet, a high chol diet, and a combination high chol diet with simv. The effects of the interventions were determined by measuring plasma sterols and UMVA and by monitoring for adverse effects. In these subjects, changing the diet from low to high chol resulted in a 24% increase in plasma chol, 12% decrease in plasma 7DHC, and 51% decrease in UMVA. A combination of high chol diet and simv maintained plasma chol levels while reducing 7DHC by 28% and UMVA by 67%($p<0.02$). Simv did not lower chol in SLOS as it does in FH. Simv reduced the ratio of plasma 7DHC/chol by 40% vs 31% reduction with high chol diet alone ($p<0.01$). There was a significant correlation between %reduction in plasma 7DHC and UMVA ($r=0.7$, $p=0.02$). We conclude that feedback inhibition of HMG CoAR by dietary chol results in reduced substrate flux through the chol biosynthetic pathway leading to reduced 7DHC, and that these effects are augmented by simv. We further conclude that a combination of high chol diet and simv has additive beneficial effects to a high chol diet and shows preliminary evidence of safety.

Locus Specific Databases: from mutations to gene therapy by exon-skipping. *C. Beroud, D. Hamroun, S. Tuffery-Giraud, A. Disset, G. Collod-Béroud, M. Claustres.* Dept of Molecular Genetics, CHU de Montpellier, Montpellier, France.

Thousands of mutations are identified in diagnostic and research laboratories yearly. To collect and analyze these data we developed a generic software called Universal Mutation Databases (UMD) to create locus-specific databases (http://www.umd.be). This freely available tool allows the creation of LSDBs for virtually any gene and includes a large set of analysis tools. Thus, we have created specific routines to help researchers to design new therapeutic strategies such as exon skipping. The archetype for exon skipping is the DMD gene associated with Duchenne (DMD) and Becker dystrophies (BMD). Most of the DMD mutations consist in large genomic deletions. The out-of-frame deletions lead to premature stop codons that result in the severe phenotype (DMD) while deletions that produce in frame mRNAs leading to shorter proteins are responsible for a milder myopathy (BMD). In patients as well as in animal models, rare dystrophin-positive fibers have been reported. It has been suggested that restoring the reading-frame by exon skipping is the most likely cause of this natural phenomenon. Therefore many groups are designing strategies for gene repair/modulation based on the use of compounds interfering with splicing, thus inducing exon skipping. Because the DMD gene contains 79 exons, exon skipping can produce more than 3.000 potential transcripts. We developed various tools to select the best exon(s) skipping(s) to rescue the largest number of DMD patients. If the skipping of exons can be carried out by various approaches, the choice of the target sequences is of primary importance. Because algorithms searching for ESE, ESS and branch points are based on consensus sequences, it results a strong proportion of false positive signals. To optimize these algorithms, we developed collaborations with various teams able to identify functional sequences and validate software predictions. The combination of fully documented molecular and clinical data from DMD and BMD patients, the in vitro assays and bioinformatics approaches should thus make it possible to identify the best target sequences in order to consider clinical trials of patients.

Intracranial Pressure and Late Ophthalmalogic and Neurologic Outcome in Hurler Syndrome after Bone Marrow Transplantation. *L. Charnas[1], K.G. Belani[2], D. Beebe[2], C.G. Summers[3], S.J. Haines[4], C.B. Whitley[1].* 1) Deparments of Pediatrics,; 2) Anesthesiology; 3) Ophthalmalogy; 4) Neurosurgery, Univ of Minnesota, Minneapolis, MN.

Background: Elevated ICP and hydrocephalus occur in MPS I but the time course of resolution and long term effects on cognition and vision after bone marrow transplantation are poorly understood. **Methods:** Serial lumbar punctures (LP) were obtained in 19 children with Hurler syndrome undergoing bone marrow transplantation. LPs under general anesthesia with end tidal CO_2 between 30 -35 mm Hg were performed prior to transplant and at days 28, 100, and 200 in all patients during measurements of CSF glycosaminoglycans and then yearly until ICP was normal. **Results:** No infectious or bleeding complications were associated with lumbar puncture in these patients. 8 of 19 patient had elevated CSF pressures prior to transplant (> 20 cm H_2O) while 5 of the 8 had significant elevation (> 30 cm H_2O). Three patients were treated with ventriculoperitoneal shunts for elevated ICP without clinical symptoms. Nine patients had ventriculomegaly by cranial CT scan, with six of the nine showing decreased perventricular attenuation suggesting periventricular edema. Papilledema was identified in 6 children. Four other children demonstrated optic atrophy. OFC and fontanel size correlated poorly with ICP. ICP > 30 cm H_2O was associated with papilledema and optic atrophy but did not predict visual outcome. ICP normalized in all children by 18 months post transplant. Cognitive outcome was not statistically associated with elevated ICP or its treatment. **Conclusions:** Serial lumbar puncture is safe in the acute transplant period. Mild ICP elevation (< 30 cm H_2O) resolves with transplantation without adverse outcome. Significantly elevated ICP (> 30 cm H_2O) can be associated with optic nerve findings. Additional factors other than increased ICP also contribute to adverse visual and cognitive outcome.

Does the blood group phenotype affect the ex-vivo expansion or clonogenic capacity of umbilical cord hematopoietic stem cells? *J. Santolaya-Forgas[1], I. Galan[2], J. De Leon[2], R. Hume[1].* 1) Prof OB/GYN & Pediatrics, Wayne State University, Detroit, MI; 2) Amarillo Women's Health Research Institute, Texas Tech Health Science Center at Amarillo, TX.

Objective: Umbilical cord hematopoietic stem cells, UCHSC (CD34positive,Lin-), have been used for allogenic transplantation in inherited disease. The effect of the blood group phenotype on the proliferative and clonogenic capacity of hematopoietic stem cells is not known. Our aim was to evaluate the ABO antigenic system effect on umbilical cord derived stem cell ex-vivo response to growth factors.

Study Design: UCHSC were collected from 3 placenta with different ABO blood groups under a Texas Tech IRB#2041 protocol. CD34 cell isolation following standard methods. 125 thousand cells from each cord were first cultured for 7days in platforms containing a 3-D biocompatible matrix coated with full-length fibronectin, RPMI with fetal bovine serum and one of 4 different sets of hematopoietic growth factors (Stem cell factor, thrombopoietin, IL3, IL6 and FLT3ligand). Ten thousand viable cells from each blood group were then seeded on the platforms for 7 days in each condition. Dunn's Multiple Comparison Test was used.

Results: Freshly prepared cord blood CD34positive,Lin- cells were planted and cultured efficiently in all platforms. O positive cells had greater expansion in all four culture conditions (cells counts: O 425k, B 315k, A 320k; $p<0.05$). UCHSC self-renewal for O, A and C cells were comparable (percentage: 23, 21 and 19; $p>0.05$).

Conclusion: This study suggests that the antigenic load within the cell membrane may determine the proliferative capacity of hematopoietic stems cells in response to growth factors. Clinical studies to determine if UCHSC from universal blood donors (O, Rh-negative) lead to functional hematological reconstitution in recipient patients in shorter periods of time may have important prognostic value. Lineage of differentiation optimization may require specific culture conditions.

A follow-up study: Can donepezil improve quality of life of Down syndrome patients? *T. Kondoh[1], M. Kojima[2], A. Tanaka[1], M. Nakashima[3], K. Aikawa[2], H. Sasaki[3], H. Moriuchi[1].* 1) Dept Pediatr, Nagasaki Univ Hospital, Nagasaki, Japan; 2) Faculty of Education, Nagasaki Univ, Nagasaki, Japan; 3) Dept Hosp Pharmacol, Nagasaki Univ Hosp, Nagasaki, Japan.

This is a follow-up report of the clinical trial of donepezil therapy to a total of 21 Down syndrome (DS) patients for 36 months. Our protocol of donepezil therapy for DS patients is described as below: (1) AST, ALT, LD, BUN, Cr, Amy, fT3, fT4, TSH and ECG are checked as pre-treatment examinations. (2) The loading dose of donepezil is usually 3 mg daily. (3) The aforementioned examinations and plasma donepezil concentrations are checked at 24 h after administrations of the last dose on the 28th treatment day. (4) Their general condition is checked by physical examinations and interviews from their parents at regular hospital visits. Their QOL is assessed by Tanaka-Binet test, Picture Vocabulary test, Social Maturity scale, and Adaptive Behavior scale. When efficacy of donepezil is considered suboptimal, necessity of dose-up is evaluated in consideration of adverse effects and plasma concentration. (5) When therapeutic dose is changed, plasma concentration is measured after one month. Our 36-month clinical trial yielded four implications. First, when DS patients have liver dysfunction, donepezil treatment should be prudently monitored. One DS patient with fatty liver suffered from nonalcoholic steatohepatitis although causal relation was unknown. Second, plasma donepezil concentrations tend to be higher in DS patients than in normal controls. Since such distinct pharmacokinetics may contribute to the likelihood and severity of adverse effect, careful monitoring and dose adjustment will be critical for the safe use. Third, subjective assessment by parents under the double-blinded condition indicated efficacy to improve the ability of daily activity in many DS patients. Furthermore, increase in scores of adaptive behavior scales or Binet intelligent scale was noted in some DS patients after donepezil therapy. Fourth, donepezil might also be effective in some DS patients with rapidly progressive deterioration. In conclusion, donepezil is promising for improvement of QOL of some DS patients.

Therapeutic strategies based on mRNA splicing modification in human genetic disease. *S. Slaugenhaupt[1], M. Hims[1], E. Ibrahim[2], M. Leyne[1], J. Mull[1], S. Gill[1], L. Liu[1], R. Reed[2].* 1) Center for Human Genetic Research, Massachusetts General Hospital; 2) Department of Cell Biology, Harvard Medical School.

It has been estimated that approximately 15% of all mutations that lead to human genetic disease alter mRNA splicing. Further, the role of alternative splicing in creating genetic complexity is highlighted by the lower than expected estimate of the number of human genes following the completion of the human genome sequence. Our studies have focused on familial dysautonomia (FD), a hereditary sensory and autonomic neuropathy that is caused by a splice mutation in the *IKBKAP* gene. The mutation results in variable skipping of exon 20 in *IKBKAP* mRNA, which leads to a tissue-specific reduction of IKAP protein. The fact that FD patients retain the capacity to make both normal mRNA and protein offers an exciting, direct approach towards therapy. Using both *in vitro* and *in vivo* minigene splicing models we have shown that in its native state exon 20 is very weak, and that we can correct exon 20 skipping using a variety of sequence alterations.

Last year we reported that kinetin, a plant cytokinin, enhances exon 20 inclusion and dramatically increases the amount of wild-type *IKBKAP* mRNA and IKAP protein in FD cells. Hybridization of Affymetrix chips with RNA isolated from kinetin treated cells has identified two splicing factors with altered expression in response to kinetin. We are currently cloning and expressing these factors to determine if they directly alter *IKBKAP* splicing. Studies using *IKBKAP* minigene constructs show that the ability of kinetin to enhance splicing efficiency is not dependent on either the presence of the FD mutation or the wider regulation of *IKBKAP* transcription or translation. Recent evaluation of a panel of deletion constructs has allowed us to identify a specific sequence element in exon 20 that is required for kinetin activity. Precise characterization of this sequence element will permit *in silico* analysis which will lead to the identification of other human disease genes harboring splice mutations that might respond to kinetin.

Pre-clinical validation of a multiplex real-time RT-PCR assay to quantify SMN transcripts in whole blood samples from SMA patients. *L.R. Simard[1], M-C. Bélanger[1], M. Wride[2], K.J. Swoboda[2].* 1) Dept Ped, Ctr de Recherche, Hopital Ste-Justine, Montreal, PQ, Canada; 2) University of Utah, Salt Lake City, Utah, USA.

SMN2, a duplicate copy of *SMN1*, is the only known modifier gene of Spinal Muscular Atrophy (SMA), a devastating childhood neurodegenerative disease; a premise supported by the inverse relationship between *SMN2* copy number and disease severity. Consequently, *SMN2* is an attractive therapeutic target and drug screens for compounds that alter SMN splicing or up-regulate *SMN* expression led to the proposed use of phenylbutyrate (PBA) and valproic acid (VPA) to treat SMA. As these drugs are expected to increase the amount of full-length SMN protein, we developed a multiplex real-time RT-PCR assay to quantify SMN transcripts in whole blood samples drawn from SMA patients. Published data indicated an increase in full-length SMN mRNA of about 2-fold; thus, we determined whether SMN expression was stable over time and established an experimental design to minimize variability between real-time measurements. Briefly, we exploited the PAXgene^{TM} Blood RNA system (QIAGEN) to obtain RNA samples from patients recruited by multiple centers across North America. Blood samples were sent to a centralized laboratory equipped to run real-time experiments; shipments occurring within a 24 hour period. Overall, we obtained good quality and sufficient amounts of total RNA. These RNA samples were stable for a >2 year time interval. The latter allows one to assay SMN transcripts from patient samples collected over a 9 to 12 month period in a single run, thus avoiding inter-experimental variability. Total mRNA was prepared and the amount of full-length SMN transcripts detected using a fluorescent probe spanning the 7-8 exon boundary. Efficiency of the reverse transcription and PCR reactions were monitored by simultaneously measuring phosphoglycerate kinase (PGK1; ABI) transcripts. In general, SMN expression varied minimally over a >12 month period indicating that this assay can be used to follow the effect of drug treatment on SMN expression in SMA clinical trials. Detailed findings will be presented so that uniform protocols can be adopted across different SMA drug trials. Funded by Families of SMA.

