Established techniques of immunohistochemistry and *in situ* hybridisation enable the study of cells and biomolecules in their natural context. Thus, molecules are analysed inside the cells where they reside *in vivo*, and cells are analysed in their tissue context. Since molecules do not function by simply existing, but by interacting with and affecting other molecules, it is important to know where a molecule is, when it is there, and what other molecules are around. A simple example is an mRNA molecule with a mutation disabling its export into the cytoplasm. While such a molecule would exist, it would get not get beyond the nucleus, and it would not be able to mediate the synthesis of the appropriate protein. Likewise, any multi-cellular organism relies on communication between cells to control and modulate their function and behaviour. To understand what goes on inside a cell, it may therefore be necessary to know what other cells are present and what they do. A prime example is found in embryology, where a single cell develops into a great variety of vastly different cells depending upon what organ or tissue they end up in. Many pathological processes must be understood in this context as well, not least cancer, where the sick cells relies on ignoring the appropriate signalling and on producing their own signalling to fool the body into not eradicating them. Main limitations to *in situ* analysis relate to the sensitivity of the detection and the resolution of details. Thus, detection requires the summed up contributions of a number of molecules for them to be visualised, and small variations in the molecules, such as point mutations or splice variants in mRNA, generally escapes detection. We present new technology, capable of resolving minor molecular details in bio-molecules and of visualizing individual target molecules *in situ*. This is obtained with circular hybridisation probes and localised DNA synthesis in a rolling circle format, creating a tandem repeat covalently linked to the original hybridisation target. The circular probes can resolve point mutations in DNA and splice patterns in mRNA, and the rolling circle DNA synthesis produces enough copies of the probe to enable single probe molecules to show up in the microscope.

Comparative human-mouse analysis of congenital diaphragmatic hernia (CDH) after genome-wide CGH using BAC microarrays. *D.A. Scott[1], M. Klaassens[5,6], S.A. Yatsenko[1], P. Stankiewicz[1], C.J. Fernandes[3], K.P. Lally[4], A. de Klein[5], D. Tibboel[6], W.W. Cai[1], M.J. Tsai[2], S.Y. Tsai[2], B. Lee[1,7].* 1) Dept Mol & Hum Genet, Baylor Col Med, Houston, TX; 2) Dept Mol & Cell Bio, Baylor Col Med, Houston, TX; 3) Dept Peds, Baylor Col Med, Houston, TX; 4) Dept Ped Surg, Univ of Texas Med School, Houston, TX; 5) Dept Clin Genet, Erasmus Med Centre, Rotterdam, The Netherlands; 6) Dept Paed Surg, Erasmus Med Centre, Rotterdam, The Netherlands; 7) Howard Hughes Medical Institute.

Congenital diaphragmatic hernia (CDH) is a common birth defect with variable morbidity and mortality. Most cases are sporadic making linkage based approaches to gene identification impractical. In an alternative approach, we used whole-genome microarray comparative genome hybridization (aCGH) to screen for CDH-related chromosomal regions that are duplicated or deleted in 15 infants with CDH and other non-pulmonary anomalies (CDH+). Infants with trisomy 13, 18 and 21 were excluded. Chromosomal anomalies were identified in five CDH+ patients (30%) and in two cases (13%) the chromosomal anomaly was identified by aCGH after a normal G-banded chromosome analysis. This demonstrates that chromosomal anomalies are a common cause of CDH+ and that inclusion of aCGH analysis can increase the detection sensitivity. Identified chromosomal abnormalities included Turner syndrome (45,X), mosaic trisomy 14q, duplication 6p21.3-p25.3, duplication 11q23-qter/deletion 12qter, and duplication 2q37-qter/deletion 15q26-qter. Deletions of chromosome 15q26 have been identified in individuals with CDH and a minimal deletion region for CDH that contains *COUP-TFII*, a transcription factor gene regulated by the retinoic signaling pathway, has been described previously. To determine if *COUP-TFII* plays a role in CDH, we generated mice that are homozygous for a targeted tissue-specific deletion of *COUP-TFII*. Mice that are homozygous for the *COUP-TFII* deletion have left-sided posterolateral CDH similar to the most common form of CDH in humans (Bochdalek-type). This strongly suggests that haploinsufficiency of COUP-TFII contributes to the development of CDH in individuals with 15q26 deletions.

Common genomic polymorphisms in 24 psychiatrically normal controls. *S.L. Christian[1], H.L. Fritz[1], J. Conroy[2], N. Nowak[2], E.S. Gershon[1].* 1) Dept Psychiatry, Univ Chicago, Chicago, IL; 2) Roswell Park Cancer Institute, Buffalo, NY.

Whole genome screening using BACs in a microarray format, termed array comparative genomic hybridization (aCGH), has emerged as a valuable new tool to identify regions of gene dosage imbalance. This technique has the potential to identify many previously unrecognized deletions and duplications associated with human disease. However, to interpret these data common polymorphisms present in an unaffected population need to be identified. Several studies have examined normal populations, however, these subjects were not screened for psychiatric disorders. To apply aCGH to common psychiatric disorders such as autism, bipolar disorder and schizophrenia, a database of polymorphisms found in controls screened for psychiatric disorders is needed. In this study genomic DNA from 24 psychiatrically normal control subjects were analyzed using a 6k human BAC microarray to identify normal polymorphisms. An average of 4600 autosomal clones and 189 X chromosome clones were evaluated further for each subject. The average number of autosomal clones with abnormal dosage was 25.1 for < or > 3 SDs from baseline and 5.6 clones for < or > 4 SDs. Microsatellite confirmations showed mostly false positives using a 3 SD threshold. 91 different BACs showed abnormal dosage among these 24 subjects using a 4 SD threshold. 32 contain segmental duplications and/or map to other chromosomes using build 35. 3 clones contain gaps, 8 map to centromeres and 12 map to telomeres. A comparison with previously published reports showed 16 clones in common with Iafrate et al. 2004 and 9 in common with Sebat et al. 2004. 2 clones were in common between all 3 studies and 64 clones were unique to this study. Followup studies using a 19k human BAC microarray are in progress. Overall, the level of genomic polymorphisms identified in psychiatrically normal controls indicates the need for extensive evaluation of control subjects to interpret aCGH results on ill subjects.

Maternal uniparental disomy 16 in a fetus with trisomy 16 mosaicism. *J. Puechberty[1], A.M. Chaze[1], V. Cacheux[1], P. Blanchet[1], C. Coubes[1], P. Lewin[2], G. Lefort[1], P. Sarda[1].* 1) Dept Medical Genetics, CHU Arnaud de Villeneuve, Montpellier, France; 2) Pasteur Cerba Laboratory, 95066 Cergy Pontoise cedex 9 France.

Second trimester serum screening in a gravida2 para1 34-year-old mother showed elevated beta-hCG levels indicating a Down syndrome risk of 1:10. Amniocentesis was performed at 18 WG. Karyotype analysis detected level III trisomy 16 mosaicism in a female fetus. A control amniotic fluid sample at 21 WG reported only 46,XX cells and concomitant scans were interpreted as normal. At 23 WG ultrasound noted short femora (<3rd centile) and the couple was referred for genetic counselling. The prospective parents were informed of the cytogenetic and ultrasound findings and offered fetal blood sampling and a third amniocentesis. Blood chromosomes were normal but amniotic fluid karyotype again showed trisomy 16 mosaicism At 28 WG scanning detected intrauterine growth retardation and a dilated digestive tract, suspected a heart defect and was unable to visualize the biliary duct. The couple elected to terminate pregnancy at 30 WG. Postmortem study confirmed most ultrasound findings and trisomy 16 mosaicism was found in placenta and various fetal tissues. Maternal [upd(16)] was diagnosed on the second amniotic fluid sample. The outcome of this pregnancy is discussed in the light of the double contribution of trisomy 16 mosaicism and maternal [upd(16)].

EVALUATION OF CURCUMIN IN RADIATION INDUCED GENETIC DAMAGE IN MURINE CHROMOSOME STUDIES. *A. Corona-Rivera[1,2], L. Ruvalcaba-Ortega[1], C. Ortega-de la Torre[1], T. Montiel-Roldán[1], J. Vargas-Lares[1], R. Silva-Cruz[1], K. Contreras-Venegas[1], J.R. Corona-Rivera[1], M.A. Ramirez-Herrera[1], M.L. Mendoza Magaña[1], L. Bobadilla-Morales[1].* 1) Lab de Citogenética Genotoxici, Univ Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Hospital Civil de Belén Fray Antonio Alcalde, OPD.

Ionizing radiation induces chromosome aberrations and cell cycle alterations. On the other hand, it has been proposed that curcumin inhibits radiation-induced genetic damage detected with chromosome aberrations, micronuclei and comet assay. In this work we investigated the radioprotective action of curcumin trough observation of chromosome aberrations in mouse bone marrow cells.We worked with 34 Bal-C male mice of 6 weeks old divided in 6 groups. Mice were fed with curcumin for 5 days to different dosis and were irradiated with 6Gy at day 5. Femur bone marrow samples were obtained 24 hours after the irradiation. Group 1 was the negative control; group 2 was the irradiation positive control; group 3 was just fed a diet containing 0.1% of curcumin; group 4 received irradiation and were fed a diet containing 0.01% curcumin; group 5 received irradiation and were fed a diet containing 0.1% curcumin, and group 6 received irradiation and were fed a diet containing 0.5% curcumin. There were analyzed all groups versus control with chi-square test and there were found statistically significative decreases of damage in all groups except in fourth group. We propose that curcumin is able to protect against genomic damage induced by ionizing radiation in a dosage dependent manner.

Uniparental disomies, micro-deletions and trisomies in spontaneous abortions. *S. Sonta[1], Q.Y. Li[1,2], R. Kimura[1], T. Ono[1], A. Makino[2], M. Tanemura[2], M. Sugiura-Ogasawara[2], K. Suzumori[2].* 1) Dept Genetics, Inst Developmental Research, Aichi Human Service Center, Kasugai, Japan; 2) Nagoya City University Medical School, Nagoya, Japan.

While the causes of about half of spontaneous abortions having a normal karyotype are mostly unknown, the fact that typical chromosomal abnormalities cause a large portion of spontaneous abortions suggests the possibility that functional, structural and constitutional abnormalities, such as uniparental disomy (UPD), micro-deletion, and abnormal X-inactivation, which are undetectable by usual chromosomal analysis, may serve to cause these abortions. To investigate such causes, polymorphic analyses of microsatellites were performed in 482 cases of spontaneous abortion with and without typical chromosomal abnormality. Of 482, 251 cases had various chromosomal abnormalities; they were trisomies, including 6 double trisomies and one triple trisomy, X-monosomies, polyploids, and others. The microsatellite analyses revealed that extra chromosomes of double and triple trisomies were all of maternal origin. Moreover, all extra chromosomes in each case occurred by nondisjunction at the same division, the first meiotic or mitotic division. These findings suggest the possibility that abnormal separation of two or more chromosomes may occur simultaneously in oogonia and ovum of aged women. In the remaining 231 cases with a normal karyotype, we found four cases with uniparental disomy: UPDs 14, 15, and 16, and partial UPD of chromosome 7. In analysis of microsatellite polymorphism on the X chromosome, on the other hand, polymorphic patterns of PCR products using some primer sets was not seen in two cases of 46,XY and one case of 45,X. We analyzed these 3 cases to confirm the deleted structure of the X chromosome in each case. The findings suggest the possibility that UPDs and micro-deletions may cause spontaneous abortions. This work was partially supported by Grant #16390481 from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

Identification of the DFNA44 hearing-loss gene. *M.A. Moreno-Pelayo[1], S. Modamio-Hoybjor[1], A. Mencia[1], R. Goodyear[2], I. del Castillo[1], G. Richardson[2], F. Moreno[1].* 1) Unidad Genetica Molecular, Hospital Ramon y Cajal, Madrid, Spain; 2) School of Life Sciences, University of Sussex, Falmer, Brighton BN1 9QG.

Non-syndromic hereditary hearing loss (NSHHL), in which hearing loss is the only clinical symptom, has proven to be extremely heterogeneous genetically. Autosomal dominant forms account for up to 20% of cases with more than 40 loci (DFNA) now mapped and 20 genes currently identified. Recently, we mapped the DFNA44 locus in a Spanish family with postlingual progressive NSHHL. Here we have characterized the mutation responsible for DFNA44 and established the spatio-temporal expression pattern of the gene in the mouse inner ear. DFNA44 candidate genes were screened for mutations by heteroduplex analysis and direct sequencing of the coding region and exon-intron boundaries. The spatio-temporal expression pattern of DFNA44 protein in the mouse inner ear was investigated in cochlear sections from different developmental stages with affinity-purified rabbit antisera raised against two peptides at the C-and N-termini of the DFNA44 protein. The identified mutation consists of an 8-bp tandem duplication in exon 11 leading to a frameshift that replaces the last 15 amino acids of the human protein by a novel, 36 amino acid sequence. At embryonic day (E) 14.5, DFNA44 protein is expressed in the otic mesenchyme (MS), in the cells lining the lumen of the primitive cochlear duct, and in the nerve fibers of the spiral ganglion. At E17.5, DFNA44 is mainly localized in the MS. By postnatal day (P) 2, strong staining is seen in the apical region of the pillar cells (PCs), and a weak signal is seen in the outer hair cells and in the stria vascularis (SV). At P12 and P16, strong staining is seen in both PCs and weak staining is seen in the MS and SV. At P19, the staining is strong in the PCs, Deiter's cells and SV, but very weak in the MS. By P33 the protein is only detected in the SV. At all stages the protein is expressed in the epithelial cells of the vestibular maculae and in the three semicircular canals. The DFNA44 protein may play a crucial role in inner-ear development and auditory function given that its cochlear localization and expression levels vary dynamically with time.

Large scale gene expression profiles of mouse early inner ear development. *S. Sajan[1], M. Warchol[2], M. Lovett[1].* 1) Departments of Genetics and; 2) Otolaryngology, Washington University, St. Louis MO.

Up to 30 million Americans suffer from some form of hearing loss, with one-third of those being between the ages of 21 and 65. While environment plays a role, genetic factors account for half of all hearing loss cases. Many of the genes that cause heritable deafness also play a role in the normal development of the inner ear. Only a handful of genes and pathways that affect this process are currently known, however. The mammalian inner ear consists of the hearing organ (the cochlea), and the balance (vestibular) organ. The latter contains three semi-circular canals for sensing angular acceleration, plus the utricle and saccule, both for sensing linear acceleration. To better understand the genetic program of these structures, we micro-dissected inner ear structures from mouse embryos at stages E9 to E15 at half-day intervals (covering the earliest discernible structures of the inner ear up until the development of true hair cells). Mouse Affymetrix gene chips were used to profile otic vesicles from E9 to E10, the rudimentary vestibular and cochlear organs from E10.5 to E12, and the saccule, utricle, and cochlea from E12.5 to E15. Two litters were obtained per time-point, each serving as a replicate. We used duplicate gene chips per time-point and identified ~1300 genes whose expression changed by at least 2-fold between any given stages of development. Among these were 15 genes known as important markers of inner ear hair and supporting cell development and differentiation. Some of these included *Atoh1*, *Hes5*, *Myo7a*, *Ush1c*, and *Gjb2*. Genes highly expressed in the cochlea, that had not been previously described, included *Forkhead box G1*, *Hey2*, *Irx3*, and *Hypothetical protein BC024118*. Among those highly expressed in the utricle were *Fgf7*, *Vanin1*, *Dlx1*, and *Rgs2*. In the saccule, four of the most highly expressed genes were *Gelsolin*, *Otoancorin*, *Claudin10*, and *Protocadherin8*. We validated many of these observations by RNA *in-situ* hybridizations. Finally, we employed bioinformatics tools to parse these genes into pathways and interactions based on function. One example of such a pathway (among at least 6 that we have identified to date) is the TGFB pathway.

Characterization of a leucine-rich repeats containing protein selected from a human cartilage EST sequencing project. *S. Schlaubitz[1,2], C. Stelzer[2], B. Lee[1], B. Zabel[2].* 1) Dept. Hum. & Mol. Gen. & HHMI, Baylor College of Medicine, Houston, TX; 2) Childrens Hospital, Mainz/ Germany.

Starting from an EST sequencing project of 5000 clones from a human fetal cartilage library, we selected clones of interest that - after detailed bioinformatically analysis - seemed to have a putative function in cartilage and/or bone development and that were not been described yet. According to their putative protein domain structure, some of these selected clones are transcription factors that could have important regulatory functions in developmental pathways; while others show interesting expression patterns in cartilage and bone structures. One of these is a protein with four leucine rich repeats (LRRs) and a transmembrane domain (TMD) that shows similarities to several collagen binding proteins out of the family of small leucine-rich proteoglycans. Even though these proteins have additional C- and N-term. spec. recognition sequences and do not have a TMD that may function as an anchor for our gene of interest, the amino acid similarities within the LLRs are significant. In situ hybridization shows highest expression in proliferating chondrocytes of E13.5 mice embryos and a specific expression in the inner cortex of long bones of E17.5 mice. Northern Blot hybridization also shows an ubiquitously expression in newborn tissues, although the strength is not homogeneous. It is highly conserved both at nucleotide and amino acid level through a variety of organisms including human, mice, rat, C.elegans, drosophila and xenopus. Co-immunoprecipitation, performed by others, showed its interaction with vinculin, a gene product involved in the attachment of actin-based microfilaments to the plasma membrane. By fluorescence microscopy using antibodies and dyes for different compartiments and structures of the cell, we confirmed the co-localization with vinculin. We hypothesize that this gene might be involved in the structure of the microfilament network and could function as an anchoring plasma membrane protein able to interact with structural proteins. We expect that this function is specifically important in skeletal structures and are in progress to establish an animal model.

Abnormal chondrocyte proliferation and differentiation in osteochondromas of Multiple Hereditary Exostoses patients. *C. Benoist-Lasselin[1], J.F. Mallet[2], A. Munnich[1], J. Bonaventure[1], L. Zylberberg[3], L. Legeai-Mallet[1].* 1) INSERM U393, Hopital Necker, Paris, France; 2) Service de Chirurgie Pédiatrique-CHU Caen-France; 3) CNRS FRE 2696, université Paris 7-Paris-France.

Multiple hereditary exostoses (MHE) is an autosomal dominant skeletal disorder caused by mutations in one of the EXT genes (EXT1 or EXT2), characterized by multiple osteochondromas that generally occur near the ends of growing long bones. Ext genes encode a type II transmembrane protein with glycosyltransferase activity. In MHE EXT gene haploinsufficiency is correlated with reduction of heparan sulfate in osteochondromas. In order to investigate the potential changes in chondrocyte proliferation or hypertrophic differentiation during endochondral ossification in sessile osteochondromas, exostoses samples from seven MHE patients were obtained for morphological and immunohistological studies. Indian hedgehog (IHH), Fibroblast Growth Factor Receptor 3 (FGFR3) and Parathyroid hormone receptor 1 (PTHR1) transcripts were detected in the pre/hypertrophic chondrocytes of osteochondromas and some Proliferating Cell Nuclear Antigen (PCNA)-positive chondrocytes were revealed with an anti-PCNA antibody. In addition, ectopic expression of collagen type I and other bone markers were observed in the cartilaginous osteochondromas, including osteocalcin (OC), osteopontin (OP) and bone sialoprotein (BSP). These data indicate that EXT mutations in cartilaginous osteochondromas induce an increased chondrocyte proliferation and a phenotypic change of chondrocytes. The differentiated cells fail to undergo apoptosis but instead exhibit bone-forming cell characteristics. We conclude that, defective heparan sulfate biosynthesis caused by EXT mutations in MHE maintains proliferative capacity and promotes transdifferentiation of chondrocytes into bone-forming cells.

Necdin and MAGEL2: candidate genes for Prader-Willi syndrome. *R. Wevrick, J.R. Bush, M.A. O'Neill, A.A. Tennese, S.L. Kuny, C.L. Walker.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

The necdin and MAGEL2 genes are both inactivated in PWS, along with two other protein-coding genes (SNURF/SNRPN and MKRN3) and a gene for a set of regulatory RNAs (IC RNA and snoRNAs). Necdin and MAGEL2 are highly related proteins that share a conserved 189 amino acid MAGE homology domain. To determine the etiology of PWS, it is critically important to understand the role of necdin and MAGEL2 deficiency in humans, and to correlate findings in necdin-null and Magel2-null mice with the clinical and pathological findings in PWS. The necdin (Neurally differentiated Embryonic Carcinoma-cell derived factor) protein is up-regulated during terminal differentiation of neurons; necdin is also expressed in muscle and other tissues. Expression of Magel2 is developmentally regulated and becomes limited to distinct regions of the hypothalamus by the time of birth. Our new studies suggest that in response to specific developmentally regulated transcription factors, necdin is expressed and interacts with nuclear transcriptional repressor proteins that regulate the exit of neuronal precursor cells from the cell cycle. We also found that necdin and Magel2 act at the centrosome (microtubule organizing center) to assist conversion of this specialized cytoskeletal structure from one that forms a mitotic spindle in dividing neuronal precursors, to a highly organized structure that is essential for the development and elongation of bundled axonal tracts and for axonal transport in post-mitotic neurons. We propose that necdin and MAGEL2 are involved in the critical events whereby the transcriptional events that lead to cell cycle exit are coupled to the cytoskeletal events required for terminal differentiation. We have identified novel neurological developmental abnormalities of terminal differentiation and axonal outgrowth in necdin null mice, mirroring some of the neurodevelopmental abnormalities in PWS. In summary, our studies examine the contribution of loss of necdin and MAGEL2 function to the complex neurobehavioral outcomes in individuals with PWS. Research supported by CIHR, NSERC, and AHFMR.

The Zic2 gene in pre and peri implantation mouse development. *S. Brown, L. Brown.* Dept OB/GYN, Columbia Univ, New York, NY.

Heterozygous mutations in Zic2 result in HPE and HPE-like malformation in mice, indicating that CNS development is quite sensitive to Zic2 gene dosage. Existing literature about the role of Zic2 in brain development suggests that it may act as a mediator of Sonic hedgehog (Shh) signaling in a manner analogous to Gli2 and other Gli genes. The fact that Zic genes and Gli genes are closely structurally related makes this plausible, but it is difficult to understand this model from the point of view of gene expression: Zic2 is expressed dorsally and does not overlap with Shh, which acts ventrally to pattern the forebrain and eye into paired structures. Another piece of evidence that argues that Zic2 acts earlier in development than Shh is the fact that a point mutation in Zic2 results in a more severe phenotype than that associated with loss of Shh. These observations taken together with our experimental observation that mis-expression of Zic2 during early development seems to lead to lethality at or before the time of implantation has led us to examine the expression of Zic2 in early embryos and in embryonic stem cells. We find that Zic2 is expressed in the inner-cell-mass (ICM) of E3.5- E4.5 blastocysts in a pattern similar to that of other genes such as Oct4, Sox2 and Nanog, known markers of pluripotentiality. Pluripotent ES cells, a tissue culture proxy for the ICM also robustly express Zic2. In-vitro differentiation into mature neurons results in down-regulation of Zic2. Although many Zic2 positive cells are present in cultures after neural differentiation, they do not express markers of neural, glial or astrocyte differentiation. However, Zic2 positive cells continue to express Sox2. We speculate that Zic2 may have a role in defining an early step in the path towards the development of a neural fate and that its role in the pre and preimplantation embryo may be relevant for later neural development.

A functional genomic approach to find genes responsible for Holoprosencephaly. *M. Zollo[1], P. Carotenuto[1], L. Garzia[1], A.M. Bello[1], G. Vitale[1], N. Marino[1], C. Roma[1], N. Tata[1], A. Faedo[3], J. Rubenstein[3], S. Wilson[4], A. Bulfone[2].* 1) CEINGE, Biotecnologie Avanzate SCARL, Naples, Italy; 2) SCRI - HSR, Istituto Scientifico San Raffaele, Milan, Italy; 3) Nina Ireland Laboratory of Developmental Neurobiology, University of California at San Francisco, San Francisco, CA, United States; 4) Department of Anatomy and Developmental Biology, at University College London, UK.

Holoprosencephaly (HPE) is the most common congenital anomaly of the forebrain during embryogenesis. Our starting point strategy to identify new candidate genes for HPE is a collection of murine neuro-developmental highly expressed telencephalon genes. These transcripts which are unique and not available in public databases have been fully characterized (Bulfone and Zollo et al. 2005, in press). This approach allowed us to further select novel and rare transcripts involved in forebrain development, in the regulation of neural progenitor cell properties, including 48 new microRNAs. We will present data on 14 selected novel and rare transcripts including 2 novel microRNAs from this cDNA collection and candidates for HPE. To verify this, we are using the knowledge of brain development in Zebrafish animal model. A functional assay by interfering regular brain development using morpholino technology and/or overexpressing any of our candidates genes is now in progress and will give us clues on HPE potential involvements. Additionally an in vitro neurogenesis model such as P19, NSC and Neuro2A cells are carried out as mean of overexpression by creating stable clones, or down-regulation by using si-RNA technology. These experiments are performed in order to verify if any abnormal conditions will effect neural proliferation, differentiation, and specification, phenomena involved in HPE. Reference: TESS (Telencephalic Embryonic Subtractive Sequences): a Unique Collection of Neurodevelopmental Genes Bulfone and Zollo et al. Journal of Neuroscience 2005 (in press). Financing support: MIUR-FIRB RBA-U01RW82 grant (Ministero Italiano Università e Ricerca).

Inhibitors of Differentiation (ID1, ID2, ID3 & ID4) genes are neuronal targets of MeCP2. *S. Peddada, J.M. LaSalle.* Med Micro & Imm, UC Davis Sch Med, Davis,CA.

Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder caused by mutations in MECP2, encoding methyl-CpG binding protein 2 (MeCP2). MeCP2, a predicted repressor of methylated genes, is hypothesized to be required for neuronal maturation by the regulation of multiple target genes. Identifying primary gene targets in either *Mecp2*-deficient mouse or human RTT brain has proven difficult. In order to identify primary targets of MeCP2 during neuronal maturational differentiation, a genome-wide expression microarray analysis was performed on human neuroblastoma SH-SY5Y cells induced to differentiate with and without transfection of a methylated wild type MeCP2 oligonucleotide decoy (MDWT) to disrupt the binding of MeCP2 to endogenous targets. The gene lists were analyzed using dChip for those transcripts with the highest fold changes and significant differences with differentiation that were specifically and significantly changed by MDWT transfection. Interestingly, of the genes showing significant expression differences with MDWT, all four members (ID1-4) of the same subfamily of helix-loop-helix proteins called ID genes (Inhibitors of DNA binding or Inhibitors of Differentiation) were identified as potential MeCP2 targets. *ID1*, *ID2*, and *ID3* expression decreased with differentiation while *ID4* increased, however, all four showed increased expression in MDWT transfected cells. Quantitative real-time PCR confirmed the increased expression of all four ID genes in MDWT transfected cells and *Mecp2*-deficient mouse brain compared to controls. Chromatin immunoprecipitation analysis confirmed MeCP2 binding to methylated CpG sites within *ID2* and *ID3* promoters in differentiated SH-SY5Y cells, suggesting that these genes are primary targets of MeCP2 during neuronal maturation. All four ID proteins were significantly increased in expression in *Mecp2*-deficient mouse and RTT human brain using immunofluorescence and laser scanning cytometric analysis. These results suggest that members of the ID family of cell differentiation regulators are ideal primary targets for MeCP2 regulation of neuronal maturation that can explain the molecular pathogenesis of RTT.

Fate mapping *Pitx2*-lineage neurons in the developing heterozygous and homozygous mutant mouse brain demonstrates defects in neuronal location. *D.M. Martin[1,2], J.M. Skidmore[1], J.F. Martin[3].* 1) Pediatrics, University of Michigan Medical Center, Ann Arbor, MI; 2) Human Genetics, University of Michigan Medical Center, Ann Arbor, MI; 3) Alkek Institute of Biosciences and Technology, Texas A&M System Health Science Center, Houston, TX.

PITX2, a paired-like homeodomain transcription factor, is mutated in Rieger syndrome, a haploinsufficiency disorder affecting eyes, teeth, and umbilicus, with occasional cardiac and pituitary defects. Reports of individuals with Rieger syndrome and mental retardation or hydrocephalus have implicated *Pitx2* in central nervous system development. In mice, *Pitx2* is highly expressed in postmitotic neurons of the developing thalamus, midbrain, and hindbrain, and in the adult subthalamic nucleus, posterior hypothalamus, red nucleus, and deep layers of the superior colliculus. Our prior studies identified abnormal gene expression and neuronal projections in the subthalamic nucleus and superior colliculus in midgestation homozygous *Pitx2* null mice, but were limited by lack of reporter expression in wildtype or mutant cells. Here we report a *Cre/loxP* fate mapping approach for labeling *Pitx2* lineage neurons in heterozygous and homozygous mutant neurons in the central nervous system, using *Pitx2-Cre* knock-in mice and a previously characterized transgenic -actin conditional *lacZ* reporter strain. Mutant *Pitx2*-lineage neurons were severely reduced in the subthalamic nucleus, a basal ganglia region that is critical for suppressing unwanted movements and is overexcited in patients with Parkinsons disease. Mutant *Pitx2*-lineage neurons were ectopically placed in the *Pitx2* mutant embryonic superior colliculus, such that labeled cells were located deeper in the neuroepithelium in comparison to heterozygous null embryos. These observations suggest that *Pitx2* promotes regionally specific neuron formation and migration in the developing mouse brain, with potential secondary effects on axon outgrowth. Ongoing studies are directed toward identifying *Pitx2* cell fates in the embryonic and adult brain, and exploring the molecular mechanisms involved in *Pitx2* regulation of regionally specific neuronal differentiation and migration.

Mice with a mutation in Rai1 display neurological phenotypes. *W. Bi[1], L.A. Yuva-Paylor[1], B.A. Antalffy[2], A. Goldman[3], J.W. Yoo[3], J.L. Noebels[3], D.L. Armstrong[2], R. Paylor[1], J.R. Lupski[1,4,5].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pathology, Baylor Col Medicine, Houston, TX; 3) Dept Neurology, Baylor Col Medicine, Houston, TX; 4) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 5) Texas Childrens Hospital, Houston, TX.

Smith-Magenis syndrome (SMS) is a mental retardation disorder associated with a ~ 3.7 Mb deletion in 17p11.2 and characterized by craniofacial features, developmental delay, and neurobehavioral abnormalities. Point mutations in retinoic acid induced 1 (*RAI1*), encoding a PHD zinc finger containing transcriptional regulator, were identified in nine published and one newly identified SMS patients without detectable deletion. All these patients displayed neurological anomalies including mental retardation, sleep disturbance, self-injurious behaviors, and two of them had seizures, suggesting that RAI1 plays a role in the nervous system. To further understand how mutations of *RAI1*, cause phenotypes in SMS, we generated mice with a null mutation of *Rai1*, and simultaneously inserted a *lacZ* reporter gene into the *Rai1* locus. Craniofacial abnormalities and obesity, which have been reported in SMS mouse models containing a hemizygous deletion, were observed in ~ 18% *Rai1+/-* mice. The vast majority of homozygous mice died during gastrulation and organogenesis. Heterozygous mice didnt show significant obvious behavioral, neurological abnormalities, or seizures, but they had abnormal electroencephalogram. The few surviving *Rai1-/-* mice displayed neurological phenotypes including hindlimb clasping, motor impairments, and electrographic seizures. Consistently, -galactosidase assays in the brain of *Rai1+/-* mice showed that the hippocampus and cerebellum were strongly stained and the staining was also observed in neurons in cerebral cortex, striatum, and thalamus. Our data further support that RAI1 functions in the nervous system, and *Rai1* mutant mice provide a useful tool for examining the expression pattern and for understanding the functions of this disease gene.

Association of a putative mouse model candidate gene, GRHL3, with spina bifida meningomyelocele. *K.-S. Au[1], M.R. Dewhurst[1], T.J. Kirkpatrick[1], A.J. Jordan[1], J.M. Fletcher[1], I.T. Townsend[1], G. Villareal[3], G.H. Tyerman[4], S.M. Jane[5], S.B. Ting[5], T.M. King[2], H. Northrup[1,6].* 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Dept Int Med, Univ Texas Medical Sch, Houston, TX; 3) Dept Pediatrics, Baylor College of Med, Houston, TX; 4) Shriners Hospital for Children, Los Angeles, CA; 5) Bone Marrow Research Lab, Royal Melbourne Hosp, Melbourne, Australia; 6) Shriners Hospital for Children, Houston, TX.

Neural tube defects (NTDs) are a common birth defect with an overall incidence of 1-2/1000 live births in the United States. Spina bifida meningomyelocele (SBMM) (lack of closure of the spinal cord caudal to the head) represents a significant portion of NTDs. Of more than 100 known mouse NTD models, two [Axd (axial defects) and ct (curly-tail)] represent the best models for non-syndromic SB in humans. After communication with Dr. Jane in Melbourne, Australia, mutations of the coding regions in a putative candidate gene for the ct mouse were tested in 96 selected American Caucasian SBMM patients. Dr. Janes group created a grainy-head like 3 gene (Grhl3; also named Tfcp2l4) KO mouse that showed thoraco-lumbar-sacral SB. The Grhl3 gene is a mouse homolog of Drosophila grainy-head gene, a gene necessary for epidermal barrier wound repair in damaged Drosophila embryos. The Grhl3 gene is highly conserved and maps to the same region as the ct gene. The Grhl3 protein is a transcription regulator and functions as a master protein in many aspects of epidermal movement and fusion. We screened for mutations in the 18 known and 5 putative exons of the human Grhl3 homolog GHRL3 (also termed TFCP2L4) gene in DNA from 96 SBMM patients by sequencing. We identified 19 single nucleotide polymorphisms (SNPs) in the coding and non-coding regions flanking the exons. Nine of the 19 SNPs are not present in the dbSNP database. We are currently genotyping these SNPs in 100 Caucasian control samples and an additional SB study patients (~400) to evaluate whether any of these variants have alleles that may confer risk for development of SBMM. Significant allele frequency deviation from the control samples would suggest a possible role of the GRHL3 gene in SBMM formation.

BRCA1 mutations show association with lesion location in spina bifida. *T.M. King[1], K.-S. Au[2], T.J. Kirkpactrick[2], J.M. Fletcher[2], K. Copeland[3], D. Francis[3], I. Townsend[2], G. Villareal[4], G.H. Tyerman[5], H. Northrup[2,6].* 1) Internal Medicine, University of Texas - Houston, Houston, TX; 2) Pediatrics, University of Texas - Houston, Houston, TX; 3) Psychology, University of Houston, Houston, TX; 4) Pediatrics, Baylor College of Medicine, Houston, TX; 5) Shriners Hospital for Children, Los Angeles, CA; 6) Shriners Hospital for Children, Houston, TX.

In the Brca1-deficient mice, 40% of the embryos had spina bifida and anencephaly with a disorganized neuroepithelium. We examine the relationship between two BRCA1 mutations to the position of the spinal lesion in patients with spina bifida meningomyelocele (SBMM). We examined the population structure of this gene in both Caucasians and Hispanics. Our affected case population consisted of 227 males and 182 females; 169 were Caucasian and 240 were Hispanic. Thirteen patients had lesions in the T10-T12 region, 98 patients had an L1-L4 lesion and 277 had a lesion at the L5 region and below. Twenty-one had lesions that overlapped more than one of the defined regions. We genotyped two intragenic microsatellite markers denoted BRCA1 F1 and BRCA F4 in our patients. Using ETDT, we observed over-transmission of the 164 allele in the BRCA1 F1 and the 133 allele in the BRCA1 F4 and under-transmission of the 170 allele in the BRCA1 F1 and the 139 allele in the BRCA1 F4. We used chi-square and ANOVA techniques. Lesion level was evaluated grossly and by specific vertebrae. Individuals with two copies of the 164 allele for BRCA1 F1 had SB lesions that were more caudal than individuals with the other genotypes. Individuals with one copy of the 139 allele of the BRCA1 F4 were likely to have lesions that were more rostral. From this, we conclude that the 164 BRCA1 F1 allele acts recessively and the 139 BRCA1 F4 allele acts dominantly. Compound carriers of BRCA1 F1 164/164 and BRCA1 F4 139/- had lesions that were equivalent to those individuals who carried the other genotypes, suggesting a counterbalancing effect. We conclude that BRCA1 participates in the phenotypic variability seen in SBMM.

Ontogenetic changes in serum S100B in Down syndrome patients. *C.A. Goncalves[1], C.B.O. Netto[1,2], L. Portela[1], C. Kieling[3], U. Matte[2], T. Felix[2], T.R. Silveira[3], D.O. Souza[1], R. Giugliani[2].* 1) Biochemistry, UFRGS, Porto Alegre, RS, Brazil; 2) Genetics,UFRGS-HCPA, Porto Alegre,Brazil; 3) Paediatrics, UFRGS-HCPA, Porto Alegre, Brazil.

Introduction: Down syndrome (DS) is the most common genetic cause of mental retardation and most cases result from trissomy of human chromosome 21 and over expression of genes residing in the DS cricital region (DSCR). Some of the genes present at the DSCR express proteins commonly associated with neurodegenerative disorders, including APP, SOD-1 and S100B. Objectives: Investigate whether serum S100B protein concentration in DS children was increased and exhibited an ontogenetic variation, compared to control individuals. Material and Methods: Blood samples were collected from 48 DS patients (12-132 months) and 42 control subjects (6-120 months). All DS patients examined were confirmed to possess the chromosome abnormality (trisomy 21). Serum S100B protein levels were determined using commercial luminescence assay (BYK-Sangtec). Results: We observed significantly higher levels of S100B in the Down syndrome group (median of 1.354 mg/L) than in control group (median 0.38 mg/L). In agreement with the results obtained by Portela et al (2002), we also found a negative log correlation between serum S100B and age. However, there was no correlation ($p>0,05$) between the levels of serum S100B and age in the Down patients group. Discussion: This study indicates that S100B in Down syndrome patients is higher than in normal individuals, however this effect is not age- dependent, as it is in normal individuals. The more elevated and persistent extracellular levels of S100B in DS patients is present since the fetal period, possibly due to gene-dosage effect at beginning; this contributes to the general idea that S100B precedes amyloid lesions in Alzheimer disease. Support: FAPERGS, CNPq.

Overexpression of SCN5A mutation N1325S is significantly linked to apoptosis of cardiac myocytes in the transgenic mice. *T. Zhang, Q.K. Wang.* Department of Molecular Cardiology, Cleveland Clinic Foundation, Cleveland, OH 44195, USA.

Long QT syndrome (LQTS) is a cardiac disorder characterized by prolongation of the QT interval on electrocardiograms and ventricular tachyarrhythmias (VT), which may lead to syncope, cardiac arrest, or sudden death. Mutations in the cardiac sodium channel gene SCN5A are responsible for LQT3. We previously generated an animal model for LQT3 by transgenic overexpression of SCN5A mutation N1325S in the heart. The LQT3 mice manifested the clinical features of the LQTS including spontaneous VT and sudden death. However, the molecular mechanism for arrhythmogenesis needs further characterization. Increasing evidence supports the existence of apoptosis in the cardiac pathogenesis. Yet, its contribution to cardiac arrhythmogenesis is not clear. In this study, we examined the myocardium of LQT3 mice for the presence of apoptosis. Cardiac apoptosis was analyzed at a continuum of ages using the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) assay. Compared to wild type littermate control mice, the LQT3 mice displayed a significant increase of apoptotic cardiomyocytes ($p<0.001$). We further found that cardiac apoptosis in the LQT3 mice is age-dependent with older mice developing a significantly higher level of apoptosis. To the best of our knowledge, this is the first time that cardiac apoptosis has been detected in LQTS. Our results suggest that apoptosis may play an important role in the pathogenesis of LQTS and may be a novel mechanism for arrhythmogenesis.

Knockdown of Sterol Co-A Destaturase (SCOD) causes craniofacial defects. *S. Beiraghi[1], J.J. Essner[2], J.D. Larson[1], S.A. Wadman[2], A. Nasevicius[2], M.C. Eide[2].* 1) Arnold & Mabel Beckman Center for Transposon Research, University of Minnesota, Minneapolis, MN; 2) Discovery Genomics, Minneapolis, MN.

Disruptions in the human *Acyl Co-A Destaturase 4 (ACOD4)* gene is associated with cleft lip and palate. There are two genes similar to human *ACOD4, zebrafish zACOD* and *zSCOD*, both expressed in the zebrafish embryo through 7 days-post-fertilization (dpf) as determined by RT-PCR. **Objective:**The objective of this study was to investigate the function of *ACOD4* during craniofacial development using zebrafish as a model system. **Method:** Morpholino phosphorodiamidate oligonucleotide (MPO)-based targeted gene knockdowns of *zACOD* and *zSCOD* were performed to determine the function of these genes during early zebrafish development. Defects in craniofacial development observed by alcian blue staining of the cartilage. Analysis of early neural crest migration and specification in the *zSCOD* knockdown embryos performed by *in situ* hybridization with *crestin, distalless2, forkhead6, and fgf3*. **Results:** While *zACOD* did not show a localized expression pattern by *in situ* hybridization, *zSCOD* was observed in the zebrafish central nervous system (CNS) from 1 dpf through 3 dpf. Knockdown of *zACOD* resulted in embryos that displayed normal development. In contrast, the knockdown of *zSCOD* caused severe defects in craniofacial development. The observed defects included reversal of the ceratohyoid cartilage, lower jaw anomalies, and branchial arch defects. Analysis of early neural crest migration and specification in the *zSCOD* knockdown embryos by *in situ* hybridization with *crestin, distalless2, forkhead6,* and *fgf3* revealed normal expression patterns, indicating that the craniofacial defects arise subsequent to these early steps. **Conclusion:** While the knockdown of zebrafish *zACOD* does not appear to be similar to patients with mutations in *ACOD4*, the knockdown of zebrafish *zSCOD* results in defects of the cranial skeleton and indicates a conserved role for this gene family in craniofacial patterning.

Disruption of *NFIA* is associated with neural tube defects and CAKUT. *W. Lu[1,4], F. Quintero-Rivera[2], Y. Fan[1], H.L. Ferguson[1], F. Alkuraya[1], A.W. Higgins[1], R.E. Peters[1], R.M. Gronostajski[5], C.G. Campbell[6], B. Rilliet[7], P. Parvex[7], D.J. Harris[3], A.H. Ligon[1], B.J. Quade[1], G.A.P. Bruns[3], J.F. Gusella[2], C.C. Morton[1], R.L. Maas[1].* 1) Brigham & Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Childrens Hospital, Boston, MA; 4) Boston University Medical Center, Boston, MA; 5) State University of New York at Buffalo, Buffalo, NY; 6) Children's Hospital of Western Ontario, London, Canada; 7) University Hospital, Geneva, Switzerland.

Congenital anomalies of the kidney and urinary tract (CAKUT) are a family of diseases with a diverse anatomical spectrum, including renal dysplasia and vesicoureteral reflux (VUR). About 1% of human fetuses have CAKUT, which are the primary cause of end stage renal failure in children. Neural tube defects (NTD) are commonly associated with nephro-urological complications such as neurogenic bladder and renal insufficiency. Despite their association, little is known about the developmental link between CAKUT and NTD and the molecular pathogenesis of these disorders. To identify genes that cause CAKUT, as part of the Developmental Genome Anatomy Project (DGAP), we studied a patient (DGAP104) with bilateral dysplastic kidney and VUR. This patient has a balanced chromosomal translocation, 46,XX,t(1;20)(p31.3;q13.31), and a NTD including congenital hydrocephalus, thin corpus callosum, Chiari I malformation, tethered spinal cord, and a low vertebral deformity. Using fluorescence *in situ* hybridization, we identified the 1p31.3 breakpoint within intron 2 of *NFIA*. *NFIA* belongs to the nuclear factor I (NFI) family of transcription factors that function both in regulation of adenoviral DNA replication and cellular gene expression throughout development. Tissue *in situ* hybridization revealed *Nfia* to be highly expressed in the developing mouse kidney, brain and ventral ependymal layer of the neural tube. *Nfia* knockout mice show hydrocephalus, agenesis of the corpus callosum, and dysplastic kidney with incomplete penetrance. Analysis of *NFIA* in familial NTD with renal defects is underway to test the hypothesis that dysregulation of *NFIA* is pathogenetic some cases of NTD and CAKUT.

Neural crest deficit in craniofacial skeleton precursors of Ts65Dn mice, a model for Down syndrome. *R.J. Roper, R.H. Reeves.* Dept of Physiology, Johns Hopkins Univ Sch Med, Baltimore, MD.

Ts65Dn mice are trisomic for orthologs of about half of the genes found on human chromosome 21 and exhibit several phenotypic similarities to Down syndrome (DS). Dysmorphology of the craniofacial skeleton, a distinguishing feature found in all DS individuals, is also seen in Ts65Dn mice. Because many tissues affected in DS have a neural crest cell (NCC) component, it has been hypothesized that trisomy 21 causes a defect in NCC, but no direct experimental evidence supports or refutes this hypothesis. To test whether trisomy affects NCC and contributes to the etiology of DS craniofacial dysmorphology, we crossed Ts65Dn mice to mice homozygous for the *Wnt1-lacZ* transgene which is expressed in NCC at embryonic day 9.5 (E9.5). E9.5 Ts65Dn x *Wnt1-lacZ* offspring were age matched by somite number, and trisomic and euploid embryos identified by FISH analysis of the yolk sac. At E9.5, we saw no selection against or gross developmental delay of trisomic embryos. Unbiased stereology revealed a significantly reduced NCC number and volume of the 1st pharyngeal arch (PA1), the mandibular precursor, in Ts65Dn vs. euploid littermates. Fewer NCC were found between the neural tube and PA1 in Ts65Dn embryos, suggesting a deficit in NCC generation or migration. Additionally, a reduction in PA2 NCC in Ts65Dn embryos implied a generalized NCC defect with trisomy. This is the first direct demonstration that trisomy affects NCC and supports further investigations into the etiology of the NCC deficit and its contribution to mandibular hypoplasia in Ts65Dn mice and DS.

A novel hypothesis for the development of gastroschisis in humans: embryologic basis and implications for research. *M. Feldkamp[1], J.C. Carey[1], T. Sadler[2].* 1) Pediatrics, University of Utah, Salt Lake City, UT; 2) Twin Bridges, Montana.

Objective: Gastroschisis is a ventral body wall defect whose embryological origin remains an enigma. Four mechanisms have been proposed to describe how gastroschisis occurs, with the most recent of these, the vascular disruption hypothesis, most widely accepted. We present a new hypothesis to explain the developmental basis of this defect. Background: Four folds are essential for ventral wall closure which draws down in a purse string effect around the umbilical region. The edge of this area is the future umbilical ring, the transition zone between embryonic ectoderm covering the body wall and the amnion. Passing through the ring are the connecting stalk containing allantois, umbilical vessels, and the canal connecting the intra- and extraembryonic cavities, and the yolk stalk (vitelline duct). At 27 days post-conception, the vitelline duct diameter is narrower than the connecting stalk, but the 2 structures remain as separate entities. Early in the 5th week, the gut tube begins to lengthen to form the primary intestinal loop that remains attached to the yolk sac via the vitelline duct. Also, in the 5th week, the vitelline duct and connecting stalk are in close proximity until they merge to form the umbilical cord. A vitelline duct remnant results in a Meckels diverticulum. A Meckels diverticulum occurring with gastroschisis would require the bowel to prolapse prior to the merging of the vitelline duct and connecting stalk. Conclusion: We posit that gastroschisis is a defect involving altered embryonic folding of the ventral body wall before the end of the 5th week. The presence of a Meckels diverticulum in cases supports this hypothesis. This hypothesis suggests an earlier origin than other and has implications for designing studies of etiology and candidate genes.

Molecular and expression analysis extends the phenotypic spectrum of GLI3 mutations to agnathia and oligosyndactyly. *S. MOUGOU-ZRELLI[1], S. AUDOLLENT[1], J. MARTINOVIC[1], M. LE MERRER[1], A.L. DELEZOIDE[2], C. OZILOU[1], L. DEVISME O. BOUTE[3], D. SANLAVILLE[1], A. MUNNICH[1], F. RAZAVI[1], M. VEKEMANS[1], T. ATTIE-BITACH[1].* 1) Genetics and INSERMU-393, Hopital Necker, Paris; 2) Biologie du développement, Hopital R. Debré, Paris; 3) Génétique et foetopathologie, CHU de Lille, France.

GLI3 mutations lead to Greig cephalopolysyndactyly (GCPS), Pallister-Hall (PHS) and postaxial polydactyly type A/B. PHS first described as a neonatally lethal condition associates hypothalamic hamartoblastoma (HH), post axial polydactyly (PD) and imperforate anus (IA).GCPS is less severe and combines polydactyly and craniofacial features. Recently, a phenotype-genotype correlation has been shown both for the location and the nature of GLI3 mutations, suggesting different roles of GLI3 during development. Here we report on a molecular study of GLI3 in 15 children referred for GCPS or PHS, as well as in 20 fetuses selected for either HH and PD (8) or IA plus 2/5 features of the PHS spectrum (12) i.e. growth retardation (IUGR), micropenis, limb, heart, or renal anomaly. Most of the latest were VACTERL cases. We identified a heterozygous GLI3 truncating mutation in 6/15 children (5 GCPS and 1 PHS) and 3 fetuses, as well as a large GLI3 gene deletion (GCPS). All mutations were novel and consistent with the genotype-phenotype correlation. Among fetuses, one typical PHS was confirmed. In another, the association of IUGR, PD, bilateral renal agenesis without HH or IA led first to the suspicion of Smith-Lemli-Opitz (SLO). The third fetus had a severe and unusual phenotype with agnathia and absence of oral orifice, oligosyndactyly of 4 limbs, HH, IA and absence of kidneys, vagina, adrenals, pituitary gland and corpus callosum. Microarray CGH analysis (1 Mb) was normal. In situ hybridisation of GLI3 confirmed its early expression in human pharyngeal arches then mandible. No mutation was identified in cases with HH and PD as part of another syndrome (ODFVI, Meckel, short ribs-PD) or in VACTERL cases. Our results emphasise on the possible lethality of GLI3 mutations during development, extend the phenotypic spectrum to severe craniofacial and reductional limb defects and show the overlap between PHS and SLO.

Severe growth retardation and perinatal death of mice with disrupted *Nedd4* gene. *P. Shi[1], X. Cao[1], N. Lill[2], P. Kirby[3], E. Sweezer[1], J. Van der Veer[1], T. Kinney[1], K. Volk[4], J.B. Stokes[4,5], B. Yang[1].* 1) Obstetrics & Gynecology, University of Iowa, Iowa City, IA; 2) Pharmacology, University of Iowa, Iowa City, IA; 3) Pathology, University of Iowa, Iowa City, IA; 4) Internal Medicine, University of Iowa, Iowa City, IA; 5) VA Medical Center, Iowa City, IA.

Nedd4 (neural precursor cell expressed, developmentally down-regulated 4) is ubiquitin ligase. There are two isoforms in mouse, the ubiquitously expressed Nedd4, and Nedd4-2, which has more restricted (liver and kidney) expression. Nedd4-2 interacts with and negatively regulates epithelial sodium channel. The Nedd4 function is unknown and it is thought to be involved in the down-regulation of growth factor receptors, including insulin-like growth factor-I receptor, through the interaction with Grb10 (growth hormone receptor binding protein). The aim of this study was to elucidate the function of this protein. Mice with *Nedd4* disrupted were generated from ES cells obtained in the gene-trap experiment. At birth the body weight of -/- mice was 1/3 of that of +/+ littermates and -/- mice died right after birth. Immature or delayed development was seen in lungs, skeletal muscle (including diaphragm), skin and spinal cord in -/- newborn. Mouse embryonic fibroblasts (MEFs) isolated from -/- embryos showed reduced mitogenic activity relative to +/+ MEFs, as reflected by their decreased rate of growth in 10% serum and reduced colony formation following low density seeding. The percentage of cells at G0-G1 phase was significantly increased, while the percentages of cells in G2-M and S phases were significantly decreased in -/- MEFs compared to +/+ MEFs. Although +/- mice were 25-30% smaller than +/+ mice from birth till about 5 mos old, no clinically significant differences were observed between these two groups (hematocrit, blood pressure, fasting blood glucose, serum and urine [Na]/[K], and daily food and water consumption). Glucose tolerance test and in vivo resistant to oxidative stress, caused by injection of herbicide paraquat, did not show significant difference between those two groups of mice. Thus, Nedd4 has shown to play an important role in promoting cell growth and differentiation during development.

Neuron-specific protein family member 1 (*Nsg1*) is a putative MeCP2-regulated gene. *I.J. Delgado[1], M. Yaylaoglu[3], D. Sun Kim[1], R. Amir[1], R. Sierra[1], Z. Yu[1], C. Thaller[3], I. Van den Veyver[1, 2].* 1) Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 2) Molecular and Human Genetics, BCM, Houston, TX; 3) Biochemistry and Molecular Biology, BCM, Houston, TX.

Rett syndrome (RTT) is a neurodevelopmental disorder that affects 1/15,000 females. Most RTT patients have mutations in the *MECP2* gene, encoding the methylation-sensitive transcriptional repressor methyl-CpG binding protein 2. Candidate approaches have identified verified MeCP2 targets, such as BDNF. In contrast, expression microarray analysis on brain of RTT mouse models and human patients have been less successful at finding MeCP2 targets; probably because mixed brain regions and/or cell types are interrogated. Furthermore, these studies have not searched for MeCP2 targets during neuronal differentiation. To study the role of MeCP2 during neuronal differentiation and identify target genes using a purer cell population, we performed *in vitro* neuronal differentiation of mutant $Mecp2^{R308/Y}$ and wild-type (WT) mouse embryonic stem (ES) cells using a standard retinoic acid induction protocol. We interrogated gene expression profiles at day 5 of differentiation on total RNA from 3 pooled WT and 3 pooled $Mecp2^{R308/Y}$ ES cell cultures on oligonucleotide arrays and identified 65 upregulated genes and 146 downregulated genes. Real-time quantitative RT-PCR (qPCR) so far confirmed statistically significant changes for 3 genes. We selected neuron specific protein family member 1 (*Nsg1*), a highly-expressed neuron-specific protein involved in receptor recycling at the early endosomes for detailed analysis. A 6-fold upregulation in $Mecp2^{R308/Y}$ differentiating ES cells was found by qPCR. Similar analysis of various mouse brain regions at 5 weeks of age showed a ~2-fold upregulation in cerebral cortex of $Mecp2^{R308/Y}$ mutant mice. RNA in situ hybridization on E14.5 embryos confirmed this upregulation in cortex. These results indicate that *NSG1* expression levels in cortex are regulated by *MECP2* during development and after differentiation. We are currently investigating if *Nsg1* is directly regulated by MeCP2 and how its upregulation when *Mecp2* is mutated contributes to the complex features of RTT.

Human nasal embryonic luteinizing hormone releasing hormone (NELF), a secreted protein, stimulates GnRH neuron migration. *N. Xu[1,2], L.P. Chorich[1,2], W.C. Xiong[2], L.C. Layman[1,2].* 1) Section of Reproductive Endocrinology, Infertility, & Genetics, Dept OB/GYN; 2) Developmental Neurobiology Program, Institute of Molecular Medicine & Genetics, Medical College of Georgia, Augusta, GA.

Kallmann syndrome (KS) is a disease consisting of the combination of idiopathic hypogonadotropic hypogonadism (IHH) and anosmia or hyposmia. One of the candidate genes for KS is nasal embryonic luteinizing hormone-releasing hormone factor (NELF), which is purported to have a crucial role during the migration process of GnRH neurons from the olfactory placode to the hypothalamus. The cDNA of human NELF was previously cloned in our lab, and the protein does not have any homology to other sequences in the genome and lacks a signal peptide. To test whether NELF is a secreted protein that regulates the migration of GnRH neurons, we made mammalian expression constructs encoding NELF which were tagged with c-myc either at the C or N terminus. Transient transfection of NELF in COS-7 cells and Western blot analysis demonstrated that the NELF protein can be detected in the cultured medium, suggesting that it is secreted. Moreover, immunostaining analysis of transfected COS-7 cells without permeabilization reconfirmed that the NELF protein is distributed on the cell surface. Finally, using conditioned media that contains NELF protein, we demonstrated an increased cell migration of GN11 and NLT cells, but not GT1-7 cells by the Boyden chamber assay. Taken together, these findings indicate that human NELF is a secreted protein that stimulates GnRH neuron migration. The Boyden chamber assay will be a useful in vitro assay to analyze the functional effects of human NELF mutations in patients with IHH. (L.C.L. is supported by NIH grants HD040287 and HD033004; W.C.X. is supported by NIH grants GM063861 and AR048120).

Discoveries with Computational Analysis of SAGE Data of Mouse Germ-Cell Transcriptome at Different Stages of Spermatogenesis. *T.L. Lee, D. Alba, V. Baxendale, O.M. Rennert, W.Y. Chan.* Lab of Clinical Genomics/NICHD, National Institutes of Health, Bethesda, MD.

Serial analysis of gene expression (SAGE) provides a global analysis platform for profiling mRNA populations present in cells of interest without the constraint of gene selection and the ambiguous nature of data obtained. However, most of reports to date provide data on SAGE analysis and germ cell development are limited to descriptive analysis. Here, we report a series of bioinformatic analysis using recent published SAGE data on the transcriptome of mouse type A spermatogonia (Spga), pachytene spermatocytes (Spcy), and round spermatids (Sptd). Tags with at least a total count of 20 by combing Spga, Spcy and Sptd were examined. Our aim was to identify and discover pathways and their regulators involved at different stages of spermatogenesis. Unsupervised hierarchical clustering based on tag expression and gene ontology analysis were applied to identify genes and biological process over-represented at a particular stage of development. Potential biological networks were then constructed to reveal the link between the gene candidates. The 5 cis-regulatory elements were also examined for common regulators in different functional clusters. Biological pathways related to the three germ cell stages were constructed. A number of key transcription regulators were commonly found along the process, which included NF-B, SP1, AP-1 and Egr1. Taken together, the approach led to the generation of signature networks and promoter modules essential for specific stages in spermatogenesis, which provide information for designing male contraceptive drugs and a better understanding on male infertility.

TaqMan-based miRNA profiles classify ES and differentiated cells. *C. Chen[1], A.J. Broomer[1], D.A. Ridzon[1], K.J. Guegler[1], W.M. Strauss[2].* 1) Advanced Research & Technology, Applied Biosystems, Foster City, CA 94404, USA; 2) Department of Molecular, Cellular, & Developmental Biology, University of Colorado, Boulder, CO 80309, USA.

TaqMan miRNA assays have been developed using stem-loop primers for reverse transcription (RT) followed by real-time PCR. A total of 252 mouse and human miRNA assays were tested with four different mouse embryonic stem (ES) cell lines and five differentiated embryoid bodies (EBs) and six mouse tissues. Of 238 human miRNAs examined, 215 (90%) were detected in mouse tissues. MicroRNA expression profiles or fingerprints can classify the ES cells, differentiated EBs and adult tissues. MicroRNA expression levels globally increase upon ES cell differentiation. We have identified a number of ES-specific and differentiation-related miRNA candidates that could be used as molecular markers to determine ES cell identity and to monitor its spontaneous differentiation. There exists significant variability in miRNA expression among four ES lines, suggesting that some ES cell cultures may contain a variable portion of spontaneously differentiated cells. Pre-amplification based TaqMan miRNA assays are being developed to detect all miRNAs from a single ES cell. Single-cell miRNA profiles will be invaluable in exploring stem cells and the different types of cells that stem cells can differentiate into. We have also developed TaqMan siRNA assays that can be used to monitor the level of siRNA and to optimize shRNA constructs.

Genetic modifiers of 22q11DS by expression profiling. *J. Liao, S. Nowotschin, V. Aggarwal, B.E. Morrow.* Dept Molecular Genetics, Albert Einstein Col Medicine, Bronx, NY.

The 22q11.2 deletion syndrome (22q11DS, aka velo-cardio-facial syndrome/DiGeorge syndrome) is a congenital anomaly disorder affecting structures derived from the pharyngeal apparatus including the craniofacial region, thymus gland and heart. Most affected individuals have the same sized 3 Mb deletion, yet the disorder varies in severity. One of the greatest challenges is to determine the basis for its varied expressivity. Haploinsufficiency of *TBX1*, a T-box containing transcription factor, is responsible for the main physical malformations of the syndrome. Stochastic, environmental and genetic factors likely modify the phenotype. Genes in the molecular pathway of *TBX1* may serve as genetic modifiers. The strongest evidence is provided by genetic background effects on the severity of the syndrome in Tbx1 +/- mouse mutants. Heterozygous mice were backcrossed over 10 generations in different genetic backgrounds. We found 45% of Tbx1 +/- mice die when congenic in C57Bl/6 but not in FVB, where they survive in normal Mendelian ratios. One way to identify modifiers is to ascertain whether there is a genetic interaction between co-expressed genes. One particular candidate modifier gene is *Pitx2*, the gene for Rieger syndrome. It is expressed asymmetrically in the anterior heart field. We found that most Tbx1 +/-; Pitx2 +/- mice die at birth with multiple heart defects. Tbx1 and Nkx2.5 synergistically activate the *Pitx2c* enhancer. Another way to identify modifiers is to assess global gene expression changes. We performed Affymetrix expression microarray studies on microdissected pharyngeal arches in wildtype and Tbx1 -/- mouse embryos at multiple developmental stages. *Dlx1*, *Dlx5* and *Lhx8* in the neural crest, *Pax9* and *Gcm2* in the endoderm, *Myf5*, *Gata4*, *Gata6* and *Tbx5* in the mesoderm, comprise a subset of relevant genes identified that have been validated by *in situ* hybridization. Some of them are dependent on the *Tbx1* null mutation and others are changed due to morphology differences. We are working towards identifying a set of strong candidate genes to then test for association in human 22q11DS patients with the same sized deletion.

Sequence variants of the NANOS3 gene are associated with testis atrophy and a pure sterility phenotype in men.

K. Kusz[1], L. Tomczyk[1], J. Bierla[2], A. Latos-Bielenska[3], P. Jedrzejczak[4], L. Pawelczyk[4], J. Jaruzelska[1]. 1) Inst Human Genetics, Poznan, Poland; 2) Department of Histology, University of Medical Sciences, Poznañ, Poland; 3) Department and Chair of Medical Genetics, University of Medical Sciences, Poznañ, Poland; 4) Division of Infertility and Reproductive Endocrinology, University of Medical Sciences, Poznañ, Poland.

Nanos proteins are highly conserved family of RNA-binding proteins and play critical role in germ cells development in many organisms. There are three homologous proteins in human testes: NANOS1, NANOS2 and NANOS3, and they are encoded by autosomal genes. We previously demonstrated that NANOS1 is critical for generation and/or maintenance of spermatogonia stem cells in man. However, the role of NANOS2 and NANOS3 in human germ cell development is still unknown. We screened 124 infertile males with various histological phenotypes of seminiferous tubules (Sertoli Cell Only Syndrome, maturation arrest, hypospermatogenesis or testicular atrophy) for mutations in NANOS2 and NANOS3 genes. We found two types of NANOS3 point mutations in two patients and no mutations in NANOS2 gene. The first mutation was insertion of single amino acid codon, while the second one single nucleotide deletion at +25 position of the intron donor site. These mutations were present only in one allele (the second one being the wild-type) and were absent in 400 fertile men having at least two offspring. The men carrying NANOS3 mutations were azoospermic (lack of germ cells in semen), had partial testicular atrophy, manifesting with thinning of seminiferous tubules and lack of germ cells except spermatogonia. Testes histological phenotype of the patients carrying NANOS3 mutations suggests a potential role of this gene in self renewal of spermatogonia. However, further experiments are needed to find out whether mutations we identified are a cause of male infertility.

A transcriptional function for SRY in mammalian sex determination. *V.R. Harley[1], L. Ludbrook[1,2], S. Bagheri-Fam[1], H. Sim[1], P. Bernard[1], R. Sekido[3], R. Lovell-Badge[3], K.C. Knower[1,2].* 1) Human Molecular Genetics, Prince Henry's Institute of Medical Research, Clayton, VIC, Australia; 2) Department of Biochemistry and Molecular Biology, Monash University, Melbourne, Victoria, Australia; 3) Division of Developmental Genetics, MRC National Institute for Medical Research, London, UK.

The mammalian sex determination pathway is chromosomally controlled as XX gonads develop into ovaries and XY gonads develop into testes. On the Y chromosome is the *SRY* gene which initiates the development of the testis and the male phenotype. In humans, mutations in *SRY* cause male-to-female sex reversal in XY individuals. SRY is a member of the SOX protein family and contains a highly conserved HMG box which binds DNA in a sequence-specific manner *in vitro*, consistent with a role for SRY acting as a transcription factor. Despite 15 years since the discovery of *SRY*, its *in vivo* function has not been established, hampered by the lack of a defined target gene and experimental cell culture systems. Soon after Sry is expressed in the developing XY gonad, *Sox9* is up-regulated. Using a novel reporter assay, we investigated the mechanism by which SRY activates a urogenital ridge specific enhancer element of the *SOX9* gene. The assay revealed facets of SRY action including defects in SRY clinical mutants, post-translational modifications of SRY, subnuclear localisation, and co-activators required to activate the *SOX9* enhancer. Up-regulation of *SOX9* in the testis is a key process of sex determination observed in a wide range of vertebrates, regardless of the presence/absence of *SRY*. This study is the first to establish a cell-based assay for SRY transcriptional function and to demonstrate, at least in humans, that the role of SRY is to up-regulate *SOX9*.

LHX9, EMX2, FGF9, GATA4, FOG2 AND M33 Appear to be Sex-Determining Genes in the Developing Human Gonad. *H. Ostrer, H. Huang, R. Masch, E. Shapiro.* New York University School of Medicine, New York, NY.

Mouse mutant models of Lhx9 and Emx2 are associated with gonadal agenesis, and mouse mutant models of Fgf9, M33, Fog2 and Gata4 are associated with gonadal dysgnesis in XY animals. To test whether LHX9, EMX2, FGF9, GATA4, FOG2 and M33 function as sex-determing genes in humans, we assessed their expression in developing gonads, using antibodies specific to these genes and to specific cell types. Gonads and genitourinary structures were obtained from human fetuses, 7 to 22 weeks gestational age. Representative sections were stained with antibodies to P450scc, PECAM, smooth muscle actin, SOX9, C-KIT and AMH to identify specific cell types and then with antibodies to LHX9, EMX2, FGF9, GATA4, FOG2 and M33. At 7 weeks, prior to testis determination, cytoplasmic expression was observed for LHX9, FGF9 and M33, membranous expression was observed for EMX2, and cytoplasmic and nuclear expression was observed for GATA4 and FOG2. After 7 weeks, expression was observed for all of the genes in multiple cell types in both testis and ovary. In the developing testis, expression was observed in Sertoli cells for all of the genes. These observations suggest that these genes are testis-determining in humans and provide criteria for identifying new candidate genes for testis development. These genes should be expressed in undifferentiated gonadal ridges and should continue to be expressed in Sertoli cells after testis determination has taken place - similar to what we have observed previously for SRY, SOX9, DAX1, WT1, and SF1. Nuclear expression does not appear to be required as the proteins can apparently be shuttled into the nucleus, if that is their apparent site of action. Expression in both developing testis and ovary following gonadal determination suggests that these genes play other roles in gonadal development.