Long term dietary cholesterol supplementation in Smith-Lemli-Opitz syndrome. *S. Sparks[1], H. Goodwin[2], C. Wassif[2], A. Gropman[3], E. Tierney[4], F. Porter[2].* 1) NHGRI/NIH, Bethesda, MD; 2) NICHD/NIH, Bethesda, MD; 3) Georgetown University, Washington, DC; 4) Kennedy Krieger Institute, Baltimore, MD.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder of cholesterol biosynthesis. The defective enzyme, 3-hydroxysterol 7-reductase encoded by *DHCR7*, is responsible for the final step of the conversion of 7-dehydrocholesterol to cholesterol. Children with SLOS have elevations of dehydrocholesterol and decreased serum and tissue cholesterol, resulting in the characteristic clinical and behavioral features of SLOS. Current therapy of SLOS patients consists of dietary cholesterol supplementation. We phenotypically characterized 50 patients with SLOS at the NIH Clinical Center and evaluated the long term efficacy of dietary cholesterol supplementation on the biochemical and clinical aspects of SLOS. All patients were placed on dietary cholesterol supplementation (150-200 mg/kg/d) using a suspension of crystalline cholesterol in Ora-Plus. Patients were evaluated every 6-12 months. Plasma cholesterol, 7-dehydrocholesterol and 8-dehydrocholesterol were determined using GC/MS. For group comparison, sterol levels were normalized to initial values at diagnosis. Patients were categorized as mild (n = 29), classical (n = 15) or severe (n = 6) based on physical manifestations. Genotypes and residual DHCR7 activity were determined for all patients. Decreased enzyme activity correlated with increased clinical severity. In mild SLOS patients, dietary cholesterol treatment for 60 months resulted in an initial increase in cholesterol which peaked at 24 months and subsequently fell. Dehydrocholesterol levels remained relatively constant. In classical SLOS patients treated with cholesterol for 60 months, the cholesterol level gradually increased to approximately 2.5 fold over baseline. Dehydrocholesterol levels remained unchanged. Dietary cholesterol supplementation over 24 months in severe SLOS patients also resulted in increased cholesterol levels to 2 fold above initial levels and dehydrocholesterol levels that were unchanged. Dietary cholesterol may have beneficial effects on children with SLOS, however it does not affect the dehydrocholesterol levels.

Progressive Mesenteric and Mediastinal Lymphadenopathy Despite Enzyme Therapy in a Patient with Gaucher Disease. *T. Burrow, M. Cohen, A. Choudhary, G. Deutsch, R. Bokulic, G. Grabowski.* Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Enzyme therapy (ET) in Gaucher disease (GD) has led to remarkable improvements in the hepatic, splenic, hematologic, and bony involvement in affected patients. However, the CNS, lung, and in certain cases, the bone, have demonstrated a deficient response to ET and may be relatively inaccessible compartments. The lymph node system also appears, in selected patients, to be an inaccessible compartment. A patient with subacute neuronopathic (type 3) GD received ET (60 U/kg) every two weeks from 1 year of age. By 5 years of age, his massive hepatosplenomegaly and hematologic abnormalities had resolved. Beginning at 3 years of age, he experienced intermittent bouts of diarrhea and abdominal bloating as well as slowly progressive bronchospastic disease. Chest x-ray and MRI showed progressive interstitial infiltration of the lungs and mediastinal lymph node enlargement. By 4 years of age, extensive mesenteric and retroperitoneal lymphadenopathy was present, which progressed to massive replacement of the mesentery and lymph nodes with calcified masses within one year. This was coincident with the development of hypoalbuminemia without hepatic or renal dysfunction, indicative of a protein losing enteropathy. Exploratory laparotomy to rule out malignancy showed replacement of the mesentery with massive lymph nodes. Histopathology of these mesenteric masses showed lymph nodes replaced by sheets of macrophages, some resembling Gaucher cells with PAS positive proteinaceous material and others containing cholesterol crystals and lipid droplets. This suggested to us that the lymphadenopathy was due to the relative inaccessibility of the lymph nodes to ET. The hypoalbuminemia was stabilized with an MCT containing diet. The use of increased ET (60 U/kg weekly) and substrate depletion approaches are being evaluated. Such unusual cases highlight the need for comprehensive therapies in affected patients and the presence of poorly accessible compartments in patients with GD and other lysosomal diseases receiving ET or other therapeutic modalities.

ER retention and aggregation induced apoptosis associated with neuropathy causing MPZ truncating mutants are abrogated by curcumin treatment. *M. Khajavi[1], W. Wiszniewski[1], T. Ohyama[1], K. Inoue[2], G. Jackson Snipes[3], J.R. Lupski[1, 4, 5].* 1) Deptartment of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan; 3) Deptartment of Pathology, Baylor College of Medicine, Houston, TX; 4) Texas Childrens Hospital, Houston, Texas; 5) Deptartment of Pediatrics, Baylor College of Medicine, Houston, TX.

Mutations in *MPZ*, encoding myelin protein zero the major protein constituent of peripheral myelin, can cause the adult onset inherited neuropathy Charcot-Marie-Tooth (CMT) disease as well as a more severe childhood onset Dejerine-Sottas Neuropathy (DSN) and congenital hypomyelinating neuropathy (CHN). Most *MPZ* truncating mutations associated with severe forms of peripheral neuropathy result in premature termination codons (PTCs) within the terminal or penultimate exons that are not subject to nonsense mediated decay (NMD) and are stably translated into mutant proteins with a potential dominant-negative activity. However, some truncating mutations at the 3 end of MPZ escape the NMD pathway and yet cause a mild peripheral neuropathy phenotype. We examined the functional properties of MPZ truncating proteins that escaped NMD and found that frameshift mutations associated with severe disease cause intracellular accumulation of mutant proteins, primarily within the endoplasmic reticulum (ER), that induces apoptosis. Curcumin, a chemical compound derived from the curry spice tumeric, releases the ER-retained MPZ mutants to the cytoplasm and is accompanied by a lower number of apoptotic cells. Our findings suggest that curcumin treatment is sufficient to relieve the toxic effect of mutant aggregation induced apoptosis and may potentially have a therapeutic role in selected forms of inherited peripheral neuropathies.

Anderson-Fabry disease - changes in typical facial features in response to enzyme replacement therapy. *A.G. Milligan, M. Blincoe, R. Bruce, S. Goodwin, A. Holmes, D. Hughes, M. Reed, L. Richfield, A. Mehta.* LSDU, The Royal Free Hospital, London, United Kingdom.

INTRODUCTION: Deficiency of alpha-galactosidase-A results in deposition and progressive accumulation of globotriaosylceramide and related glycosphingolipids in many tissues with a predilection for vascular endothelial and smooth muscle cells resulting in the clinical manifestations of Anderson-Fabry disease. Many adult hemizygous males develop typical coarse facial features similar to those observed in patients with acromegaly. In acromegaly high levels of insulin-like growth factor-1 (IGF-1) are found and this cytokine leads to growth and differentiation of many different cell lines including keratinocytes and fibroblasts. METHODS: In order to document changes in facial appearances in response to enzyme replacement therapy facial photographs were taken by a medical photographer prior to commencing treatment with agalsidase alpha and serially following 6- 12 months of therapy. Written consent was obtained from all patients. RESULTS: The serial photographs show a noticeable change in the facial features. There is clear increase in definition of the nasal bridge and reduction in peri-orbital swelling and supra-orbital soft tissue. The patient in figure 2 had gained considerable weight between follow up visits and the changes are less obvious. Patient 3 shows changes over 24 months of agalsidase alpha. CONCLUSIONS: Clearance of storage material (Gb3) from other tissues and organ systems with agalsidase alpha is well documented with measurable improvement in clinical parameters such as left ventricular mass. Serial medical photography of facial features in those patients with the typical Fabry facies at baseline and at 6 to 12 monthly intervals of treatment demonstrate a gradual and subtle change in facial features. Whilst serial single dimensional color photography is a useful tool in documenting these changes the interpretation is subjective, more refined techniques using 3 dimensional images will provide quantitative evidence of response to therapy.

Intrathecal Enzyme Replacement Therapy in a Patient with Mucopolysaccharidosis and Symptomatic Spinal Cord Compression. *R. Giugliani[1], M.V. Munoz R.[1], P. Dickson[2], T. Vieira[1], R. Costa[1], L. Vedolin[3], S. Canani[1], L. Jardim[1], E. Kakkis[4].* 1) Medical Genetics Service, Hosp Clin P Alegre, Porto Alegre, RS, Brazil; 2) Division of Medical Genetics, LA Biomed. Inst. at Harbor-UCLA, Torrance, CA, USA; 3) Imaging Service, Mae de Deus Center, Porto Alegre, RS, Brazil; 4) Biomarin Pharmaceutical Inc., Novato, CA, USA.

Introduction: In MPS I, deficiency of -L-iduronidase and subsequent glycosaminoglycan (GAG) storage can cause spinal cord compression in the cervical meninges. Surgical treatment carries a high risk of morbidity and mortality. As intravenous enzyme replacement therapy (ERT) is not likely to cross the blood-brain barrier, we investigated intrathecal recombinant human -L-iduronidase (IT rhIDU) in an MPS I patient with spinal cord compression. To our knowledge, IT therapy in humans has not been attempted previously for this disorder. Purpose: To evaluate the safety and efficacy of IT rhIDU for spinal cord compression caused by cervical meningeal storage in a MPS I - Scheie patient. Methods: We assessed a MPS I - Scheie patient with spinal cord compression at baseline with clinical, biochemical evaluations, 4-extremity somatosensory evoked potentials (SSEP), 12 minute walk test (12MWT) and conventional MRI and diffusion tensor imaging (DTI) studies of the CNS. He was monitored for changes in these parameters during 4 IT infusions of rhIDU administered monthly via lumbar puncture (LP). Results: No adverse events were observed. After 3 infusions he reports improvements in cord compression symptoms, including decreased numbness and tingling, increased stability when rising from a chair, and ability to reduce the frequency of his pain medication. CSF opening pressure at baseline was normal (130 mm H2O), decreasing to 90 mm by the third LP. There were no clinically significant changes in serum chemistries or CSF protein, glucose, or cell count. 12MWT presents a modest (~7%) improvement so far, and CNS imaging studies reveal no progression of hydrocephalus or white matter lesions. Further evaluation is ongoing, and available results will be presented. Conclusion: IT rhIDU appears to improve spinal cord compression in this MPS I patient.

Monthly, quarterly, and low-dose intrathecal iduronidase for canine MPS I. *S. Le[1], P. Dickson[1], C. Vogler[2], B. Levy[2], M. McEntee[3], C. Guerra[1], M. Peinovich[1], C. Jagabat[1], H. Manuel[1], E. Kakkis[4].* 1) Med. Genetics, LA Biomed at Harbor-UCLA, Torrance, CA; 2) Dept. of Pathol., St. Louis Univ., St. Louis, MO; 3) Dept. of Pathol., Coll. of Vet. Med., Univ. Tenn., Knoxville, TN; 4) Biomarin Pharmaceutical, Inc., Novato, CA.

Intrathecal recombinant human -L-iduronidase (IT rhIDU) given weekly in canine mucopolysaccharisosis I (MPS I) reduces central nervous system glycosaminoglycan (GAG) storage. Monthly, quarterly, and low-dose monthly IT rhIDU were tested to determine if less frequent IT injections were as effective. MPS I dogs received 1 mg of IT rhIDU once/month for 3-4 doses (monthly regimen, MR, n=4), 1 mg every 3 months for 3 doses (quarterly regimen, QR, n=4), or 0.46 mg once/month for 4 doses (low-dose regimen, LDR, n=2). Dogs also received weekly IV rhIDU. Iduronidase (IDU) levels reached 23-fold normal in brain, 7-fold in spinal cord, and 423-fold in meninges with MR, vs. 19-, 5-, and 264 -fold with QR. IDU levels were lower with LDR, at 3.4-fold normal in the brain (spinal results N/A). Brain GAG with MR was 4.000.596 g/mg dry weight (p=0.0008 vs. untreated), with QR 4.480.740 (p=0.0019), and with LDR 4.650.482 (p=0.02). These are similar to brain GAG levels in normal dogs (5.401.82, n=9) and roughly half the levels of untreated MPS I dogs (8.261.23, n=4). In the spinal cord, which has little storage, GAG levels were not significantly reduced (MR 4.050.62, p=0.18; QR 4.620.64, p=NS; LDR 5.030.91, p=NS; untreated 5.040.93, n=2; normal 3.020.71, n=4). GAG levels in the spinal meninges were reduced in all regimens by 61-70% (MR 13.94.13, p=0.003; QR 12.22.69, p=0.0006; LDR 10.62.09, p=0.01; untreated 35.93.03, n=2; normal 4.780.818, n=4). Brain pathology showed reduction of storage in MR and QR-treated dogs in neocortical meninges, perivascular spaces and neurons vs. untreated MPS I dogs (LDR results N/A). Pathology of the spinal cord and spinal meninges showed reduced GAG storage in MR, QR, and LDR-treated vs. untreated MPS I dogs. Some dogs developed mild-moderate lymphoplasmacytic meningitis. Monthly, quarterly, and low-dose monthly IT rhIDU may be effective alternatives to weekly treatment for canine MPS I.

Molecular and cellular determinants of adenoviral gene therapy-associated toxicity. *V. Mane[1], G. Toietta[1], L. Medina-Kauwe[3], C. Clarke[1], L. Pastore[1], A.L. Beaudet[1], B. Lee[1,2].* 1) Dept Molec & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Cedars-Sinai Medical Center, UCLA, Los Angeles, CA.

Replication-deficient adenovirus (rAd) serves as an efficient gene therapy vector for liver directed gene transfer. Helper dependent vectors can carry up to 36 kb of therapeutic DNA and avoid cell mediated immune responses to viral proteins. Although they can mediate long term expression of both intracellular and secreted transgenes, e.g., urea cycle enzymes and clotting factors, they stimulate a robust innate immune response and acute toxicity after systemic delivery. By identifying host factors that contribute to this response, we may be able to decrease acute toxicity associated with a given vector dose.

By comparing rAd administration among several immunodeficient mouse strains, we found that TNF null mice exhibited decreased thrombocytopenia and decreased interleukin-6 production after rAd injection, compared to wild type mice. Importantly, mice pretreated with Enbrel, an FDA-approved inhibitor of TNF signaling, demonstrated a toxicity profile similar to null mice suggesting that pharmacological blockade of TNF has protective effects on rAd-induced acute toxicity.

Additionally, we addressed the cellular basis of host/vector interactions as a cause of the threshold effect, or nonlinear dose response, associated with systemic rAd delivery. Kupffer cells (KC) are liver macrophages whose location within the hepatic sinusoids facilitates engulfment of circulating vector particles. We used soluble adenoviral capsid proteins in an effort to block adenovirus-specific receptors on KC. Using this Kupffer cell saturation strategy, we demonstrated markedly increased transgene activity from low doses of rAd, compared to non-KC-saturated animals.