Functional identification of candidate genes using hematopoietic stem cell (HSC) expression data and genetic screening. *E. Mendenhall[1], C. Eckfeldt[1], C. Verfaillie[1], S. Ekker[2].* 1) Stem Cell Institute, University of Minnesota, Minneapolis, MN; 2) Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, USA.

Introduction: The genetic mechanisms that govern HSCs are poorly understood. To delineate these mechanisms we compared the expressed gene profile of cells enriched for HSC with cells enriched for hematopoietic progenitors, from bone marrow (BM) and umbilical cord blood (UCB). Subsequently, we performed gain-of-function (GOF) and loss-of-function (LOF) genetic screens in zebrafish to rapidly identify genes with a functional role in hematopoiesis. **Results:** 277 genes were differentially expressed in both UCB and BM HSC vs. HPC. Currently, 73/277 human genes that had a putative zebrafish orthologue and had no known role in HSC biology were identified as candidate genes. For LOF studies, we designed antisense morpholino oligos (MOs) against the 73 genes and injected into zebrafish embryos. 14/73 MOs lead to observable defects in hematopoiesis. To quantify this we used Q-RT-PCR for hemoglobin (Hb) and L-plastin. For 5/7 MOs, a >2 fold reduction in Hb and L-plastin mRNA was detected. Specificity of antisense targeting was confirmed using a second MO of independent sequence for 4/5 genes. These candidate genes include SPRY1, FOXM1, SNX5, PRKCB, and JJAZ1. We also performed a GOF screen for 7 genes that did not have an orthologue in zebrafish by cDNA overexpression of the human gene in zebrafish. 1/7 genes showed a decrease in blood formation; hence direct overexpression of human genes in zebrafish can be used to identify candidate genes. Mammalian studies are ongoing for many of these genes. We overexpressed SPRY1 cDNA in human UCB cells via lentiviral transduction and transplanted them in NOD/SCID mice. The SPRY1 overexpressing cells failed to contribute to hematopoiesis compared to mock-transduced cells (0.06% vs. 9%), confirming our zebrafish data indicating a role for SPRY1 in hematopoiesis. **Conclusions:** We show that the combination of gene expression analysis and LOF and GOF screens in zebrafish offers a quick and effective way to identify candidate genes critical to developmental processes.

Dual expression domains of *Tbx1* in the otic vesicle and periotic mesenchyme are required for normal patterning of the ear. *J.S. Arnold[1], E.M. Braunstein[1], T. Ohyama[2], J.M. Hebert[1], E.B. Crenshaw[3], A.K. Groves[2], M.C. Brown[4], J. Adams[4], B.E. Morrow[1].* 1) Albert Einstein Col Medicine, Bronx, NY; 2) House Ear Institute, Los Angeles, CA; 3) The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Massachusetts Eye and Ear Infirmary, Boston, MA.

Tbx1, the gene responsible for 22q11 deletion syndrome, is required for ear development. The outer and middle and inner ear fail to form in Tbx1 -/- mutants. In contrast, the cochleovestibular ganglion (CVG), is duplicated in Tbx1 -/- embryos, suggesting that *Tbx1* both induces sensory organ formation and suppresses neural cell fate determination. *Tbx1* is expressed in the otic vesicle and the surrounding periotic mesenchyme. Epithelial-mesenchymal interactions between the two tissues are necessary for normal patterning of the ear. To determine the role of *Tbx1* in each cell type we generated a conditional allele of the gene. Foxg1-Cre was used to drive otic vesicle specific ablation of *Tbx1*. Inactivation of *Tbx1* in the otic vesicle resulted in hypoplasia of the inner ear sensory structures and duplication of the CVG. The Foxg1-Cre strain also mediates *Tbx1* ablation in the first pharyngeal pouch endoderm, which forms the auditory tube. In the conditional mutants the first pouch did not extend towards the external auditory meatus preventing the outer and middle ear from forming. To assess the specific role of *Tbx1* in inner ear development, we used the Pax2-Cre strain to ablate the gene in the otic vesicle while maintaining the expression domain in the first pouch. Mutant mice had normal outer and middle ears but had the same inner ear defects as *Tbx1* null mice, underscoring its importance in the otic vesicle. In a complementary experiment, we used Brn4-Cre mice to ablate *Tbx1* in the periotic mesenchyme. While mutant mice showed normal outer and middle ear development, the cochlea had significant malformations. These results show that *Tbx1* in the periotic mesenchyme is responsible for cochlear formation, as mutants had cochlear hypoplasia but normal capsule and middle ear bones. Overall, our data demonstrate the essential role of *Tbx1* in epithelial-mesenchymal interactions responsible for patterning the ear.

Genetics of Vertebrate Caudal Limb Field Specification. *J.A. Lehoczky[1], D. Beier[2], W.-W. Cai[3], J. Moran[2], J.W. Innis[1].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Division of Genetics, Harvard Medical School,Brigham and Women's Hospital, Boston, MA; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Studies into the genetics of vertebrate limb initiation and patterning have identified tissues and specific genes associated with the process of limb bud outgrowth. However, the mechanisms responsible for establishing limb fields prior to the expression of outgrowth genes such as TBX4/5, Wnts, and FGFs, in specific A/P locations are poorly understood. We have characterized a new, spontaneous mouse mutant, Polypodia (Ppd), which we discovered here at the University of Michigan. This mutant exhibits ectopic caudal limbs and we hypothesize that Ppd activates a limb and caudal appendage-inducing activity. Humans with ectopic lower limbs with or without pelvic anomalies, but not spine duplication, have been described extensively in the literature. Ppd is autosomal dominant with 20% penetrance on the C3H background and has a normal karyotype. We crossed Ppd to C3H and genotyped 402 SNP markers and numerous STR markers in each of 45 affected offspring. Current SNP haplotype and STR allele data has allowed us to exclude are large amount of the genome including the relevant chromosomal regions of Pitx1, Tbx4, Tbx5, Fgf8, Fgf10, the Disorganization locus, Raldh1, Raldh2, Raldh3, Cyp26-a1, -b1 and -c1, and the RAR/RXR genes. To further our genetic mapping we have initiated a new cross to CAST/Ei. We have also completed a comparison of the genomes of Ppd animals with controls using Array CGH. In these experiments, genomic DNA from the original Ppd male was compared to CD-1 DNA, and a generation 4, Ppd female on the C3H background was compared to a wild-type C3H female in arrays with 19,200 BACs across the entire mouse genome. No large scale (>100 kb) deletion or duplication was observed. Ppd is a novel, new mouse mutant without any counterpart that will promote new knowledge into the genetic constituents that define the position and number of caudal limb fields.

A novel spontaneous mouse mutation that causes congenital dipypus (caudal duplication) and sex cord tumors. *K. Tatsumi[1], A. Lindgren[2], S. Eames[1], A. Wolfe[2], K. Millen[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Pediatrics, University of Chicago, Chicago, IL.

Recently, a spontaneous mutation arose in our mouse colony resembling congenital dipygus, an extremely rare human birth defect characterized by supernumerary lower limbs and/or pelvis. Affected mice have a variable phenotype with supernumerary limbs caudal to the normal hindlimbs with fur, bone and vasculature. Radiographs and skeletal staining reveal that the ectopic legs are usually attached to a mirror-image duplication of pelvic structures, located directly posterior to the normal pelvis along a slightly elongated spine. This developmental abnormality is not simply a posterior axial duplication since the tail is not concurrently duplicated. Several internal organ abnormalities have also been noted. In particular, all affected mice also have had sex cord tumors - granulosa cell tumors in females and Sertoli cell tumors in males. Extensive breeding analysis has determined that this is a dominant mutation with low penetrance. The homozygous phenotype is apparently embryonic lethal. Mapping studies are underway. Affected mice have phenotypes reminiscent of the Disorganization (Ds) mutation. Ds is a dominant, gain of function mutation with low penetrance that maps to mouse chromosome 14. Ds mutants have disorganized body plans and display a range of developmental defects so great that no two mice show the same phenotype. Ds mice never develop cancer. In contrast, our new mutant has a generally consistent phenotype which includes tumors, suggesting that this new mutation represents a novel mouse locus. Since the observed skeletal abnormalities present a challenge to current theories of body axis and limb formation, analysis of this new mutant is certain to provide new insights into vertebrate patterning.

Mouse models of Down syndrome trisomic for all human chromosome 21 syntenic regions. *Y. Yu[1,2], Z. Li[1], P. Szurek[1], A. Pao[1], S. Rivera[3], S. Matsui[1], J. Roder[4], A. Bradley[5].* 1) Genetics Program, Roswell Park Cancer Inst, Buffalo, NY; 2) New York State Center of Excellence in Bioinformatics & Life Sciences; 3) Baylor College of Medicine, Houston, TX; 4) Mount Sinai Hospital Research Inst, Toronto, Canada; 5) Sanger Institute, Hinxton, UK.

Approximately 95 percent of Down syndrome (DS) patients carry an extra copy of the entire human chromosome 21, which is the leading genetic cause of mental retardation. Genes in different regions of human chromosome 21 are associated with a broad range of cellular pathways or processes. Triplications of key genes in different regions may perturb these events, leading to mental retardation, which is consistent with data from studies of segmental trisomy 21. Since the identities of many of the key genes in these regions are unknown, an ideal mouse model should be segmentally trisomic for all of the human chromosome 21 syntenic regions, which are located on mouse chromosomes 10, 16, and 17. To develop this model, we have generated mice carrying a 2.3-Mb trisomy for the entire syntenic region on mouse chromosome 10 by using chromosome engineering. Furthermore, our preliminary result suggests that a 1.2-Mb duplication that spans the entire syntenic region on mouse chromosome 17 may have been established in ES cells. Finally, we have targeted a loxP to the 1st endpoint in ES cells in order to generate a 22.9-Mb duplication in the syntenic region of mouse chromosome 16. Chimeras have been developed with these cells and the targeting vector for the 2nd endpoint has been generated. The desired model derived from this effort will be more complete than Ts65Dn, which is trisomic for about 56 percent of the orthologous genes of human chromosome 21. We will characterize the phenotypes of the new mouse models that may be related to DS-associated mental retardation by using behavioral, neurophysiological, and neuropathological approaches. These studies will lay the foundation for achieving our long-term goal of unraveling the molecular mechanism of DS-associated mental retardation and may lead to new opportunities for developing effective therapeutic interventions for the clinical manifestations of DS, including mental retardation.

Phenotypic, genetic and developmental characterization of *cpo1*, a recessive ENU-induced mouse model of cleft palate. *B.C. Bjork[1], A.R. Vieira[2], S. Faust[3], S.A. Camper[3], J.C. Murray[2], D.R. Beier[1].* 1) Div Genetics, Brigham & Women's Hospital, Boston, MA; 2) Dept. Pediatrics, Univ. of Iowa, Iowa City, IA; 3) Depts. Human Genetics and Internal Medicine, Univ. of Michigan, Ann Arbor, MI.

Our ENU mutagenesis screen generates a large spectrum of recessive phenotypes similar to human congenital disorders, including several craniofacial defects. Clefting occurs frequently in mice, but those with isolated clefts are ideal models of human non-syndromic cleft lip/palate (NSCL/P). The *cleft palate only 1* (*cpo1*) mutation is an excellent such model.

The *cpo1* mutant phenotype is due to a mutation that affects splicing efficiency of the zinc finger transcription factor *Prdm16* on chr 4 (Hs. 1p36) and is likely hypomorphic. Mutant mice have a specific defect in palatal shelf elevation. Preliminary palate explant culture shows that *cpo1* palate shelves elevate and meet at the midline upon removal of the mandible and tongue, suggesting that a physical obstruction is primarily responsible for the clefting phenotype. *Prdm16* expression in developing craniofacial structures is consistent with it playing a critical role during palatogenesis.

We identified three potential etiologic missense mutations in a screen of 200 NSCL/P cases from Iowa and the Philippines; these are not observed in 200 controls. One of these, a G819S mutation, was subsequently identified in 54/1064 individuals in the CEPH Diversity panel but a modifying role remains a possibility. The *Prdm16* paralog *Evi-1* is known to act in the *Tgf* signaling pathway. Therefore, we are utilizing *in vitro* analysis of a *TGF*?responsive luciferase reporter to assay the effect of *PRDM16* on *TGF* signaling and any potential functional consequence of the three *PRDM16* missense mutations.

We continue to refine the *Prdm16* expression pattern and have begun to look for misexpression of craniofacial markers in *cpo1* mutants to place *Prdm16* in a genetic pathway. Finally, in addition to gene targeting, we are using RNAi transgenesis to rapidly "knock down" *Prdm16* in mouse embryos and validate the etiology of the *cpo1* mutation.

Gene Expression Profiling of Cardiac Angiogenesis Using a Canine Model. *C. Gregory, T. Masters, A. Fokin, F. Robicsek.* Heineman Medical Research Laboratory, Carolinas Heart Institute, 1001 Blythe Blvd., Charlotte, NC.

Coronary heart disease remains the leading cause of morbidity and mortality in the United States. Despite the advances in myocardial revascularization, a large group of patients are not candidates for current surgical or cardiological interventions to restore blood flow. A possible treatment for these patients may be neovascularization via angiogenesis. Numerous studies have implicated various growth factors to be involved in this process. However, the precise sequence of gene expression involved in initiation and maintenance of angiogenesis has not been delineated for clinical application. Using a canine model of myocardial ischemia, angiogenesis was amplified by an AV fistula (distal occluded circumflex to adjacent cardiac vein). Tissue from collateral vessels was taken, on day 8 after the AV fistula, from 5 experimentals and 4 controls. Gene expression profiling was accomplished using the Affymetrix GeneChip Canine Genome Array. Using ArrayAssist and PathwayAssist, ~3,900 probe sets were significantly up or down regulated. Further refinement found 168 probe sets with differential expression log scale of -1 and 109 probe sets with +1 and a p value 0.05. Annotation of the probe sets, revealed an array of upregulated candidate genes involved in cell proliferation, differentiation, motility, and regulation of signal transduction. Some of the genes included in this group are LECT2, APBA1, RAD52, ANGPT1, MBL1, IMPD2, UCK2 and KHDRB. Hierarchical cluster analysis showed 3 distinct groups (53, 20, 8 probe sets) of temporal patterns from the animals that demonstrated development of angiogenesis. In the cluster of 53 probes, 33 were unknown status and 20 were annotated. The 20 annotated genes of the cluster were found to be involved with cell proliferation, differentiation, and regulation of signal transduction. In conclusion, this study has provided a snapshot of gene expression patterns at day 8 in the process of angiogenesis. This data enables further refinement of the genes that will be critical to initiate and maintain neovasuclarization.

DNA methylation and gene expression at the candidate locus for transient neonatal diabetes mellitus is tissue specific during fetal and postnatal development. Implication for pancreatic cells function. *G. Marcelin[1], A. Nicole[1,2], C. Diatloff -Zito[1,3].* 1) Inserm U383, Groupe Hospitalier Necker-Enfants Malades 149-161 rue de Sèvres 75743 Paris Cedex 15 France; 2) Faculté de Médecine Paris 5; 3) CNRS.

Epigenetic alterations are involved in a number of human diseases including developmental abnormalities, cancer and endocrine diseases. Defects within the imprinted region of chromosome 6q24.2 have been implicated in transient neonatal diabetes mellitus (TNDM), a developmental disease of insulin production characterized by hyperglycemia at birth, absence or low levels of insulin. About 65% of TNDM patients will have type 2 diabetes at adolescence. Loss of methylation at CpG island within the (differentially methylated region) DMR was observed in most patients studied with a normal karyotype. The DMR of *ZAC1/HYMAI* may potentially regulate expression of imprinted genes within the domain, and epigenetic or genetic mutations of this region may result in TNDM by affecting expression of *ZAC1/HYMAI* and new candidates. In order to test this hypothesis and approach mechanisms involved in TNDM pathogenesis, genomic DNA methylation coupling to gene transcription of *Zac1* and other epigenetically regulated regions within the locus,were determined in mice pancreas and heart in vivo. The 10A2 mouse locus syntenic to the human 6q24.2 are highly conserved in the two species. Data from mice heart and pancreas tissues at different fetal ages (E12 to birth) and postnatal (4 weeks to one year), as well as from pancreatic islets, ex vivo and MIN-6 culture cells, in vitro are reported. Evidences showing that spatio-temporal methylation dynamic and transcription is tissue specific are provided. An active epigenetic process of the 6q24.2/10A2 locus related to pancreas physiological activity is suggested.

Gene expression microarray analysis of mouse orofacial development. *R. Spritz[1], W. Feng[2], T. Pfang[3], L. Hunter[1,3], M. Geraci[1,4], T. Williams[1,2].* 1) Hum Med Genet Prog, Univ Colorado Hlth Sci Ctr, Aurora, CO; 2) Dept Craniofacal Biol, Univ Colorado Hlth Sci Ctr, Aurora, CO; 3) Dept Pharmacol, Univ Colorado Hlth Sci Ctr, Aurora, CO; 4) Dept Medicine, Univ Colorado Hlth Sci Ctr, Aurora, CO.

Orofacial clefts are among the most common of all birth defects, cleft lip cleft palate (CL/P) occurring with a frequency of ~1/500 to 1/2500 in different populations. Despite much effort, few CL/P genes have been identified in humans. We are using the mouse as a model system to identify potential candidate genes for human orofacial clefts. In vertebrates the face develops mainly from 3 bilaterally paired prominences: maxillary prominences (MxP), frontal nasal prominences (FNP), and mandibular prominences (MdP). In mouse most orofacial morphogenesis takes place from embryonic day (ED) 10.5 to 12.5. We have dissected the MxP, FNP, and MdP separately from wild-type (C57BL6/J) ED10.5 to ED12.5 mouse embryos at 0.5 ED intervals, extracted RNA, and carried out microarray analyses using Affymetrix mouse genome 430 2.0 arrays, which interrogate expression of ~39,000 transcripts. All dissections and microarray assays have been carried out in 7-fold replicate to provide high data reliability. Data reproducibility has been excellent, and expression of specific indicator genes has been used to monitor purity of dissected tissues. Data mining has yielded lists of genes whose expression is either tissue-specific or that vary in a time-dependent manner during orofacial development. We have specifically analyzed developmental expression patterns of a number of genes that have been implicated in human syndromic and non-syndromic orofacial clefts. We are also carrying out analogous parallel dissections and analyses of two lines of mutant mice, one with mid-facial clefting and one with bilateral cleft lip cleft palate, to provide important comparisons between normal and abnormal orofacial developmental patterns. We anticipate that these studies will highlight new candidate genes, genetic networks, and developmental pathways that may be involved the pathogenesis of human orofacial clefts.

Group 13 HOX proteins interact with the MH2 domain of R-Smads and modulate Smad transcriptional activation functions independent of HOX DNA binding capability. *J.W. Innis[1,2], T.M. Williams[1], M.E. Williams[1], J.H. Heaton[1], T.D. Gelehrter[1].* 1) Department of Human Genetics, Univ. Michigan, Ann Arbor, MI; 2) Department of Pediatrics, Univ. of Michigan, Ann Arbor, MI.

Interactions with cofactors provide a means by which HOX proteins exert specificity. To identify candidate protein interactors of HOXA13 we created and screened an E11.5-E12.5, distal limb bud yeast two-hybrid prey library. Among the interactors we isolated the BMP-signaling effector Smad5, which interacted with the paralogous HOXD13 but not with HOXA11 or HOXA9, revealing unique interaction capabilities of the AbdB-like HOX proteins. Using deletion mutants, we determined that the MH2 domain of Smad5 is necessary for HOXA13 interaction. This is the first report demonstrating an interaction between HOX proteins and the MH2 domain of Smad proteins. HOXA13 and HOXD13 also bind to other BMP and TGF-/Activin-regulated Smad proteins including Smad1 and Smad2, but not Smad4. Furthermore, HOXD13 could be co-immunoprecipitated with Smad1 from cells. Expression of HOXA13, HOXD13 or a HOXD13 homeodomain mutant (HOXD13IQN>AAA) antagonized TGF--stimulated transcriptional activation of the pAdtrack-3TP-Lux reporter vector in Mv1Lu cells as well as the Smad3/Smad4-activated pTRS6-E1b promoter in Hep3B cells. Finally, using mammalian one-hybrid we show that transcriptional activation by a GAL4/Smad3-carboxy terminus fusion protein is specifically inhibited by HOXA13. Our results identify a new cofactor for HOX group 13 proteins and suggest that HOX proteins may modulate Smad-mediated transcriptional activity through protein-protein interactions without the requirement for HOX monomeric DNA binding capability.

Expression of Pax3 and Pax7 during mouse embryogenesis: comparison to MyoD and Myogenein. *J. Horst[1], D. Horst[2], C. Sergi[2], H. Jürgens[3], E. Vorobyov[1].* 1) Institut für Humangenetik, Universitätsklinikum Münster, Germany; 2) Institut für Pathologie, Medizinische Universität Innsbruck, Austria; 3) Klinik und Poliklinik für pädiatrische Hämatologie/Onkologie, Universitätsklinikum Münster, Germany.

Pax3 and Pax7 encode homologous transcription factors the expression of which is known to be required for the dermomyotome formation in the developing trunk. However, it is not yet clear whether these genes are required for myogenic cell specification in the head and for the post-somitic myogensis per se. In part, this uncertainty is due to the scarce information about their normal time course and pattern of expression. Here, we present a systematic in situ analysis of spatiotemporal characteristics of Pax3 and Pax7 gene expression in comparison to that of MyoD and Myogenin, with special attention to the developing muscles of the head. The expressed proteins were immunohistochemically detected on adjacent sections of embryos at stages E11-15 and postnatal muscles. The observed patterns of expression suggest that Pax3 is not involved in myogenesis in the head, and its post-somitic expression in the trunk and limb muscles is repressed after stage E13. In contrast, Pax7 expression is shared among all striated muscles and exhibits a uniform pattern that can be explained by an asymmetric cell division. In the developing muscles of the head Pax7 is activated after MyoD and as such cannot be considered as a myogenic inducer in the head. These data reveal that Pax3 and Pax7 exhibit distinct spatiotemporal expression modes in myogenic precursors during embryogenesis.

Gene Expression Profiling of Human Pharyngeal Arch 2. *J. Cai[1], D. Ash[1], L. Kotch[1], E.W. Jabs[1], Y. Korshunova[2], R. Tidwell[2], D. Messina[2], J. Winston[2], M. Lovett[2], T. Attié-Bitach[3], J. Augé[3], G. Mattei[3], H. Etchevers[3], M. Vekemans[3].*
1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Washington Univ, St Louis, MO; 3) Hospital Necker Enfants Malades, Paris, France.

Craniofacial abnormalities are one of the most common birth defects in humans, yet little is known about the genes that control these important development processes. To identify relevant genes, the COGENE consortium is profiling gene expression to study normal human craniofacial development. Using microdissected, normal human craniofacial structures, we constructed 12 SAGE (Serial Analysis of Gene Expression) libraries and sequenced 606,532 tags. We also performed Affymetrix microarray analysis on 25 craniofacial targets. We then analyzed expression profiles of pharyngeal arch 2 (PA2) that forms the stapedial artery, muscles of facial expression, the posterior belly of the digastric, stylohyoid and stapedius muscles, stapes, styloid process, stylohyoid ligament and facial nerve VII. Comparison between SAGE libraries revealed that 27 tags were upregulated and 50 tags were downregulated (p0.01), whereas microarray analysis revealed that 11 and 23 genes were upregulated and downregulated (p0.01), respectively, from 4th to 5th week PA2. Protein biosynthesis was overrepresented in the differentially expressed genes determined by SAGE, and cell communication process was overrepresented in the differentially expressed genes determined by microarray analysis. By comparing SAGE and microarray data, genes that are enriched in PA2 were identified, many of which were previously unknown to be expressed in PA2. Whole mount in situ hybridization was performed on mouse embryos at corresponding stages to study the conservation of expression patterns observed in humans. For example, the Wbscr1 gene, whose human homolog is in the Williams-Beuren syndrome critical region, was expressed both in mouse PA2 precursor cells at GD8.5 and in PA2 at GD9.5, and by GD10.5, it was highly expressed in PA2, especially in the posterior half. This data should provide useful information of gene expression in normal PA2 development, and help in identifying pathways and genes that contribute to common pharyngeal arch defects.

Pretranslational Upregulation of COL1A2 is not Responsible for the Type I Collagen Glomerulopathy in COL1A2 Deficient Mice. *A.C. Brodeur, B.J. Pfeiffer, J.R. Gentry, D.A. Wirth, A.M. Roberts-Pilgrim, C.L. Franklin, L.W. Reneker, C.L. Phillips.* Univ of Missouri-Columbia, Columbia, MO.

We recently identified a novel type I collagen glomerulopathy in COL1A2 deficient mice (homozygous for a functional null pro2(I) collagen gene), which synthesize exclusively homotrimeric type I collagen, $1(I)_3$. The role of the homotrimer is currently unknown. Examination of COL1A2 deficient mice revealed type I collagen deposition in the mesangium of glomeruli in both homozygous and heterozygous mice. Using *in vivo* and *in vitro* approaches, we investigated the pathological and mechanistic significance of the COL1A2 deficient glomerulopathy. To evaluate pathologic significance we used two histologic scoring systems to study the presence and severity of the glomerulopathy within individual animals. We demonstrate that the glomerulopathy initiates postnatally following glomerular maturation and is progressive with a gene dosage effect. To determine the role of type I collagen synthesis in glomerular deposition we examined steady state 1(I) and 2(I) collagen mRNA levels across all genotypes from 1 day to 1 month of age by *in situ* hybridization (ISH). ISH analyses showed similar temporal 1(I) and 2(I) collagen mRNA levels in glomeruli of all three genotypes. To confirm the ISH findings, we performed quantitative real-time PCR on total mRNA isolates from age-matched kidneys of each genotype. Real-time data confirms that there is no significant difference in temporal 1(I) and 2(I) mRNA. Therefore, we suggest glomerular deposition seen in the type I collagen glomerulopathy is not due to pretranslational mechanisms. Degradation of type I collagen within the glomerulus is primarily regulated by matrix metalloproteinases (MMPs). Previous studies have identified the presence of MMPs 1, 2, 3, 9, 13, and 14 in the kidney. MMPs 1, 2, 3, 8, 9 and 13 are known to cleave type I collagen and its molecular components. Preliminary studies using *in vitro* enzymatic analysis suggest that there is differential cleavage of hetero- and homotrimeric type I collagen by specific MMPs. Further studies will elucidate the involvement of individual MMPs.

Identification of Genes Regulated by the Nuclear Receptor *Nr2e3* to Direct Photoreceptor Development. *N. Haider.* Department of Genetics, Cell Biology and Anatomy, Univ Nebraska Medical Ctr, Omaha, NE.

Mutations in *Nr2e3* cause Enhanced S-Cone Syndrome in humans and are responsible for the *rd7* phenotype in mice. We used the *rd7* mouse as a model to study the molecular mechanisms underlying human retinal degeneration. Our previous studies revealed that *Nr2e3* is important for the development and specification of rod and cone photoreceptors; its absence disrupts retinal integrity and photoreceptor function. *rd7* mice exhibit an abnormal increase in cone photoreceptor population which is due to continued cone cell proliferation beyond the time when photoreceptors normally exit the cell cycle. In the present study, we use the *rd7* mouse to identify molecules that are regulated by *Nr2e3* to direct proper development of photoreceptors. Real-time PCR analysis was performed on over 100 candidate transcriptional targets of *Nr2e3*. Misregulated genes were evaluated for the presence of upstream response elements that NR2E3 could bind. These elements were tested by *in vitro* electrophoretic mobility shift assay to determine which genes are direct targets of NR2E3 . In addition, differential expression of proteins was evaluated in *rd7* mice at critical times during photoreceptor development. Differentially expressed proteins were identified and also evaluated for the presence of upstream regulatory sites to which NR2E3 may bind. Our studies demonstrate that *Nr2e3* is a dual regulator affecting the processes of proliferation and differentiation during development as well as photoreceptor function in the adult retina.

Opposite effect of genetic background in acoustic startle response of fragile X knockout mice. *F. Kooy[1], R. D'Hooge[2], E. Fransen[1], P. De Deyn[2], V. Errijgers[1].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Department of Neurochemistry and Behavior, Institute Born-Bunge, University of Antwerp, Antwerp, Belgium.

In this study we have further analyzed the acoustic startle response (ASR) in fragile X knockout mice bred in different genetic backgrounds, including C57BL/6J, (C57BL/6J x 129P2/OlaHsd) F1 and F2 intercross mice. The fragile X knockout mouse lacks Fmrp and shows abnormalities comparable with the symptoms observed in human fragile X patients, including mild to severe learning difficulties, macroorchidism and behavioural alterations. The fragile X knockout mouse model is a valid animal model to study the human disorder.

The ASR can be used as a behavioral tool to assess the neuronal basis of behavior. All mice tested showed an increasing startle response in relation to increasing stimulus intensity. We found differences in ASR between knockouts and controls dependent on genetic background and stimulus intensity. Fragile X knockout mice bred in a C57BL/6J background showed an increase in ASR in response to the lowest stimulus of 90 dB compared to control mice and a decrease in ASR in response to the highest stimulus of 110 dB. Remarkably we found an opposite ASR between F1 and F2 mice. Knockouts of the F1 generation showed a decreased ASR in response to each stimulus intensity used compared to controls, whereas knockouts of the F2 generation showed an increased ASR. Since both F1 and F2 mice consist each of 50% of genetic material from either parental strain, these results show for the first time that the different distribution of the genetic material from the parental strains may influence the fragile X knockout phenotype in the ASR. This suggests that modifier genes may strongly influence the ASR in fragile X syndrome.

Non-random genetic abnormalities lead to non-random epigenetic changes in leukemia. *S. Rossetti[1], C. Stanciu[1], A.T. Hoogeveen[2], N. Sacchi[1].* 1) Dept Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) Erasmus Medical Center, Rotterdam, The Netherlands.

Non-random leukemia chromosomal abnormalities are a hallmark of distinct leukemia subtypes. Evidence is accumulating that hypermethylation of CpG islands is also non-random in leukemia. We hypothesize that there is a mechanistic link between non-random chromosomal abnormalities involving genes encoding chromatin regulators and epigenetic changes at specific target genes. To test this hypothesis we used as a model AML1-MTG16, a fusion protein produced in t(16;21)-positive leukemia. This protein retains the DNA binding domain of AML1, a transcription factor crucial for normal hematopoiesis, and most of the functional domains of MTG16, encoding a transcriptional corepressor able to recruit histone deacetylase (HDAC) activity. For this reason, AML1-MTG16 is expected to aberrantly regulate AML1 target genes by inducing repressive epigenetic modifications. By integrating gene expression analysis and bioinformatics we identified several aberrantly regulated AML1-target genes in AML1-MTG16-positive cells. By chromatin immunoprecipitation we proved that the AML1-consesus sequence present in the promoter regions of two downregulated genes were directly bound by AML1-MTG16. Noteworthy, these promoter regions were associated with repressive chromatin changes, such as histone H4 deacetylation and aberrant DNA hypermethylation. Our results indicate that integrated approaches can efficiently identify the links between non-random chromosomal abnormalities and non-random epigenetic changes in leukemia.

Features of imprinting signature at the 6q24.2 locus for transient neonatal diabetes mellitus. *C. Diatloff-Zito[1,2], A. Nicole[1,3], G. Marcelin[1], JJ. Robert[4].* 1) INSERM U383, Hopital Necker Enfants Malades, Paris, France; 2) CNRS, Paris 16; 3) Faculté de Médecine Paris 5; 4) Fédération de Pédiatrie.

Loss of genomic imprinting is involved in a number of developmental abnormalities, neuro behavioral problems and cancer. ZAC1 and HYMAI are imprinted genes expressed from the paternal allele of chromosome 6q24.2 within a region known to harbor a tumor suppressor gene activity and identified as the candidate locus for transient neonatal diabetes (TND). Imprinting defect in the region occurs in TND. A loss of maternal methylation at CpG island within the differentially methylated region (DMR) was observed in most patients studied (61%) of our series with a normal karyotype. The DMR at the 5end of ZAC1 and HYMAI genes may regulate expression of imprinted genes within the domain and epigenetic or genetic mutations of this region may result in TND by affecting expression of ZAC1 or HYMAI in pancreas or the pituitary. Methylation analysis in patients and control individuals shows that the DMR is not homogeneously methylated with discrete tissue specific local pattern supporting the idea of bipartite epigenetic regulation process. Alterations at chromatin level may cause the disease in 23% of the TND patients with no other defect identified. Inter-individual variability in control DNA from blood and pancreas samples, is suggestive of epigenetic polymorphism that may potentially underlie local genomic plasticity.

Submicroscopic chromosomal rearrangements in Beckwith-Wiedeman patients. *M.P. Recalcati[1], S. Russo[1], P. Finelli[1,2], S. Ferraiuolo[1], D. Giardino[1], F. Cavalleri[1], F. Cogliati[1], M.G. Tibiletti[3], L. Zoccante[4], M.T. Bonati[5], L. Larizza[1,6].* 1) Lab Medical Genetics, Istituto Auxologico Italiano, Milano; 2) Dipartimento di Biologia e Genetica, Università di Milano, Milano; 3) Lab di Anatomia Patologica, Ospedale di Circolo, Varese; 4) Servizio Autonomo, N.P.I., Policlinico G. Rossi, Verona; 5) Genetica Medica, Istituto Auxologico Italiano, Milano; 6) Genetica Medica, Dipartimento di Medicina, Chirurgia e Odontoiatria, Università di Milano.

Beckwith-Wiedemann syndrome (BWS; MIM 130650) is a disorder of growth regulation, characterized by prenatal and postnatal overgrowth, macroglossia, anterior abdominal wall defects and tumor predisposition. The etiology involves genetic and epigenetic alterations affecting a genomic region of approximately one megabase on human chromosome 11p15, which is organised into two imprinted domains under the control of DMR1, 4Kb distal to 5H19, and DMR2 in KVLQT1 IVS10. Only 2% of BWS patients were found to carry cytogenetic abnormalities such as chromosome 11 duplications and translocations. 60 BWS patients was investigated for the most common pathogenetic mechanisms: 11p15 mosaic paternal UPD and defects in methylation pattern of the imprinted H19 and LIT1 genes. Microsatellite segregation analysis, carried out to search 11patUPD, showed in two patients a profile compatible with the presence of subchromosomal duplications. FISH analysis confirmed that one case, trisomic for D11S318 and showing both paternal methylated H19 alleles, carries a de novo dup(11)(p15.5p15.5), likely resulting from unequal recombination at meiosis I in paternal gametogenesis. BAC FISH characterization evidences the breakage separates the two IC domains controlling the BWS region. The second patient was found to carry a der(21)t(11;21)(11p15.4;q22.3)pat originated from missegregation of a cryptic paternal translocation. An additional patient with Wolf syndrome and unusual height was shown to carry a der(4)t(4;11)(p16.3;p15.4)pat characterised by FISH analysis.The latter case with the interstitial direct duplication might provide a tool to investigate the role of each BWS IC in the aetiopathogenesis of the syndrome.

Complementation test indicates that an IAP transposon insertion at Wnt9b contributes to multifactorial cleft lip and palate in the mouse model. *D.M. Juriloff[1], M.J. Harris[1], T.J. Carroll[2], A.C. Lidral[3].* 1) Dept Medical Genetics, U British Columbia, Vancouver, BC, Canada; 2) Dept Internal Medicine, UT Southwestern, Dallas, TX; 3) Dept Orthodontics, U Iowa, Iowa City, IA.

The genes involved in the genetically complex etiology of human nonsyndromic cleft lip and palate (CLP) have not been identified. The A/WySn mouse strain is a good model; 20 percent of fetuses or neonates have nonsyndromic CLP. Previous work showed that the etiology of the A/WySn defect is digenic - the joint effect of the clf1 recessive gene on Chr11 and the clf2 semidominant gene on Chr13, plus a strong A/WySn maternal effect. Previous extensive work to identify the clf1 mutation excluded sequence differences in the most plausible candidate genes; comparison with recent ancestral sequence pointed to an IAP transposon insertion 6.6 kb from the 3' end of the Wnt9b gene in A/WySn as being the clf1 mutation. Recent gene knockout studies in mice found that about 50 percent of Wnt9b null embryos have CLP as part of a syndrome of defects (Carroll & Lidral in prep). In the present study a complementation test was done by crossing Wnt9b+/- males with A/WySn females (a/a at Wnt9b). 83 F1 fetuses were obtained, examined and genotyped by PCR. The ratio of a/+ to a/- was Mendelian overall. There were 13 CLP fetuses, and all were a/-, indicating noncomplementation between the A/WySn allele at Wnt9b and the null allele, and supporting the interpretation that the IAP interferes with Wnt9b expression in A/WySn. The homologous region for clf1 is on human 17q and has been implicated in human multifactorial CLP. These studies point to the WNT9B gene as a candidate and transposons as a source of the etiological complexity of human CLP.

Cyp26a1 in embryocarcinoma differentiation: an epigenetic switch? *S. Pozzi, S. Rossetti, G. Bistulfi, N. Sacchi.*
Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY.

Retinoic acid (RA) is a signaling molecule that plays a pivotal role in vertebrate development. RA concentration is critical for the determination of the antero-posterior axis during embryonic development. RA action is mediated by specialized transcription factors, the nuclear RA receptors (RARs), that regulate the expression of genes containing a RA responsive sequence (RARE). Cyp26a1, the gene encoding the cytochrome P450 RA-specific hydroxilase, contains a RARE sequence and is critical for the development of the embryo. Here we show that Cyp26a1 is under the direct control of the RAR beta 2 receptor, which in turn is regulated by another RA receptor, RAR alpha, in pluripotent P19 embryocarcinoma cells. RNA interference of RAR beta 2 transcription in P19 cells revealed that there is a mechanistic link between RAR beta 2, Cyp26a1 regulation, and P19 differentiation, in response to RA. Thus, impairing the integration of RA-signaling through RAR beta 2 leads to stable Cyp26a1 downregulation marked by repressive epigenetic changes of Cyp26a1 chromatin. These data point at Cyp26a1 as an epigenetically regulated switch of embryocarcinoma differentiation.

Allelic expression imbalance of *BAPX1* in patients with the oculo-auriculo-vertebral spectrum (OAVS). *S. Fischer, H.J. Lüdecke, D. Wieczorek, G. Gillessen-Kaesbach, M. Trommler, R. Kubica, B. Horsthemke.* Institut für Humangenetik, Universitätsklinikum Essen, Germany.

The oculo-auriculo-vertebral spectrum is a developmental disorder characterized by hemifacial microsomia, epibulbar tumors, ear malformations and vertebral anomalies. Most cases are sporadic, but rare familial cases suggest that OAVS has a genetic basis. To date, however, no gene defect has been identified. We have studied a patient with OAVS, multiple exostoses and a translocation 46,XX,t(4;8)(p15.3;q24.1). The translocation disrupts the multiple exostoses gene *EXT1* on chromosome 8 and the *RAB28* gene on chromosome 4. To investigate whether *RAB28* plays a role in OAVS, we sequenced this gene in 75 patients, but did not find any mutation. The *BAPX1* gene maps 76.4 kb proximal to the chromosome 4 breakpoint. As shown by studies in mice, zebrafish and Xenopus, the homeobox containing protein BAPX1 plays an important role in craniofacial development. Thus, *BAPX1* is a good positional and functional candidate gene for OAVS. We screened 105 patients for *BAPX1* mutations. In twelve patients we found six different rare nucleotide changes, three with and three without an effect on the amino acid sequence. In two families the amino acid changes were also found in non-affected relatives. We also discovered a frequent single nucleotide polymorphism in exon 1. By quantitative primer extension analysis of fibroblast RNA we found that *BAPX1* was expressed at a balanced allelic ratio in nine control individuals, but at a skewed allelic ratio in three of six patients (fishers exact test; p=0.044). In two families the unaffected father also had a skewed allelic expression ratio. Interestingly, one of these patients inherited the downregulated allele from the unaffected mother, who had a balanced allelic expression ratio, thus excluding *cis*-acting genetic variation in this case. Treatment of cultured fibroblasts from two patients with the histone deacetylase inhibitor trichostatin A, but not with the DNA methyltransferase inhibitor 5-azacytidin led to reactivation of the downregulated allele. We propose that epigenetic mechanisms causing allelic expression imbalance of *BAPX1* are involved in OAVS.

Genome-wide Analysis of DNA Methylation in Autism Brain. *X. Zhang, T. Sahoo, Y. Jiang, A.L. Beaudet.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

We have proposed a mixed epigenetic and genetic and mixed de novo and inherited (MEGDI) model for autism (Am J Med Genet, 131:1, 2004). In an attempt to test this hypothesis, we have performed genome-wide analysis of DNA methylation in autism brain using the methylation-sensitive amplified fragment length polymorphism (MS-AFLP) method. DNA was digested with NotI and MseI, ligated with adapters, and amplified using PCR. This method potentially will detect two NotI-MseI PCR products from each unmethylated NotI site in the genome. The DNA was further amplified in 16 different PCR reactions with a random nucleotide added to each primer so that 1/16 of the fragments would be expected to amplify in each reaction. The NotI primer was fluorescently labeled in the final PCR, and reaction products were analyzed on the ABI gene scanner. Using this method, DNA samples from five autism brains and five control brains were compared. Perhaps surprisingly, the pattern of fragments was remarkably similar among different control brains and in comparison between control and autism brain samples. Occasional differences were identified that might represent either polymorphic restriction enzyme sites or differences in DNA methylation. Some of the changes were present in multiple autism brains but not in control brains. An additional five control brain samples and five autism samples are being analyzed, and the most promising candidate differences will be studied in greater depth. The MS-AFLP products are also being analyzed using array-CGH with human BAC DNAs. Array analysis offers the possibility for analysis of a larger number of potential methylation sites and for immediate identification of individual sites of variation or disease-related changes.

A Whole-Genome Linkage Scan Reveals an Imprinted Locus for Wilms Tumor on Chromosome 11p15. *S. Shete[1], C. Amos[1], C. Wu[1], X. Zhou[1], L. Strong[2], V. Huff[3].* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Cancer Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX; 3) Dept Clinical Cancer Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

Wilms tumor is one of the most common solid tumors of childhood, accounting for 8% of all childhood cancers. The etiology of Wilms tumor is genetically heterogeneous. Standard linkage analyses have shown suggestive evidence of linkage on chromosome 11p15. Because this region contains clusters of imprinted genes and because approximately 70% of Wilms tumors exhibit loss of imprinting, we performed genome-wide joint linkage and imprinting analyses in nine Wilms tumor families that do not carry mutation in tumor suppressor protein WT1. One family, WTX502, had a LOD score of 3.0 for linkage at the HRAS1 locus at 11p15.5 when a software program that allows for linkage analysis in the presence of imprinting is used. The heterogeneity LOD score based on all nine families was 2.2, with the estimated proportion of linked families equal to 0.38. The difference in LOD scores using the imprinting model and standard linkage analysis was 1.4. The empirical p-value for imprinting based on these analyses was 0.0024. Our results strongly suggest the existence of an imprinted gene at chromosome 11p15.5 that is implicated in the causation of familial Wilms tumor.

Identification of *cis*- and *trans*-acting factors modifying the risk of epimutations on chromosome 15. *C. Zogel[1], S. Böhringer[1], R. Varon[2], K. Buiting[1], B. Horsthemke[1].* 1) Institut fuer Humangenetik, Universitaetsklinikum Essen, Germany; 2) Institut fuer Humangenetik, Humboldt Universitaet Berlin, Germany.

Approximately 1-4% of patients with Prader-Willi syndrome (PWS) or Angelman syndrome (AS) have an imprinting defect on chromosome 15. In some of these patients, the incorrect imprint is the result of a microdeletion affecting the imprinting center (IC), which consists of two elements (the PWS-SRO and the AS-SRO). In most of the patients, however, the incorrect imprint is an epimutation that occurred in the absence of a DNA mutation. We have investigated whether common IC sequence variants are associated with an increased susceptibility to epimutations. We identified ten polymorphisms within the IC and found that the PWS-SRO and the AS-SRO lie on separate haplotype blocks. Using the transmission disequilibrium test, we did not observe preferential transmission of a paternal haplotype in 41 PWS trios, but found a trend for preferential maternal transmission of an AS-SRO haplotype (H-AS3) in 48 AS trios ($P = 0.058$). Furthermore, we obtained significant *P*-values for three combinations of three AS-SRO polymorphisms ($P = 0.021$), with two variants only found on H-AS3. We hypothesize that these polymorphisms affect the binding of a maternal imprinting factor and consequently the establishment of the maternal imprint. We also obtained evidence that homozygosity for the 677C>T variant of the 5,10-methylenetetrahydrofolate reductase (*MTHFR*) gene increases the risk of a maternal imprinting defect: the frequency of the TT genotype was significantly higher in 52 mothers of AS patients than in the patients' fathers or the general population ($P = 0.028$). MTHFR plays an important role in the synthesis of S-adenosyl-L-methionine (SAM), which serves as a methyl group donor for methyltransferases. Low SAM levels resulting from low enzymatic activity of the T variant may impair DNA methylation in the female germ line. In summary, our findings suggest that women with the IC haplotype H-AS3 or homozygosity for the *MTHFR* 677C>T variant have an increased risk of conceiving a child with an imprinting defect, although the absolute risk is low.

Definition of the minimal regions for the imprinting phenomenon : transgenic and evolutionary approches. *A. Paoloni-Giacobino, J.R. Chaillet.* Molecular Genetics and Biochem, Pittsburgh University, Pittsburgh, PA.

Genomic imprinting is an epigenetic mechanism of gene regulation in which only one parental allele of a gene is expressed. It is a conserved phenomenon in eutherian mammals, with regards both to the genes that are imprinted and the mechanism of epigenetic inheritance leading to monoallelic gene expression. Epigenetic modifications of alleles of imprinted genes are established in oocytes and sperm, and these modifications are then inherited. Differentially methylated domains (DMDs) of imprinted genes are the genomic sites of these inherited epigenetic imprints. As such, these regions might be the imprinting backbone upon which the fundamental processes of sex-specific methylation and imprinted gene expression are built. To define the minimal DMD sequence needed for imprinting, we choose two different approaches. First, we used a well characterised RSVIgmyc transgene which has been shown to be consistently imprinted at multiple random chromosomal integration sites. By substituting the RSVIgmyc DMD with DMD sequences from endogenous mouse and human imprinted genes, we have identified the tandem repeat portions of DMDs as being required for transgene imprinting in human and mice. In the second approach, we examined the conservation of the tandem repeats during primate evolution. Surprisingly, despite the functional significance of these tandem repeats, we found that their nucleotide sequences were poorly conserved. However, their repetitiveness and high CpG dinucleotide content were found to be strikingly well conserved. Together, these observations suggest an essential role for certain CpG-rich tandem repeats in the process of genomic imprinting.

Quantitative methylation-PCR analysis in Angelman syndrome patients with an imprinting defect. *K. Hosoki[1], K. Takano[1, 2], S. Saitoh[1].* 1) Department of Pediatrics, Hokkaido University Graduate School of Medicine, Sapporo, Japan; 2) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, NCNP, Kodaira, Japan.

About 2-5% of Angelman syndrome (AS) cases are caused by an imprinting defect (ID). IDs refer to a unique class of aberrant imprinting resulting in abnormal gene silencing. Most AS patients with an ID are sporadic and caused by an epimutation, while a small but significant proportion of patients carry a microdeletion in an imprinting center and inheritance is familial. Nazlican et al. (2004) reported that 30% of sporadic AS patients with an ID were associated with mosaic DNA methylation, and the ratio of normal DNA methylation was correlated with milder clinical symptoms. Thus, a quantitative methylation PCR (QmPCR) assay would be valuable for evaluating AS patients with an ID. We developed a QmPCR assay to detect the DNA methylation level at the *SNURF-SNRPN* CpG-island, a key imprinted gene in 15q11-q13. Bisulfite treatment was followed by PCR specific for the methylated and unmethylated alleles, and signal intensity was measured. We tested this method for a patient with a mosaic +idic(15)(q12), and the quantitative result was consistent with the ratio of chromosome mosaicism, confirming the usefulness of the system. We then investigated 5 sporadic AS patients with an ID, but did not detect maternal (methylated) signals in any patients. Therefore, we conclude that our series of AS patients with an ID are not associated with mosaic DNA methylation, suggesting that 30% of AS ID patients in our population have mosaic methylation. Nonetheless, the QmPCR analysis to detect DNA methylation in *SNURF-SNRPN* was reproducible and should provide a useful tool to investigate mosaicism in AS patients with an ID, and other rearrangements in 15q11-q13. Investigation of the ~ 15% AS patients with apparently normal *SNURF-SNRPN* methylation but without *UBE3A* mutations using QmPCR may uncover AS patients with a hidden ID and relatively high mosaicism, and we are now conducting such an investigation.

Epigenetic inheritance of three distinct methylation profiles in the *H19* DMR and their correlation to monoallelic expression. *J. Tost[1], H. Jammes[2], J.-M. Dupont[2, 3], M. Fellous[2, 4], I.G. Gut[1], D. Vaiman[2].* 1) Technology Development, Centre National de Genotypage, Evry , France; 2) Unité INSERM 709, Paris, France; 3) Université Paris 5, France; 4) Université Paris 7, France.

Imprinted genes are expressed from only one of the parental chromosomes. Generally they are located in clusters and epigenetically marked by DNA methylation, histone acetylation/deacetylation and histone methylation. Their parent-of-origin specific expression is classically associated with differential methylation of specific CpG-rich DNA regions (DMRs). We characterized the methylation status of DMRs associated with *IGF2* (the DMR homologous to mouse *Igf2* DMR2) and *H19*, two imprinted genes located on human chromosome 11p15.5 in placentas and lymphocytes. Quantitative methylation analysis at each consecutive CpG dinucleotide was performed by pyrosequencing. The methylation level of successive CpGs within the *IGF2* DMR was highly variable, yielding a DMR-specific profile irrespective of the biological sample, or individual. The average methylation level was compatible with the expected hemi-methylated state. Unexpectedly, the *H19* DMR, located upstream of *H19* often departed from the expected median-methylated stage in maternal lymphocytes as well as in placental samples. Rather, three distinct methylation levels were observed that were specific for a certain individual. A predominantly monoallelic expression of *H19* was preserved independently of the DMR methylation status demonstrating that DMR allele-specific methylation and allele-specific expression of imprinted genes are not always correlated. In addition, we could demonstrate a positive correlation between the expression levels of *IGF2* and *H19* in human placenta challenging the established point of view of inverse correlation between these two genes. Mendelian transmission of the methylation profile was tested using lymphocyte DNA from related individuals. The inheritance pattern of the methylation profiles was compatible with a simple model considering one gene with three alleles constituting the first example of transmission of an effect that impacts on DNA methylation profiles in a non pathological situation with this degree of complexity.

Beckwith-Wiedemann syndrome and Wilms tumor as a result of an epigenetic/genetic sequence rather than a single event. *D. Prawitt[1], T. Enklaar[1], C. Spangenberg[1], D. Reutzel[1], E. Lausch[1], J. Limon[2], D.E. Housman[3], J. Pelletier[4], B.U. Zabel[1].* 1) Molecular Genetics Lab, Children's Hosp/ Univ Mainz, Mainz, Germany; 2) Dept. Biology & Genetics, Medical University of Gdansk, Poland; 3) Cancer Research Center, Massachusetts Institute of Technology, Cambridge, MA, USA; 4) Dept. Biochemistry & McGill Cancer Center, McGill University, Montreal, Canada.

Genetic diseases can be caused by defects in genomic imprinting, a mechanism that normally leads to epigenetic silencing of one parental allele. A congenital overgrowth condition associated with imprinting defects in the chromosomal region 11p15.5 is Beckwith Wiedemann syndrome (BWS), with about 5% of the children developing embryonal tumors, mainly Wilms tumor (WT). Most frequently epigenetic alterations that cluster in two imprinting centers (IC), loss-of-function alterations in the *CDKN1C* gene and uniparental paternal disomy (patUPD) are observed. Hypomethylation of the proximal imprinting center (IC2), mediates silencing of the *KCNQ1* and *CDKN1C* genes. The distal IC1 is a differentially methylated repeat cluster positioned between *H19* and *IGF2*. Allelespecific binding of the zincfinger protein CTCF to IC1 regulates access of both genes to upstream enhancers. Inhibition of CTCF DNA interaction due to methylation of the CTCF binding sites on the paternal chromosome results in activation of the paternal *IGF2* promoters. Maternal microdeletions or hypermethylation of CTCF binding sites result in loss of imprinting (LOI) of *IGF2*. Consequentially biallelic *IGF2* expression has been thought to be causative for BWS. In an extraordinary familial case of BWS with WT we describe a maternally inherited IC1 microdeletion, associated with *IGF2* LOI and upregulation of *IGF2*-mRNA but without disease manifestation. As an additional event, one affected family member displays a genomic duplication of the maternal 11p15.5 allele harbouring the IC1 microdeletion. Based on our findings we propose a model in which the BWS-WT phenotype is characterized by an increase of IGF2 levels due to a defined series of (epi-)genetic lesions resulting in critical activation of the receptor signaling cascade.

Deregulated expression of nuclear *Ube3a-ATS* upon shRNA-mediated knockdown of *Ube3a*. *M.A. Calciano, V.N. Sotirova, M. Landers, M. Lalande.* Genetics & Dev. Biol., Univ. Connecticut School of Medicine, Farmington, CT.

Failure to inherit a normal active maternal copy of the gene encoding ubiquitin protein ligase E3A (UBE3A) results in the neurogenetic disorder, Angelman syndrome. UBE3A is transcribed predominantly from the maternal allele in brain but is expressed from both alleles in most other tissues. A current hypothesis is that brain-specific silencing of the paternal UBE3A allele is mediated by a large (>500 kb) paternal noncoding antisense transcript (UBE3A-ATS). The murine P19 embryonic carcinoma (EC) cell line is a widely used model of *in vitro* neuronal differentiation and is suitable for studying certain aspects of the interaction between *Ube3a* and *Ube3a-ATS*. We have used a 7SK polymerase III promoter vector system to express shRNAs against *Ube3a* and achieved stable knockdown of *Ube3a* RNA and protein levels in P19 cells. Knockdown of *Ube3a* does not appear to affect either gross neuronal morphology during P19 cell differentiation or the expression of neuronal markers such as *Gabr3*, *-tubulin III*, *MAP2* and *Tau-1*. shRNA-mediated knockdown of *Ube3a* in P19 cells does, however, result in increased expression of *Ube3a-ATS*. The levels of the *Ube3a-ATS* transcript are augmented in the nuclear fraction of P19 cells in which *Ube3a* is knocked down, a result consistent with the predominant nuclear localization of *Ube3a-ATS* in P19 cells. The cell fractionation experiments also reveal that *Ube3a* is a predominantly nuclear transcript and that the shRNAs are efficiently silencing *Ube3a* in the nucleus. These results strongly suggest a nuclear mechanism whereby *Ube3a* modulates *Ube3a-ATS* rather than the exclusive reciprocal interaction that is common to other imprinted genes. While the nature of the sense-antisense interaction at the *Ube3a* locus remains to be elucidated, we favor a model whereby *Ube3a* represses *Ube3a-ATS* via a transcriptional or chromatin silencing mechanism. We also report that up-regulation of *Ube3a-ATS* is observed in a mouse model of Angelman syndrome and suggest that the increased levels of *Ube3a-ATS* may contribute to the phenotypic manifestations of this neurogenetic disorder.

Genomic imprinting of *Ube3a* is not entirely dependent on an antisense RNA. *D.C. Colosi, V.N. Sotirova, M. Lalande.* Dept. of Genetics and Developmental Biology, University of Connecticut, Farmington, CT.

The majority of Angelman syndrome (AS) cases result from the failure to inherit a normal maternal allele of the imprinted gene encoding ubiquitin ligase E3A (UBE3A). In normal brain (mainly hippocampus, cerebellum, olfactory bulb), *Ube3a* is expressed predominantly from the maternal allele, while a non-coding antisense RNA (*Ube3a-ATS*) is exclusively transcribed from the paternal allele. The current hypothesis is that the brain-specific *Ube3a-ATS* silences the paternal *Ube3a* in cis.

We are studying the imprinted expression of *Ube3a* in R1 murine embryonic stem (ES) cells. The R1 ES cell line is derived from a cross between the 129/SvJ and 129/Sv-+$^{Tyr+p}$ mouse strains. In the paternal 129/Sv-+$^{Tyr+p}$ strain, a segment of chromosome 7 that includes all genes from the AS/Prader-Willi syndrome critical region, is of non-129 origin. As a result, the parental *Ube3a* alleles can be discriminated using single nucleotide polymorphisms. Upon retinoic acid-stimulated neuronal differentiation of R1 ES cells, *Ube3a-ATS* transcription is detectable by seven days after induction.

Here we report that, in undifferentiated R1 ES cells and at early time points after induction, expression of *Ube3a* is predominantly from the maternal allele. Since *Ube3a-ATS* is not expressed until later during the process of neuronal differentiation, our data strongly suggest that imprinting of Ube3a does not strictly depend on the expression of *Ube3a-ATS*. However, a more marked repression of *Ube3a*, and a decreased paternal contribution is observed in the ES cell derived-neurons that co-express *Ube3a-ATS*. Our studies suggest that the mechanism of imprinting of *Ube3a* in stem cells, and during the very early stages of differentiation is independent of *Ube3a-ATS*. in fully differentiated neurons, however, it appears that *Ube3a-ATS* plays a role in enhancing repression of the paternal *Ube3a* allele. These findings suggest the possibility of distinct imprinting mechanisms for *Ube3a* in stem cells and stem cell-derived neuronal cells. Supported by NIH R01-NSO30628 and T32DE07302.

Genome-wide methylation in MZ twin pairs concordant and discordant for reading ability using an optimized oligonucleotide array. *E. Hatchwell[1], Y. Wang[1], T. Richmond[2], R. Plomin[3], I.W. Craig[3].* 1) Cold Spring Harbor Laboratory, 1 Bungtown Road, Cold Spring Harbor, NY11724, USA; 2) NimbleGen Systems Inc., One Science Court, Madison, WI 53711, USA; 3) SGDP Centre, Box PO 82, Institute of Psychiatry, Denmark Hill, London SE5, UK.

Discordance in monozygotic (MZ) twins is a widely observed phenomenon but one for which few explanations are generally lacking. We have studied genome-wide methylation patterns in 8 MZ twin pairs, 4 concordant and 4 discordant for reading ability. Our pilot study has two broad aims: 1. To estimate the level of DNA methylation variability in MZ twins in general; 2. To search for genomic regions whose methylation pattern is dramatically, and abnormally altered in our discordant twin pairs. We have designed and optimized a genome wide oligonucleotide array, which interrogates MspI/HpaII sites distributed throughout the genome. Our basic design approach is as follows: 1. In silico restriction analysis was used to generate a list of small (200-800bp) MspI fragments; 2. Arrays containing 50-mer oligonucleotides recognizing these small MspI fragments, and chosen to be as non-repetitive as possible, were synthesized using Maskless Array Synthesis (MAS) technology (NimbleGen Systems Inc, Madison); 3. A subset of all 50-mers was selected for the final design on the basis of ratiometric changes observed after pre-digestion of HpaII fragments with a variety of frequent 4-cutters. For this approach to be successful, it was necessary to optimize the method of generating HpaII representations from small amounts of starting material. This was achieved in a 2-step PCR protocol. Briefly, genomic DNA was digested with HpaII, adapters ligated and material amplified by PCR in two stages. Our protocol results in the amplification of fragments in the range 200-800bp, closely mimicking the design of the arrays. Our preliminary evidence suggests the presence of wide variability in methylation status at many genomic sites. We are currently validating a representative portion of altered HpaII sites using pyrosequencing and other methodologies.

Quantitative Methyl Sensitive PCR as an Alternative to Southern Analysis for Molecular Diagnosis of Beckwith-Wiedemann Syndrome. *B. Coffee, K. Muralidharan.* Dept Human Genetics, Emory University, Atlanta, GA.

Beckwith-Wiedemann Syndrome (BWS) and isolated hemihyperplasia are associated with DNA methylation defects at 11p15. The DNA methylation defects can occur at one of two differentially methylated regions (DMRs) located immediately upstream of the H19 gene or in the promoter of the Lit1 gene (referred to as DMR1 and DMR2, respectively). About 50% of the cases of BWS have loss of DNA methylation at the Lit1 promoter, whereas only 2% of the cases have identifiable hypermethylation at the H19 locus. Another 10-20% of cases are due to paternal uniparental disomy (UPD) of 11p15. Currently, molecular diagnosis of BWS testing is done by assessment of DNA methylation by Southern blot analysis using methylation sensitive restriction enzymes. Here we describe the use of a quantitative methyl sensitive PCR (MSP) as an alternative to Southern analysis. This method takes advantage of the differential deamination of cytosine and 5-methylcytosine to uracil by sodium bisulfite allowing the distinction between methylated and unmethylated DNA. This method will detect both loss of Lit1 DNA methylation as well as paternal 11p15 UPD, accounting for 60-70% of the cases of BWS and the majority of cases of isolated hemihyperplasia. The advantages of the quantitative MSP method is that it requires far less DNA, is less labor intensive and has a faster turn around time than the traditional Southern method.

Analysis of Epigenetic Control of *MECP2* in Autism. *M. Shinawi[1], A. Haldipur[1], YH. Jiang[1], R. Stevenson[2], AL. Beaudet[1].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Greenwood Genetic Center, South Carolina 29646, USA.

Genetic predisposition to autism is evident from family and twin studies. So far, genome-wide linkage studies have failed to provide a strong evidence for major autism-related loci. Male sex is the strongest and most consistent risk factor in autism. *MECP2* is an X-linked gene encoding a methyl-CpG binding protein that has been implicated recently in regulating genes involved in social behavior. Furthermore, there is evidence that duplication of *MECP2* (the Rett gene) with presumptive over-expression causes neurologic abnormalities in males. Despite the resemblance between the phenotypes of autism and Rett, *MECP2* mutations are an infrequent cause of essential autism. We are testing the hypothesis that epigenetic abnormalities (epimutations) rather than mutations of *MECP2* might be a more common cause of autism. We analyzed the methylation of the CpG island at the promoter of *MECP2* in lymphoblast cell lines of 44 autistic males and 14 autistic females from the AGRE, NIMH, and South Carolina Autism Project collections, and compared these to 28 controls (13 females and 15 males). In addition, brain samples from 8 autistic individuals were examined and compared to 5 normal brains. The methylation status was tested by Southern blot analysis after digestion with methylation sensitive enzyme. In all lymphoblast and brain samples from males, the DNA was completely unmethylated. For all brain samples and lymphoblast lines from control females and for most lymphoblast lines from females with autism, the data were consistent with the interpretation that the inactive X chromosome was methylated and the active X unmethylated. However, two lymphoblast cell lines from unrelated females with autism demonstrated hypomethylation. Additional studies are underway to test more brain samples, to perform ChIP assay, to precisely evaluate the DNA methylation by bisulfite sequencing, and to test fresh blood samples to avoid the possible artifacts of methylation arising in cell culture. We propose that epigenetic dysregulation of *MECP2* could be a causative factor in some fraction of autistic patients.

Comprehensive DNA Methylation Profiling by Real-time Quantitative PCR. *M.O. Dorschner, M. Weaver, A. Schafer, K. Lee, J. Neri, J. Goldy, J.A. Stamatoyannopoulos.* Molecular Genetics, Regulome Corporation, Seattle, WA.

We have developed a high-throughput methylation profiling technology based on real-time quantitative PCR (HMqPCR) and the sensitivity of the restriction enzyme, McrBC to DNA methylation. Large genomic segments can be rapidly scanned for methylation sensitivity at 250 bp intervals by interrogating a region of interest with a series of contiguous qPCR assays. Methylation sensitivity is expressed quantitatively as a copy number ratio of the McrBC-digested versus undigested DNA and reported as a methylation score ranging from 0 to 1. After plotting methylation scores according to genomic position, a sophisticated outlier detection algorithm is employed to identify regions of methylation sensitivity. To demonstrate the capability of our assay to detect localized hypo- and hypermethylation, we applied this technique to two 500kb regions of the human genome, one containing the beta globin (HBB) locus and the other, insulin growth factor 2 (IGF2). A 15kb region harboring the ^{A} and ^{G} genes, was found completely unmethylated in cell line K562, while the beta- and delta globin promoters were heavily methylated. A large region of hypermethylation was observed immediately upstream of the beta globin LCR. This region coincides with a chromatin domain boundary. A differentially methylated region (DMR) of ~25kb, located downstream of IGF2 was found completely unmethylated in transformed lymphoblasts. This segment corresponds precisely to a DMR known to play a role in imprinting. The regions flanking the DMR contained many sites of localized hyper- and hypomethylation, as well as a number of methylation hotspots. Methylation of repetitive DNAs was remarkably heterogeneous. HMqPCR can be used: 1) to identify DMRs, 2) to localize sites exhibiting inter-individual variation in methylation, 3) to identify tissue-specific sites of methylation, 4) to establish detailed methylation profiles of large genomic regions and 5) to develop biomarkers for the molecular diagnosis of disease. All these goals are critical to our understanding of epigenetic control of gene expression and how aberrant DNA methylation contributes to human genetic disease.

High-throughput detection and quantification of CpG sites methylation levels in the genome using MASSCleave technology. *I. Ragoussis[1], L. Marcelline[1], V. Viprakasit[2, 3], S. Smiley[2], R. Gibbons[2], D. Higgs[2], S. Collela[1].* 1) Wellcome Trust Ctr Human Gen, Univ Oxford, Oxford, United Kingdom; 2) 2MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK; 3) 3Department of Pediatrics and Siriraj-Thalassemia Research Program, Faculty of Medicine, Siriraj Hospital, Mahidol University, Bangkok 10700, Thailand.

Epigenetics contribution to human disease is very well recognized, but not completely understood. Epigenomics, i.e. the whole-genome study of epigenetic variation, is possible thanks to new technologies and the availability of genome sequences. We used MassCLEAVE technology (Sequenom) to detect methylation at multiple CpG sites in a given DNA sequence. This protocol, originally developed for SNP discovery, can be used to detect the C to T chemically induced modification after bisulfite treatment at CpG sites in the genome sequence (where a C will be detected if methylation is present). We focused our analysis on a number of CpG sites known to be affected by methylation; including the INK4A (p16) promoter and three sites in the -globin cluster on chromosome 16. The MASSCleave protocol on bisulfite treated DNA readily detects the methylation status of multiple CpG sites interrogated in a single amplicon. We used serial dilution experiments to test the sensitivity of the method in the quantification of methylation levels. To evaluate the quantification potential of MASSCleave approach, we compared our data with the established Allelotyping protocol for some of the CpG sites for which we could design MASSExtend assays. We performed statistical analyses to compare the performance of these two approaches in DNA methylation profiling. In conclusion, MassCLEAVE offers a valuable platform for high-throughput methylation analysis and allows semi-quantitative analysis of the methylation levels. The implementation of robust high-throughput epigenomics profiling methods is paramount for a better understanding of the role of epigenetics alteration to complex diseases susceptibility.

Direct comparison of two different strategies to sequence bisulfite-treated genomic DNA for DNA methylation analysis in genetic diseases and cancer samples. *M.F. Fraga[1], A. Rico[2], B. Finkelnburg[3], M. Esteller[1].* 1) Epigenetics Laboratory, Spanish National Cancer Center, Madrid, Madrid, Spain; 2) Applera France, Applied Biosystems; 3) Applera Deutschland GmbH, Applied Biosystems.