Our results suggest that transient modulation of inflammatory signals and cellular clearance mechanisms may lead to an improved therapeutic effect coupled to decreased toxicity of adenoviral gene therapy.

Immune tolerance improves urinary GAG reduction during iduronidase replacement therapy in canine MPS I.

H. Manuel[1], P.I. Dickson[1], M.C. Peinovich[1], S. Le[1], C. Jagabat[1], M.B. Passage[1], E.D. Kakkis[2]. 1) Medical Genetics, LA Biomed at Harbor-UCLA, Torrance, CA; 2) Biomarin Pharmaceutical, Inc., Novato, CA.

To test whether immune responses to enzyme therapy might affect efficacy, we studied the effect that induction of immune tolerance in MPS I dogs had on efficacy of intravenous recombinant human -L-idurondiase (IV rhIDU) as measured by the degree of reduction in urinary glycosaminoglycans (GAG). 7 dogs with canine MPS I received oral cyclosporine and azathioprine combined with weekly low-dose (0.056 mg/kg) IV rhIDU (see Kakkis et al., PNAS 101(3):829-34, 2004). These dogs became tolerant to rhIDU (anti-iduronidase (IDU) antibody titer < 20 OD U/mL). 5 dogs received immune suppressive drugs in experimental tolerance regimens that failed to induce tolerance to rhIDU; these dogs had intermediate anti-IDU antibody titers (28.4-119 OD U/mL). All dogs were then treated with 0.58 mg/kg IV rhIDU weekly for 19-44 weeks. These were compared with 4 nontolerant (anti-IDU antibody titer 78.5-2295 OD U/mL) MPS I dogs receiving 0.58 mg/kg IV rhIDU alone for 9-14 weeks. The average reduction in urinary GAG excretion for tolerant dogs was 84.8 7.01%, vs. 60.0 11.9% reduction for nontolerant dogs (p =0.0017 vs. tolerant) and 53.4 11.8% for intermediate dogs (p=0.0002 vs. tolerant). Biochemical evaluation of kidney tissue was performed in 5 tolerant, 3 non-tolerant, and 5 intermediate dogs. IDU levels in tolerant dogs were higher, at 4.05 3.37 units/mg protein in the renal medulla and 12.2 10.5 in the cortex, than nontolerant: 1.30 0.865, p=0.23 medulla and 1.30 0.589, p=0.13 cortex; or intermediate: 0.916 0.390, p=0.07 medulla and 5.03 3.43, p=0.18 cortex. Renal GAG levels were lower, 11.8 1.85 g/mg dry weight medulla and 8.20 2.22 cortex in tolerant, than nontolerant: 21.7 13.1, p=0.07 medulla and 19.3 11.3, p=0.13 cortex, or intermediate: 25.6 5.70, p=0.0009 medulla and 19.3 3.16, p=0.0002 cortex. Immune tolerance to rhIDU can improve efficacy of IV rhIDU treatment as measured by urinary GAG excretion in canine MPS I, and this may be due to improved enzyme uptake or activity as reflected in greater GAG storage reduction in the kidney.

Dramatic improvement of visual impairment in an MPS Is (Scheie) patient treated by laronidase. *V. Valayannopoulos[1], S. Hakiki[2], A. Chabli[3], K. Mention[1], C. Caillaud[4], JL. Duffier[2], M. Lemerrer[5], V. Cormier-Daire[5], P. de Lonlay[1], A. Munnich[5].* 1) Metabolic Ped & Neurology, Necker-Enfants Malades Hosp, Paris, France; 2) Ophthalmology Department,Necker-Enfants Malades Hosp, Paris, France; 3) Biochemistry B Department,Necker-Enfants Malades Hosp, Paris, France; 4) Biochemistry Department, Cochin Hosp, Paris, France; 5) Genetics Department,Necker-Enfants Malades Hosp, Paris, France.

Mucopolysaccharidosis I (MPS I) is a lysosomal storage disorder due to alpha-L-iduronidase deficiency resulting in the storage in all tissues of glycosaminoglycans (GAG) responsible for a progressive, multisystemic disease. Enzyme replacement treatment (ERT) is now available (laronidase, recombinant human alpha-L-iduronidase). Although major improvements in sleep apnoeas and joint range of motion occurred in patients with the most severe symptoms, ERT has shown no significant efficacy on central and peripheral nervous system, eye and heart involvement. We report a 12 year old girl, presenting with MPS I (Scheie phenotype): restricted mobility, carpal tunnel syndrome, a slightly coarse face, hearing loss with tinnitus, cardiac involvement with mitral valve prolapse but no mental retardation. This patient suffered an acute unilateral visual loss, related to a left optic nerve compression by mucopolysaccharide infiltration shown by B-mode ultrasonography. Visual field assessment revealed a superior nasal defect. The patient was started on laronidase 100 U/kg weekly infusions. Visual acuity and visual field impairment dramatically improved within six months of treatment. This improvement has persisted so far after 18 months of treatment. Moreover she showed improved joint mobility («able to comb her hair »), better physical condition and improved hearing with no tinnitus. No adverse effects occurred during the infusions. In conclusion, this case report illustrates a unique efficacy of ERT in MPS retinal involvement, despite several previous reports of unsuccessful treatment of this condition.

Impact of long term Aldurazyme (laronidase) replacement therapy on cardiac disease progression in MPS I patients. *M. Sifuentes[1], R. Doroshow[2], R. Hoft[1], G. Mason[1], J. Phillips[1], I. Walot[1], M. Diament[1], S. Okazaki[1], K. Huff[1], G. Cox[3], B. Lyons[4], S. Swiedler[4], E. Kakkis[4].* 1) Dept of Pediatrics, Harbor-UCLA Medical Center, Torrance CA; 2) Children's National Medical Center, Washington DC; 3) Genzyme Corp, Cambridge MA; 4) BioMarin Pharmaceutical Inc, Novato CA.

In mucopolysaccharidosis I (MPS I), accumulation of partially degraded glycosaminoglycans (GAG) occurs in a variety of tissues. Cardiovascular lesions occur across the disease spectrum and progressively worsen often leading to death in many patients (pts) by the second or third decade. Six years (yr) follow-up data from 5 MPS I pts (4 Hurler-Scheie, 1 Scheie) assessed in an observational study were reviewed to evaluate the long term effects of Aldurazyme treatment on the cardiac status. A cardiac function scoring system was devised that combined data from the NYHA classification, ECG, echocardiogram, chest X-ray, and the cardiology physical exam to consolidate the wide ranging changes into a single score. The mean age of the 5 pts at follow-up was 18.4 yrs (range 14-24 yrs). At pretreatment, all pts had abnormal functional capacity (NYHA Class II (n=3), III (n=2)). By 1 yr of treatment, 3 had improved to NYHA Class I and by 6 yrs, 4 had improved to NYHA Class I. The cardiac function score (a higher score represents more disease) reduced from 11.5 (mean; range[8- 17]) at pretreatment to 9.2 (mean; range [5-12]) at Yr 6. Three pts had increases in score from pretreatment, ranging from 0.5 points to 1.5 points, and 2 pts had decreases of 1.5 points and 12 points, respectively. A slight increase in valvular regurgitation scores was noted from week 52 to Yr 6. At Yr 6 cardiomegaly assessed on X- ray remained stable in 2 pts worsened in 1 and improve in 2 patients. After 6 yrs of Aldurazyme, cardiac function remained stable or slightly deteriorated in a phenotype and age group where important cardiac disease progression was expected. Increases in endurance reflected by the NYHA classification most likely represent improvement across many organ systems, including the heart. Longer follow-up is required to assess if the impact of therapy on cardiac function scores translate in increased life expectancy.

Dose-response assessment in Gaucher patients on enzyme replacement therapy: long-term monitoring with ^{99m}Tc-Sestamibi scintigraphy. *G. Mariani[1], P.A. Erba[1], F. Minichilli[2], A. Pierini[2], F. Giona[3], A. Amendola[3], M. Filocamo[4], F. Buffoni[5], R.O. Brady[6].* 1) Dept. of Nuclear Medicine, University of Pisa Medical School, Pisa, Italy; 2) CNR Institute of Clinical Physiology, Pisa, Italy; 3) Dept. of Cell Biotechnologies and Hematology, University of Rome La Sapienza, Rome, Italy; 4) G. Gaslini Childrens Hospital, Genoa, Italy; 5) Nuclear Medicine Service, Town Hospital, Leghorn, Italy; 6) Developmental and Metabolic Neurology Branch, NINDS, NIH, Bethesda, MD, USA.

Skeletal responses to enzyme replacement therapy (ERT) in Gaucher pts occur slowly. Assessment of the skeletal component of Gaucher disease for monitoring efficacy of ERT over time is problematic. ^{99m}Tc-Sestamibi scintigraphy provides a score of bone marrow infiltration closely correlated with overall severity of Gaucher disease. We determined the utility of such score to monitor ERT efficacy in Gaucher pts. 48 Gaucher pts underwent a baseline ^{99m}Tc-Sestamibi scan, then again 10-134 months later (mean 49.7). Statistical analysis was based on the stepwise backward and cross sectional time series approach. More pts on ERT reached normal scintigraphic score when clinical disease duration was <10 yr (33.3% versus 5.6%, p=0.03-0.049), and more pts whose age was <20 yr reached normal score on ERT (42.8% versus 8%, p=0.03-0.07). Improvement in the scintigraphic score was correlated with ERT dose/month (p=0.011-0.047), ERT duration (p=0.017) and ERT cumulative dose (p=0.014-0.047). The mean dose/month inducing improvement in the score (36.852.94 U/kg per month) was significantly higher than in pts who did not improve on ERT (24.044.92 U/kg, p=0.004), as also higher was the cumulative ERT dose (878.8168.5 U/kg vs 495.5154.6 U/kg, p=0.0112). The ^{99m}Tc-Sestamibi score is an excellent predictor of response to ERT in Gaucher pts. Score changes are more closely correlated with the ERT variables than other clinical scores. Better score responses to ERT are expected in younger pts and in pts with shorter clinical disease duration. A dose-response relationship was identified between ERT and scintigraphic score. The minimum amount of enzyme required to improve the scintigraphic score was defined.

IMPROVEMENT OF SYMPATHETIC SKIN RESPONSES AFTER ENZYME REPLACEMENT THERAPY IN FABRY DISEASE. *C.B.O. Netto[1], L.B. Jardim[1,2], J. Becker[2], D. Nora[2], U. Matte[1], F. Pereira[1], M. Burin[1], I. Gomes[2], R. Giugliani[1].* 1) Genetics, UFRGS-HCPA, Porto Alegre, Porto Alegre, Brazil; 2) Neurology, UFRGS-HCPA, Porto Alegre,Brazil.

Introduction and Objectives:Fabry disease is an X-linked disorder caused by deficient activity of the lisosomal enzyme alfa-galactosidase A. We report the effect of 24 months of enzyme replacement therapy (ERT), in sympathetic skin responses (SSR) of patients with FD. Patients and methods: 7 male patients from 4 families were included in an open-label protocol using agalsidase-alpha. Two main measurements were done at baseline, and one and two years after the start of ERT: (1) a standard neurological examination (NE); (2) and SSR amplitudes. Results: in the 2nd year of ERT, there was a general improvement in the subjective reports of acroparesthesias, episodes of diarrhea and reduced sweating. There were no significant differences between NE in this time period, although thermal perception tended to worse. Before the start of ERT, SSR amplitudes were either too small or even absent (4/7 patients): the average (range) amplitude of 122 mV (0 to 492) was statistically smaller than those found in control group - 1453.6 mV (619.7 to 2754) ($p < 0.0001$, t test). Mean sd SSR amplitude aroused to 683 442, in the 1st year, and to 1088 690 mV, in the 2nd year of ERT, reaching the range found in normal, control group. Discussion: ERT continuously improved sympathetic function in Fabry patients, measured by SSR, in 2 years of observation. Although the mechanism of SSR improvement is unknown, this response to ERT can be clinically significant, if this is reflecting a normalisation of sweating, and, perhaps, of the body thermal control, with an expected reduction in acroparesthesias. Support: TKT.

Aldurazyme therapy in children less than 5 years of age with MPS I:preliminary data on urinary GAG and antibodies. *E. Wraith[1], N. Guffon[2], A. Van der Ploeg[3], M. Beck[4].* 1) Royal Manchester Children Hosp, Manchester, United Kingdom; 2) Hôpital E Herriot, Lyon, France; 3) Sophia Childrens Hospital, Rotterdam, the Netherlands; 4) Children`s Hospital, University of Mainz, Germany.

It has been postulated that patients with severe mucopolysaccharidosis I (MPS I) patients and no residual -L-iduronidase would be more likely to develop a strong immunologic response to treatment with Aldurazyme (laronidase, recombinant human -L-iduronidase) that might impair the clearance of GAG and lead to more adverse events. An open-label, 52 wk study of the safety and efficacy of Aldurazyme in 20 MPS I patients less than 5 yrs of age was recently carried out. As part of this study, antibody (IgG) titers to Aldurazyme and urinary GAG (uGAG) levels were measured. Patients initially received Aldurazyme at the label dose of 0.58 mg/kg (100 U/kg) IV once weekly. At Wk 26, 4 patients had their dose doubled to 1.16 mg/kg because of uGAG levels that remained above 200 mg/g creatinine at Wk 22. Adverse events were monitored throughout the study. The mean age of patients at baseline was 35 months (range 6-62 months). Of the 20 patients, 16 were classified as Hurler and 4 as Hurler-Scheie. Most patients (n=18) developed IgG antibodies to laronidase by Wk 4. The maximum antibody titer was 1/204800. Peak antibody titers occurred between Wk 4 and 20 and then began to decrease in some patients after Wk 12. The mean uGAG level at baseline (n=19) was 569 mg/g creatinine (sd 174.3; range: 211,5 - 926,7). The mean decrease in uGAG level was 56.3%; (sd 13.2%) (n=19) after 26 wks therapy with Aldurazyme. A similar reduction was observed after 52 wks in the first 10 patients with available data. Preliminary safety data suggests that Aldurazyme appears to be well-tolerated by these young patients, including those who received the 1.16 mg/kg dose. Final analysis of the complete dataset is currently in progress.