Enzymatic methylation on the cytosine of genomic DNA (gDNA), specifically methylation of cytosines (C) at CpG motifs located in the CpG island promoter regions, shuts down gene expression. A well known method to study methylation patterns is to treat gDNA by sodium bisulfite to distinguish methylated cytosine (5mC) from unmethylated C, which is deaminated to uracil (U) and replaced by thymine (T) in subsequent amplification. 5mC still remains as C. Subsequent amplification can focus on selective amplification of methylation patterns in CpG islands (methyation specific PCR, MSP) or on amplification of bisulfite treated (converted) gDNA (Bisulfite treatment specific PCR, BIS). Selection of PCR focus is done by primer design. After PCR, sequencing can clarify the methylation pattern. Due to very imbalanced nucleotide composition after bisulfite treatment bias in amplification of bisulfite treated gDNA as well as in sequencing products may lead to experimental problems. PCR improvements during amplification of bisulfite-converted gDNA by the use of universal tailed primers, combined with changes in thermal cycling and reactant concentrations are described earlier. These PCR products can be sequenced by using the universal primer tails. This method will be compared to the cloning of BIS PCR products for sequencing the bacterial clones. For the whole comparison two different primer design softwares were used to generate primer sets for 2 regions of the BRCA1 gene. All primer sets will be used untailed as well as with universal tails for direct sequencing of PCR products. Only untailed PCR products will be cloned. The rate of success will measured by number of steps necessary to generate a specific PCR product, number of steps to generate specific sequences and quality of sequences. Finally we will discuss the usefulness of both methods with respect to specific issues targeted by the scientific community, e.g. quantification of methylation.

Promoter methylation of the TSLC1/IGSF4 and DAL-1/4.1B genes involving a novel tumor suppressor cascade in human non-small cell lung cancer detected by bi-sulfite SSCP analysis. *Y. Murakami[1], S. Kikuchi[1], D. Yamada[1], T. Fukami[1], M. Masuda[1], M. Sakurai-Yageta[1], Y.N. Williams[1], T. Maruyama[1], H. Asamura[2], Y. Matsuno[3].* 1) Tumor Suppression Project, Natl Cancer Ctr Research Inst, Tokyo, Japan; 2) Dept. Thoracic Surgery, Natl. Cancer Ctr Hospital, Tokyo, Japan; 3) Dept. Diagniostic Pathology, Natl. Cancer Ctr Hospital, Tokyo, Japan.

TSLC1/IGSF4 is a tumor suppressor gene in human non-small cell lung cancer (NSCLC) that we have previously identified by functional complementation. TSLC1/IGSF4 encodes an immunoglobulin-like cell adhesion molecule and is expressed in most epithelial tissues including the lung, while the expression is lost in many human cancers including NSCLC. We also identified that TSLC1/IGSF4 protein associated with an actin-binding protein, DAL-1/protein 4.1B, through its cytoplasmic domain, suggesting that TSLC1/IGSF4 and DAL-1/4.1B cascade is involved in cell adhesion coupled with cytoskeleton organization. In the present study, we examined the methylation status of the TSLC1/IGSF4 and DAL-1/4.1B genes by bisulfite-SSCP analysis. Bisulfite-SSCP is a sensitive method for the quantitative detection of the methylation status on the basis of the allelic information. Using this method, we found that the promoters of the TSLC1/IGSF4 and DAL-1/4.1B genes were methylated in 46 (45%) and 59 (57%) of 103 primary NSCLC, respectively. Methylations of the TSLC1/IGSF4 and DAL-1/4.1B promoters were significantly associated with a shorter disease-free survival in adenocarcinoma patients (p=0.049 and p=0.0011, respectively). Furthermore, DAL-1 methylation was observed preferentially in tumors with advanced stages in adenocarcinomas (p=0.0026). On the other hand, the TSLC1/IGSF4 methylation was significantly associated with heavy smoking (Brinkman index >800) (P=0.0054). Finally, about 70% of primary NSCLC tumors represented epigenetic inactivation of either the TSLC1/IGSF4 or the DAL-1/4.1B gene. These results strongly suggest that the aberration of the TSLC1/IGSF4 and DAL-1/4.1B cascade is deeply involved in the majority of primary NSCLC tumors and provides an indicator for poor prognosis.

High-throughput DNA methylation profiling using universal bead arrays. *M. Bibikova[1], Z. Lin[2], L. Zhou[1], E. Chudin[1], E. Wickham[1], B. Wu[1], N. Thomas[2], Y. Wang[2], C. Seifart[3], D. Barker[1], M. Chee[1], J. Floros[2], J. Fan[1].* 1) Illumina Inc., San Diego, CA; 2) Penn State University, Hershey, PA; 3) Philipps-University of Marburg, Germany.

We developed a multiplexed DNA methylation detection method based on high-throughput genotyping of bisulfite-converted genomic DNA. The technology uses Illuminas standard GoldenGate assay format and BeadArray^{TM} technology platform for genetic analysis. We developed a set of internal controls to monitor the assay performance, and demonstrated that current assay sensitivity and specificity is sufficient to detect changes in methylation status at more than 1,000 different sites simultaneously with 200 nanograms of human genomic DNA. Reproducible DNA methylation profiles were obtained within replicates (an average R^2 of 0.98). We estimated that our assay can resolve a 10% methylation difference between samples with 95% confidence.

We used the assay developed for 370 genes for methylation profiling in seven normal DNA samples derived from different tissues and 17 colon, breast, lung and prostate cancer cell lines. All cancer samples were correctly separated from normal, and highly specific methylation signatures were obtained for each cancer type. Methylation levels of five loci in six lung cancer cell lines and normal lung tissue were validated using methylation-specific PCR.

We applied this technology to DNA methylation analyses in lung cancer. We analyzed the methylation status of 370 genes (>1500 CpG sites) in 46 lung cancer and normal tissue samples, to discover methylation-based biomarkers for lung cancer. Panels of squamous cell carcinoma specific and adenocarcinoma specific methylation markers were identified at high confidence ($P < 0.001$). The markers identified for the adenocarcinoma were further validated in an independent sample set ($N = 24$). This technology should prove useful for DNA methylation analyses in large populations, with potential application to the classification and diagnosis of a broad range of cancers.

Self-association of human DNMT3A and DNMT3B DNA methyltransferases. *Z.X. Chen, A.D. Riggs.* Division of Biology, Beckman Research Institute of the City of Hope, Duarte, California, 91010.

Proper control of DNA methylation patterns is essential for mammalian development. Abnormal methylation patterns have been linked to cancer and several human genetic diseases. Two de novo DNA methyltransferases, Dnmt3a and Dnmt3b, have been shown to be required for the establishment of DNA methylation patterns in germ cells and early embryos. The mechanism by which DNMT3A and DNMT3B carry out de novo methylation remains largely unknown. Here, we demonstrate, using the yeast two-hybrid system and co-immunoprecipitation analysis, that human DNMT3A and DNMT3B are capable of self-association. Deletion analysis revealed that the C-terminal catalytic domain is responsible for the self-interaction. Since most mutations causing immunodeficiency, centromeric instability, and facial anomalies (ICF) syndrome occur in the catalytic domain of DNMT3B, we investigated whether these mutations can affect the ability of DNMT3B to self-interact. Two DNMT3B ICF mutants (H814R and D817G) show reduced ability to interact with themselves in the yeast two-hybrid system. In addition, DNMT3A can interact with DNMT3B through their C-terminal catalytic domains. Taken together, these results suggest that both DNMT3A and DNMT3B might functionally exist as dimers or higher-order oligomers. We propose that the self-association of catalytic domain may play a role in regulating activity and function of DNMT3 methyltransferases.

Epigenetic profiling of CpG islands in sporadic breast cancers : a pilot study. *J. Flanagan[1], N. Waddel[2], S.C. Wang[1], P. Simpson[3], S.R. Lakhani[3], A. Petronis[1], G. Chenevix-Trench[2].* 1) Dept Neurogenetics, Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) Queensland Institute of Medical Research, Herston, Brisbane, Australia; 3) Department of Pathology, University of QLD. Brisbane, Australia.

There is a large body evidence for an involvement of methylation of an increasing number of genes in sporadic breast cancer. This pilot study aimed to assess microarray based epigenetic profiling for the identification of differentially methylated genes in sporadic breast cancer. Hypomethylated DNA was enriched using methylation sensitive restriction digestion and adaptor mediated PCR from pairs of macrodissected tumor cells and normal breast epithelium (N=5). These enriched fractions were hybridised in duplicate to CpG Island microarrays containing 12,192 individual CpG island clones from the Sanger Institute. A modified CGH protocol was also performed to discriminate DNA sequence variations (SNPs, deletions, insertions) from methylation variations. Validation of the arrays was performed using bisulphite modifification and primer extension using the ABI SNaPshot assay. There was considerable heterogeneity among the breast tumour/normal pairs with 65-203 out of 12,000 CGIs identified as methylated in each tumour relative to the matching normal breast. However, combined data for the 5 tumours show 13 CpG islands methylated in normal but not tumour, and 39 CpG islands methylated in tumour but not normal. The CGH analysis identified 845 spots that show genomic gain in the tumour samples compared to the normal and 63 spots that show genomic loss in the tumour sample compared to normal. Combining the methylation and CGH data identified 10 CpG islands methylated in normal but not tumour and 15 CpG islands methylated in tumour but not normal. The SNaPshot assay validated 8/13 spots suggesting a validation of approximately 60%. This pilot study has shown that microarray-based epigenetic profiling can identify differentially methylated genes in breast tumor DNA. This study also highlights the importance of discriminating between SNPs and real methylation differences when using methylation sensitive enzymes.

Deconstructing position effects: *SOX9* regulation via the Shh pathway and distal regulatory elements. *G.A. Bien-Willner[1], P. Stankiewicz[1], J.R. Lupski[1,2,3].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Position effect, or the change in a genes expression resulting in patient phenotype without intragenic mutations, has been described in patients with chromosome translocations even when the breakpoints occur at some distance from the causative gene. This has resulted in speculation of the importance of chromatin interactions occurring upwards of a megabase proximal or distal from the gene, and effecting its expression. *SOX9* is one such gene susceptible to position effects; it is responsible for male sexual determination and bone formation. Several patients with campomelic dysplasia (CD) have been described without *SOX9* mutations and with translocation breakpoints as far as 932 kb from the gene. Studying one such case (900 kb upstream *SOX9*) led to the prediction of two possible *cis*-acting regulatory elements of *SOX9*, named SOX9cre1 and SOX9cre2, located 1.1 Mb proximal to *SOX9*. Here, we investigate the possible role of these regulators in *SOX9* expression using reporter assays in the *SOX9*-expressing chondrosarcoma cell line SW1353, and assess their role in the tissue-specific activation of the gene. SOX9cre1 and SOX9cre2 increase the expressional activity of a minimal *SOX9* promoter nearly two-fold, consistent with an enhancer role. *In silico* studies identify a GLI1 binding site in the 2.1 Kb SOX9cre1, suggesting that *SOX9* may be activated directly through the sonic hedgehog (Shh) signaling pathway. The implication of the Shh signaling pathway in *SOX9* expression prompts us to test these regulators potential interactions with Gli1, Nkx3.2, and BMP in EMSA studies, as well as locate other long-range regulators of *SOX9* utilizing ChIP-on-chip experiments. Our experiments are further revealing the sea of regulation that lies in the gene desert proximal to *SOX9*.

Deletion of the endogenous *HPRT* promoter on the active X chromosome leads to complex alterations of histone modification patterns. *S. Rodriguez-Jato, J. Shan, S.L. Kang, J.O. Brant, A. Heggestad, T.P. Yang.* Dept. Biochemistry and Molecular Biology, College of Medicine Univ. Florida, Gainesville, FL. 32610.

Transcriptionally active and repressed genes are associated with distinct patterns of histone modifications. Promoter regions and their associated factors have been postulated to recruit modifying enzymes that establish and/or maintain these patterns. We are examining the role of the promoter in maintaining transcriptionally active epigenetic states. We targeted a 323 bp deletion of the endogenous *HPRT* promoter on the active X chromosome in human HT1080 cells which removed nearly all known transcription factor binding sites in the promoter and abolished transcription. Previous analysis of this deletion showed loss of the DNase I hypersensitive site in the *HPRT* promoter region, but little or no change in general DNase I sensitivity or DNA methylation patterns across the locus. We now have examined the effect of this deletion on histone modification patterns using ChIP assays on the control parental and mutated cells. Analysis of nine sites across the wild type locus detected high levels of dimethylated H3 lysine 4 (H3-K4diMe) over the promoter and 5 transcribed region which decreased to background levels ~12 kb downstream of the promoter. Additionally, high levels of acetylated H4 (H4 Ac), H3-K9Ac and H3-K4triMe in control wild type cells were confined to the 5 transcribed region. Deletion of the minimal promoter resulted in a significant decrease in the levels of H3-K9Ac and H3-K4triMe. However, the mutation also led to an increase in H4Ac levels (predominantly in the 5 flanking region), and had no effect on H3-K4diMe levels. Our data suggest that H4 hyperacetylation and H3-K4diMe are not dependent on regulatory elements in the minimal promoter (and/or active transcription), and are not sufficient to maintain DNase I hypersensitivity of chromatin in the region. In contrast, maintaining H3-K9Ac and H3-K4triMe appear to require one or more regulatory elements associated with the minimal promoter region and/or active transcription. Thus, different mechanisms may be involved in maintaining specific types of histone modification patterns on active genes.

RNAi is an intrinsic mechanism for human L1 retrotransposon control. *N. Yang, H.H. Kazazian.* Dept Genetics, Univ Pennsylvania, Philadelphia, PA.

LINE-1s or L1s are highly abundant retrotransposons comprising ~17% of the human genome. A full-length human L1 (L1Hs) is ~6 kb, containing a 5UTR, two ORFs and a 3UTR. As an autonomous non-LTR retrotransposon, L1 moves by a copy and paste mechanism, i.e., the precursor L1 is transcribed into RNA and then reverse transcribed and integrated into a different locus of the genome. Most L1Hs are retrotransposition-defective due to 5 truncation, inversion or mutation, still there are ~5,000 full-length L1Hs and ~100 of them are potentially retrotransposition-competent in the average diploid genome. Although driving genome evolution in constructive ways, L1 retrotransposition can also be detrimental to the host and has to be controlled. Since transcription of L1Hs starts around the +1nt of 5UTR and an antisense promoter (ASP) has been reported to be located within the 5UTR, we tested the hypothesis that bi-directional transcripts of L1Hs 5UTR could produce small interfering RNAs (siRNAs) and reduce retrotransposition via an RNAi mechanism. In the present work, we successfully detected the antisense transcript driven by ASP, mapped its start site by 5RACE and found L1Hs specific ~21nt siRNAs using Northern blot. To facilitate further study, we used a Flp-In system and established stable cell lines expressing the d2EGFP gene driven by a variety of 5UTR fragments. We found that deletion of the ASP promoter region increased d2EGFP expression in established cell lines and increased L1Hs retrotransposition activity in a cell culture based assay. Finally, targeting of Dicer1, a key component in RNAi pathway, almost doubled the retrotransposition activity of full-length L1Hs; however, this effect was abolished by the deletion of the ASP promoter region. In conclusion, we provide the first evidence that an RNAi mechanism triggered by antisense transcript may control retrotransposition of full-length L1Hs in an efficient and economic way. Therefore, RNAi may be an evolutionarily conserved mechanism of genome defense against invading nucleic acids, such as transposons and viruses, even in mammalian systems. Our work may also shed light on the understanding of the regulatory role of abundant antisense transcripts in the eukaryotic genome.

Examining the question of chromosome counting in X inactivation using human triploid fibroblasts. *S.M. Gartler[1,2], K.R. Varadarajan[2], P. Luo[2], T.K. Canfield[2], D.K. Barden[3], R.S. Hansen[2].* 1) Dept. Genome Sciences Univ. Washington, Seattle, WA; 2) Div. Medical Genetics, Univ. Washington, Seattle, WA; 3) Dept Laboratory Medicine, Univ. Washington, Seattle, WA.

Dosage compensation in mammals is achieved by the transcriptional silencing of one of the two X chromosomes in the female early in development (X chromosome inactivation; XCI). It is widely assumed that an early event in XCI is a counting step that results in one active X chromosome per diploid autosomal set, with any additional Xs rendered inactive. For normal female diploids and X chromosome aneuploids, however, there is no need to assume a chromosome counting step to achieve this ratio. Simply marking one X for active status would be sufficient if inactivity is the default state for all remaining Xs. To critically evaluate the chromosome counting idea, a system is needed in which the one active X per diploid autosomal set cannot be achieved, such as in triploids. If chromosome counting is involved, XCI in triploids is expected to be unstable, as suggested by Jacobs et al. (Am J Hum Genet 31:446-457, 1979), particularly during the developmental window when XCI is established. Several human triploid cultures are mosaic with respect to the number of inactive X chromosomes. This mosaicism could result from: 1) XCI instability because of the abnormal X:autosome counting problem, 2) stochastic XCI because of a limiting autosomal factor involved in a threshold mechanism, or 3) a one-X-active marking mechanism followed by inactive X chromosome loss and cell selection. Our data on cultures of mosaic triploid fibroblasts and derived clones excludes the one-X-active model, implying that the XCI mosaicism seen in triploids reflects choices made during X inactivation. These data, therefore, are compatible with XCI models involving X:autosome counting and/or threshold mechansims for marking the active X using autosomal factors.

Skewed XCI leads to the expression of Hemophilia A in three heterozygous females in an Atlantic Canadian kindred. *N. Renault[1], S. Dyack[2], M. Dobson[3], T. Costa[4], W. Greer[1].* 1) Pathology; 2) Medicine; 3) Biochemistry, Dalhousie University, Halifax, NS; 4) Medical Genetics, Ste-Justine Hospital, Montreal, QE.

Background: A family presented with 3 heterozygous females affected with hemophilia A (HA), an X-linked recessive (SXR) bleeding disorder typically expressed in males and homozygous females. In rare cases, skewed X-chromosome inactivation (XCI) in heterozygous women has led to the expression of HA and other SXR disorders. Our objective is to elucidate the mechanism of HA expression in these heterozygous females.

Hypothesis: We hypothesize that our participants (ppt) are affected with HA because of skewed XCI, and, since multiple females in the family are affected, the skewing is due to genetics, rather than to random chance.

Results: We assessed 14 ppt for the factor VIII gene (F8) inversion common in severe HA. We found 2 males, and 6 carrier females with the type II inversion, and 6 normals. We measured factor VIII levels in 14 ppt and found 3 with severe HA (2 males, 1 female), and 2 females with mild HA. 9 females were informative for XCI skewing at the HUMARA locus. 4 had severe skewing (>80%) in peripheral blood lymphocytes. The factor VIII levels in carrier females correspond to the prevalence of active Xs containing normal F8 in all cases. Preliminary evaluation of buccal mucosa suggests that skewing at this site does not differ significantly from blood. Through microsatellite analyses, we have identified a region, Xq24-q27, that segregates with the skewing phenotype in this family. This contains a region (Xq24-25) previously associated with familial XCI skewing.

Conclusions: Skewed XCI is the mechanism by which 3 heterozygous females are expressing HA, furthermore, in accordance with the literature, we feel that since there are 4 females skewed >80%, the skewing observed is due to genetic control.**Future directions:** More ppt have been recruited and more microsatellites are being analyzed to narrow down the critical region, and we are exploring the development of a cell culture system for analyzing XCI skewing.**Funding:Killam Foundation, CIHR, CDHA**.

Genetic Study of Glaucoma and Age-Related Macular Degeneration Using the Utah Population Database. *J. Baird[1,2], N. Zabriskie[2], P.S. Bernstein[2], Z. Yang[1], K. Zhang[1,2], Y. Yao[1], D. Gibbs[1], J. Meyer[1], R. Gomez[1].* 1) Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Ophthalmology and Visual Sciences, University of Utah, Salt Lake City, UT.

Introduction: Age-related macular degeneration (AMD) and primary open-angle glaucoma (POAG) are two leading causes of blindness in the US and the developed world. Genetic predisposition plays an important role in AMD and POAG, but identification of genes for these two conditions has been hampered by the multi-factorial nature of the disease. The Utah Population Database (UPDB) was created by the University of Utah and contains over 20 million records. It is made up of many data sets including genealogies, birth and death certificates, and drivers license data. There are two major data sets from which family members can be identified: 1.6 million genealogy records and 1.8 million Utah birth certificates. The genealogy records can span as many as eleven generations. **Methods:** We searched the medical record database of the University of Utah Hospitals and Clinics and identified patients with AMD and glaucoma. We then performed cross-match analysis with genealogy records at the UPDB to identify and recruit extended families with clustering of AMD and glaucoma. **Results:** We identified 5,172 AMD and 4,328 POAG patients from 1.5 million medical records. Cross-matching and clustering analyses with the UPDB identified 15 extended large families with AMD and 14 with POAG using our criteria of having five or more living affected members within each family. We have also established B lymphoblastoid cell lined for 454 AMD patients, 54 POAG patients, and 270 normal age-matched controls. **Discussion:** We have identified large pedigrees with multiple affected members with AMD and POAG. The resources established will aid greatly in our effort to identify genes causing these diseases.

Inversion at the X-linked FLN-EMD locus is common and recurrent. *D.L. Nelson[1], N. Lamb[2], S.T. Warren[2], P.E. Bonnen[1,3].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) Rockefeller University, New York, NY.

Genomic rearrangements are increasingly recognized for their role in susceptibility to disease and in genetic variation. The question of whether such rearrangements are stable enough to be transmitted and tracked in studies for disease susceptibility remains unresolved, and there is little data regarding the frequency of inversions in humans. The first polymorphic inversion described in humans comprises a 48 kb region spanning the emerin (EMD) and filamin (FLN1) genes located in Xq28. This region is flanked by 11.3 kb inverted repeats that share greater than 99% sequence identity. The two alternative orientations of this region were found at an ~80:20 ratio in X chromosomes from a largely Caucasian population by Southern blot studies (Small et al. 1997). We have extended these data to characterize the stability of the EMD/FLN1 inversion by genotyping worldwide populations for the inversion and for six SNPs that span the inversion region. We characterized 430 individuals (681 X chromosomes) from 41 different populations for the EMD/FLN1 inversion. The majority of individuals typed have the cen-FLN1/EMD-ter orientation. However, nearly all Africans typed have the cen-EMD/FLN1-ter orientation making this the most likely ancestral orientation. Genotypes were obtained for 268 males (of the 430 total individuals) who were typed for the EMD/FLN1 inversion for six SNPs spanning 131 kb surrounding the inversion. Haplotype analysis shows both orientations of the inversion to be present on multiple haplotypic backgrounds indicating recurrence or instability of this inversion. Genotyping the inversion in 10 human sperm DNA samples showed the presence of both orientations in all individuals typed, despite the presence of a single orientation in DNA derived from blood samples in the same individuals. Thus, both population genetic and direct analysis of germ cells indicate suggest that the EMD/FLN1 inversion polymorphism is recurrent.

Extensive traffic of genetic information between segmental duplications flanking the typical 22q11.2 deletion in velo-cardio-facial syndrome/DiGeorge syndrome. *A. Pavlicek[1], R. House[2], A.J. Gentles[1], J. Jurka[1], B.E. Morrow[3].* 1) Genetic Information Research Institute 1925 Landings Drive Mountain View, CA 94043; 2) Department of Biochemistry Albert Einstein College of Medicine 1300 Morris Park Avenue Bronx, New York, 10461; 3) Department of Molecular Genetics Albert Einstein College of Medicine 1300 Morris Park Avenue Bronx, New York, 10461.

Segmental duplications or low copy repeats (LCRs) are highly unstable segments in the human genome prone to frequent recombinations. To delineate regions in LCRs that might contain hotspots for genomic rearrangements, we generated an algorithm to detect sites of altered recombination by searching for polymorphic positions in BAC clones mapped to the LCRs. This method distinguishes single nucleotide polymorphisms from paralogous sequence variants and complex polymorphic positions. Sites of shared polymorphism are considered potential sites of gene conversion or double cross-over between the LCRs. We applied this method to two 240 kb long low copy repeats termed LCR22-2 and LCR22-4, which flank the typical 22q11.2 deletion in velo-cardio-facial syndrome/DiGeorge syndrome. After excluding gaps and highly unstable simple repeats, alignment of well-mapped BAC clones spanning these regions revealed 2,308 polymorphic positions. We found an inverse correlation between regions of paralogous sequence variants that are unique to a given position within one LCR22 and clusters of shared polymorphic sites. This, together with the presence of both LCRs in the chimpanzee genome suggest that these clusters are products of past transfers of DNA information between the LCR22s and not remnants of ancestral single nucleotide polymorphisms. Clusters of shared polymorphic sites depleted in paralogous sequence variants predict regions especially prone to genomic rearrangements in the two LCR22s. Interestingly, we found that recombination/gene conversion can transfer indels up to 1.5 kb long between LCR22s. Nucleotide identity seems be the major factor discriminating recombining from non-recombining regions. Finally, we propose that high levels of genetic exchanges may be hallmarks of disease-associated LCRs.

Visualization of Human multivariate genomic data via sonic modeling. *G. Wyckoff[1], A. Solidar[1], M. Brommelsiek[2], J. Batzner[3], D. McIntire[3], P. Rudy[3].* 1) Mol. Biol. & Biochem; 2) Center for Creative Studies; 3) Conservatory, U. Missouri-Kansas City, Kansas City, MO.

A common problem in the analysis of large genomic data is the visualization of the data in a meaningful, information-rich way. Most approaches attempt to simplify specific components of multivariate data to compress the portrayed information into one or more 2D figures. At worst, data is simply presented in tabular format, which is difficult to visually extract information from. The Genetic Auralization Project (GAP) explores a novel method of data presentation utilizing sound. Sound and music can portray complex data in a straightforward, meaningful, and intuitive way. This sort of sonic modeling has to the best of our knowledge never been utilized for large scale biological data(1). We employ this methodology to examine evolutionary rate information generated from our analysis of human patterns of substitution, chromosomal location, and expression(2,3). We identified several categories of genes, including genes with high Ka/Ks, genes with strong conservation in regions of moderate evolutionary rate, positively selected genes with narrow expression, and genes with a small domain of rapid evolution). We utilized the GAP prototype to screen through genes in each category. Genes with significantly aberrant patterns (>2 S.D from mean values), were detected at significantly high rates ($p<0.01$ versus random gene assignmen) in all examined classes. While our interests are in the detection of positive selection and identification of evolutionary patterns in primates, the techniques we present here can be adapted to work with many of the types of complex data generated by datamining and genomic studies within humans and related species. We argue that sonic modeling, or auralization, can increase the utility and precision of data visualization for human genomic studies. 1. SNPdetector: a Software Tool for Sensitive and Accurate Detection of Single Nucleotide Polymorphisms and mutations in fluorescence-based resequencing. *J. Zhang[1], D. Wheeler[2], I. Yakub[2], S. Wei[2], R. Sood[3], W. Rowe[1], P. Liu[3], R. Gibbs[2], K. Buetow[1].* 1) Lab Population Genetics, NCI, Bethesda, MD; 2) Human Genome Sequencing Center & Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Genetics and Molecular Biology Branch, NHGRI, Bethesda, MD.

Identification of Single Nucleotide Polymorphisms (SNPs) and mutations is important for the discovery of genetic predisposition to complex diseases. PCR re-sequencing is the method of choice for de novo SNP discovery. However, manual data analysis has been a major bottleneck for its application in high-throughput screening due to lack of a sensitive and accurate computational method for automated SNP detection. We developed a software tool, SNPdetector, for automated identification of SNPs and mutations by fluorescence-based resequencing. SNPdetector was designed to model the process of human visual inspection and has a very low false positive and false negative rate. We demonstrate the superior performance of SNPdetector in SNP and mutation analysis by comparing its results with those derived by human inspection, a popular SNP detection tool polyphred, and independent genotype assays in three large-scale investigations. The first study identifies and validates inter- and intra-subspecies variations in 4,650 traces of 25 inbred mouse strains that belong to either the Mus musculus species or the Mus spretus species. Unexpected heterozgyosity in Cast/Ei strain was found in two out of 1,167 mouse SNPs. The second study identifies novel SNPs in 133,440 traces in four ENCODE regions of the human genome (ENCODE Consortium, 2004). The third study detects ENU-induced mutations (at 0.04% allele frequency) in 64,896 traces of 1,236 zebra fish. The three large and diverse test data sets analyzed in this study demonstrate that SNPdetector is an effective tool not only for genome-scale research investigation but also for clinical studies involving a large sample. SNPdetector runs on Unix/Linux platform and is available publicly (http://lpg.nci.nih.gov).

Possible founder mutation for juvenile hyaline fibromatosis in Brazil. *M.D. Ramaswami[1], P.S. Hart[2], A.C. Acevedo[3], D. Pallos[4], T.C. Hart[1].* 1) Section on Craniofacial & Dental Genetics, NIDCR, Bethesda, MD; 2) Office of the Clinical Director, NHGRI, Bethesda MD; 3) University of Brasilia Brasilia, Brazil; 4) School of Dentistry, University of Taubate, Taubate, Brazil.

Juvenile hyaline fibromatosis (JHF) and infantile systemic hyalinosis (ISH) are allelic autosomal recessive disorders caused by mutations in the anthrax toxin receptor 2 (*ANTXR2*) gene, also known as the capillary morphogenesis protein 2 (*CMG2*) gene. JHF and ISH share many clinical similarities, including papulonodular skin lesions, gingival hypertrophy, and flexion contractures, but ISH usually has an earlier age at onset, a more painful and severe course, and often death in infancy from multisystem failure. A total of 18 different mutations have been described in 22 families with JHF or ISH. Of these mutations, 3 have been found in two kindreds and 1 (c.1073_1074insC) has been found in five kindreds. We have recently ascertained three unrelated Brazilian families segregating JHF, two of which were known to be consanguineous. PCR amplification and direct sequencing of all the *ANTXR2* exons revealed that all affecteds were homozygous for the same mutation: a single nucleotide deletion in exon 13 (c.1074delT). This mutation causes a frameshift and introduces a premature truncation site (p.K361fsX408). Haplotype analysis of intra- and intergenic polymorphisms suggests the presence of a common ancestor for all three families. This mutation has been previously reported in a Kuwaiti family with ISH. The difference in phenotype may be related to ethnic differences, modifying genes or to polymorphisms within the *ANTXR2* gene. The c.1074 region may represent a mutational hotspot as 3 of the 18 known mutations occur at this region.

Molecular evolution of Ataxin-1 CAG repeat in primates. *T. Kurosaki, A. Ninokata, S. Ueda.* Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan.

Spinocerebellar ataxia type 1 (SCA1) is a dominant neurodegenerative disorder characterized by degeneration of cerebellar Purkinje cell and neurons within brain stem and spinal cord. Expression of unstable translated CAG repeats that encodes a poly-glutamine tract in coding region of Ataxin1 has been implicated as a cause of the neuronal disorder. The repeat range of a poly-glutamine tract in normal individuals is 6-44, whereas mutant protein carries 39-82 repeat. It has been controversial whether the poly-glutamine tract of Ataxin1 innately has a molecular function or not, whereas poly-glutamine binding protein 1 (PQBP1) was recently reported to bind the tract and was involved in the pathology of SCA1. Interestingly, the poly-glutamine tract is absent in murine Ataxin1 homologue. To make clear an evolutionary history of the poly-glutamine tract in primates, we determined the repeat regions of 25 primate species (2 prosimians, 7 New World monkeys, 12 Old World monkeys and 4 apes). The repeats of prosimians and New World monkeys did not compose homopolymeric state in which they were interrupted with proline cording CCRs. Prosimians and New World monkeys examined in this study were homozygous, whereas 5 in 12 Old World monkeys and 2 in 4 apes were heterozygous. All of the Old World monkeys had uninterrupted CAG repeat whereas apes and human fundamentally contained interruptions. While CAT interruptions are observed in orangutan, gorilla, chimpanzee and human, not CAT but CAA was found in gibbons. This indicates that the nucleotide substitution on the third position of CAG (G to A/G to T) was occurred twice or more in the hominid lineage. Taking into account that the uninterrupted CAG repeat tends to increase the length variability and almost all SCA1 patients contain uninterrupted CAG repeat, the nucleotide interruption makes a contribution to lineage specific polymorphism and might be playing a role for the repeat stability.

A variant of the gene encoding Leukotriene A4 Hydrolase confers ethnic specific risk of myocardial infarction. *A. Helgadottir[1], A. Manolescu[1], A. Helgason[1], G. Thorleifsson[1], U. Thorsteinsdottir[1], D. Gudbjartsson[1], S. Gretarsdottir[1], K.P. Magnusson[1], A. Hicks[1], S.F.A. Grant[1], A.I. Levey[2], V. Gudnason[3], A.A. Quyyumi[2], E.J. Topol[4], D.J. Rader[5], J. Gulcher[1], H. Hakonarson[1], A. Kong[1], K. Stefansson[1].* 1) DeCode Genetics, Reykjavik, Iceland; 2) Emory University School of Medicine, Atlanta, GA; 3) Icelandic Heart Association, Reykjavik, Iceland; 4) Cleveland Clinic Foundation, Cleveland, OH; 5) University of Pennsylvania School of Medicine, Philadelphia, PA.