Long-term improvement in joint range of motion in mucopolysaccharidosis I (MPS I) patients treated with Aldurazyme (laronidase) in a Phase 3 extension study. *G. Pastores[1], J. Muenzer[2], M. Beck[3], L. Clarke[4], E. Wraith[5].*
1) Neurology, New York University School of Medicine, New York; 2) Pediatrics, University of North Carolina, Chapel Hill, NC; 3) Pediatrics, Johannes Gutenberg Universität, Mainz, Germany; 4) Medical Genetics, University of British Columbia, Vancouver, Canada; 5) Willink Biochemical Genetics Unit, Royal Manchester Childrens Hospital, Manchester, UK.

All patients from a 26-week randomized, double-blind, placebo-controlled study with Aldurazyme (laronidase-rhIDU) were enrolled into an open-label study. Patients crossing over from placebo to rhIDU (N=23; total exposure 144 weeks) were designated placebo/rhIDU, the others (N=22; total exposure 170 weeks) were designated rhIDU/rhIDU. Active flexion and extension of left and right shoulders and knees was measured. Two patients with symptomatic cervical cord compression were excluded from this analysis. Mean shoulder flexion in the rhIDU/rhIDU group gradually improved by 4.3 degrees, 8.7 degrees, 12.4 degrees, and 13.7 degrees at 50, 62, 86, and 110 weeks. At Week 170, the mean improvement in shoulder flexion was 15.5 degrees in this group. Patients in the placebo/rhIDU group demonstrated a mean improvement of 14.5 degrees by Week 144. A similar pattern of improvement was seen in the other joint range of motion measurements. Mean shoulder extension in the rhIDU/rhIDU group gradually improved by 4.6 degrees, 6.0 degrees, 7.1 degrees, 9.6 degrees at 50, 62, 86, and 110 weeks. At Week 170, the mean improvement in shoulder extension was 12.7 degrees, and in the placebo/rhIDU group the mean improvement at week 144 was 10.0 degrees. Mean knee flexion and mean knee extension improved in the rhIDU/rhIDU group by 13.4 degrees and 8.5 degrees. In the placebo/rhIDU group, the improvements amounted to 5.1 degrees and 4.0 degrees. Approximately 50% of the patients experienced infusion related events, the majority of which did not require treatment. Continued improvements in joint range of motion have been observed over the first three years of treatment. These changes are expected to translate into increased abilities to carry out activities of daily living.

Children with Fabry disease reveal the importance of very early treatment. *C.P. Lorentz[1], R.J. Desnick[2], C.B. Whitley[1].* 1) University of Minnesota, Minneapolis, MN; 2) Mt. Sinai School of Medicine, New York, NY.

Fabry disease is an X-linked lysosomal storage disorder caused by deficiency of alpha-galactosidase A. Clinical onset in childhood includes debilitating acroparesthesias and excruciating pain crises, hypohidrosis, and gastrointestinal problems. With advancing age, patients develop renal failure, cardiac disease and strokes leading to early demise. Double-blind randomized placebo-controlled trials in adults of enzyme replacement therapy (ERT) with Fabrazyme at 1 mg/kg have shown clearance of the accumulated globotriaosylceramide (GL-3) in the plasma, vascular endothelium, heart, liver, skin, and kidney. However, limited experience is available on the effects of ERT in children with Fabry disease. Here we report the response to Fabrazyme treatment (1 mg/kg every 2 weeks) in two affected boys aged 4 and 11/12 yr (Patient 1; genotype I270T) and 12 and 1/6 yr (Patient 2; genotype Y216D). Patient 1 had episodes of acrimonious hand-shaking, abdominal cramping, and 6 to 10 bowel movements daily. After 6 weeks of therapy, there was a dramatic resolution of abdominal pain and diarrhea. Plasma GL-3 decreased from 10.6 to 5.6 mg/L (normal <7 mg/L). Patient 2 also complained of frequent abdominal cramping and diarrhea, episodic acroparesthesias of the hands and feet, and heat intolerance due to hypohidrosis. His acroparesthesias stopped after 6 weeks of treatment; by 6 months, his sweating was normal, and he was able to play 9 innings of baseball in warm weather for the first time. His plasma GL-3 declined from 8.7 to 2.4 mg/L. In these children, the acroparesthesias, hypohidrosis, and gastrointestinal manifestations, the early severe, debilitating symptoms of Fabry disease that impaired their quality of life, were resolved by ERT. Thus, ERT in affected boys and symptomatic heterozygous females is recommended to prevent and/or treat the early disease symptoms and to prevent permanent, irreversible disease damage. Fabry disease should be treated as early as possible and especially in childhood, as recommended by a recent expert consensus article (Desnick et al., Ann Intern Med 138:338, 2003).

KIDNEY FUNCTION EVALUATION AFTER 24-MONTHS OF ENZYME REPLACEMENT THERAPY FOR FABRY DISEASE. *E. Barros[1], C.B.O. Netto[2], C. Cecchin[2], M. Burin[2], S. Brustolin[2], L. Jardim[1,2], R. Giugliani[2].* 1) Internal Medicine, UFRGS, Porto Alegre, RS, Brazil; 2) Genetics, UFRGS-HCPA, Porto Alegre,Brazil.

INTRODUCTION AND AIMS: Fabry disease (FD) is X-linked metabolic disorder due to the deficiency of alfa-galacosidase A. We report our experience after 2 years of ERT concerning the kidney function. METHODS AND PATIENTS: Nine FD patients (7 males) were included in an open-label protocol using agalsidase-alpha..We measured the following outcomes at baseline, 12 and 24 months of ERT: urinary protein, glomerular filtration rate (GFR), plasma creatinine, and the estimated creatinine endogenous clearance (CEC). RESULTS: Non-nephrotic proteinuria was present in 5/9, 3/8 and 3/6 patients at baseline, 12 and 24 months of ERT, respectively. The mean (sd) of the following variables, obtained at the same time points were: 105 (38), 116 (39) and 105 (37) ml/min for the GFR; 0.8 (0.5), 0.7 (0.1) and 0.8 (0.05) mg% for plasma creatinine; and 127 (40), 125 (24) and 102 (12) ml/min, for estimated CEC. At baseline, two patients were at the beginning of their renal diseases: patient four, age 28, progressed to end-stage renal disease and had kidney transplantation by the 12th month; and patient one, age 46, who in spite of ERT, continued to lose renal function by around 12 ml/min/. CONCLUSIONS: non-nephrotic proteinuria was found in the same proportions as those already reported in studies on the natural history of FD, and showed no changes during the 2 years of ERT. Only two patients of the present series started their ERT with renal disease already established, and therefore, only they could be compared with historical controls of FD without treatment. We conclude that adequate follow up is required to judge ERT effects over kidney, especially because our patients were still young, and/or free of renal dysfunctions. Support: TKT.

Successful reinstitution of agalsidase beta therapy in patients with previous IgE antibody production or positive skin testing. *D.C. Bodensteiner[1], D.P. Germain[2], C.R. Scott[3], K.B. Sims[4].* 1) U Kansas Medical Center, Kansas City, KS; 2) Hôpital Européen George Pompidou, Paris, France; 3) U Washington School of Medicine, Seattle, WA; 4) Massachusetts General Hospital, Boston, MA.

Enzyme replacement therapy (ERT) with 1 mg/kg of recombinant human -galactosidase A (agalsidase beta; Fabrazyme) administered intravenously every 2 weeks is a safe and effective treatment for Fabry disease. Of 169 patients treated with agalsidase beta in clinical studies, 7 developed serum IgE antibodies or had a positive skin test to agalsidase beta. A rechallenge protocol was tested in a multicenter, open-label, Phase 2 study to determine if ERT with agalsidase beta could be safely reinstituted in these patients. ERT was performed under supervision of the investigator and a qualified allergist. Infusions 1 and 2 were administered a week apart at 0.5 mg/kg; the initial infusion rate of 0.01 mg/min could be doubled every 30 min up to 0.25 mg/min if no significant infusion-associated reactions (IARs) occurred. After infusion 2, a dose of 1.0 mg/kg every 2 weeks was allowed at infusion rates that could be progressively increased, but total infusion duration had to be 2 hr. For infusions 1 through 4, pretreatment medication was prohibited so IARs could be readily identified. Subsequently, antihistamines, antipyretics, -agonists, and steroids were permitted for managing IARs. Patients were continuously monitored for adverse events (AEs) during and up to 2 hr after infusions. Among the 6 patients enrolled, 5 successfully received agalsidase beta at doses of 0.5 to 1.0 mg/kg; 1 withdrew voluntarily due to IAR recurrence. There were no reports of anaphylaxis. All AEs were of mild or moderate severity, with IARs accounting for most AEs. Four serious AEs, all considered IARs, occurred in 3 patients and were managed by infusion rate reductions and medication. Urticaria, the most common IAR, was not associated with histamine release and appeared to be complement-mediated. Hence, agalsidase beta therapy can be safely reinstituted in patients with positive skin testing or IgE antibody production using a graded approach to dose and infusion rate, medication to mitigate IARs, and careful patient monitoring.

Efficacy of reduced-dose alglucerase therapy in gaucher disease. *A.F. Moore[1], H. Zhu[2], D. Kuter[1].* 1) Internal Medicine, Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Massachusetts General Hospital, Boston, MA.

INTRODUCTION: Gaucher disease is a lysosomal storage disorder caused by decreased glucocerebrosidase activity. Enzyme replacement therapy with alglucerase is efficacious in treating Gaucher Disease at a cost of over $500,000 annually. This cost has prompted interest in finding the lowest effective dose; however, there are few studies of long term, reduced-dose therapy. This paper describes the 10-year experience of 15 patients on reduced-dose alglucerase therapy (30 U/kg every 2 weeks) at the Massachusetts General Hospital (MGH). OBJECTIVES: To evaluate the efficacy of reduced-dose alglucerase therapy. SUBJECTS AND METHODS: Data over 10 years was recorded at MGH for 15 patients. Response was measured with annual measurements of hematocrit, platelet counts, angiotensin-converting enzyme (ACE) levels, ferritin levels, spleen and liver size, and bone crisis frequency. Body mass index (BMI) was calculated from serial height and weight measurements. RESULTS: Patients treated with reduced-dose alglucerase therapy demonstrated clinically significant increases in hematocrit and platelet count. Most anemic patients achieved a 6 percent increase in hematocrit within 4 years of initiating therapy, and a majority of patients normalized their platelet counts within 2 years. During the final 3 years of the study, both the average hematocrit and platelet counts decreased but never returned to initial values. ACE and ferritin levels, biologic markers of Gaucher disease activity, returned to normal within 1 year of initiating therapy and remained normal for the remainder of the study. Organ size was measured by computed tomography volumetric reconstruction of 2 patients, both of whom demonstrated reduction of initial organomegaly. Patients gained weight during therapy with 29% increasing their BMIs at least 20%. CONCLUSION: Gaucher disease can be effectively treated with low-dose alglucerase therapy at a dose of 30 U/kg every 2 weeks (60 U/kg/month) with similar efficacy as other higher-dose regimens for the initial 5 to 7 years of therapy. Some attenuation in response may occur when patients are treated longer.

Dose responsive toxicological findings following intravenous administration of recombinant human acid sphingomyelinase(rhASM) to acid sphingomyelinase knock-out(ASMKO) mice. *C. Nickerson, J. Murray, A. Vitsky, M. Hawes, S. Ryan, P. Ewing, B.L. Thurberg, L. Andrews.* Genzyme Corporation, Framingham, MA.

ASM is a lysosomal enzyme that cleaves sphingomyelin into ceramide and phosphorlycholine. ASM deficiency results in the allelic disorders known as Niemann-Pick disease(NPD) Types A and B. The ASMKO mouse is being used for the evaluation of the pharmacodynamic effects of rhASM and the development of rhASM as a potential enzyme replacement therapy for NPD. While single dose and chronic repeated dose toxicity studies conducted in normal animals have shown no adverse effects from rhASM administration up to the highest doses administered, the ASMKO mouse has been shown to be a sensitive model for the evaluation of the toxicity of rhASM. Single dose toxicity studies show dose responsive histopathological findings in the liver and adrenals of ASMKO mice when compared to vehicle, with no significant adverse effects in the C57BL/6 mice. Findings at low doses included randomly scattered hepatocellular ballooning degeneration and apoptosis as well as mild adrenocortical necrosis. Lesions in the adrenal and kidney at high doses correlate with systemic effects of hypotension and shock. These results suggest the toxicity is related to the substrate or substrate degradation products. In a repeated dose toxicity study, ASMKO mice received rhASM every other week for 12 weeks, with a four week recovery. Histopathological findings in the liver and adrenal were similar to single dose studies though changes were milder and reversible. Single or repeated therapeutic doses of rhASM that reduce substrate levels, followed by a known toxic dose, results in the reduction or prevention of the toxicity. These data suggest the toxicity is associated with the Cmax of rhASM and the amount and rate of substrate degradation. Results of these studies in normal animals and transgenic mice demonstrate the utility of including animal models of disease in the toxicological evaluation of potential therapeutics. Additional studies are underway to further characterize the molecular basis of toxicity in ASMKO mice and to identify potential safety biomarkers for use in human clinical trials of rhASM.

Testing of new therapeutic interventions in Fanconi Anemia. *M. Grompe[1], M. Noll[1], S. Houghtaling[1], Y. Akkari[1], M. Finegold[2], S. Olson[1], M. Kay[3].* 1) Dept Molec/Med Genetics, Oregon Health & Sci Univ, Portland, OR; 2) Baylor Coll of Med, Houston, TX; 3) Stanford Univ., Palo Alto, CA.

The life span of patients with Fanconi Anemia (FA) is severely shortened by bone marrow failure and malignancies and currently, allogeneic bone-marrow transplantation is the only therapeutic option. We are using mouse models of FA to preclinically test various therapeutic interventions. First, non-viral methods for gene transfer into hematopoietic stem cells (HSC) are being tested. In FA retroviral vector gene therapy is hampered by the requirement for prolonged ex vivo manipulation and the scarcity of HSC. We therefore utilized the non-viral Sleeping Beauty (SB) transposon system to facilitate stable, gene transfer of the human FANCC cDNA without ex vivo culture. This was achieved either by electroporation of naked DNA into whole bone marrow or by direct injection into the femur cavity. We show that a) HSC from Fancc -/- mice can be transduced by plasmid DNA; b) stable transposition of plasmid DNA into the genome of HSC is possible and c) long-term therapeutic benefit could be achieved using this method. Non-viral gene transfer may be a viable alternative for the treatment of hematopoietic diseases. Second, methods to reduce the number of solid tumors in FA patients are being tested.. Fancd2-/-p53+/- mice develop epithelial tumors at about one year of age. We are using this strain of mice to test the efficacy of drugs which may have the potential to delay tumor formation. Recently, it was shown that the superoxide dismutase mimetic drug tempol (4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl) can significantly delay tumor onset in a murine model of telangiectasia. It is thought that tempol reduces DNA damage induced by free oxygen radicals and thereby ameliorates tumor formation. Oxidative damage also plays a role in FA oncogenesis. We have generated 40 female Fancd2-/-p53+/- mice, which have a 50% expected rate of epithelial tumor formation by age 15 months. Half of these animals are being treated with a control diet and half are being given tempol. At an average age of ~9 months, significant numbers of tumors have not yet been observed in either the treated or control mice. Data for an average treatment duration of 14 months will be presented.

Construction of a novel human artificial chromosome (HAC) and its use for gene delivery. *M. Oshimura[1, 2, 3], R. Xianying[2], A. Otsuki[1], M. Kakeda[4], M. Hiratsuka[2], H. Yamada[1], T. Suda[1], Y. Kazuki[1], M. Nishikawa[4], K. Tomizuka[4], M. Kawahara[5], T. Nagamune[5], M. Katoh[3], T. Inoue[3], A. Kurimasa[1].* 1) Dept. Biomed. Sci., Inst. Regenerative Med. and Biofunction; 2) Dept. of Mol. & Cell Genet; 3) Dept. Hum. Genome Sci., Grad. Sch. Med. Sci., Tottori Univ., Yonago, Tottori, JAPAN,; 4) Pharm. Res. Lab., Pharm. Div., Kirin Brewery Co., Ltd. Takasaki, Gunma, JAPAN,; 5) Dept. Chem. & Biotech., Grad. Sch. of Engineering, The Univ. of Tokyo, Hongo, Bunkyo-ku, Tokyo, JAPAN.

Ex vivo gene delivery followed by autologous transplantation is a way for gene therapy and regenerative medicine. Prerequisites for gene delivery vectors are 1) long term stable maintenance in host cells, 2) no risk for disrupting host genome by integration and 3) appropriate regulation of transgene in host cells. Previously, transfer of engineered human chromosome to mouse ES cells via microcell fusion achieved production of mice expressing functional human immunoglobulin, suggesting the potential use of chromosome vector. Thus, we addressed the feasibility of constructing chromosome-based ex vivo gene delivery system. We have developed a structurally defined HAC into which circular DNA can be loaded by a Cre/loxP-system. In chicken DT40 cells, distal q- and p-arm were truncated by telomere seeding from the sequence-defined human chromosome 21, and a loxP site was introduced. These 21HACs were transferable and stably maintained in human HT1080 and mouse ES cells. The EGFP gene on the HAC was expressed persistently in these cells, indicating that the 21HAC might be useful for functional study of transgene in vitro. Progress in testing the performance of the HAC vector will be reported; 1) tetracycline-inducible expression of DNA-Pkcs gene, 2) induction of tissue-specific expression of EGFP reporter gene accompanying in vitro differentiation in human Mesenchymal Stem Cells, 3) construction of non-beta cells capable of inducible expression of insulin, 4) persistent expression of erythropoietin gene in normal human fibroblasts, 5) exogenous gene expression and antigen-mediated growth regulation of human hematopoietic cells.

Development of therapeutic siRNAs that specifically target keratin 6a for treatment of the skin disorder pachyonychia congenita. *R. Kaspar[1], F. Smith[2], W. McLean[2], M. Landthaler[3], R. Leube[4], R. Hickerson[1].* 1) TransDerm, Santa Cruz, CA; 2) Ninewells Medical School, Dundee, UK; 3) Rockefeller University, NY; 4) Johannnes Gutenberg-Universität, Mainz.

The discovery that siRNAs silence gene expression without inducing an immune response has resulted in intense therapeutic development efforts. Due to recent advances in nucleic acid skin delivery, siRNA offers a novel approach for treating skin disorders. Pachyonychia congenita (PC) is a rare autosomal dominant disorder that results in hypertrophic nail dystrophy and focal palmoplantar keratoderma with blisters. Two types of PC have been described: PC-1 is caused by mutations in genes encoding keratin (K) 6a or K16 genes, PC-2 from mutations in K6b or K17. In K6a, there are several recurrent mutations at the N171 site, which is either deleted or a single nucleotide (nt) is mutated resulting in an amino acid change (e.g. N171K). We show that a fusion protein consisting of K6a and YFP reporter (K6a-wt/YFP) results in keratin filaments in transfected PLC cells as assayed by fluorescence microscopy. A similar construct with a PC K6a N171K mutation results in aggregate formation and filament disruption. To investigate whether siRNAs can rescue the aberrant filaments, siRNAs were designed to target the N171K mutation. Co-transfection of the K6a-YFP constructs (wt or N171K) and siRNAs into 293 cells revealed inhibitors that preferentially target mutant K6a mRNA (e.g. one siRNA had IC50 values of 0.6 nM and 0.1 nM against wt and mutant constructs, respectively). Due to the strong sequence homology between K6a and K6b (and the apparent functional redundancy of K6a in knockout mice), we designed inhibitors that target unique regions of K6a, specifically in the 3UTR. Co-transfection experiments with the K6a-wt/YFP construct and K6a 3UTR-specific siRNA inhibitors showed decreased K6a-wt/YFP expression (IC50 <0.2 nM). These studies suggest that siRNAs developed against K6a in general, or PC-specific mutations, may be effective PC therapeutics and further suggest that designer siRNAs may allow effective treatment of a host of genetic skin disorders and other tissues using a tailored approach.

Nonviral gene transfer in the Mucopolysaccharidosis I murine model. *U. Matte[1], M. Camassola[1,2], L.M. Braga[2], A.D. Canedo[2], T.P. Dalberto[2], M. Burin[3], N. Nardi[2], R. Giugliani[1,3].* 1) Center for Gene Therapy, HCPA, Porto Alegre, RS, Brazil; 2) Genetics Department, UFRGS, Porto Alegre, RS, Brazil; 3) Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil.

Mucopolysaccharidosis I (MPS I) is a lysosomal disorder characterized by a deficiency of the enzyme alpha-L-iduronidase (IDUA), that leads to the accumulation of glycosaminoglycans (GAGs). Presently, available treatments include bone marrow transplantation and enzyme replacement therapies, both of which are limited in their effects. In this work, knockout (KO) MPS I mice were treated with a nonviral vector containing the human IDUA cDNA. KO mice were transfected by hydrodynamic injection of pRIDUA in the caudal vein (iv, n = 3) or by intraperitoneal injection of pRIDUA/Superfect complexes (ip, n = 3). GAG level and IDUA activity were analyzed in the kidneys, spleen, lungs, brain and liver. The expression of IDUA in the organs of iv- and ip-treated mice was also analyzed by real-time reverse transcription (RT) PCR and compared by relative quantification. The concentration of GAGs in the organs was different between KO and wild-type mice. In the spleen and liver, GAG levels were lower in iv- and ip-treated KO mice than in control nontreated animals. Real-time RT-PCR showed that the transgene is expressed in all the analyzed organs of ip- and iv-treated KO mice. Enzyme activity was similarly observed in all the organs analyzed. Our data suggest that this kind of transfection may be a useful tool for studies of nonviral protocols for gene therapy of MPS. (Finacial support: CNPq, FAPERGS, FIPE-HCPA).

High Efficiency Hepatic Transduction with Minimal Toxicity Following Hydrodynamic Injection of HDAd into Nonhuman Primates. *N. Brunetti-Pierri[1], C. Mullins[2], G.E. Stapleton[2], D. Palmer[1], M. Finegold[3], K. Rice[4], D. Carey[4], A.L. Beaudet[1], P. Ng[1].* 1) Dept Molec & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics Cardiology, Baylor College of Medidicine, Houston, TX; 3) Dept. of Pathology,Baylor College of Medidicine, Houston, TX; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

Helper-dependent adenoviral vectors (HDAd) are attractive vectors for liver-directed gene therapy because they can mediate sustained, high level transgene expression with no long-term toxicity. However, as a consequence of a threshold effect, high vector doses are required to achieve efficient hepatic transduction by peripheral intravenous injection which results in a dose-dependent activation of the innate inflammatory response. Systemic hydrodynamic injection of HDAd into mice resulted in exceedingly high levels of hepatic transduction and reduction in both systemic vector dissemination and acute proinflammatory cytokines compared to conventional injection. Hydrodynamic injection cannot be applied to larger animals due to the large injection volume. We have developed a minimally invasive method to mimic hydrodynamic injection in nonhuman primates which does not require injection of large volumes. This method involves the use of balloon occlusion catheters percutaneously positioned in the inferior vena cava to transiently obstruct hepatic venous outflow to increase the intrahepatic pressure prior to simple peripheral intravenous injection of HDAd in a small volume. We demonstrate that this novel method of vector delivery results in an exceedingly high and unprecedented level of hepatic transduction with low vector doses resulting in stable, long-term transgene expression. The procedure itself was uneventful and was accompanied by minimal evidence of liver injury and minimal, transient elevations of proinflammatory cytokines. This novel method of delivering HDAd is simple, minimally invasive, and clinically relevant since it increases the therapeutic index of HDAd for liver-directed gene therapy by allowing high efficiency hepatic transduction with low vector doses and with negligible acute or chronic toxicities.

High Efficiency Hepatic Transduction and Long-Term Transgene Expression by Delivering Helper-Dependent Adenoviral Vectors into the Surgically Isolated Liver of Nonhuman Primates. *D.J. Palmer[1], N. Brunetti-Pierri[1], T. Ng[2], D. Iannitti[2], W. Cioffi[2], M. Finegold[3], K. Rice[4], D. Carey[4], A.L. Beaudet[1], P. Ng[1].* 1) Dept. Mol & Human Genetics, Baylor College of Medicine, Houston,TX; 2) Department of Surgery, Brown Medical School, Providence, RI; 3) Dept. Pathology, Baylor College of Medicine, Houston,TX; 4) Southwest Foundation for Biomedical Research, San Antonio,TX.

Helper-dependent adenoviral vectors (HDAd) are attractive vectors for liver-directed gene therapy because they can mediate long-term, high level transgene expression with no long-term toxicity. However, as a consequence of a threshold effect, high vector doses are required to achieve efficient hepatic transduction by peripheral intravenous injection which unfortunately results in a dose-dependent activation of the innate inflammatory response. Strategies to overcome the threshold to efficient hepatic transduction are needed to improve the therapeutic index of HDAd. We hypothesized that this obstacle could be surmounted by delivering the vector exclusively to the liver. To test this hypothesis, we have injected HDAd directly into surgically isolated livers via the portal vein in nonhuman primates. Total hepatic isolation was achieved by occluding both hepatic inflow and outflow. Prior to total hepatic isolation, saline was infused into the portal vein to flush blood out of the liver. The vector was then injected into the liver via the portal vein and allowed to dwell for 30 minutes, following which unabsorbed vector was flushed out via a catheter placed in the vena cava to minimize systemic vector dissemination. Our results revealed that significantly higher hepatic transduction efficiencies can be achieved with relatively low vector doses compared to peripheral intravenous injection. Importantly, stable, high levels of transgene expression were observed for up to one year with no long-term toxicity. This approach may increase the safety and efficacy of HDAd-mediated, liver-directed gene therapy by minimizing the dose required to achieve efficient hepatic transduction and by minimizing systemic vector dissemination.

Aerosol delivery of helper-dependent adenoviral vector into nonhuman primate lungs results in high efficiency pulmonary transduction with minimal toxicity. *P. Ng[1], N. Brunetti-Pierri[1], D. Koehler[2], R. McConnell[3], J. Katkin[3], D. Palmer[1], D. Dimmock[1], J. Hu[2], M. Finegold[4], D. Carey[5], K. Rice[5], A.L. Beaudet[1], P. Hiatt[3].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Programme in Lung Biology Research and the Canadian Institutes of Health Research Group in Lung Development, Hospital for Sick Children, Toronto; 3) Dept of Pediatrics, Baylor Col Medicine, Houston, TX; 4) Dept Pathology, Baylor Col Medicine, Houston, TX; 5) Southwest Foundation for Biomedical Research, San Antonio, TX.

Cystic fibrosis is caused by recessive mutations in a membrane chloride channel gene (CFTR) expressed in the airway epithelium and is characterized by persistent, progressive inflammation and infection, eventually leading to lung failure. A major obstacle to CF gene therapy is inefficient pulmonary transduction by viral and nonviral vectors in large animals and humans. To address this obstacle, we have used a novel strategy for efficient aerosol delivery into nonhuman primate lungs of a helper-dependent adenoviral vector (HDAd) bearing a human airway epithelial cell and submucosal gland cell-specific expression cassette driving either LacZ or bAFP. The AeroProbe, an intracorporeal nebulizing catheter, was used to aerosolize HDAd formulated in 0.1% L--lysophosphatidylcholine directly into the airways of nonhuman primates. Extensive and unprecedented high levels of transduction of the ciliated epithelium of the trachea, bronchi and bronchioles as well as submucosal glands were observed. None of the animals treated showed signs of respiratory distress or chest X-rays abnormalities. Laboratory findings (chemistries, cell counts, cytokines, etc) in the blood and BAL fluid were unremarkable. This study demonstrates a novel and promising strategy to achieve high efficiency transduction of the trachea, the proximal and distal airway epithelium and submucosal glands in a large animal model for HDAd-mediated, lung-directed gene therapy for CF.

Development of long-term treatment for hypertension using human skin gene therapy to deliver systemic Atrial Natriuretic Peptide (ANP). *J-P. Therrien, C.L. Tock, M. Ohyama, J.C. Vogel.* Dermatology Branch, NCI/NIH, Bethesda, MD, 20892-1908, USA.