We recently reported that variants of the gene encoding 5-lipoxygenase activating protein (ALOX5AP/FLAP), a member of the leukotriene pathway, confer risk of myocardial infarction (MI) and stroke. Here we report the association of a variant of another gene in the same pathway, leukotriene A4 hydrolase (LTA4H) to MI. In an Icelandic cohort, a haplotype (HapK) across the LTA4H confers modest risk of MI, especially of MI with additional atherosclerotic manifestations (P=0.009, RR = 1.45). In addition, we show that HapK is positively correlated with the production of leukotriene B4 (P=0.01), the main product of the enzyme encoded by LTA4H, suggesting that the risk is mediated through an upregulation of the leukotriene pathway. In a study of 3 large cohorts from the United States the association of HapK to MI was replicated, both in European Americans (P=0.019, RR=1.16) and in African Americans (P=0.000022, RR=3.57). Notably, the observed risk in the African Americans is significantly greater (P < 0.001) than in individuals of European ancestry. About 27% of European American controls carried at least one copy of HapK, compared to only 6% of African American controls. Our analysis indicates that HapK is rare in Africa, suggesting that the occurrence of HapK in African Americans is primarily due to admixture. In support of this notion we demonstrate that African American carriers of HapK have, on average, more European ancestry, than African Americans who do not carry HapK (P = 0.0007), although this excess is not sufficient to explain the observed association between HapK and MI.

Functional polymorphism in Secretogranin II associates with human essential hypertension in African-American population. *G. Wen[1], J. Wessel[1], S.K. Mahata[1], M. Mahata[1], N.R. Mahapatra[1], F. Rao[1], M. Stridsberg[2], D.W. Smith[1], P. Mahboubi[1], N.J. Schork[1], D.T. OConnor[1], B.A. Hamilton[1].* 1) Dept Medicine, Univ California, San Diego, La Jolla, CA; 2) the Department of Medical Sciences, University Hospital, Uppsala, Sweden.

Secretogranin II (SCG2) is a member of the chromogranin/secretogranin, which is costored and coreleased with catecholamines from secretory vesicles. To find polymorphisms that could alter SCG2 function we resequenced the entire gene and proximal promoter region with ~6.5 kb footprint in total from 180 ethnically diverse human subjects. We identified 35 SNPs and one mono-repeat polymorphism in proximal promoter. Only four SNPs have minor allele frequencies greater than 5% in the general population. However, by subgroups, the African-American population has as many as 10 common SNPs, Asian and Hispanic populations only have one common SNP, and the Caucasian population does not have any common SNPs. The most common SNP of SCG2 in general population, SNP_736, appeared common only in African-American samples. The nucleotide diversity value (=0.000203) across the entire gene in general population is several folds lower than average values for several loci examined in the same samples. Three SNPs whose minor alleles are ancestral (shared with chimp) are located in a conserved intron region. To ask whether these polymorphisms are associated with plasma secretoneurin and hypertension we resequenced more subjects (383 in tortal) in African American population and found that significantly associates with secetoneurin (SNP_964, P=0.016) and hypertension (SNP_736, P=0.0046) for two of these SNPs. Admixture analysis from 33 loci across human genome ruled out the possibility of population stratification (X^2=27.83, P=0.7223. Standard neutrality tests and haplotype network suggests positive selection in this locus.Reporter gene assays showed A allele was able to enhance gene activity significantly compared with G allele in transfected cells. In conclusion, we found a functional polymorphism that associates with human hypertension in African-American population and positive selection might be a driving force in shaping its distribution.

simuPOP: a forward-time population genetics simulation environment. *B. Peng, M. Kimmel.* Dept Statistics, Rice Univ, Houston, TX.

simuPOP is a forward-time population genetics simulation environment. The core of simuPOP is a scripting language (Python) that provides a large number of objects and functions to manipulate populations, and a mechanism to evolve populations forward in time. Using this R/Splus-like environment, users can create, manipulate and evolve populations interactively, or write a script and run it as a batch file. Due to its flexible and extensible design, simuPOP can simulate large and complex evolutionary processes with ease. At a more user-friendly level, simuPOP provides an increasing number of built-in scripts that perform simulations ranging from basic population genetics models to generating datasets under complex evolutionary scenarios.

Use of the Norfolk Island Genetic Isolate to Identify Genetic Risk Factors for CVD. *L.R. Griffiths[1], C. Bellis[1], R.A. Lea[1], R. Hughes[1], S. Quinlan[1], S. Heath[2], J. Blangero[3].* 1) Genomics Research Centre, School of Medical Science, Griffith Uni Gold Coast, Australia; 2) Centre National de Génotypage, Crémiuex, Evry, France; 3) Department of Genetics, Southwest Foundation for Biomedical Research, Texas, US.

Geographical isolation and limited environmental variation make genetic isolates powerful tools for gene mapping. Our research is aimed at identifying the genes that play a role in cardiovascular disease (CVD) risk and the Norfolk Population may be of significant use in these endeavours. Norfolk Islanders are primarily descended from 18th Century English (Bounty) sailors and Polynesian women. There have strong family groupings and well-documented family histories, providing unique characteristics for a genomic investigation into complex disease. We have recruited individuals from this isolate, to investigate the genes involved in CVD. DNA samples from two-thirds of the Islands adult permanent population have been prepared for these studies. 602 individuals have been collected with information and phenotypes relating to risk of cardiovascular disease including blood pressure, cholesterol, triglyceride, BMI, exercise, smoking levels and diet. Most of these individuals fit within a single large, 12-generational (~6500 individuals) pedigree extending back to the original founders. Heritability and power estimates indicate that this population should be particularly useful for identifying QTL that relate to CVD risk. We conclude that the pedigree should provide a unique and powerful resource for complex disease gene mapping and we are currently investigating implicated genomic loci.

Effects of B Group Vitamins and the MTHFR C677T Polymorphism on Carotid Intima-Media Thickness in Normal Population. *W.L Cheng[1], H.W Chen[2], H.C Chiang[2], C.S Huang[1], C.L Kuo[1], C.S Liu[1,2,3].* 1) Vascular & Genomic Res, Changhua Christian Hosp, Changhua, Taiwan; 2) Institute of Nutritional Science, Chung Shan Medical University, Taichung, Taiwan; 3) Department of Neurology, Changhua Christian Hospital, Changhua, Taiwan.

Methylenetetrahydrofolate reductase (MTHFR) genotype; concentrations of folate, vitamin B6, and vitamin B12; and age were significantly correlated to the plasma homocysteine (Hcy) concentration ($P < 0.05$). With stratification by age and B vitamin concentrations, 3 risk factors were found to enhance the effect of the MTHFR 677TT genotype on the increase in carotid IMT: age > 50 y, plasma folate < 8.3 mg/dL, and vitamin B12 < 618 pg/mL ($P < 0.05$). A similar effect of the MTHFR 677TT genotype on the increase in plasma Hcy was also found when the subjects were stratified by age, plasma folate, and plasma vitamin B12. Age, folate, and vitamin B12 may be 3 determinant factors in predicting the MTHFR 677TT related carotid atherosclerosis.

New dbSNP resources to support genotype and haplotype submissions. *S.T. Sherry.* NCBI, National Library of Medicine, National Institutes of Health, Bethesda, MD.

The growth and acquisition strategy for dbSNPs current inventory of 26.2 million SNPs for 25 species will be discussed in the context of the assay sources, validation rules, and placement filters used to establish variation annotation on genome assemblies. Specific details will be provided for the filtering rules used to provide 8.2 million human SNPs to the International HapMap project as potential targets for genotype selection. The presentation will cover new dbSNP resources for visualizing and downloading genotype and frequency data, enhanced programmatic access to dbSNP via NCBI eUtil services, and conclude with the the current status of haplotype representation and content in dbSNP. Details of the haplotype data model, submission requirements, and accessioning scheme will be presented for comment.

ALFRED - The ALlele FREquency Database - an update. *S. Stein[1], H. Rajeevan[2], U. Soundararajan[1], K.-H. Cheung[2], J.R. Kidd[1], A.J. Pakstis[1], R. Gadagkar[2], P.L. Miller[2], K.K. Kidd[1].* 1) Department of Genetics, Yale University School of Medicine, CT 06520-8005, USA; 2) Center for Medical Informatics, Yale University School of Medicine, New Haven, CT 06520-8005, USA.

ALFRED (http://alfred.med.yale.edu) is an actively curated database designed to make allele frequency data on anthropologically defined human population samples readily available to the scientific community. The database continues to expand and now contains over 30,000 allele frequency tables. Many research questions involve interpreting allele frequencies in a geographic context. ALFREDs newest feature is the implementation of a prototype web-based geographic map interface using GIS (Geographic Information System). Populations are located graphically on a world map and detailed information on them is retrieved by clicking on the points displayed. This interactive map can also display pie charts to represent allele frequencies. When a polymorphism is selected, pie charts depicting allele frequencies across populations are displayed on the world map. A more global view displays a pie chart (frequencies averaged across samples within a population) at the location of each population having data on that site. The interface can also provide a detailed view showing allele frequencies as pie charts for each sample within a selected population. Anthropologic genetics is plagued by an empty matrix problem: the paucity of markers uniformly typed on a large number of populations. This presents a problem for those in population genetics who want to do an integrated analysis. ALFRED can be used to counter this problem. A survey of data assembled in ALFRED shows that only approximately 2 dozen markers have been uniformly studied on the same 100+ populations. Solely by virtue of their having already been typed on multiple populations, these 2 dozen markers became a logical initial set for use in new populations to maximize global comparability. ALFRED is supported by the U. S. NSF (BCS0096588).

dbRIP: a Database of Retrotransposon Insertion Polymorphisms in Human. *P. Liang[1], J. Wang[1], L. Song[1], D. Grover[2], S. Azrak[1], M.A. Batzer[1].* 1) Dept of Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) Dept of Biological Sciences, Louisiana State Univ, Baton Rouge, LA.

*Alu*s and L1s are the two major types of active retrotransposable elements in the human genome with ~1 million and half million members, respectively, constituting over 30% of the genome. These elements play important roles in the genome and generate a unique and significant part of genome diversity among humans through their recent and ongoing integrations. Polymorphic (for presence or absence) retrotransposon insertions are very useful genetic markers in population genetics studies as being identical-by-descent and free of homoplasy. We have constructed, dbRIP, a database of Retrotransposon Insertion Polymorphism (RIPs) to document all known human genetic polymorphisms derived from retrotransposon insertion. Currently, dbRIP contains a non-redundant list of 1598 and 560 polymorphic *Alu*s and L1s, respectively, and it is our plan to expand dbRIP in future to include other types of retrotransposons, such as SVA. In dbRIP, we deploy the utilities of the genome browser developed at the University of California at Santa Cruise for user-friendly querying and browsing of RIPs along with all other genome information. Users can query RIPs by genetic IDs (gene IDs, accessions, STS, etc), chromosome locations, and DNA or protein sequences using the utilities of the genome browser. A special query interface is also implemented to allow search of RIPs by ethnic group, allele frequency, RIP IDs, subfamily, gene context, disease association, and author. For each RIP, user have access to the detailed RIP information including sequences (flanking genomic regions, TSDs, and retrotransposon), classification, primers, PCR conditions, genotype data, known associated disease, and publications describing the polymorphism. dbRIP is accessed at http://falcon.roswellpark.o rg:9090/, and the entire RIP data set is available for downloading. This research is in part supported by NCI grants CA16056 (RPCI), CA101515 (PL), and GM59290 (MAB), by NSF grant BCS-0218338 (MAB), by Roswell Alliance Developmental Fund (PL), and by the Louisiana Board of Regents Millennium Trust Health Excellence Fund (MAB).

The Singapore human polymorphism/mutation database: a country-specific database for mutations and polymorphisms in inherited disorders and candidate gene association studies. *E.C. Tan[1], M. Loh[2], D. Chuon[2], Y.P. Lim[2].* 1) Defense Medical Env Res Inst, DMERI@DSO, Kent Ridge, Singapore; 2) Bioinformatics Institute, Republic of Singapore.

There is good evidence for population-specific mutations for single gene disorders and ethnic difference in the frequencies of genetic variations involved in complex disorders. The Singapore Human Polymorphism/Mutation Database is thus created to provide clinicians and scientists access to a central genetic database for the Singapore population. The data catalogued include mutations identified for Mendelian diseases, and frequencies of polymorphisms which had been investigated in either healthy controls or samples associated with specific phenotypes. Data from journal articles are identified by searching through PubMed, other online resources, and via personal communication with researchers. The relevant articles used come from 63 different journals dated from 1972 to 2005. There are also direct submissions of unpublished data from researchers. The total number of polymorphisms/mutations included in the database is currently 298 for 104 genes, which are categorized alphabetically and also searchable by name and disease. Information captured for each variant of the gene includes protein encoded, phenotype associated, gender, size and ethnic origin of the samples, as well as genotype distribution and allele frequencies for each group. There are also direct links to OMIM and the corresponding abstracts on PubMed. With online submission and frequent update from PubMed searches, the database will be kept current so it will be an important resource for academic and clinical users to facilitate molecular diagnosis of Mendelian disorders and improve study designs for complex traits. It will be useful not only to researchers in Singapore, but also countries with similar ethnic background such as China, Taiwan, Hong Kong, Indonesia and Malaysia. Besides Southeast Asian countries, western countries such as the United States, Canada and the United Kingdom which have significant number of immigrants with similar ethnic origin will also find the database useful for patients from such ethnic origin.

African American mitochondrial DNAs are likley to match common African mtDNA haplotypes. *B. Ely[1], J.L. Wilson[2], B.A. Jackson[2].* 1) Department Biological Sciences, University of South Carolina, Columbia, SC; 2) Department of Work Environment, University of Massachusetts, Lowell, MA.

Mitochondrial DNA (mtDNA) haplotypes are useful tools for tracing maternal ancestry. Numerous studies have demonstrated that human mtDNA haplotypes can be used with confidence to identify the continent where the haplotype originated. Ideally, mtDNA haplotypes also could be used to identify a particular country or ethnic group from which the maternal ancestor emanated. However, the geographic distribution of mtDNA haplotypes is greatly influenced by the movement of both individuals and population groups. Furthermore, mtDNA haplotypes are passed from one ethnic group to another by intermarriage. As a consequence, common mtDNA haplotypes are shared among multiple ethnic groups. We have been studying the distribution of mtDNA haplotypes among West African ethnic groups to determine whether mtDNA haplotypes can be used to reconnect blacks of the Americas and the Caribbean to a country or ethnic group of a maternal African ancestor. The nucleotide sequence of the mtDNA human variable region I (HV-1) usually provides sufficient information to assign a particular mtDNA to the proper haplogroup, and it contains most of the variation that is available to distinguish a particular mtDNA haplotype from closely related haplotypes. In this study, samples of African American and Gullah HV-1 haplotypes were compared to a database of 3200 HV-1 haplotypes from sub-Saharan Africa and the incidence of perfect matches was recorded for each sample. We found that more than 40% of the sampled haplotypes exactly matched common haplotypes that were shared among multiple African ethnic groups. Another large fraction did not match any sequence in the database, and fewer than 15% were a perfect match to a single African ethnic group. Thus, the most common African haplotypes found in America are exact matches to the most common haplotypes found in sub-Saharan Africa. These results indicate that mtDNA sequence information is unlikely to provide sufficient information by itself to conclusively link most individual African American mtDNAs to either a single ethnic group or a particular country in Africa.

No association between gr/gr deletions and infertility in Brazilian males. *S.D.J. Pena[1], C.M.B. Carvalho[1], L.W. Zuccherato[1], L. Bastos-Rodrigues[1], F.R. Santos[2].* 1) Dept. Biochemistry, UFMG, Belo Horizonte-MG, Brazil; 2) Dept. General Biology, UFMG, Belo-Horizonte-MG, Brazil.

The Y chromosome carries several spermatogenesis genes distributed in three regions: AZFa (azoospermia factor a), AZFb, and AZFc. Microdeletions in these regions have been seen in 10-15% of sterile males with azoospermia or oligozoospermia, the most frequent of them being complete deletion of AZFc region (3.5 Mb). Sequencing of AZFc showed a highly repetitive structure with several palindromic segments, thus explaining the high frequency of rearrangements in this region. A partial AZFc deletion named gr/gr, which removes only some gene copies, has been singled out as a risk factor for spermatogenic failure. However, other authors disagree and prefer to consider it as of no clinical relevance. We then decided to investigate the association of gr/gr deletions and infertility in Brazilian males. We analyzed 357 individuals (117 azoospermic, 122 fertile and 118 of unknown, presumably normal, fertility) with the following STSs: sY1161, sY1191, sY1201, sY1206, sY1258 and sY1291. We observed 12 gr/gr deletions: five in infertile men (4.3%), three among fertile males (2.5%) and four in individuals of unknown fertility (3.4%). These differences were not statistically significant. We then decided to ascertain whether the clinical impact of the gr/gr deletion was associated with the Y chromosome genetic background. We typed Y chromosome haplogroups using 23 unique event polymorphisms (UEPs). We found that the gr/gr deletions occurred in six different Y chromosome backgrounds, suggesting that it occurred recurrently at least six different times. The haplogroups found were R, K* (xMNOP), F*(xJ), E1, E3b2, E3b*, all common in white Brazilian males. There was no single haplogroup associated with infertility. Taken together, these results show a lack of association between the occurrence of gr/gr deletions and the infertile phenotype in Brazilian men.

A3243G and A12026G variants in mitochondrial DNA of Diabetes Mellitus Type 2 Mexican Patients. *J.M. Oliva[1,2], A. Sarralde[2], J.M. Escalante-Pulido[2], O.A. Rivera-Martinez[1], I.P. Davalos[1,2], L.E. Figuera[1,2], L. Sandoval[1,2].*
1) Doctorado en Genética Humana, CUCS, U de G., Guadalajara, Jalisco, México; 2) División de Genética CIBO, UMF No. 167, UMAE, CMNO, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México.

Mitochondrial (mtDNA) variants have been associated to Diabetes Mellitus type 2 (DM). Previous studies in Japanese population showed an association between variants A3243G, A12026G in mtDNA and DM2. A3243G variant in the tRNA gene MT-TL1 is the most common with a prevalence of 1-4 % in Asian population, this mutation is involved in the synthesis of tRNA leu(UUR) and the transcription terminal factor. The variant A12026G prevalence in DM2 patients is of 3.95% (10 of 253) in Japanese DM2 patients, it is located in the MT-ND4 gene in the complex I mitochondrial. Objective: Identify A3243G and A12026G variants in mtDNA of DM2 Mexican patients. Methods: 200 DM2 DNA samples were analyzed to identify mtDNA-A12026G and A3243G variants by PCR/RFLP`s (ApaI and HincII respectively). Results: A3243G mutation frequency was 2% (2/200) and A12026G variant was no present. Conclusion: A12026G variant is not present in the study population and A3243G mutation frequency in DM2 Mexican population was similar to other population studies in DM2 patients.

Evolution of DSCAM and its related genes. *K. Onishi[1], S. Ueda[2].* 1) Biosciences Information Research, Research Information Research Division, National Institute of Informatics 2-1-2 Hitotsubashi, Chiyoda-ku, Tokyo 101-8430, Japan; 2) Dept. of Biological Science, Graduate School of Sciences, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan.

Human DSCAM (Down syndrome cell adhesion molecule) and its paralogue, DSCAML1, express mainly in central nervous system and have characteristic domain structures: nine immunoglobin (Ig) domains, four fibronectin type III (FN III) domains, one Ig domain, and two FN III domains, in this order (Ig(9)-FNIII(4)-Ig(1)-FNIII(2)). Their putative orthologous genes also exist in insects (but not in nematode), which have four alternative exon clusters and can generate as many as tens of thousands of splicing isoforms. Both of them have the same domain structures, however, their orthologous relationships between vertebrates and invertebrates remain unclear. Here, we constructed phylogenetic trees based on each of the two domains (Ig and FN III) and found that they indeed are orthologous. Sax-3/Robo genes of vertebrates and invertebrates (including nematode) are homologous to the DSCAM genes and have both Ig and FN III domains (Ig(5)-FNIII(3)). We also analyzed the evolution of genomic structures of the two gene structures (DSCAM and Sax-3/Robo) from the viewpoint of their domain structures. Our results strongly suggest that both DSCAM and Sax-3/Robo genes exist in the common ancestor of vertebrates and invertebrates, and that their genomic structures, as well as their amino acid sequences, are highly conserved in vertebrates.

Genetic analysis of Y, mtDNA, and STR variation in castes populations of Tamil Nadu, India. *W.S. Watkins[1], B. Mowry[2], H. Smith[2], E. Marchani[1], L. Zhou[3], S. Tirupati[4], R. Thara[4], R. Padmavati[4], J. Sujit[4], K. Soundari[4], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Queensland Centre for Mental Health Research, Wacol, Brisbane, Australia; 3) Department of Pathology, University of Utah, Salt Lake City, UT; 4) Schizophrenia Research Foundation India, Chennai, Tamil Nadu, India.

To test the hypothesis that caste populations of the Indian subcontinent are genetically structured, we analyzed 181 Y haplotypes from 4 caste populations living in Tamil Nadu, India. Using 15 polymorphic lineage-defining Y chromosome markers, we demonstrate that Y genetic distances are positively correlated with differences in caste rank (rho = 0.93, $p < 0.01$). R lineages, dominated by the Eurasian R1a, and central Asian/Indian R2 haplogroups, occur at frequencies of 0.5 in 2 Brahmin groups (high status), 0.31 in Mudaliars (middle status) and 0.22 in Dalits (lower status). Thus, this major Y lineage demonstrates a negative correlation with differences in caste status (rho = -1.0, $p < 0.01$). In contrast, the H lineage, which is largely restricted to India and is thought to have originated there, occurs at high frequency in the Dalit population (0.49) but is found at < 0.18 in higher status groups. Genetic distances derived from mitochondrial HV1 sequences or 45 autosomal STRs are lowest for Tamil-speaking Brahmins and Europeans. Exclusion of the linguistically distinct non-Tamil speaking Brahmin group yielded positive correlations between genetic distance and caste rank for STR and mtDNA (rho = 0.87, $p > 0.3$; rho = 0.87, $p > 0.3$). We have observed a similar correlation in caste populations from the neighboring state of Andhra Pradesh. Between-group differentiation for Y markers is greater than that found for mtDNA or STRs (F_{ST}/R_{ST}: 0.061, 0.046, and 0.007, respectively). These data are consistent with a structured, historical influx of Eurasian male lineages into the caste system.

Y Chromosome Evidence of Southern Origin of the East Asian Specific Haplogroup O3-M122. *H. Shi[1,2,6], Y. Dong[3], B. Wen[4], C. Xiao[3], P.A. Underhill[5], P. Shen[5], R. Chakraborty[7], L. Jin[4,7], B. Su[1,2,7].* 1) Key Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoolgy, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Kunming Primate Research Center, Chinese Academy of Sciences, Kunming, Yunnan, China; 3) Key Laboratory of Bio-resources Conservation and Utilization & Human Genetics Center, Yunnan University, Kunming, Yunnan, China; 4) State Key Laboratory of Genetic Engineering and Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 5) Department of Genetics, Stanford University, CA; 6) Graduate School of Chinese Academy of Science, Beijing, China; 7) Center for Genome Information, University of Cincinnati, OH.

The prehistoric peopling of modern humans in East Asia remains controversial in view of the early population migrations. Here we presented a systematic sampling and genetic screening of an East Asian specific Y chromosome haplogroup (O3-M122) in 2,332 individuals from diverse East Asian populations. Our results indicated that the O3-M122 lineage is dominant in East Asian populations with an average frequency of 44. 3 %. The microsatellite data showed that the O3-M122 haplotypes in southern East Asia is more diverse than those in northern East Asia, suggesting a southern origin of the O3-M122 mutation. It was estimated that the early northward migration of the O3-M122 lineages in East Asia occurred about 25,000-30,000 years ago, consistent with the fossil records of modern humans in East Asia.

Lack of Evidence for Balancing Selection on PRNP M129V in Chinese. *Q. Zan[1], B. Wen[1], Y. He[1], Y. Wang[1], S. Xu[1], J. Qian[1], D. Lu[1], L. Jin[1,2].* 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Center for Genome Information, Fudan University, Shanghai, China.

The M129V in PRNP is the primary susceptible site to prion diseases such as kuru. It has been shown that balancing selection played a critical role in shaping the distribution of 129V in worldwide populations. However, the statistic evidence in Japanese was substantially weaker, possibly due to a lower level of variation in PRNP gene in East Asians. We therefore surveyed the frequency of 129V in 10 Han Chinese populations and examined the role of balancing selection on the PRNP gene by sequencing a substantially larger genomic segment (15kb) which encompasses the entire genomic region of the PRNP gene. We showed that the balancing selection that exerted on 129V in the other parts of the world was less likely to have played a significant role in East Asians.

Lactase persistence in East Africans and Bedouins is not associated with the extended haplotype found in Europeans. *C.J.E. Ingram[1], M. Elamin[1,2], C.A. Mulcare[1], M.E. Weale[1], M.G. Thomas[1], N. Bradman[1], D.M. Swallow[1].*
1) Department of Biology, University College London; 2) University of Khartoum.

Background Lactase, the intestinal enzyme responsible for digestion of lactose in milk is downregulated in mammals after weaning. However in humans, lactase persistence (expression of the enzyme in adulthood) is a polymorphic trait. It has been shown in Europeans that lactase persistence is controlled by a regulatory element, *cis*-acting to the lactase gene *LCT*, and is located within a region of strong linkage disequilibrium, with only 3 common haplotypes. One of these haplotypes, designated **A**, forms the core of an extended (500kb+) haplotype, which is associated with lactase persistence and is at high frequency, probably due to the effect of selection for this trait (Poulter et al, 2003 Ann Hum Genet 67:298, Bersaglieri et al 2004, Am J Hum Genet 74:1111). However the single SNP (-13.9kb*T) proposed to be causative of lactase persistence (Enattah et al 2002 Nat Genet 30:233) was absent in several groups in sub-Saharan Africa, in which the trait is common (Mulcare et al 2004 Am J Hum Genet 74:1102). **Aims** To examine the association of allele and haplotype frequencies with lactase persistence in populations of non-European ancestry. **Methods** We studied 3 African groups where lactase persistence is prevalent; pastoralist Fulani from Cameroon (n=74), Beni-Amer (n=100) and Jaali from Sudan (n=91), and three Middle Eastern Bedouin groups (n=86) as well as neighbouring Arabs. For the Africans we collected milk drinking data, and in one group, lactose tolerance data. We tested C-13.9kbT, and 4 other SNPs that discriminate the core LCT haplotypes previously found in Europeans and Africans. **Results** The presence of -13.9kb*T was confirmed in the Fulani (0.367), and was in most cases on an **A** haplotype chromosome. The allele and haplotype frequencies in the Beni-Amer, Jaali and Bedouins were very different; -13.9kb*T was very rare (0.005-0.02), and the core **A** haplotype was not associated with lactase persistence. **Conclusions** The long European *LCT* **A** haplotype is not frequent in East African and Middle Eastern milk drinkers, where there may be another cause of lactase persistence.

Evolution of the Agouti Signaling Protein Gene (*ASIP*) in Primates: The Loss-of-the *ASIP* in the Gibbons. *K. Nakayama, T. Ishida.* Department of Biological Sciences, Graduate School of Science, The Universtiy of Tokyo, Tokyo, Japan.

Agouti signaling protein is an endogenous antagonist of melanocortin receptors, which control a wide range of physiological functions in humans. The central role in regulation of the melanocortin system implied that agouti signaling protein has been relevant to evolution of various physiological traits in humans and other primate species. In the present study, we have tried to determine DNA sequences of the agouti signaling protein gene (*ASIP*) of various primate species to know molecular evolutionary properties of the *ASIP*. Unexpectedly, we found that the whole coding region of the *ASIP* was missing from the gibbons, which is a large group of ape species from Southeast Asia. This 100kb deletion was mediated by an unequal homologous recombination between *AluSx* elements and apparently occurred prior to the divergence of the present gibbon species. The maximum likelihood analysis for successfully determined *ASIP* sequences from primates and other mammalian species showed that the *ASIP* has been under purifying selection throughout the evolution of the mammals. This suggested that agouti signaling protein has carried important physiological roles, probably in pigmentation and in energy homeostasis. The loss-of-the *ASIP* is considered to have had momentous contributions in the formation of biological characteristics regarding the melanocortin system in the gibbons, although it is still unclear whether a lineage specific relaxation of functional constraints or positive selection was responsible for the fixation of such large deletion during the evolution of the gibbons.

Molecular Evolution of 5' Flanking Regions of 87 Candidate Genes for Atherosclerotic Cardiovascular Disease. *I. Kullo, K. Ding.* Cardiovascular Dept, Mayo Clinic, Rochester, MN.

Background. Inter-individual variation in quantitative traits as well as in disease susceptibility may be due to differences in the level and spatio-temporal pattern of gene expression. An evolutionary model of genetic variation in cis-regulatory regions may help identify loci of interest in the study of the genetic basis of complex diseases such as atherosclerotic cardiovascular disease (ASCVD).

Methods and Results. We studied the molecular evolution of 87 candidate genes for ASCVD to assess for signatures of selection in 5' flanking regions. Resequenced data for these genes was available in 24 African-Americans, 23 European-Americans, and 1 chimpanzee (Pan troglodytes). Statistical tests of evolutionary neutrality (Tajimas D and Fay & Wus H) were performed using coalescent simulation under a standard neutral model and a population structure model for African-Americans and European-Americans to differentiate selection from human demographic history. Evidence suggestive of selection was present in 5' flanking regions of 4 genes in African-Americans and 7 genes in European-Americans. A modified McDonald-Kreitman test was used to test the neutral theory of molecular evolution in 5' flanking regions, and 10 genes in African-Americans and 11 genes in European-Americans showed a significant excess or deficit of fixed changes over polymorphisms. Haplotype configuration was assessed in 5' flanking regions of genes showing deviation from evolutionary neutrality in either of the above tests. An unusual pattern of haplotypes was noted in 6 genes in African-Americans and 8 genes in European-Americans, providing further evidence for selection in the regulatory regions of these genes.

Conclusion. These results indicate that selection may play a role in establishing variation in 5' flanking regions of a subset of candidate genes for ASCVD and motivate further studies of these loci in determining inter-individual susceptibility to ASCVD.

The evolution of satellite III DNA subfamilies among primates. *M. Jarmuz, C.D. Glotzbach, K.A. Bailey, L.G. Shaffer.* Health Research and Education Center, Washington State University, Spokane.

Satellite DNA is a dynamic component of eukaryote chromosomes and may play an important role in chromosome structure and karyotypic evolution through the facilitation of exchange events. In our study we analyzed satellite III DNA (satIII DNA) from two subfamilies characterized by their sequence composition: the GGAAT monomer sequence is predominant in the first group, whereas the second has a roughly equal representation of GGAAT and GGAGT motifs. Both groups are present in the short arms of the acrocentric chromosomes and in chromosomes 9 and Y in human and share high homology. We determined the distribution of six subfamilies of satIII DNAthree from group 1 (pTRS-63, pW-1 and pK-1) and three from group 2 (pR-2, pR-4 and pTRS-47)in 25 primate cell lines by PCR with primers specific to each subfamily and sequencing analysis of PCR products. We also determined the presence or absence of the subfamilies in four human reference cell lines and a panel of monochromosomal hybrids of the acrocentric chromosomes. These satellite III subfamilies were not detected in squirrel monkey, african green monkey, baboon, or rhesus monkey. The group 1 subfamily was found only in human cell lines and in corresponding monochromosomal hybrids of the acrocentric chromosomes. The pTRS-47 subfamily was detected in orangutans, gorilla, chimpanzee and bonobo, whereas the pR-2 and pR-4 subfamilies were found in gibbon. Sequence analysis indicated a higher conservation of pTRS-47, than pR-2 and pR-4, for species closely related to humans. In addition, sequence analysis showed that the percentage of sequence divergence between primate and human was higher in pR-2 than pR-4. The presence of pR-2 and pR-4, and absence of pTRS-47 in the gibbon cell lines, indicate that the pR-2 and pR-4 subfamilies are more ancient than pTRS-47. In addition, these findings indicate that the group 2 subfamilies appeared suddenly in gibbon and that they are older than subfamilies from group 1.

An examination of selection at the molecular level in the forkhead transcription factor gene family. *C.D. Fetterman, M.A. Walter, B. Rannala.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

One manner in which gene families are thought to evolve is through gene duplication and subsequent selection. If one member of a duplicated gene maintains its original function, the other member may mutate and develop a novel function. Positive selection will maintain mutations that enhance fitness while negative selection will eliminate deleterious mutations. To discover the molecular basis underlying the evolution of the disparate members of the forkhead transcription factor gene family, the phylogenetic relationships between genes containing the forkhead domain are being determined to identify residues in forkhead gene family members under strong selection. Nucleotide and protein sequences of genes containing the forkhead domain in all species for which sequence data are available were obtained from the NCBI Conserved Domain database through CDART. A total of 383 unique sequences from 51 different species were chosen for analysis. ClustalX and DIALIGN are being used to align the protein sequences. The MRBAYES program is being utilized to elucidate the phylogenetic relationships among the gene family members. These experiments are yielding a phylogenetic tree of the forkhead gene family. Residues that are targets of strong positive or negative selection are being identified using a codon-based model contained in the PAML program. Genes with residues under strong positive selection may have evolved novel functions and the residues under selection may be key to these new functions. Identifying these sites can help direct future investigations into gene function. Residues under strong negative selection can indicate how genes with different functions diverged from a common ancestor.

Evolutionary Mechanism of Diversification of Multiple Variable Exons in the Human Genome. *Q. Wu, C. Li.*
Human Genetics, University of Utah, Salt Lake City, UT.