Skin is a very attractive organ for targeted gene therapy to systemically deliver therapeutic proteins to treat a variety of disorders, including genetic anomalies. Skin is a renewable tissue, the ability to achieve long-term stable expression of a therapeutic gene requires targeting keratinocytes stem cells (KSC), but specific extracellular markers to isolate living KSC do not exist. We have therefore developed an *in vivo* system using a bicistronic retroviral vector expressing the desired therapeutic gene and a selectable marker (MDR) combined with topical colchicine treatment to select and enrich for cells expressing the vector. As a model to validate our system we have chosen ANP as a therapeutic gene to treat hypertension. Although studies have demonstrated that ANP infusion can decrease blood pressure in hypertensive patients and animal models, stable long-term expression of ANP from a targeted tissue such as skin will be required for clinical application. We have now constructed and produced a retroviral vector containing ANP and MDR genes and achieved viral titer 10^4-10^5 cfu/ml, similar to titers obtained in other studies using MDR in a bicistronic system. FACS analysis with anti-MDR antibody, shows that up to 32.5% and 18.6% of transduced-fibroblasts (Fb) or keratinocytes (Kc), respectively, express MDR. The more sensitive rhodamine exclusion assay demonstrated higher percentages of transduced-cells expressing a functional MDR in the plasma membrane, Fb (40.3%) and Kc (36.8%). We anticipate that colchicine selection will further increase the percentage of Kc expressing ANP, as well as ANP expression longevity. Human skin equivalent (HSE) expressing ANP/MDR has been engineered *in vitro*, with histology similar to normal human skin. Using an immuno-radiometric assay specific for ANP, bioengineered HSE were able to secrete significant levels of ANP, between 12 to 42 pg/ml, into the culture media. The genetically modified HSE is being grafted onto immunocompromised mice to determine the level of systemic human ANP achieved and the effect on murine blood pressure.

Developing AAV-Mediated Gene Therapy For Acute Intermittent Porphyria: Vector Optimization Studies. *M. Yasuda, M. Domaradzki, D.F. Bishop, R.J. Desnick.* Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY.

Acute Intermittent Porphyria (AIP), the most common hepatic porphyria, is an autosomal dominant disorder caused by the half-normal activity of Hydroxymethylbilane Synthase (HMBS). Clinically, AIP is manifested by life-threatening, acute neurological attacks that are provoked by various factors (e.g. cytochrome P450 inducing drugs, fasting, alcohol, and hormonal changes). Currently available therapy alleviates, but does not prevent the symptoms of the acute attacks. Thus, our goal is to develop a preventative therapy for AIP, using Adeno Associated Viral (AAV) vectors. For vector optimization, different combinations of liver-specific enhancers and promoters were evaluated for hepatic transgene expression levels. The murine HMBS cDNA was cloned into four expression vectors, each carrying a unique combination of liver-specific enhancers and promoters: HMBS-1 [human 1-microglobulin (1MG)/ 1-antityrpsin (1AT)], HMBS-2 [1MG/ human serum albumin (HSA)], HMBS-3 [human prothrombin (PT)/ HSA] and HMBS-4 [PT/ 1AT], and these HMBS constructs were transiently transfected into HepG2 cells. While all four constructs displayed increased HMBS activities compared with the mock transfection, HMBS-1 had the highest levels, with a ~9 fold increase over endogenous levels. Using the hydrodynamic technique, the HMBS constructs were then co-injected with a control luciferase construct into an AIP mouse model (Lindberg et al., Nat Genet 12: 195, 1996). 24 hours post-injection, the peak expression time for HMBS in vivo, livers were isolated from the mice and assessed for transgene expression. Again, the HMBS-1 construct displayed the highest levels, with a ~7 fold increase over the saline-treated mice. In conclusion, HMBS-1, carrying the 1MG enhancer and 1AT promoter, achieved the highest levels of hepatic HMBS expression, both in vitro and in vivo studies. Therefore, a rAAV-vector with these regulatory elements is being used to obtain rAAV, to evaluate the efficacy and safety of AAV-mediated gene therapy in the AIP mice.

In Vivo Evaluation of Coagulation Factor VIII Variants for the treatment of Hemophilia A. *V. Cerullo[1], W.M. McCormack[1], R. Garcia[1], C. Clarke[1], S. Pipe[2], B. Lee[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI.

Hemophilia A is an X-linked bleeding disorder resulting from a deficiency of coagulation factor VIII (FVIII). FVIII expression after gene transfer is limited by unstable mRNA, interaction with endoplasmic reticulum (ER) chaperones, a requirement for facilitated ER to Golgi transport through interaction with the mannose-binding lectin LMAN1, and the instability of the activated form of FVIII (FVIIIa). Bioengineering of different variants of recombinant FVIII molecules by rational design can overcome these limitations. In this study we evaluated the in vivo efficacy of six different variants of recombinant FVIII. To this end, we generated six different helper dependent adenoviral vectors carrying human cDNA's regulated by the liver tissue restricted PEPCK promoter. To compare the short term efficacy and duration of hFVIII expression and infectivity of the different HDV hFVIII variants, FVIII deficient mice were treated with each vector at a dose of 5X1012 vp/kg via tail vein injection. Plasma was collected at baseline, two and four weeks post-injection and the FVIII biological activity was quantified by Coatest chromogenic bioassay. In this experiment, all vectors expressed functional FVIII at two weeks post-injection. FVIII activity varied from 2-8% in WT FVIII to up to 70% in other constructs. Functional FVIII activity dropped significantly in all vectors by 4 weeks except in the mice treated with an inactivation resistant rFVIII (HDV IR8 hFVIII) suggesting that this variant may exhibit an improved immunological profile. Interestingly, another construct containing the F309S substitution which decreases binding to the ER protein BiP to increase the rate of secretion of the FVIII variant, appears to significantly improve activity over WT hFVIII in vivo. By using these engineered FVIII variants, longer-lived protein with improved immunological profiles can be generated for gene transfer and protein therapy.

Improved intracellular stability of multimeric hammerhead ribozymes. *D. Basel[1], B. Peace[2], Z. Lada[1], R.J. Wenstrup[2], M.W. Kilpatrick[1], P. Tsipouras[1].* 1) Gen&Dev Biol,UCHC, Farmington, CT; 2) CCHRF, Cincinnati, OH.

Hammerhead ribozymes are small catalytic RNA molecules that can be engineered to cleave RNA in a sequence-dependent manner. In earlier studies we have shown that ribozyme can efficiently abolish the mutant transcript in a cellular model of Osteogenesis Imperfecta. Additionally, we have shown that ribozyme multimers capable of cis-cleaving to catalytically active monomeric subunits have greater intracellular activity than their constituent monomers. Interestingly, extending the 3 tail of a monomeric ribozyme resulted in both increased stability and efficacy. We postulated, therefore, that the greater efficacy of multimeric ribozymes in the cell might result from the larger ribozyme construct being more stable than the smaller monomer. To test this hypothesis, cell lines expressing a ribozyme monomer, a cis-cleaving ribozyme multimer and a non-cis cleaving ribozyme multimer were established. Total RNA preparations from cells expressing the monomeric ribozyme and cis-cleaving multimeric ribozyme were analyzed for the presence of ribozyme by ribonuclease protection assay and slot-blot analysis. Initial data indicates that the half-life of the ribozyme monomer is approximately one third that of the cis-cleaving multimer. This supports our hypothesis that the larger transcript is more resistant to intracellular degradation. The second phase of this work is to compare the cis- and non cis-cleaving ribozyme multimers, which both contain six copies of the active ribozyme, and differ only in their ability to cleave or not-cleave, to monomeric sub-units. These ribozymes specifically cleave their mutant Col1A1 mRNA target in a test tube and, as expected, the cis-cleaving multimer self cleaves to its monomeric subunit while the non cis-cleaving multimer remains a single molecule. Analysis of cell lines that stably express each of these two ribozyme constructs will both compare the half life of cis-cleaving multimer to that of a non cis-cleaving multimer and determine their relative intracellular target cleaving efficacies. This data may lead to new ways of designing ribozymes for intracellular expression and subsequent application in targeted gene therapies.

Inability of an insulator element to prevent insertional activation of oncogenes and tumorigenesis. *J. Lenz, K. Mitra.* Dept Molecular Genetics, Albert Einstein Col Medicine, Bronx, NY.

Retrovirus gene therapy vectors have proven successful in treating human inherited disorders. However, trials of murine gammaretrovirus (MLV) vectors in humans have encountered the complication of insertional activation of host oncogenes by the viral vectors leading to tumorigenesis. One strategy that has been widely proposed to prevent this complication and improve the safety of gene therapy vectors is to use insulator elements to prevent transcriptional enhancers in the vector from activating the promoters of adjacent oncogenes. However, this has not been tested directly. We analyzed the ability of the chicken -globin HS4 insulator (cHS4) element to prevent insertional activation of oncogenes and T-cell lymphomagenesis by an MLV. MLVs have been extensively used for genome-based, high throughput molecular identification of oncogenes (http://rtcgd.ncifcrf.gov/). Enhancer activation of oncogenes, usually from distances >10 kbp, is by far the most frequent mechanism of tumorigenesis by these retroviruses. We inserted the cHS4 element into the LTR of a T-cell lymphomagenic, replication-competent MLV. The element was stable within the viral genome for multiple rounds of viral replication in cultured cells. Infection of mice induced a modest, though statistically significant, slowing of the appearance of lymphomas. We then applied a genomics-based approach to determine the insertion sites of MLVs in the genomes of the tumor cells. This analysis showed that inserted proviruses were able to activate flanking oncogenes (*Myc, Rras2, Rasgrp1, Ccnd3, Kras, Runx1, Gfi1, Fos, Pim1*) by an enhancer mechanism even when the cHS4 element was positioned between the viral enhancer and the promoter of the mouse oncogene. Moreover, the percentage of tumors with such activation events was the same with either the insulated or the wild type virus. Thus the cHS4 element did not prevent insertional activation of oncogenes. These results mean that the use of insulators to block oncogene activation by inserting gene therapy vectors is not a simple issue. Rather it will require careful experimentation to devise an effective approach.

Correction of the disease phenotype in the mouse model of Stargardt disease by lentiviral gene therapy. *R. Allikmets[1,2], J. Kong[1], S.R. Kim[1], K. Binley[3], S. Naylor[3], P. Leboulch[4], J.R. Sparrow[1,2], P. Gouras[1].* 1) Dept Ophthalmology, Columbia Univ, New York, NY; 2) Dept Pathology & Cell Biology, Columbia Univ, New York, NY; 3) Oxford BioMedica, Oxford, UK; 4) Genetix Pharmaceuticals, Cambridge, MA.

Stargardt disease (STGD) is a macular dystrophy caused by mutations in the *ABCA4 (ABCR)* gene. The most recognized phenotypic feature of STGD patients and the mouse model, the Abca4$^{-/-}$ mice, is lipofuscin (A2E) accumulation in retinal pigment epithelium (RPE), considered to be the cause of RPE cell death at late stages of the disease. Here, we tested whether delivery of the normal (wt) human ABCA4 gene to the subretinal space of the Abca4$^{-/-}$ mice via lentiviral vectors would correct the disease phenotype, i.e., reduce A2E accumulation. Human immunodeficiency virus (HIV) and equine infectious anemia virus (EIAV)-derived lentiviral vectors were constructed, with the human *ABCA4* gene, or the reporter gene *LacZ*, under the control of constitutive (CMV, EF1) or photoreceptor-specific (Rho) promoters. Abca4$^{-/-}$ mice were injected subretinally with 1-3x10^5 IU of each virus at P4-5 in one eye; the mock-injected contralateral eye served as a control. Mice were sacrificed at 4, 6, and 8 months after injection and the A2E content was determined by HPLC. Subretinal injections of ~10^5 IU of the HIV-LacZ effectively transduced RPE cells, but less effectively (<5%) photoreceptors (PR). In comparison, the same amounts of EIAV-LacZ vectors were more effective in transducing PR in both mice (>30%) and rabbits (100%). Most importantly, a single subretinal injection of 3x10^5 IU of HIV-EF1-ABCA4 to Abca4$^{-/-}$ mice practically eliminated A2E accumulation compared to mock-injected controls. Treated eyes of Abca4$^{-/-}$ mice accumulated 4-6 pmol/eye of A2E 4-8 months after treatment (amounts similar to wt controls), while mock-treated eyes had 6-8 times more A2E (22-35 pmol/eye). In summary, the excessive A2E accumulation in the mouse model of STGD disease was eliminated by lentivirus-based gene therapy, suggesting that lentiviral gene therapy is a potentially efficient tool for treating *ABCA4*-associated diseases.

Evaluation system for siRNA duplexes conferring allele-specific gene silencing. *Y. Ohnishi[1,2], K. Tokunaga[1], K. Kaneko[2], H. Hohjoh[2].* 1) Depertment of Human Genetics, Graduate School of Medicine, The university of Tokyo, Tokyo, Japan; 2) National Institute of Neurosience, NCNP, Tokyo, Japan.

We have developed an easy evaluation system for small interfering RNA (siRNA) duplexes conferring allele-specific gene silencing, i.e., allele-specific RNA interference (RNAi). The system depends on heterozygous reporter plasmids encoding the Photinus and Renilla luciferase genes, whose 3'f untranslated regions carry allelic sequences of interest; e.g., one is mutant allelic sequence, and the other is corresponding wild-type sequence. In this study, we chose the Swedish- and London-type amyloid precursor protein (APP) mutants related to familial Alzheimer'fs disease as model mutant alleles, and effect of the siRNA duplexes designed against the mutants on allele-specific gene silencing and also off-target gene silencing against the wild-type APP allele were simultaneously determined under heterozygous condition generated by cotransfeciton of the reporter alleles and siRNA duplexes into cultured mammalian cells. The siRNA duplexes conferring allele-specific gene silencing consistently reduced the amounts of the mutant APP and also beta-amyloid peptide in'@heterozygous Cos-7 cells with the Swedish- and wild-type APP expression plasmids. Therefore, the system presented here could allow us to design and/or select most suitable siRNA duplexes conferring allele-specific gene silencing to mutant alleles before using them in vivo or in therapeutic trials.