Fifty three neural protocadherin (Pcdh) proteins are encoded by three closely-linked gene clusters on the human chromosome 5 and are expressed in cell-specific patterns in the brain. Two of the three clusters have a striking genomic organization consisting of a tandem array of multiple variable exons and a common set of constant exons, similar to that of the immunoglobulin and T-cell receptor gene clusters. By a genome-wide computational analysis, we found that the human genome contains a large number of genes, including the drug-metabolizing UDP glucuronosyltransferase (UGT1), with multiple variable exons. We performed comprehensive comparative analyses for the vertebrate Pcdh and UGT1 clusters and found that there are species-specific duplications in vertebrate Pcdh and UGT1 genes. Phylogenetic analysis demonstrated that this variable and constant genomic organization is vertebrate-specific and is conserved throughout vertebrate evolution. In addition, comprehensive analysis of the complete repertoire of the closely-related UGT2 clusters in the human, mouse, and rat genomes revealed striking gene conversion and extensive lineage-specific duplication. These results suggest that the tremendous diversity of these clusters is achieved through gene conversion and concerted evolution, in conjunction with the birth-and-death evolution of the duplicated exons and their independent mutations. Moreover, analyzing the pattern of nonsynonymous and synonymous nucleotide substitutions identified codon sites that are likely to have been subject to positive Darwinian selection at the molecular level. These diversified residues of the human Pcdh and UGT proteins likely play an important role in providing the staggering diversity required for neuronal connectivity, chemical detoxification, and drug clearance. These results also suggest that the adaptive natural selection of the specific codon sites play an important role for enhancing the human Pcdh and UGT diversity. This study has interesting implications regarding the evolutionary mechanisms for generating molecular diversity required for neuronal connections in the brain and drug biotransformation in the body.

High-resolution haplotype analysis in a large European population. *A. Montpetit[1], M. Nelis[2], P. Laflamme[1], X. Ke[3], L. Cardon[3], A. Metspalu[2], T.J. Hudson[1].* 1) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 2) IMCB University of Tartu, Estonian Biocentre and The Estonian Genome Project Foundation, Tartu , Estonia; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, United Kingdom.

The HapMap project recently generated genotyping data for more than 1 million SNPs in four populations. The main application of the data is in the selection of SNPs (or tag SNPs) to test in association studies. However, the usefulness of this selection process needs to be verified in populations outside those used for the HapMap project. In addition, it is not known how well the data represents the general population since only 90 to 120 chromosomes were used to build each population's haplotype map and since the genotyped SNPs were selected to have a high minor allele frequency (MAF) in those samples. In this study we analysed more than a thousand individuals from Estonia. The population of this northern European country has been influenced by many different migrations from European and Asian populations. We genotyped 1536 randomly selected SNPs from two 500 kb ENCODE regions on chromosome 2. All these SNPs had been identified through a resequencing study, as part of the HapMap project. We observed that the tag SNPs selected from the CEU sample (derived from U.S. residents with northern and western European ancestry) were very efficient at capturing the variation in the Estonia sample (between 85-90% of the SNPs with a MAF above 2% had an r2 of at least 0.8 with the tag SNPs). An approach using tag SNPs from the combined CEU, CHB and JPT populations was even more effective as it captured about 90-95% of the SNPs (although with an increase of about 30% in the number of tag SNPs used). Using the opposite approach, tags selected from the Estonia samples could almost equally well describe the CEU samples. However, using random data sets of 120 chromosomes to select tag SNPs we show that the sample size used has an important effect on the robustness of the results.

Neolithic split of R1a1 Y-chromosomes in Northern Eurasia. *M. Derenko[1], B. Malyarchuk[1], G. Denisova[1], M. Wozniak[2].* 1) Institute of Biological Problems of the North, Magadan, Russian Federation; 2) The Nicolaus Copernicus University, Forensic Medicine Institute, Bydgoszcz, Poland.

Y-chromosome variation in a total sample of 1358 males from 14 ethnic groups of Siberia (Altaians-Kizhi, Teleuts, Shors, Tuvinians, Todjins, Tofalars, Sojots, Khakassians, Buryats, Evenks), Central/Eastern Asia (Mongolians and Koreans) and Eastern Europe (Kalmyks and Russians) was studied using 17 SNPs/indel and twelve STR loci. Distribution pattern of Y-chromosomal haplogroups, results on AMOVA and admixture analyses demonstrate the significant differentiation between populations of Eastern Siberia and Altai region. These regional differences can be best explained by different contribution of Central/Eastern Asian and Eastern European paternal lineages into gene pools of modern South Siberians. The populations of Eastern Siberia demonstrate the absolute prevalence of Central/Eastern Asian lineages, whereas in populations of Altai region the highest (70%-98%) paternal contribution resulted from Eastern European descent is revealed. The major component responsible for the high impact of Eastern European lineages into gene pools of Altaians-Kizhi, Shors and Teleuts is R1a1-haplogroup. Our data on Y-chromosome STRs variation demonstrate the clear differences between South Siberian and Eastern European (Russian) R1a1-lineages (with only 6% of haplotypes shared), which can be best explained by apparently ancient than very recent events in South Siberian population history. Despite the haplotypic diversity value of Eastern European R1a1-lineages exceeds that in South Siberia (0.994 0.002 and 0.932 0.018, respectively), the estimated ages for this haplogroup are almost equal in both regional groups - 11,270 4,070 years in Siberia and 11,380 3,200 years in Eastern Europe. These values are very close to the divergence time between two regional groups studied (10,3103,140 years). Moreover, the analysis of R1a1 Y-chromosomes revealed two subclades with distinct, South Altaian and Eastern European, geographic distributions. This work was supported by Russian Foundation for Basic Research (grant 04-04-48746).

A curious pattern of variation at the ALDH2 locus. *H. Oota[1,2], A.J. Pakstis[1], W.C. Speed[1], J.R. Kidd[1], K.K. Kidd[1].* 1) Dept Genetics, Yale University School of Medicine, New Haven, CT 06520-8005 USA; 2) Dept Integrated Biosciences, Graduate School of Frontier Science, University of Tokyo, Kashiwa, Chiba 277-8581 Japan.

Acetaldehyde dehydrogenase 2 (ALDH2) , encoded by the ALDH2 gene on 12q24.2 in humans, is a key enzyme in ethanol metabolism along with alcohol dehydrogenase (ADH) enzymes. We previously presented LD and haplotype analyses of the ALDH2 region spanning 40 kb and found high LD values across the region, suggesting a lower recombination rate in this region (Oota et al. 2004 Ann. Hum. Gen. 68:93-109). We have extended this study to include more SNPs across 85 kb, encompassing the ALDH2 gene, and have increased the number of populations from 37 to 42. Analyses have revealed 3 distinct regions defined by Fst values that fall into the tails of the Fst distribution: unusually high Fst (95th percentile) at the two ends of the gene and unusually low Fst (5th percentile) across the middle. Each region has high LD with low LD between the regions. The downstream region contains the exon 12 dominant-negative allele that is present only in East Asia and has been postulated to have been subject to positive selection; the markedly different allele and haplotype frequencies in East Asia are responsible for this regions high Fst (0.25-0.36). The Fst values at the upstream end of the gene are as high (0.24-0.38), suggesting selection may also have occurred for this region, but it is the Europeans that have the outlier frequencies in this region. In sharp contrast, the 31 kb region across the middle of ALDH2 has only two common haplotypes averaging 81% and 17% and these account for 98% of the chromosomes in all populations studied with virtually no deviation from this pattern globally (Fst ~0.05 for all SNPs) and the pairwise LD values are very strong (r^2 0.65) in all populations. The similar frequency pattern of these two common haplotypes worldwide is extremely unusual and suggests balancing selection. Supported in part by NIH AA09379.

Variation in the MBL2 gene and in Native South Americans its relationship to tuberculosis prevalence. *A.K. Wilbur[1], A.M. Hurtado[2], K.R. Hill[2], A.C. Stone[1].* 1) Dept Anthropology, Arizona State University, Tempe, AZ; 2) Department of Anthropology, The University of New Mexico, Albuquerque, NM.

Tuberculosis infection and disease prevalence are especially high in Native South American populations, and among the Aché of Paraguay, exposure to M. tuberculosis is thought to be universal. Our extensive ethnographic and molecular data indicate that prevalence of active disease among the Aché and a neighboring Native group, the Avá, is greater than 30%. Despite extensive evidence that host genetics help determine susceptibility and resistance to tuberculosis in various populations around the world, very little research has been conducted on Native American susceptibility. This project examines the potential interplay of host genetics and environmental factors in tuberculosis susceptibility in Aché and Avá using SNPs at the MBL2 gene, which codes for the mannose-binding lectin (MBL) protein. MBL is a component of both the innate and acquired immune systems, and is particularly important as a nonspecific immune "first responder" before acquired immunity to a pathogen is developed. Three highly variable regions of exon I, previously associated with tuberculosis in other populations, show reduced variability among Aché and Avá. Further, the B allele of codon 54 is associated with TB susceptibility in Aché, and this allele is present in the Aché and Avá at frequencies much higher than those previously reported for any other group in the world. These data are discussed in the context of population history and pathogen encounters.

Y chromosome haplogroups and AZFc polymorphisms of the Han Chinese in Taiwan. *P. Yen[1,2], Y.W. Lin[1,2], L. Hsu[1], Y.H. Yu[1], T.Y. Hsu[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan.

Han Chinese constitutes 98% of the population in Taiwan. About 85% of them are descendants of early settlers who emigrated from the Southeast coast of China about 400 years ago. To compare with current Han Chinese in China, we randomly selected 580 Han men from the Taiwanese population and determined their Y chromosome haplogroups by genotyping 22 SNP markers, using mostly MALDI-TOF mass spectrometry. We found that 87% of our samples belonged to haplogroup O (containing the M9 and M175 markers), with 61% in the O3 subgroup alone. Other haplogroups found in our samples are C (6%), N (5%), Q (1.2%), R (0.6%), and D (0.3%). The distribution of the various Y haplogroups in our subjects is similar to that found in Han Chinese in Southern China previously reported by other groups. We also determined the prevalence of partial deletions and duplications of the AZFc region on the long arm of the Y chromosome. This region consists entirely of very long direct and invert repeats and is prone to rearrangement. Non-allelic homologous recombination between the gr repeats or between the b2 and b3 repeats removes about half of the AZFc region and generates deletions that are quite common in some populations. We used a novel dose-sensitive PCR assay to determine the copy number of the DAZ genes within AZFc, and applied the plus/minus STS method to study the nature of the partial deletions. The overall frequencies of partial deletion and duplication in our samples were 11% and 1.4%, respectively. Both gr/gr and b2/b3 deletions were present. The frequency of deletion varied significantly among different haplogroups, ranging from 2.3% in O1 to 86% in Q. While gr/gr deletion was found in most haplogroups, b2/b3 deletion was found only in groups C, N, O2 and O3d. Our results show that AZFc partial deletions are common Y polymorphisms in Han Chinese, similar to other populations.

Genetic similarity of individuals from the same or different human populations. *D. Witherspoon[1], E.E. Marchani[1], C.T. Ostler[1], W.S. Watkins[1], M.D. Shriver[2], D. Ray[3], M.A. Batzer[3], L.B. Jorde[1].* 1) Dept Human Genetics, Univ Utah, Salt Lake City, UT; 2) Dept Anthropology, Pennsylvania State Univ, University Park, PA; 3) Dept Biological Sciences, Louisiana St Univ, Baton Rouge, LA.

Are any two individuals from a particular population as different genetically as any two people from any two populations in the world? The answer depends on the number of loci used to compute genetic distance as well as the choice of populations. We analyzed 75 L1 and 100 Alu insertion polymorphisms genotyped in 246 individuals of European, African, East Asian, and sub-continental Indian ancestry. We computed genetic distances between all possible pairs of individuals in the data set, then determined the frequency, f, with which the distance between random pairs of individuals within continental ancestry groups exceeded the distance between pairs from different groups. With 75 L1 loci, f = 0.20. Adding 100 Alu loci reduces f to 0.15. In a reduced sample including only Indians and Europeans, f = 0.28 with all 175 loci. This is due to the greater similarity of allele frequencies between these two groups relative to the dissimilarity between Africans and Asians (for which f = 0.042.) Theory and the observation of decreasing f with increasing number of loci suggest that even for slightly divergent populations, f should approach zero as the number of loci grows. To test this, we analyzed 11,555 SNP loci typed in a different sample of 248 individuals from the same four continental groups, as well as Puerto Ricans and African-Americans. Consistent with expectations, f = 0.0015 when considering just the four continental groups and 11,555 loci. With the exclusion of the Indian individuals (who are similar to Europeans), f drops to zero. However, including the two admixed populations increases f to 0.058 due to the high degree of overlap between the admixed groups and their ancestral populations (e.g., among Puerto Ricans and Europeans, f = 0.15). Thus while some populations are quite distinct by this measure, among the less divergent groups, some individuals will be more similar to members of other populations than to others in the same population - even with very large sets of markers.

Frequency of the major susceptibility haplotype for androgenetic alopecia in the Chinese and African American population. *A. Hillmer[1], T. Becker[2], F.F. Brockschmidt[1], S. Hanneken[3], S. Ritzmann[3], J. Freudenberg[4], A. Flaquer[2], C. Metzen[3], P. Propping[4], T. Ruzicka[3], S. Cichon[1], T.F. Wienker[2], R. Kruse[3], M.M. Nöthen[1].* 1) Life & Brain Center, University of Bonn, Bonn, Germany; 2) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 3) Department of Dermatology, University of Düsseldorf, Düsseldorf, Germany; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany.

Androgenetic alopecia (AGA, male pattern baldness) is the most common form of hair loss. Its pathogenesis is androgen dependent, and genetic predisposition is the major requirement for the phenotype. We recently demonstrated that genetic variability in the androgen receptor gene (*AR*) is the cardinal prerequisite for the development of early-onset AGA, with an etiological fraction of 0.46. Here we compare the haplotype diversity at the *AR* locus of 188 German, 116 African American, and 100 Han Chinese individuals by genotyping 20 genetic variants in a region of 2.5 Mb. The haplotype diversity in the African sample is, as expected, greater than the diversity in the German and Chinese sample. In the German population, the haplotype associated with AGA has a frequency of 0.46. The frequency is 0.07 in African Americans and 0.81 in Han Chinese. The low frequency in the African American sample is in accordance with the postulated lower frequency of AGA in African populations whereas the high frequency of the haplotype in the Chinese sample is in contrast to the generally assumed lower frequency of AGA in Asia.

Multiplex MIP genotyping of 25,000 non-synonymous SNP's in 270 HapMap samples from 3 ethnic populations and 10 additional non-human primates. *T.A. Cormier, J. Ireland, V.E. Carlton, M. Falkowski, M. Moorhead, K. Tran, P. Hardenbol, A. Erbilgin, R. Fitzgerald, T.D. Willis, M. Faham.* ParAllele Bioscience, SSF, CA.

The HapMap project focuses on a genome-wide approach to define the haplotype block structure. Here we examine the same samples with a focus on genic SNPs, specifically non-synonymous SNPs (nsSNP). This study covered more than 10,000 genes across the genome. The key results show a presence of selection on some nsSNPs, that in non-human primates assay success correlates with evolutionary closeness to humans and gene category, and that there are quantitative copy number variations in some HapMap samples.

Evidence for selection was detected by finding a correlation between decreased allele frequency and likelihood to cause protein damage based on PolyPhen prediction. Additionally, selection was identified by comparison of SNPs in specific Gene Ontology (GO) categories. By comparing different populations and primates, it was possible to identify GO categories where SNPs had shifted allele frequency distributions or shifted assay success rates. As expected, the primate data was also useful to confirm that evolutionary distance from humans was strongly correlated with the success rate of assays. The primate data also identified interesting regions such as 100 contiguous markers across 1.6 Mb of chromosome 11 that failed to genotype in orangutan, possible identifying a region of deletion. Lastly the MIP assay is quantitative and so we used the coverage of SNPs across the entire genome to look for copy number variations. There are several HapMap samples showing signs of megabase size insertions or loss of heterozygosity. Overall this dataset was useful for looking at genome wide events and focusing on SNPs that may have direct biological effects.

Updating the East Asian mtDNA tree and nomenclature. *Q.-P. Kong[1,2,3], H.-J. Bandelt[4], C. Sun[1,2,3], Y.-G. Yao[1], A. Salas[5], A. Achilli[6], L. Zhong[2], C.-Y. Wang[1,2,3], C.-L. Zhu[1], A. Torroni[6], Y.-P. Zhang[1,2].* 1) Laboratory of Cellular and Molecular Evolution, and Molecular Biology of Domestic Animals, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming 650223, China; 2) Laboratory for Conservation and Utilization of Bio-resource, Yunnan University, Kunming 650091, China; 3) Graduate School of the Chinese Academy of Sciences, Beijing 100039, China; 4) Department of Mathematics, University of Hamburg, 20146 Hamburg, Germany; 5) Unidad de Genética, Instituto de Medicina Legal, Facultad de Medicina, Santiago de Compostela, Galicia, Spain; 6) Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia, Italy.

The East Asian mitochondrial DNA (mtDNA) phylogeny has been reconstructed in its main features based on complete sequencing efforts in the past few years. The recently published 672 complete mtDNA sequences from Japan could in principle provide further information to refine and update the East Asian mtDNA tree. Unfortunately, these data bear several shortcomings and the employed haplogroup designations are in conflict with the earlier nomenclature, which may lead to confusion in future phylogenetic and medical studies. Moreover, some less frequent lineages observed in East Asia have not been well characterized so far. To resolve these issues, we selected 19 mtDNAs from our large sample collection for complete sequencing, and to further identify the characteristic mutations of these novel lineages, we adopted motif-search approach in order to distinguish potentially haplogroup-diagnostic mutations of novel lineages from private mutations. By incorporating the previous studies, a total of 989 (nearly) complete mtDNA sequences were (re)analyzed, which led to an updated East Asian haplogroup classification tree that reconciled the conflicts raised among the past studies and standardized the nomenclature for this region.

Novel sequence variation in the dopamine transporter gene of the cynomolgus macaque. *C. Miller-Butterworth[1], J. Kaplan[2], S. Manuck[1], R. Ferrell[1].* 1) University of Pittsburgh, Pittsburgh PA; 2) Wake Forest University School of Medicine NC.

Social rank and related behaviors (e.g. aggression and impulsivity) have been correlated with differences in central nervous system monoaminergic activity in Old World monkeys, and cerebrospinal fluid (CSF) concentrations of monoamine metabolites and certain behavioral phenotypes (e.g. impulsivity, fear/anxiety) appear to be significantly heritable. Specific genotypes of the human monoaminergic pathways have been linked to personality traits (e.g. extraversion, novelty-seeking) and to CSF monoamine metabolite concentrations. Sequence diversity in monoaminergic gene pathways produces functional variants, which may influence behavior patterns and lead to differences in social rank. This project investigates whether sequence variation in genes of the monoaminergic pathways is significantly associated with behavioral and monoamine metabolite differences previously identified between dominant and subordinate cynomolgus macaques, *Macaca fascicularis*. The dopamine transporter (DAT) was selected as a candidate gene. It regulates synaptic dopamine concentration and duration of dopamine activity through active reuptake of dopamine from the synaptic cleft into the presynaptic terminal. DNA samples were obtained from 500 *M. fascicularis*, for which social rank is known. The complete DAT gene and promoter region were sequenced in 50 randomly selected individuals and screened for novel single nucleotide polymorphisms (SNPs) and other sequence variants. Genotype and allele frequencies were determined for each of the ~80 polymorphisms identified. None of the SNPs correlated with social status. One non-synonymous SNP was identified, which may produce a functional gene variant. It was screened in all 500 individuals by restriction enzyme analysis, but was present in only one heterozygote. None of the macaque SNPs correspond to any identified in the human DAT gene. In contrast to humans, the tandem repeat in the 3 untranslated region of the macaque DAT gene does not vary in repeat number. Furthermore, the macaque gene does not appear to display any significant long range linkage disequilibrium.

Age of SOD1 A4V mutation causing ALS and founder effect. *M. Saeed[1], H.X. Deng[1], W.Y. Hung[1], N. Siddique[1], L. Dellefave[1], Y. Yang[1], S. Ullah[1], E. Usacheva[1], C. Gelera[2], P. Andersen[2], T. Siddique[1].* 1) Neurology, Northwestern University, Chicago, IL; 2) Department of Clinical Neurosciences, Umea University, Umea, Sweden.

An alanine to valine (A4V) mutation at codon 4 of SOD1 is responsible for 50% of ALS-causing SOD1 mutations in North America. This mutation is rare in Europe. We aimed to estimate the age of the A4V mutation and to search for a founder effect. Fifty-four patients with confirmed A4V mutation and 96 healthy control subjects were genotyped for 21 SNPs across a 21cM region. Also 61 samples with SOD1 mutations other than A4V and 96 sporadic ALS (SALS) cases were genotyped to define the extent of linkage disequilibrium (LD) for the A4V mutation. High-throughput SNP genotyping was performed using Taqman assay on the ABI prism 7900HT. A biallelic CA-repeat located at the 3 end of SOD1 was genotyped using SSCP on A4V, Caucasian controls and 55 Chinese control samples. Haplotype frequencies and association statistics were estimated using Haploview. P-values less than 0.05 were considered statistically significant. We used a Bayesian method for multipoint linkage disequilibrium mapping incorporated in the program DMLE+ to estimate the age of A4V. Several SNPs in a 5.86cM associated with A4V, most notably the CA-repeat (P=1.72e-14) and rs7276171 (3cM from SOD1) (P=1.78e-6). There was no association with non-A4V SOD1 except around SOD1, and none with SALS. This indicated that the association signal spread over 5.86 cM for A4V was due to LD. A single haplotype of 14 SNPs across this 5.86cM region, absent in the controls, associated with A4V (P=1.5e-11) indicating a founder effect. Haplotype of Swedish samples was different from the associated haplotype suggesting that A4V originated on a different DNA fragment in Europe. The allele frequencies of the CA repeat in Chinese were similar to A4V cases rather than Caucasian controls, indicating that the origin of the A4V in North America was possibly in an Asian population. Using haplotype frequency data the estimated age of A4V is 35.1 to 63.1 generations (~880 to 1580 years) with 90 - 99% posterior probability.

Mutagenic motifs, recurrent mutation, infinite sites, and the sampling of SNP's in human association studies. *T.J. Maxwell[1], K.E. Hyma[1], L.C. Shimmin[2], E. Boerwinkle[2], J.E. Hixson[2], A.R. Templeton[1], MICORTEX.* 1) Dept Biol, Washington Univ, St Louis, MO; 2) Human Genetics Center, UT Houston Health Science Center, Houston, TX.

Under the infinite sites model multiple mutations at a single nucleotide site are not allowed. This model is assumed both explicitly and implicitly in most human population genetic and association studies. Recurrent mutations and site-rate heterogeneity violate this assumption and can have significant impacts on association studies and the estimation of population genetic parameters (Templeton *et al.* 2005, 2000a, 2000b, Yang 1996, Tajima 1996). Templeton *et al.* (2000a) characterized polymorphisms in a 10-kilobase region of the Lipoprotein Lipase gene and found a disproportionate number of observed mutations occurring at biochemically mutagenic motifs. A substantial number of the observed polymorphisms in the region had experienced recurrent mutation. A significant bias of recurrence was found at mutagenic motifs (Templeton *et al.* 2000b). We extend this study to multiple regions in chromosome 19 that have been sequenced for haploid chromosome lines from 60 individuals. A bias towards polymorphisms at these particular motifs was found but varied from region to region. The amount of recurrent mutation is characterized and related to the mutagenic motifs. Some of these mutagenic motifs result in an asymmetric mutational bias that may exacerbate the impact of violating the infinite sites model. A biased sampling scheme of picking older and more frequent polymorphisms is commonly used in association studies and will likely increase the probability of picking SNPs with recurrent mutational histories. This study suggests site-rate heterogeneity is common and recurrent mutation is not rare.

Genetic variations of non-synonymous mutations in *MBL2* in different human populations provide evidence for recent natural selection. *T. Bernig[1], E. Tarazona-Santos[1], W.S. Modi[2], M. Yeager[2], R.A. Welch[2], S. Chanock[1].* 1) Section on Genomic Variation, POB, National Cancer Institute, Bethesda, MD; 2) Core Genotyping Facility, ATC, National Cancer Institute, Gaithersburg, MD.

Mannose-binding protein (MBL) is encoded by the *MBL2* gene and is a critical component of the innate immunity. Common *MBL2* haplotypes, which are based on 3 linked 5 variants and 3 non-synonymous SNPs in exon 1 (known as B, C and D), influence serum level and functional activity of MBL. Previously, we have described the nucleotide diversity and haplotype pattern across the entire *MBL2* gene in 102 individuals from the SNP500Cancer initiative. Now we have selected 15 tagging SNPs, which include the 6 linked variants that compromise the secretor haplotypes. We studied these variants in the CEPH Human Genome Diversity panel (1056 individuals from 52 populations) to describe the geographical pattern of genetic variation in *MBL2*. We performed the analysis with all 15 SNPs as well as with the 6 functional SNPs separately with the assumption that natural selection has played a more significant role in shaping the patterns observed on the latter group. For the 15 SNPs, our analyses show a low level of differentiation among populations (F_{ST} 0.057, $p<0.001$) and among geographic groupings of populations (Africans, Europeans, Middle East, Central/South Asians, East Asians, Oceanians, Native Americans, F_{CT} 0.041, $p<0.001$). The within-population diversity significantly decreases with an increasing distance from East Africa (Spearman =-0.659, $p<0.0001$). The 6 functional SNPs show evidence of higher levels of differentiation (F_{ST} 0.112 $p<0.001$; F_{CT} 0.093, $p<0.001$). Whereas the C-allele was only seen in populations close to East Africa (< 10,000 km), the within-population variability enlarges for the functional B-allele with distance from East Africa (Spearman =0.373, $p<0.007$). These differences among the pattern of the 15 SNPs and the 6 functional SNPs suggest that natural selection has contributed to the observed high frequencies of variant B or C alleles in populations for which there is selective advantage for heterozygosity. Additionally, we will provide extensive resequencing data to prove this assumption.

The family of genes encoding T-cell immunoglobulin and mucin-domain containing proteins (Tim), which are cell-surface molecules expressed in CD4+ T helper cells, has important roles in the immune system. Here we report three unusual patterns of genetic variation in the human hepatitis A virus cellular receptor 1 gene (*HAVCR1*) that are similar to patterns observed in major histocompatibility complex (MHC) loci. First, levels of polymorphism in exon 4 of *HAVCR1* were exceptionally high in humans (nucleotide diversity () = 45.45 x 10-4). Second, non-synonymous substitutions and insertion/deletion variants were more frequent than synonymous substitutions in that exon (10 out of 12 variants). The rate of the mean number of nucleotide substitutions at non-synonymous sites to at synonymous sites at *HAVCR1*-exon 4 is >1 (P_A/P_S=1.92 and $_A /_S$ =2.23).'@Third, levels of divergence among human, chimp, and gorilla sequences were unusually high in *HAVCR1* exon 4 sequences. These features suggest that patterns of variation in *HAVCR1*, like those at MHC loci, have been shaped by both positive and balancing natural selection in the course of primate evolution. Evidence that the effects of natural selection are largely restricted to the mucin domain of HAVCR1 suggests that this region may be of particular evolutionary and epidemiological interest.

Stratified linkage analysis of sarcoidosis based on admixture in a sample of African-American families. *C. Gray-McGuire[1], C.L. Thompson[1], B.A. Rybicki[2], M.C. Iannuzzi[3], R.C. Elston[1], S.K. Iyengar[1].* 1) Dept of Epidemiology and Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Dept of Biostatistics and Research Epidemiology, Henry Ford Health System, Detroit, MI; 3) Division of Pulmonary, Critical Care and Sleep Medicine, Mount Sinai School of Medicine, New York, NY.

Sarcoidosis is an autoimmune disorder of unknown etiology. In the United States, African-Americans are more frequently and more severely affected than Caucasians, females accounting for a large majority of the cases. The first genome scan that was conducted in African-American families ascertained through two siblings affected with sarcoidosis indicated linkage to chromosome 5 and showed marginal evidence of linkage to 6 other regions (Ianuzzi et al, Genes Immun 2005). Because of the known admixture in African-Americans with Caucasian and other populations, we evaluated these linkages in light of the admixture in our sample. The population structure of our sample was inferred via the program STRUCTURE, using the 380 microsatellite markers from our genome scan. Evidence of two subpopulations was found, with seven of the 229 families estimated to be 98% of one subpopulation, 118 estimated to be 98% of another subpopulation, and four of the families representing a mixture of the two subpopulations. The linkage analysis was repeated on the families in these two respective subpopulations using the genome scan marker set. The stratified analysis suggests that several of the regions identified in the original scan are due to subpopulation one (1p22, 11p15 and 17q21) or subpopulation two (5p15-13 and 20q13), while others remain significant in both (2p25, 5q11, 5q35 and 9q34). Evidence for a new locus only in subpopulation two (2q37) was also found. This analysis demonstrates the utility of admixture information to identify more homogeneous subsets of families in studies of complex disease. It also provides evidence for multiples genes influencing sarcoidosis and that these genes may be population specific. Further analysis to better characterize the subpopulations is underway.

De novo gene conversion in the RCA cluster (1q32) causes mutations in complement factor H associated with atypical hemolytic uremic syndrome. *J. Goodship[1], L. Strain[1], M. Jackson[1], S. Heinan[2], P. Zipfel[2], P. Sánchez-Corral[3], S. Rodríguez de Córdoba[3].* 1) Inst Human Genetics, Univ Newcastle upon Tyne, Newcastle on Tyne; 2) Hans Knoell Institute, Jena; 3) Departmento de Immunologia, Centro de Investigaciones Biologicas, Madrid.

CFH mutations are associated with atypical hemolytic uremic syndrome (aHUS; OMIM 235400). CFH is in the RCA (Regulators of Complement Activation) gene cluster on human chromosome 1q32, which contains more than 60 genes of which 15 are complement related genes. There is a high degree of sequence identity between the genes for factor H (CFH) and the five factor H-related proteins (CFHL1, CFHL2, CFHL3, CFHL4 and CFHL5). There are two nucleotide differences between the coding region of the final exon of CFH and CFHL1 leading to serine/leucine and valine/alanine differences. We have identified two patients in whom S1191L and V1197A have occurred in combination as de novo events. In both cases the changes occurred on the same allele. The amplicon encompassed three upstream intronic single nucleotide difference between CFH and CFHL1 and four downstream single nucleotide differences in the 3 untranslated region. In each case the changes affected only the two coding nucleotides, compelling evidence for gene conversion. Whilst there is circumstantial evidence for gene conversion in a number of diseases unambiguous evidence from de novo events is rare. In our cohort of patients with aHUS, we have identified CFH mutations in 25 families or individuals. 3 (including the 2 de-novo cases) are S1191L and V1197A together, 4 are S1191L and 2 have V1197A. We have confirmed in functional assays that these changes, alone or in combination, result in impaired protection of host surfaces against complement activation. We conclude that gene conversion events represent 9/25 (36%) of CFH mutations in the HUS patients we have studied.

Common polymorphic deletions in the human genome. *S.A. McCarroll[1,2], S.B. Gabriel[2], M.J. Daly[1,2], D.M. Altshuler[1,2].* 1) Massachusetts General Hospital, Boston, MA; 2) The Broad Institute, Cambridge, MA.

The specific locations, population distribution, and history of structural variants in the human genome are largely unknown. We would like to identify parts of the genome that are missing in many individuals; to discover and localize such deletions on the scale of specific exons and regulatory elements; and to distinguish between ancestral and recurring structural mutations. With these goals in mind, we have developed an approach for using SNP genotypes to discover, localize, and learn the population genetic history of common polymorphic deletions. Our approach is based on the footprint that segregating deletions leave in SNP genotypes, in the form of physical clusters of apparent Mendel conflict, Hardy-Weinberg disequilibrium, and null genotypes. Applying this approach to HapMap genotypes from 270 individuals from three continental populations, we discovered hundreds of polymorphic deletions ranging in size from 1 to 750 kb, including more than 100 common deletions. These optional components of the human genome include expressed genes thought to contribute to drug response, immune response, olfaction, and sex steroid metabolism. To determine the population genetic history of common deletions, we have typed them in hundreds of individuals from the HapMap populations and integrated this structural variation data with SNP haplotype data from the same individuals. Most common deletions appear to result from ancestral mutations that have been inherited by descent. The overwhelming majority of common deletions are in linkage disequilibrium with nearby SNPs and are therefore detectable in whole-genome disease association studies, particularly if such studies are designed with knowledge of a whole-genome deletion map.

Methods for dating of origin of mutations by using diversity at microsatellites linked with the site of the mutation. *X. Sheng, R. Chakraborty.* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Linkage studies or positional cloning analyses have identified disease-causing mutations for a number of genetic disorders and clinical phenotypes. Such data often use the presence of microsatellite markers at close vicinity of the mutation-site. The AIDS-resistance CCR5-delta32 mutation is one such example, for which the proportion of mutation-carrying chromosomes that preserved the same microsatellite haplotype has been used to date the time of occurrence of the CCR5 mutation as 27.5 generations, or approximately 690 years. Coalescence theory provided this estimate of the time of occurrence of the mutation, assuming that the mutation rate (0.001/locus/generation) at the microsatellite locus and the recombination rate (0.005 per meiosis) between the microsatellite locus and the site of mutation are both known. Since microsatellite mutation rates have a large inter-locus variance, we provide an alternative method of dating the origin of the mutation, in which haplotype retention proportion as well as allele size variance at the microsatellite locus on chromosomes carrying the mutation are jointly used to estimate the time of origin and the mutation rate at the microsatellite locus simultaneously. Recombination rate, in this procedure, is estimated from the physical map distance of the site of mutation and the microsatellite locus. Our numerical computations which include information on the dinucleotide marker more distant from the CCR5-delta32 mutation site suggest that the date estimate (22.7 generations) with the conjoint use of the allele size variance data agrees well with the estimate (19.2 generations) based on haplotype retention probability alone and the estimated mutation rate ($7.87*10^{-5}$) is more consistent with dinucleotide mutation rates published in the literature. Coalescence-based simulation experiments also provide the relative efficiency of the time estimator based on haplotype retention and allele size variance in comparison with the one based on the haplotype retention probability alone. (Research supported by the NIH grant GM 41399 to RC).