Towards a first proof-of-concept clinical study on antisense-induced exon skipping in Duchenne Muscular Dystrophy. *J. Van Deutekom[1], A. Aartsma-Rus[1], A. Janson[1], C. de Winter[1], H. Heemskerk[1], J. Verschuuren[2], G. Platenburg[3], GJ. van Ommen[1].* 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept Neurology, Leiden Univ Medical Ctr, Leiden, Netherlands; 3) Prosensa B.V., Leiden, Netherlands.

The promise of antisense oligonucleotides (AONs) as small molecule drugs for Duchenne muscular dystrophy (DMD) has unquestionably been established over the last few years. We have successfully applied human sequence-specific AONs to induce the skipping of specific exons during the splicing of the gene's pre-mRNA in cultured muscle cells from a series of DMD patients with different mutations. This exon skipping restored the open reading frame of the mutated DMD transcripts, and thus allowed the synthesis of internally truncated, but largely functional dystrophins, as found in patients with the less severe Becker muscular dystrophy (BMD). With dystrophin expression generally detected in up to 90% of treated muscle cells, the efficiency of this therapy in vitro is remarkably high. In vivo proof-of-principle for therapeutic exon skipping has been obtained in mdx mice, a DMD mouse model carrying a nonsense mutation in exon 23. Intramuscular injections of AONs that induce exon 23 skipping, restored dystrophin in up to 20% of fibers which significantly improved local muscle function. Encouraged by these promising pre-clinical results, we have set up a first proof-of-concept clinical study. For the initial assessment of safety, tolerability and efficacy, we have chosen for a local, intramuscular administration of an exon 51 skipping AON (h51AON23) in the tibialis anterior muscles of 4 to 6 DMD patients aged between 8-16 years. The clinical GMP batch of h51AON23, a 2'OMePS modified RNA molecule, has been produced and validated by reproducible dose-response curves in human muscle cell cultures. The toxicology program under full GLP compliance is in progress, and the clinical protocol has recently been optimized in rabbits. Upon final approval by the Dutch Medical Ethics Committee, the study will start at the end of this year 2005.

Development of Survival Motor Neuron Recombinant Adeno-Associated Virus Vectors. *M. Shababi[1], T. Baughan[1,2], G. Tullis[2], C. Lorson[1].* 1) Department of Veterinary Pathobiology,; 2) Department of Molecular Microbiology and Immunology. Life Sciences Center, University of Missouri,Columbia, MO, 65211.

Spinal muscular atrophy (SMA), an autosomal recessive neurodegenerative disease, is caused by loss of -motor neurons in the spinal cord. SMA is caused by the homozygous loss of the telomeric SMN1 (survival motor neuron 1) gene, that leads to extremely reduced levels of the functional SMN protein. A highly homologous centromeric copy gene (SMN2) exists in almost all SMA patients, but fails to complement SMN1 loss due to its defective splicing pattern. A single nucleotide transition in the 5 end of the SMN2 exon 7 alters splicing and gives rise to the mRNA lacking exon 7 and encodes a biochemically defective and unstable protein that is unable to protect against SMA. The fact that the SMN2 gene has the capacity to encode an identical protein to SMN1 makes this disease very amenable to therapeutic interventions. One logical gene therapy approach is to correct the splicing defect of the SMN2 gene. To accomplish this goal, we have constructed short RNAs designed to modulate SMN2 splicing that are delivered via recombinant adeno-associated virus vectors. Our results demonstrate that the viral-based delivery of these RNA molecules into SMA patient fibroblasts stimulates increased levels of the SMN full-length protein and represents a mechanism to modulate disease-causing splicing defects.

Ex vivo gene therapy for recessive dystrophic epidermolysis bullosa using safe retroviral vectors expressing type VII collagen under the control of its promoter. *M. Titeux[1], M.A. Zanta-Boussif[2], A. Rochat[3], A. Décha[1], L. Tonasso[1], Y. Barrandon[3], O. Danos[2], A. Hovnanian[1,4].* 1) U563-CPTP, INSERM, CHU Purpan, Toulouse, France; 2) Généthon III, Evry, France; 3) EPFL/CHUV, Lausanne, Swiss; 4) Service de Génétique, CHU Purpan, Toulouse, France.

Our goal is to develop the essential preclinical steps for ex vivo gene therapy for recessive dystrophic epidermolysis bullosa (RDEB, OMIM #22600). RDEB is caused by loss of function mutations in the collagen VII gene (COL7A1) encoding anchoring fibrils. It is one of the most severe genodermatoses in children and adults. The patients suffer since birth from skin blistering, and from severe local and systemic complications resulting in poor prognosis. We lack a specific treatment for RDEB, but ex vivo gene transfer to epidermal stem cells shows a therapeutic potential. The chosen approach consists of transferring the COL7A1 cDNA under the control of its promoter, using safe (SIN, Self Inactivating) retroviral and lentiviral vectors into epidermal stem cells and dermal fibroblasts. These vectors have no selection marker, they are self inactivating (reducing the risk of oncogenic events), and they provide a physiological regulation of COL7A1 expression. We have used these vectors to genetically correct primary RDEB keratinocytes and fibroblasts ex vivo. The transduced keratinocytes are able to form fully differentiated epithelia using a skin equivalent system made of a human plasma derived fibrin gel including corrected RDEB fibroblasts. This permits a fully autologous graft onto patients. We have demonstrated long term in vivo expression of recombinant type VII collagen and the formation of anchoring fibrils in these genetically corrected skin equivalents after grafting onto nude mice. The safe vectors, the tissue specificity of type VII collagen expression and the autologous skin equivalent system used constitute key assets for a clinical application. Finally, using this vector, we aim to graft skin equivalents made of genetically corrected autologous keratinocytes and fibroblasts onto the most severely affected skin areas of patients.

Enzyme Replacement Therapy for Fabry Disease: A Safe, Shorter Infusion Protocol. *M. Banikazemi, R.J. Desnick.*
Dept Human Genetics, Mount Sinai School of Medicine, New York, NY.

Fabry disease is an X-linked disorder of glycosphingolipid metabolism due to the deficient activity of the lysosomal enzyme -galactosidase A. Clinical trials of enzyme replacement therapy with Fabrazyme (Genzyme Corp,1mg/kg every 2 weeks) have shown that the enzyme safely and effectively cleared the accumulated globotriaosylceramide from the plasma, heart, kidney, liver, and skin (Eng et al., *Am J Hum Genet* 68 :711, 2001 and *New Engl J Med* 345:9, 2001). A recent phase 4 double-blinded, placebo-controlled trial demonstrated clinical benefit in slowing the progression of the renal, cardiac, and cerebrovascular complications in patients with advanced renal disease, providing further clinical evidence of the effectiveness of ERT in this disease. During the clinical trials, in order to keep the double-blind, enzyme infusion rates were prolonged (15 mg/hr regardless of weight) to minimize the incidence of infusion associated fevers and chills which occurred in some patients. For the clinical trials, the infusion solution was prepared by reconstitution of the Fabrazyme dose with 0.9% sodium chloride in total volume of 500 mL. Here, we report a safe and shorter infusion protocol using a ramping protocol that increases the infusion rate from 0.1 mg/kg body weight/hr to a maximum of 0.7 mg/kg/hr in four ramp steps. Fabrazyme (1 mg/kg) is prepared in 100 mL of 0.9% sodium chloride for injection, and then the solution is infused at a rate of 0.1 mg/kg/hr for 15 min (step 1). The rate is then increased by 0.2 mg/kg/hr every 15 to 30 minutes as tolerated (steps 2 & 3). The maximum rate at the final ramp step 4 is 0.7 mg/kg/hr. The total infusion time is under 2 hours. For example, in the clinical trial protocol, a 70 kg patient would be initially infused at a rate of 15 mg/hr for 4.67 hour. With the ramping protocol, this time would be reduced to 1.9 hr. If the infusion is well tolerated the rate can be increased so that the total infusion is accomplished in 90 min. This shorter infusion protocol is particularly well tolerated, and the time saving is appreciated by the patient and the medical staff, whether administered in the clinic or at home.

Expression in blood cells may contribute to biochemical and pathological improvements after neonatal intravenous gene therapy for mucopolysaccharidosis VII in dogs. *M. Haskins[1], B. Wang[2], T. O'Malley[1], L. Xu[2], P. Wang[1], P. O'Donnell[1], N.M. Ellinwood[3], K.P. Ponder[2].* 1) Dept Pathobiology, Sch Vet Med, Univ Pennsylvania, Philadelphia, PA; 2) Dept Int Med & Biochem & Biophys, Sch Med, Washington Univ, St. Louis, MO; 3) Dept Animal Sci, Iowa State Univ, Ames, IA.

Mucopolysaccharidosis VII (MPS VII) is a lysosomal storage disease due to deficient activity in beta-glucuronidase (GUSB) that results in the accumulation of glycosaminoglycans (GAGs) throughout the body. We have previously reported that neonatal intravenous injection of 3x10E9 transducing units (TU)/kg of a gamma retroviral vector (RV) expressing canine GUSB resulted in transduction of hepatocytes, an average serum with mannose 6-phosphate modified GUSB activity of 195+/-36 U/ml (SEM), which is 73% of normal, with reduction in clinical disease manifestations in the heart, bone, and eye. However, it was unclear if liver was the only site of expression, and the effect upon other organs was not assessed. At various time points including at 4.5 years, we demonstrated that blood cells from these RV-treated MPS VII dogs had 1 copy of retroviral vector per 100 cells, and expression of the RV RNA was at 2% of the level found in liver. Expression of GUSB in blood cells may, therefore, synergize with uptake of GUSB from blood to reduce storage in organs. At 6 months, two of the RV-treated dogs had marked biochemical and pathological evidence of reduction in storage in liver, thymus, spleen, small intestine, and lung, although the effect was only partial in kidney tubules. The brain had 3% of normal GUSB activity, and biochemical and pathological evidence of reduction in storage in neurons and other cell types. Secretion of the enzyme into blood by hepatocytes and other tissues, and expression in blood cells that migrate into organs, may contribute to correction of disease. Thus, this neonatal gene therapy approach was effective and might be used in humans if it proves to be safe.

Oral miglustat in adult and pediatric patients with Niemann-Pick type C (NPC) disease: rationale and methodology of a clinical study. *M.C. Patterson[1], D. Vecchio[1], H. Prady[2], N. Ait-Aissa[3], L. Abel[4], E. Wraith[2].* 1) Dept of Neurology, Columbia University, New York, USA; 2) Royal Manchester Children's Hospital, Manchester, UK; 3) Actelion Pharmaceuticals Ltd, Switzerland; 4) Dept of Optometry & Vision Sciences, University of Melbourne, Melbourne, Australia.

NPC is a neurodegenerative disease that is characterized by impaired intracellular trafficking and sequestration of macromolecules. In addition to unesterified cholesterol, NPC1 protein-deficient cells accumulate gangliosides and other glycosphingolipids. Miglustat is a reversible inhibitor of glucosylceramide synthase, a key enzyme in the synthesis of glycosphingolipids; miglustat crosses the blood-brain barrier. Studies in animal models of NPC disease showed that miglustat delayed the onset of neurological dysfunction, increased life span (in mouse) and reduced ganglioside accumulation and neuropathological changes. In this first clinical study of this therapeutic approach in NPC disease, 41 patients (29 adults; 12 children <12 yrs) with abnormal cholesterol esterification and filipin staining were enrolled. Adult patients were randomized 2:1 to receive miglustat, 200 mg t.i.d., or standard care for 1 year. All children received miglustat, with dosage adjusted for body surface area. At the 1-year time point, adult patients could elect to enter the extension study with active treatment for an additional year. NPC is a very heterogeneous disease, and selection of the study primary endpoint of horizontal saccadic eye movement velocity (SEMV) is based on the established correlation between the severity of supranuclear gaze palsy in NPC and disease progression. Secondary endpoints include neurological examination, tremor and swallowing assessments, MMSE, Purdue Peg Board, liver and spleen organ volumes, chitotriosidase, QoL (SF-36 and CHQ-PF50), and vertical SEMV. The pediatric substudy has simplified and corresponding age-appropriate neurological and neuropsychological assessments. Miglustat is the first substrate-inhibiting drug to be investigated in NPC patients; evaluation of its safety and efficacy will be based on the comprehensive set of outcomes described.

A clinical study to assess the safety and efficacy of oral miglustat in late-onset Tay-Sachs (LOTS) disease: baseline demographics and disease manifestations. *B. Shapiro[1], G.M. Pastores[2], E.H. Kolodny[2].* 1) Department of Neurology, Cleveland University Hospitals, Cleveland, USA; 2) Neurogenetics Unit, Department of Neurology and Pediatrics, NYU School of Medicine, New York, USA.

Tay-Sachs disease, an autosomal recessive lysosomal storage disorder caused by deficiency of -hexosaminidase A, is associated with the accumulation of G_{M2}-ganglioside in the CNS. In the adult, late-onset variant, individuals develop slurred speech, muscle weakness, tremors, unsteady gait and mental illness, particularly psychoses and depression. We describe baseline (BL) demographics and disease manifestations of the largest cohort of LOTS patients studied systematically, enrolled in a study investigating substrate reduction therapy (SRT) with oral miglustat (currently approved for adult mild-to-moderate type 1 Gaucher disease). In preclinical studies, miglustat prevented the storage of G_{M2}-ganglioside within the CNS [Zervas et al. Curr Biol 2001;11:1283-7]. **Methods**: Patients 18 years were enrolled in a study to assess the safety and efficacy of miglustat, 200 mg t.i.d., vs standard clinical care. Comprehensive BL evaluations included quantitative isometric muscle strength, speech, gait and balance assessments. **Results**: Thirty patients were enrolled (20 males). Mean age was 38.6 yrs. The most common disease manifestations noted at BL were muscle weakness (97%), tremor (93%), dysarthria (87%), ataxia (83%), ambulation difficulties (80%), dysdiadochokinesis (80%), muscle cramps (77%), dysmetria (73%), swallowing difficulties (53%), depression (40%), learning difficulties (33%), psychosis (33%) and bipolar disease (27%). Tinetti scale scores at BL were 7.8 for balance (maximum score 16), and 7.2 for gait (maximum score 12). **Conclusions**: LOTS is a progressive neurodegenerative disorder that is currently untreatable except possibly by SRT. Our study revealed wide heterogeneity in BL disease characteristics. As a model for clinical trials in small patient populations, our findings in LOTS patients point to several potential confounders in assessment of treatment effect, particularly when the period of observation is short.

ICAM-1 targeting enhances delivery of active acid sphingomyelinase in mice. *S. Muro[1], R. Dhami[3], J. Leferovich[1], V. Muzykantov[1, 2], E. Schuchman[3].* 1) Institute for Environmental Medicine and; 2) Dept. Pharmacology, University of Pennsylvania Medical School, Philadelphia, PA; 3) Dept. Human Genetics, Mount Sinai School of Medicine, New York, NY.

An inherited deficiency of acid sphingomyelinase activity (ASM) causes the lysosomal storage disorder (LSD), Types A and B Niemann-Pick Disease (NPD), affecting multiple organ systems (brain, liver, spleen, and lung). Ineffective clathrin-mediated internalization of recombinant ASM by NPD cells, which is mediated by receptors recognizing enzyme sugar-residues (mannose-6-phosphate), may hinder efficacy of enzyme replacement therapy (ERT) for NPD. We previously showed that targeting recombinant ASM to the surface glycoprotein InterCellular Adhesion Molecule (ICAM)-1 by anti-ICAM nanoparticles bypasses glycosylation-mediated binding and clathrin-mediated internalization, improving enzyme delivery to lysosomes. To evaluate the efficacy of this delivery system in vivo, we determined the pharmacokinetics and biodistribution of free ^{125}I-ASM vs. ^{125}I-ASM coupled to FITC-labeled anti-ICAM nanoparticles administered IV in C57Bl/6 mice. Both ASM and anti-ICAM/ASM nanoparticles were rapidly cleared from the circulation (38.23.2 % vs. 21.45.1 % of the injected dose, ID, by 1 min; and 17.67.8 % vs. 2.60.3 % ID by 15 min post-injection). However, ASM coupled to anti-ICAM nanoparticles showed greater levels vs. free ASM in all organs analyzed 30 min post-injection (except kidney, 0.85 fold), including heart (1.6 fold), brain (1.7 fold), liver (2.5 fold), spleen (5.3 fold), and lung (25 fold). Fluorescence microcopy confirmed the presence of ASM-loaded, FITC-labeled anti-ICAM nanoparticles in these organs. Injection of anti-ICAM/ASM nanoparticles in ASM knockout mice, a model for NPD, increased ASM activity over the endogenous levels in heart (1.5 fold), brain (1.5 fold), kidney (5.0 fold), liver (17.1 fold), lung (19.7 fold), and spleen (59.2 fold). Therefore, targeting to ICAM-1 enhances delivery of active ASM to primary pathological sites, representing a promising strategy to optimize ERT for NPD and other LSD. Funding: AHA 0435181N (SM), NIH HD 28607 (ES) and HL/GM 71175-01 (VM), and DOD PR 012262 (VM).

Dystrophin Expression in Myogenic Converted Fibroblasts from Duchenne Muscular Dystrophy using Antisense RNA/ENA Chimera. *Z. Zhang, Y. Takeshima, M. Yagi, M. Matsuo.* Department of Pediatrics, Kobe University Graduate School of Medicidne, Kobe, Japan.

The use of antisense oligonucleotides to induce exon skipping leading to generation of an in-frame dystrophin mRNA could be of benefit in around 70% of Duchenne muscular dystrophy (DMD) patients. We have previously reported that a novel antisense RNA/Ethylene-bridged nucleic acid (ENATM, Sankyo Lifetech Co., Ltd., Tokyo, Japan) chimera was 40 times as effective as a conventional phosphorothioate oligonucleotide in inducing exon 19 skipping of dystrophin gene in cultured muscle cells. To further enlarge the therapeutic application of this chemical, we here designed specific RNA/ENA chimera to target exons which located in deletion hotspots of dystrophin gene. Different with pilot experiments in human muscle cells, we use fibroblasts from two DMD patients carring different deletions as a alternative source of muscle cells. Fibroblasts were induced to differentiate to myogenic lineage by AdMyoD, and exposed to RNA/ENA chimera. The exon skipping and dystrophin expression were monitored by RT-PCR and dystrophin staining. In all cases, the targeted exon was specifically skipped at relatively high levels, which induced the synthesis of significant levels of dystrophin. These results document that myoD-forced myogenesis provide a powerful tool to study the efficiency of the antisense based therapy, and that our new RNA/ENA chimera could induce skipping of dystrophin exons located in deletion hot spots, thereby making dystrophin expression possible in a broader spectrum of DMD cases.

Results of a 22 year clinical trial: Acute, adjunctive pharmacological treatment of hyperammonemic episodes in patients with urea cycle disorders (UCD). *S.E. Gargosky[1], M. Summar[2].* 1) Research & Development, Ucyclyd Pharma, Scottsdale, AZ; 2) Vanderbilt University Medical Center DD-2205 Medical Center North Nashville, TN 37232.

UCDs are a rare, ultra-orphan group of diseases. To amass a database comprising 1045 with episodes and over 300 patients had been an enormous undertaking. This historical database provides demographics, survival as well as clinical history of these patients treated with AMMONUL (sodium phenylacetate/sodium benzoate) injection 10%/10%. On admission to the hospital, patients with hyperammonemia or a potential UCD were treated with a bolus dose of 0.25 g/kg (or 5.5 g/m2) AMMONUL over a period of 90 minutes to 6 hours, depending on the specific UCD. Infusions also contained Arginine. After completion of the bolus dose, maintenance infusions of the same dose over 24 hours were to be continued until the patient was no longer hyperammonemic or oral therapy could be tolerated. Episodes in this report occurred at 115 hospitals/316 patients/1045 episodes. The mean (SD)number of episodes per patient was 3.3 (6.18) and ranged from 1 to 77. Of the 316 patients, 185 experienced 1 episode, 53 had 5 or more episodes, 48 had 2 episodes, and 30 had 3 or 4 episodes. The mean length of hospitalization per episode was 9.4 (12.97) days and ranged from 1 to 171 days. 76%, patients were hospitalized for fewer than 10 days. The patient population was 51% male and 49% female. The mean (SD) age for all episodes was 8.5 (7.44) years, and ranged from 0 to 53 years. For all patients, the mean age at the first episode was 6.2 (8.54) years, and ranged from 0 to 53 years. Survival rates at the end of hyperammonemic episodes were substantially improved after treatment with AMMONUL, compared with historical controls. In 94% of the episodes, the patient was alive at discharge. In patients responding to therapy, mean ammonia levels decreased significantly within four hours of initiation of AMMONUL therapy and were maintained. Thus, the wide spread, rare nature and absence of regionalization makes this database a unique source for examining this patient population.

Inhibiting farnesylation of progerin prevents the characteristic nuclear blebbing of Hutchinson-Gilford progeria syndrome. *B.C. Capell[1], R. Varga[1], M.R. Erdos[1], M. Eriksson[2], J.P. Madigan[3], J.J. Fiordalisi[3], L.B. Gordon[1], C.J. Der[3], A.D. Cox[3], F.S. Collins[1].* 1) NHGRI, NIH, Bethesda, MD; 2) Karolinska Institutet, Huddinge, Sweden; 3) UNC-Chapel Hill, Chapel Hill, NC.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder characterized by dramatic premature aging and accelerated cardiovascular disease. HGPS is almost always caused by a *de novo* point mutation in the lamin A (*LMNA*) gene that activates a cryptic splice donor site, producing a truncated mutant protein, termed progerin. Wild-type prelamin A is anchored to the nuclear envelope by a modification of the C-terminal CAAX motif by a farnesyl isoprenoid lipid. Cleavage of the terminal 15 amino acids and the farnesyl group releases mature lamin A from this tether. In contrast, this cleavage site is deleted in progerin. We hypothesized that retention of the farnesyl group causes progerin to become permanently anchored in the nuclear membrane, disrupting proper nuclear scaffolding and causing the characteristic nuclear blebbing seen in HGPS cells. We further hypothesized that blocking farnesylation would decrease progerin toxicity. To test this, the C-terminal CSIM sequence in progerin was mutated to SSIM, a sequence that cannot be farnesylated. SSIM progerin relocalized from the nuclear periphery into nucleoplasmic aggregates and produced no nuclear blebbing. Further, blocking farnesylation of authentic progerin in transiently transfected HeLa, HEK-293, and NIH-3T3 cells with farnesyltransferase inhibitors (FTIs) restored normal nuclear architecture. Likewise, treatment of both early and late passage human HGPS fibroblasts with FTIs resulted in significant reductions in nuclear blebbing. To test this therapeutic approach *in vivo*, we are now administering oral FTIs to a transgenic mouse model of HGPS. This model was created by recombineering a 164 kb human BAC containing the *LMNA* gene to incorporate the 1824C>T (G608G) mutation. Mice from a stable transgenic line express the mutant *LMNA* RNA and protein (progerin) products, and display a vascular phenotype strikingly similar to the atherosclerotic disease seen in patients with HGPS.

Pharmacological reactivation of the FMR1 gene: comparative effect of 5-aza-2-deoxycytidine and valproic acid.
A. Terracciano, R. Pietrobono, E. Tabolacci, L. Ciocca, P. Chiurazzi, G. Neri. Institute of Medical Genetics, Catholic University, Rome, Italy.

To clarify the mechanisms that suppress the activity of the mutant FMR1 gene in the fragile X syndrome and the conditions that may permit its reactivation, we investigated the acetylation and methylation status of three different regions of the FMR1 gene (promoter, exon 1 and exon 16) of three fragile X cell lines, before and after 5-aza-2-deoxycytidine (5-azadC) reactivating treatment. Basal levels of histone acetylation and H3-K4 methylation were much higher in transcriptionally active wild-type controls than in inactive fragile X cell lines. Treatment of fragile X cell lines with 5-azadC induces a decrease of H3-K9 methylation, an increase of H3 and H4 acetylation and of H3-K4 methylation. Our experiments indicate that, whereas histone acetylation plays an ancillary role, H3-K4 methylation and DNA demethylation are the main epigenetic switches activating FMR1 transcription. In an effort to identify other reactivating drugs, we tested the effect of valproic acid (VPA), widely used in humans as anticonvulsant, on the epigenetic status of FMR1 in fragile X cell lines. Recent data suggest that VPA inhibits histone deacetylases (HDACs) and/or induces DNA demethylation. To test VPA toxicity, we treated cells with increasing drug concentrations and found that the best reactivating effect is obtained with three days treatment at 2mM concentration. VPA shows a modest but rapid reactivating activity, compared to 5-azadC. The comparison between these two drugs effects suggests that VPA, in contrast to 5-azadC, may work in a cell-cycle independent fashion. This work was supported by grant GGP030202 from Fondazione Telethon to G.N.

Use of Oral Citrulline as a Nitric Oxid Precursor in the Treatment of Post Cardiac Surgery Related Pulmonary Hypertension in Children. *M. Summar[1,2], H. Smith[2], G. Rice[1,2], J. Canter[1], R. Barr[1,2].* 1) Ctr Human Genetic Res, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Department of Pediatric, Vanderbilt Univ Medical Ctr, Nashville, TN.

Pulmonary hypertension can significantly complicate the perioperative course of children undergoing surgical correction of their congenital heart lesions. NO affects pulmonary vascular tone and is produced by nitric oxide synthase from arginine and its urea cycle precursor citrulline. We have shown that cardiac surgery significantly decreases concentrations of both citrulline and arginine. We hypothesize that addition of citrulline may promote better nitric oxide production with a subsequent reduction in the incidence of postoperative pulmonary hypertension. Study Design This was a randomized, placebo controlled, double-blinded study. Forty infants/children, undergoing cardiopulmonary bypass and at risk for pulmonary hypertension, received five doses (1.9 g/m2 /dose) of either citrulline or placebo, administered immediate preoperatively, immediate postoperatively, then every 12 hours for three doses. Plasma citrulline concentrations were measured at five time points. Secondary outcome measurements of systemic blood pressure, plasma arginine concentration, and presence/absence of pulmonary hypertension were collected. Results Median citrulline concentrations were significantly higher in the oral citrulline group compared with placebo immediately following bypass (36 umol/L vs 26 umol/L, P=0.012) and at 12-hours postoperatively (37 umol/L vs 20 umol/L, P=0.015). Mean plasma arginine concentrations were significantly higher in the oral citrulline group compared with placebo by 12-hours postoperatively (36 umol/L vs 23 umol/L, P=0.037). Mean systemic blood pressure during the 48-hour study period did not differ between groups (P=0.53). Nine patients developed postoperative pulmonary hypertension, all of whom had plasma citrulline concentrations less than the median concentration (37 umol/L) obtained with oral citrulline supplementation (P=0.036). Conclusions Perioperative oral citrulline administration may be a safe and effective way to reduce postoperative pulmonary hypertension.

Children's Hospital, Mainz, Germany.

Introduction: Fabry disease is an X-linked glycosphingolipid storage disorder caused by a lysosomal deficiency of -galactosidase A. Progressive accumulation of the substrate globotriaosylceramide in cells throughout the body leads to major organ failure and premature death. Studies have reported the high prevalence of disabling clinical features in heterozygous females, but little is known of the effects of enzyme replacement therapy (ERT) in female patients. Aims: This study examines the safety and efficacy of ERT in a cohort of 358 female patients with Fabry disease. 160 received treatment with agalsidase alfa. Methods: FOS - the Fabry Outcome Survey is a European outcomes database for all patients with Fabry disease who are receiving, or are candidates for, ERT with agalsidase alfa (Replagal). We analyzed this data to evaluate the safety and efficacy of agalsidase alfa administered intravenously to female patients with Fabry Disease. Design: The effects of ERT with agalsidase alfa on renal function (assessed by estimated glomerular filtration rate), heart size (assessed by echocardiography), heart function (Midwall fractional shortening), pain (assessed by the Brief Pain Inventory) and quality of life (QoL) (assessed by the European Quality of Life Questionnaire EQ-5D) were analyzed in a cohort of 160 patients. Results: Similar to males with Fabry disease ERT in females is well tolerated and safe. It reduces pain, stabilises renal function, improves QoL heart function and reduces heart size. Thus ERT is likely to alter the natural history of the disease in females.