Relationship of Ethnic Groups in Western China --Insights from Patrilineal Lineage Genetics. *Y. Chen, J. Chu.*
Medical Genetics, Ins. Med. Bio., CAMS, Kunming, Yunnan, China.

There are 56 different ethnic groups residing in China, and the research on genetic structure will help us to understand the genetic polymorphism and the relationship of these Chinese ethnic groups. To investigate the relationship between the ethnic groups in western China from the point view of patrilineal lineage genetics, the genetic polymorphism of the YAP+ and Y-SNPs haplotype were studied. For the genetic polymorphism of the YAP+, we selected the DNAs of 1006 healthy individuals in 27 ethnic groups in China. The result showed that the YAP+ frequencies in the following populations were: Zang 36.7%,Tuzu 23.8%,Yi 18.4%,Pumi 11.3%,Tajik7.4%,Bai.7%,Jino 5.1%,Shandong Han 4%,Mulao 2.7%,Maonan 2.2%. The YAP+ element could not be detected in Gansu Han, Yunnan Han, Zhuangzu, Dai, Li, Nu, Lisu, Naxi, Lahu, Dulong, Hani, She, Weiwuer, Sala, Kerkizi, Dongxiang and Wa. In these ethnic groups, the genetic studies were reported for the 1st time to conduct on Tajik, Mulao, Maonan, Sala, Kerkezi, Dongxiang and Jino populations. Conclusion: The Sino-Tibetan language families (Zang, Tu, Yi, Pumi, Jino, and Bai) carried high YAP+ frequency. Sala, Tu and Tajik known to have been originated from Central Asia by history and linguistics, also had high YAP+ frequency. Mulao and Maonan, presumably originated from Baiyue ancient ethnic groups, had comparatively high YAP+ frequency. We found that YAP+(H2 and H3) were also carried by Baiyue groups, which is different from other previous reports: ethnic groups originated from Central Asia carries a very low YAP+ frequency. Besides, 6 ethnic groups patrilineal genetic structure data of 13 Y-SNPs haplotype were analyzed, which were Tajik,Dongxiang,Weiwuer,Kerkezi,Mulao and Maonan. The results showed that Mulao and Maonan carried typical Baiyue genetic characteristics. Three ethnic groups (Kerkezi, Dongxiang and Weiwuer) of the Altai Language family and one ethnic group of Indio-European Language (Tajik) also carry similar Y-SNPs haplotype distribution. The genetic characteristics of these ethnic groups are similar to their linguistics,histories and archeology relationships .

Haplotypes and LD of the DTNBP1 locus in worldwide populations. *K.K. Kidd, A.J. Pakstis, W.C. Speed, J.R. Kidd.*
Department of Genetics, Yale University School of Medicine, New Haven CT 06520-8005 USA.

DTNBP1 on 6p22.3 has been implicated as a locus with alleles conferring susceptibility to schizophrenia in studies of several European populations. As background for planning further studies we have typed 16 SNPs across ~180 kb encompassing the gene. A 112 kb segment toward the 3' end of the gene shows strong LD in most of the 42 population samples studied but with one 11-site haplotype at a frequency of at least 50% in most populations. Within this segment the pattern of sub-segments with stronger LD is remarkably consistent among populations including African populations. However, the sub-segments with stronger LD do extend farther in the East Asian and Native American populations. Two 11-site haplotypes that exist in moderate frequencies in African and in European populations are generally absent in the East Asian and Native American samples. One 11-site haplotype that occurs at 15 to 20% in the two African Pygmy populations is rare in other African populations and is not seen outside of Africa. LD does not extend to either end of the gene except in a few of the smaller, more isolated populations. When all 16 sites are considered, 32 haplotypes occur among all populations at common frequencies of 5% or more with any single sample having 3 to 9 of these; no haplotype occurs at more than 20% frequency in any African or European population and most are 10%. There is greatly reduced variation in East Asian and Native American populations with only three haplotypes accounting for 75% of chromosomes in most East Asian populations and two of these accounting for 50% of chromosomes in Native American populations. The absence of LD between variation at the 5 end of the gene and the common haplotypes through much of the coding region may explain the association of schizophrenia with different haplotypes in different populations if regulatory variation is what is etiologically relevant. Supported in part by NIH GM57672 and MH041953.

Analysis of ancient mitochondrial DNA lineages in Yakutia. *S.A. Fedorova[1], T. Ozawa[2], A.D. Stepanov[3], E.K. Jirkov[3], L.L. Alekseeva[3], M. Adoyan[4], J. Parik[4], R. Villems[4].* 1) Department of molecular genetics, YaNC of RAMS, Yakutsk, Republic Sakha (Yakutia), Russian Federation; 2) Laboratory of Geobiology of Nagoya University, Nagoya, Japan; 3) Institute of Archaeology and Ethnography, Yakutsk, Russia; 4) Estonian Biocenter and Tartu University, Tartu, Estonia.

Molecular genetic analysis of ancient human remains are mostly based on mitochondrial DNA due to its better preservation in human skeletons in comparison with nuclear DNA. We investigated mtDNA extracted from human skeletons found in graves in Yakutia to determine their haplotypes and to compare them with lineages of modern populations. Ancient DNA was extracted from fragments of three skeletons of Yakut graves at At-Dabaan, Ojuluun and Djaraama sites (dating XVIII century) and two skeletons of Neolithic graves at Kerdugen site found in central Yakutia. Three fragments of HVSI of mtDNA were amplified 15986-16149, 16106-16271, 16209-16401. After the PCR the products were purified and the fragments of HVSI were cloned in plasmide M13. 5 - 10 clones were analyzed for each DNA fragment. Sequence reactions were performed using DYEnamic ET terminator cycle sequencing kit, Amersham Pharmacia Biotech. Haplogroups were identified by mutations against the Cambridge reference sequence. Five different haplotypes belonging to specific Asian haplogroups were identified. Lineages of mtDNA of Yakut graves belong to haplogroups C4a, D5a and B. This haplotypes were revealed earlier in the mitochondrial gene pool of modern Yakut population (Fedorova, 2003; Puzirev, 2003, our unpublished data). Our results indicate the continuity of mitochondrial lineages in the Yakut gene pool during the last 300 years. Haplotypes of two humans from Kerdugen site graves belong to haplogroups A and G2a/D. We compared these haplotypes with that of 23048 Eurasian individuals, 860 of them from Yakutia. No exact matches were found in modern populations of Yukaghirs, Chukchi, Eskimos, Koryaks and Itelmens. Phylogenetically close haplotypes (1 mutation) were found in populations of Evens, Evenks and Yakuts, as well as in some populations of Central Asia, South Siberia, Mongolia and North China.

Princess Ngonnso' and the foundation of the royal house of Nso'. *K.R. Veeramah[1], D. Zeitlyn[1], V.G. Fanso[2], B.A. Connell[3], M.E. Weale[1], N. Bradman[1], M.G. Thomas[1].* 1) The Centre for Genetic Anthropology, University College London; 2) University of Yaoundé, Cameroon; 3) York University, Toronto.

Background: The Nso' (population >300,000) live in the region of their pre-colonial empire in the western Grassfields of Cameroon. They are divided into four caste-like groups (CLGs), including a royal CLG, the *wonto'*. Accounts of the origin of the Nso' are recorded in multiple oral traditions of which the most common tells of a Princess Ngonnso' migrating from the Tikar region to the east and encountering a group of indigenous hunter-gathers (the Visale) amongst whom she settled some 250-700 years ago. Opinion differs as to whether the Princess came with a Tikar husband or married a Visale chief but it is agreed that her son became the first Fon (king) of Nso' from whom all subsequent Fons claim descent along the paternal line. **Aim:** We investigated which of the different variants (if any) of the oral history are consistent with genetic data obtained by analysing the non-recombining portion of the Y-chromosome (NRY) and mitochondrial DNA (mtDNA). We formulated prior hypotheses of the distribution of NRY and mtDNA types consistent with (1) alternative versions of the oral history and (2) none of the alternatives. The NRY of males from the Nso' and 12 other Grassfields and Tikar region groups were typed and the mtDNA HVS-1 and key coding region markers characterised in the Nso'. **Results:** We identified an NRY type characteristic of hunter-gatherer populations, thought to have been common before the expansion of the Bantu-speaking peoples, at a high frequency in the *wonto'* (>50%) but at much lower frequencies in the other CLGs and at only 0.001% in the non-Nso' groups. In contrast, we found no significant difference in the frequencies of mtDNA types among the Nso' CLGs (P>0.285)). These results are consistent with the most common origin story of the Nso': that the father of the first Fon was more likely to have been a Visale rather than a Tikar. This study demonstrates the usefulness of genetics, complementing other disciplines such as anthropology, linguistics and archaeology, in recovering the histories of peoples of sub-Saharan Africa.

Admixture Linkage Disequilibrium in African American. *S. Xu[1], H. Wang[2], Y. Wang[2], Y. Liu[2], Y. Wang[2], X. Chu[2], Y. He[1], Y. Wang[1], W. Huang[2], L. Jin[1,2,3].* 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) Center for Genome Information, University of Cincinnati, Shanghai, USA.

Linkage disequilibrium due to admixture (ALD) has important value in locating genes underlying diseases or phenotypes of distinctive ancestral history. In this study, we examined ALD in a sample of 48 African-Americans (AfAs) of 24,339 SNPs encompassing the entire chromosome 21. Overall 1,740 ancestry informative markers were selected for more detailed analyses. Putative ancestral origin of chromosomal segments in individual AfAs was inferred using 60 CEPH parents and 60 Yoruba parents in the international HapMap Project. The average European ancestry proportion of AfA individuals was estimated as 21.1% ranging from 0.3% to 78.6%. The average length of chromosomal blocks of African origin is 7 cM, while that of European origin is 2 cM. Interestingly, ALD in our sample extends on chromosome 21 much shorter than those of other studies involving other chromosomes and different African Americans. The level and pattern of admixture linkage disequilibrium is likely to specific to certain genomic regions and populations that have different admixture levels. The current results should have great implication for admixture mapping.

The genetic structure of human populations studied through short insertion-deletion polymorphisms. *L. Bastos-Rodrigues[1], J.R. Pimenta[2], S.D.J. Pena[1,2].* 1) Bioquímica e Imunologia, UFMG, Belo Horizonte, MG, Brazil; 2) GENE-Núcleo de Genética Médica, Belo Horizonte, MG, Brasil.

In 2002 Rosenberg et al. published a landmark study of the structure of human genome diversity without prior population definition, by using a set of 377 microsatellites and the HGDP-CEPH Human Genome Diversity Panel. They reported that the populations included in the study were best structured into genetic groupings that tightly corresponded to five regions: America, Sub-Saharan Africa, East Asia, Oceania and a cluster composed of Europe, Middle East and Central Asia. They also observed that the within-population differences among the individuals accounted for 93-95% and that the among-regions variation was only 3.6% of the total genetic variance. We have also studied the HGDP-CEPH Diversity Panel (1064 individuals from 52 populations) with a set of 40 biallelic slow-evolving short insertion-deletion polymorphisms (indels). We loci were widely spread in the human chromosomes and in their vast presented allelic frequencies in the range 0.4-0.5 in European population. We confirmed the partition of worldwide diversity into five genetic clusters that correspond to major geographic regions. Analysis of molecular variance (AMOVA) demonstrated that, within populations, the differences among individuals accounted for approximately 86% of genetic variation, while those differences among geographic regions constitute approximately 12%. With the indels, we have also disclosed an among-regions component of genetic variance considerably larger (12.1%) than had been estimated using microsatellites. Our results agree much better with estimates obtained in several previous studies and indicate that the probable reason for the underestimation of this component of variation in the analysis of Rosenberg et al. (2002) was not the sampling scheme, as they posited, but rather their use of fast evolving microsatellite markers. Our study demonstrates that a set of 40 well-chosen biallelic markers is sufficient for a detailed characterization of human population structure.

Assessment of global genetic diversity of the Azorean population by 24 microsatellite loci. *C.C. Branco[1,2], P.R. Pacheco[1,2], R. Cabral[1,2], L. de Fez[1,2], B.R. Peixoto[1,2], L. Mota-Vieira[1,2].* 1) Molec Gen & Pathology Unit, Hosp Divino Espirito Santo, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

The pattern of genetic diversity is the result of many evolutionary processes and, its knowledge is crucial to understand how history and demography shaped the structure of a population. Here, we describe the genetic diversity of the Azorean population, and compare it with a sample from mainland Portugal. We studied 24 microssatelite loci (TPOX, D3S1358, FGA, CSF1PO, D5S818, D6S265, TNF, D7S820, D8S1179, D9S762, D10S525, TH01, VWA, D13S317, D14S306, FES/FPS, D16S539, D17S976, D18S51, D19S433, D20S161, D21S11, D22S417 and DXS983) in 222 Azorean and 31 mainland Portuguese unrelated blood donors. These short tandem repeat (STR) markers were typed by Polymerase Chain Reaction (PCR) with fluorescently labelled primers. Allelic frequencies were statistically analysed using Arlequin v.2.0. Comparisons between samples were performed by Genepop web version and GDA. Phylogenetic trees based on Neis genetic distance were constructed with DISPAN and PHYLYP softwares. Analysis of microsatellite loci shows that the Azorean population presents lower average gene diversity (0.776) when compared with mainland Portugal (0.781). Moreover, we observe a higher inbreeding (FIS=0.0531) in the Azoreans. In both samples, the markers TPOX and D17S976 showed the lowest (0.6) and highest (0.9) values of gene diversity, respectively. The admixture coefficient (mY) reveals Portuguese as the major contributors to the genetic background of the Azoreans. This observation is corroborated by the dendrogram, in which Azores clusters with Portuguese, Spanish, Italians, and Belgians, apart from Moroccans and Cabo Verdeans. Taken together, these data complement settlement history of the Azorean population and will be important for future studies of genetic diseases. (claudiacbranco@hdes.pt). Funded by DRCT (Azores).

How likely is this structural change to be deleterious? *K. Li, L.L. Chen, H.L. Gao, B. Scaringe, S.S. Sommer.*
Molecular Genetics, City of Hope, Duarte, CA.

When an amino acid substitution not known to be a polymorphism/rare variant is found in a patient on DNA testing, what is the likelihood that it is deleterious? A "likelihood algorithm" is being validated and optimized for the factor IX gene, a uniquely advantageous system in which more than 1000 unique substitutions cause hemophilia B and more than 50 wildtype sequences across species demonstrate more than 1000 neutral amino acid substitutions. The algorithm assigns "deleterious probabilities" with confidence intervals to any given amino acid substitutions. The algorithm can be adapted to other genes by inputting the wildtype sequences known, and the deleterious and neutral variants available from mutation databases and other sources. Further validation of the likelihood algorithm with other genes will be required to demonstrate it's general utility. A likelihood algorithm may provide clinicians with an objective, real time estimate of the likelihood that a functionally deleterious missense mutation has been defined.

No association was found between three SNPs in the ghrelin precursor gene with variations in body fat and serum lipid parameters in the Newfoundland population. *G. Sun, G. Martin.* Dept Genetics, Memorial Univ Newfoundland, St John's, NF, Canada.

Ghrelin has been recognized for its involvement in food intake and control of energy homeostasis. However, the roles of genetic variations in the ghrelin precursor gene (GHRL) on body compositions and serum lipids are not clear in humans. Our study was designed to investigate three single nucleotide polymorphisms (SNPs) within GHRL to determine their relationship with body fat percentage (%BF), trunk fat percentage (%TF), and serum lipids in a large study (1182 subjects) from the province of Newfoundland and Labrador (NL), Canada. %BF and %TF were measured using dual-energy X-ray absorptiometry. Serum concentrations of glucose, insulin, total cholesterol, triglycerides, high-density lipoprotein-cholesterol, low-density lipoprotein-cholesterol, and risk ratio were determined. Genomic DNA was extracted from whole blood and all subjects were genotyped for an A/G polymorphism (mis-sense mutation) found in exon 1 (rs35684), a C/T intronic polymorphism located between exon 2 and exon 3 (rs2075356), and an A/G intergenic polymorphism found near the 3 untranslated region (rs26311) of GHRL using TaqMan Validated SNP Genotyping Assays and an ABI 7000 SDS. The frequencies for alleles A and G of the SNP located in exon 1 were 0.73 and 0.27, frequencies for alleles C and T of the intronic SNP were 0.11 and 0.89, and frequencies for alleles A and G of the SNP located in the 3 intergenic region were 0.88 and 0.12, respectively. All SNPs investigated were in Hardy-Weinberg equilibrium according to Chi-Square analysis. There was no evidence of an allele, genotype, or haplotype association between any of the variant sites with body compositions or serum lipids in our study. Analyses were also repeated after adjusting for possible confounding factors: age and sex for body compositions and age, sex, and %BF for serum lipids. The results, however, remained consistent. The results of our study do not suggest a significant role for the genetic variations in the GHRL gene in the differences of body fat and serum lipid profiles in the NL population.

Extensive polymorphism of A^1, A^2, B, O^1, O^2 alleles and identification of five novel alleles at the ABO blood group locus in a Kuwaiti population. *M.M. El-Zawahri[1], Y.A. Luqmani[2], S.P. Yip[3], P.S. Choi[3].* 1) Dept Biological Sci, Fac Sci, Kuwait Univ, Kuwait; 2) Dept Pharmaceutical Chem, Fac Pharmacy, Kuwait Univ, Kuwait; 3) Biomedical Sci, Hong Kong Polytechnic Univ, Hong Kong.

The genetic polymorphism described in the present study is the first demonstration of an extensive variability linked to alleles and sub-alleles of the ABO blood group gene in the Kuwaiti population. Kuwaiti population is composed of multiplex Kuwaiti families, mainly from 3 major Asian ancestral populations from Saudi Arabia, Iraq and Iran. Genomic DNA samples from 521 unrelated Kuwaiti donors were analyzed for the ABO alleles and sub-alleles. Genotyping of 355 DNA samples was done by a multiplex PCR-FRLP analysis. Fragments of 252(251 for O^1) bp and 843(842 for A^2) bp cover the 2 major exons 6 and 7 of the ABO gene were amplified and digested with HapaII and KpnI. Thirteen genotypes were found from the A^1, A^2, B, O^2, and O^2 alleles in the Kuwaiti sample population analyzed. Two genotypes (A^2A^2 and O^2O^2) were not detected. The frequencies of the five alleles are 0.1579, 0.0199, 0.1566, 0.6243 and 0.0413, respectively. 166 DNA samples were genotyped by a multiplex PCR-SSCP analysis. Three PCR fragments were amplified from exon 6, the 5 end and the 3 end of exon 7. Genotypes of classical alleles (A101, A102, A201, B101, O101, O201 and O303) could easily be identified. Non-standard SSCP patterns were investigated by DNA sequencing of exons 6 and 7 of the ABO gene, and intron 6 if necessary. Sixteen alleles producing a total of 31 genotypes were identified among the samples analyzed. In addition to the six classical alleles, ten variant alleles were found: one A, one B and 8 O (total frequency = 0.1175). Five of these 10 variant alleles are novel alleles defined by SNPs in exon 7 (527GA, 649CT, 687CT, 689GA and 1116GA). Three new base substitutions result in amino acid changes. The present data provide an exciting new dimension to our understanding of human genetic polymorphism in the Kuwaiti population. Supported by Kuwait University Research Administration Grant SZ 01/00 and School of Nursing, The Hong Kong Polytechnic University.

Geographic Region-specific selection in *ADH* Class I genes. *Y. Han[1], H. Oota[1], S. Gu[1], M. Osier[2], A. Pakstis[1], J. Kidd[1], K. Kidd[1].* 1) Department of Genetics, Yale University School of Medicine, New Haven, CT; 2) College of Sciences, Biological Sciences, Rochester Institute of Technology, Rochester, NY.

ADHs are a family of enzymes that catalyze the reversible oxidation of alcohol to acetaldehyde. Seven human *ADH* genes have been identified. They exist in a cluster extending > 360kb on the long arm of chromosome 4 (4q21). We have typed 42 human worldwide populations for 36 SNPs across the three Class I *ADH* genes. These genes share 95% sequence identity as a result of duplication at the base of the primate lineage and selection to maintain function. The middle gene, *ADH1B*, has a functional variant associated with protection against alcoholism (*ADH1B*47His*) in exon 3 at > 60% in East Asian populations believed to be so frequent because of region-specific positive selection. The F_{st} for this variant, 0.48, is among the highest seen for any of the *ADH* sites in these populations. Markers on either side, from 10kb upstream to 40kb downstream, also show high F_{st} values. Half of the sites (8 out of 16) have F_{st} values above the 95^{th} percentile of the reference F_{st} distribution for these 42 populations; these elevated values do not extend to the next gene upstream, *ADH7*, or the next gene downstream, *ADH6*. In both cases the F_{st} values are approximately the mean for the reference F_{st} distribution, i.e., about 0.14. Besides F_{st} statistic, another genomic test, Long Range Haplotype (LRH) test also gives statistical evidence for the positive selection for this functional variant in East Asian populations. In most populations, LD does not extend much beyond the individual *ADH* Class I genes. However, we found the extended haplotype homozygosity (EHH) of the most exclusively high frequent haplotype including that functional variant decayed more slowly than those of other haplotypes in East Asian populations. The strong extended haplotype homozygosity (EHH) is found across 10~28kb upstream and 50kb downstream of the *ADH1B* Arg47His variant in East Asian populations. Therefore, both F_{st} Statistics and LRH test support the conclusion that selection has acted around the *ADH1B* functional variant in East Asian populations. [Supported in part by NIH grant AA09379].

Using Hispanic genetic diversity to infer the haplotype structure of Native Americans. *E. Tarazona-Santos[1], M. Yeager[2], B. Staats[2], R. Welch[2], L. Burdette[2], B. Packer[2], S. Chanock[1].* 1) Section of Genomic Variation, Pediatric Oncology Branch, NCI/NIH, Bethesda, MD; 2) Intramural Research Support Program, SAIC-Frederick and Core Genotyping Facility, NCI-NIH, Bethesda, MD, USA.

Cultural and logistic factors have prevented studies about genomic diversity in Native American. Fortunately, information about their patterns of haplotype structure could be recovered studying admixed populations, whose gene pool has received contributions from Europeans, Africans and Native Americans. The SNP500Cancer initiative (http://snp500cancer.nci.nih.gov/) has generated data about the haplotype structure for more than 500 genes important in cancer in Hispanic, European and African populations. For admixed populations, such as Hispanics, the linkage model of the program Structure uses mapping information from markers and allows estimation of admixture for specific genomic regions on the basis of the admixture linkage disequilibrium, provided that enough marker density is attained. Using this approach and data from more than 5000 SNPs organized in haplotypes and 377 STR, we estimated the admixture contribution of Native American, European and African populations for specific genomic regions. The average admixture across the genome was 17% for Native American, 13% for African and 70% for European, but these estimates vary across the genome. From region-specific admixture estimators and observed haplotype frequencies in Hispanics, European and Africans, we have inferred the haplotype frequencies for an average Native American population for more than 300 genes and tested our inferences against observed frequencies for a subset of genes in a Native American sample (50 Pima-Maya individuals). This approach is particularly useful to identify genes for which haplotype frequencies differ markedly in Native American respect to the other parental populations. It should facilitate estimation of haplotype structure of Native American populations in regions where study is difficult but admixture common. An interesting anthropological application of this approach is the study of genetic diversity in extinct populations that have left traces of their gene pool in current populations.

STR's, DYS199 and DYS287 markers in three amerindian groups from Venezuelan western. *l. Borjas[1], T. Pardo[2], W. zabala[1], M.A. Sanchez[1], M.G. Portillo[1], J.A. Aranguren[3].* 1) genetic, university of zulia, Maracaibo, Venezuela; 2) biological research institute, University of Zulia; 3) genetic department, faculty of veterinary, University of Zulia, Maracaibo, Venezuela.

Zulia state is located at northwest of Venezuela, has between its main indigenous groups, Wayúu, Bari and Yukpa, which are derived from three main linguistic branches: Arawaca, Chibcha and the Caribbean respectively. In order to clarify the origin and their structure, we analyzed 78 chromosomes of masculine individuals not related, Wayúu (50), Barí (16) and Yukpa (12). The STRs systems were investigated: DYS19, DYS389I/II, DYS390, DYS391, DYS392 DYS393, DYS437, DYS438, DYS439 and DYS385 a/b. In adition, DYS199 and DYS287 markers (polymorphism of insertion Yap Alu) were characterized. The characterization was made in a ABI 310 and electroforesis in gel of agarosa to 2 % according to the case. The values of genic and haplotypic diversity, AMOVA and the obtaining of a distance matrix were calculated through the Arlequín program, version 2000. The study of Principal Components Analysis was made (PCA) using SAS program. The degree was considered in addition to mixture of parentals populations through the program Admix 3. The results generated were compared with data reported in literature for other amerindian populations. According to the STR's, the groups Barí and Yukpa have 100 % of amerindian component whereas the Wayúu group showed mainly amerindian component followed of the European contribution. Negative Yap was present in all the natives of the three groups. The Bari and Yukpa only showed ancestral T allele, whereas the Wayúu has 40 % of C allele. The three ethnic groups have different genetic structures. These data keep agreement with the historical documentation about the peoplement from the Zulia state. This work was partially subsidized by CONDES, according to Nº CC-457-01.

High resolution Y-chromosome analysis of surname association with paternal relatedness. *S.R. Woodward[1,2], N.M. Myres[1], J.B. Ekins[1], J.E. Ekins[1], L.A.D. Hutchison[1], L. Layton[1], M.L. Lunt[1], S.S. Masek[1], A.A. Nelson[1], M.E. Nelson[1], K.L. Pennington[1], U.A. Perego[1], J.L. Peterson[1], K.H. Ritchie[1], T. Tolley[1].* 1) Sorenson Molec Genealogy Fndn, Salt Lake City, UT; 2) Dept Molecular Biol, Brigham Young Univ, Provo, UT.

The correspondence of surname and relatedness has been used as an indicator of population subdivision in both epidemiological and population migration studies. Recently, a limited number of studies have used the Y-chromosome to assess the validity of using surname as a measure of paternal relatedness due to its analogous paternal transmission. These studies have reported varied results depending on the particular surname, the resolving power of the marker system, and the population(s) under investigation. To further characterize the correlation of surname and paternal relatedness we have analyzed 9,100 male samples representing 5,556 surnames at 36 Y-chromosome STR loci. We report surname frequencies and classify non-unique surnames as mono or polyphyletic. Paternal genealogies were used to identify potential ancestral and/or geographic origins for each lineage within each of the polyphyletic surname groups. These findings have application to estimating non-paternity rates, compiling forensic databases, population genetic studies, epidemiological studies, and ancestry testing.

High Throughput Genotyping of Potentially Functional Polymorphisms in Human Immune Response Genes. *H. Yonath[1], K. Bucasas[1], F. Yu[1], M. Jain[2], V. Carlton[2], J. Ireland[2], S. Fernbach[1], G. Silva[3], R. Gibbs[1], J. Belmont[1]*. 1) Baylor Col Medicine, Houston, TX; 2) ParAllele BioScience, South San Francisco, CA; 3) UNICAR Foundation, Guatemala.

Variation in genes that regulate the quality, intensity, and duration of the innate and adaptive immune responses (IR) are known to play important roles in resistance to infection, vaccine response, and susceptibility to autoimmune disorders. We are developing large standard panels of assays for human IR gene variants that may be employed in a variety of disease projects. In Stage I of this program we have designed assays in 286 IR genes, including HLA Class I, II, Toll, Chemokine, Interleukin, and Interferon pathways. 2987 SNPs were selected, according to the following order of preference: non-synonymous, synonymous, 5UTR, 3UTR, and conserved intronic. Molecular Inversion Probes (MIP) for 2529 SNPs passed the design criteria and were synthesized. To validate the assays, we genotyped anonymous control DNA samples from 4 different ethnic groups: 27 samples from African- American, 27 European-American, 25 Hispanic (Mexican American), and 25 American Indigenous (Mayan). The raw assay conversion rate was 87%. For further analysis we imposed the following QC criteria: call rate 90%, 2 duplicate concordance errors, and 1 homozygotes for the more common allele. There were significant differences in the number of non polymorphic markers between the different populations, 268 in the African- American, 394 in the European-American, 348 in the Hispanic, and 661 in the Mayan. Numerous SNPs showed population-specific departures from Hardy Weinberg equilibrium (HWE): 183 in the African- American, 182 in the European-American, 179 in the Hispanic, and 142 in the Mayan. Although IR genes present some unique challenges in assay design, genotyping error is unlikely to explain all of the observed HW disequilibrium. Comparison of these results with Phase I HapMap and formal tests for selection are underway. Selection of putative functional SNP markers represents an alternative to haplotype tagging strategies in that one might detect direct associations with medically important phenotypes.

Characterization of family-specific LD patterns in Sorenson Molecular Genealogy Foundation dataset. *K.L. Pennington[1], K.H. Ritchie[1], J.E. Ekins[1], J.L. Peterson[1], N.M. Myres[1], J.B. Ekins[1], L.A.D. Hutchison[1], L. Layton[1], M. Lunt[1], S. Masek[1], A.A. Nelson[1], M.E. Nelson[1], U.E. Perego[1], T. Tolley[1], S.R. Woodward[1,2].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; 2) Dept. of Microbiology, Brigham Young University, Provo, UT, USA.

Inference of familial relationships is a useful tool in a variety of contexts, such as disease linkage and association studies, forensic applications, and inference of personal histories. To date, Y-chromosomal and mtDNA testing have been used extensively for these purposes. However, little has been done using autosomal DNA due to the complex inheritance pattern involved. Herein we characterize family-specific LD patterns and haplotype frequencies as a tool for inferring family group assignments through relationship probabilities. Five extended Utah family groups ranging from 28 to 142 samples and one dataset of 1095 randomly selected samples were analyzed for significant linkage disequilibrium within twelve autosomal 3-locus STR haplogoups. Additionally, one locus was chosen from each of these haplogroups and LD calculations were run among these unlinked loci. Each of the families showed significantly more LD both within and between haplogroups than did the random dataset. Haplogroups and locus pairs demonstrating significant LD were further analyzed to find identify haplotypes and allele pairs with 10x expected coocurrances based on random allele frequencies. Several haplotypes were found within each family set with frequencies characteristic of that particular family group relative to the other datasets. These haplotype frequencies may be used to assign probabilities of membership of an unknown individual into these family groups.

Patterns of linkage disequilibrium between SNPs on a Sardinian population isolate and the selection of markers for association studies. *F.M. De La Vega[1], F. Hyland[1], A. Angius[2,3], I. Persico[2,3], T. Woodage[1], M. Pirastu[2,3].* 1) Applied Biosystems, Foster City, CA, USA; 2) Shardna Life Sciences, Cagliari, Italy; 3) Istituto di Genetica delle Popolazioni, CNR, Alghero, Italy.

The patterns of linkage disequilibrium (LD) determine the feasibility of association studies utilizing single-nucleotide polymorphisms (SNPs) to map genes that underlie complex traits. Interest in utilizing population isolates for LD mapping studies has grown considerably, based on the assumption that recent population bottlenecks would result in more extensive LD. We studied the profile of LD in a Sardinian population isolate in a 8 Mb segment of chromosome 22. 771 SNPs were genotyped using the SNPlex Genotyping System, a multiplexed genotyping platform based on the oligonucleotide-ligation assay. 101 unrelated individuals and 313 members of 15 families from the village of Talana in east Sardinia were genotyped. This data is compared with genotypes on a sample of 45 unrelated Caucasian individuals typed for 566 of the same SNPs using TaqMan SNP Genotyping assays, and with the data obtained by the HapMap Project. Among the common set of 566 SNPs, 6.9% were monomorphic in the isolated and 4.4% in the outbred population; and 6.5% versus 3% in the outbred population had a frequency < 5%. Minor allele frequencies were almost identical at 26-27%. The extent of LD in the two populations, however, is quite different. The decay of pairwise D and r^2 with distance is slower in the isolated as compared with the outbred population: the half-life of the decay curve is larger and the plateau is higher. Common haplotype concordance was remarkably high. We constructed metric LD maps for both populations that when plotted against the physical map show a pattern of plateaus (LD blocks), and steps (recombination hot spans) that is similar between the isolate and the outbred populations. The differences in the length of the LD maps for the region imply that useful LD for mapping may extend up to four times longer on the physical map in the population isolate than in the outbred sample, and suggest a cost-effective strategy for marker selection in isolated populations.

Large-Scale Recombination Rate Patterns Are Conserved among Human Populations. *D. Serre, R. Nadon, T.J. Hudson.* Genome Quebec Innovation Center, McGill University, Montreal, QC, Canada.

In humans, most recombination events occur in a small fraction of the genome. These hotspots of recombination show considerable variation in intensity and/or location across species and, potentially, across human populations. On a larger scale, the patterns of recombination rates have been mostly investigated in individuals of European ancestry and it remains unknown whether the results obtained can be directly applied to other human populations. Here, we investigate this question using genome-wide polymorphism data from three populations produced by Perlegen Sciences Inc. We show that population recombination rates recapitulate a large part of the genetic map information, regardless of the population considered. We also show that the ratio of the population recombination rate estimate of two populations is overall constant along the chromosomes. These two observations support the hypothesis that large-scale recombination patterns are conserved across human populations. Local deviations from the overall pattern of conservation of the recombination rates can be used to select candidate regions with large polymorphic inversions or under local selection.

Using frequency matched linkage disequilibrium reveals evidence for natural selection and improves SNP marker optimization. *M.A. Eberle, M.J. Rieder, D.A. Nickerson.* Department of Genome Sciences, University of Washington, Seattle, WA.

Linkage disequilibrium (LD) describes the non-random association between single nucleotide polymorphism (SNP) pairs and can be used as a metric when designing maximally informative panels of SNP markers for association studies in human populations. We analyzed the extent of perfect linkage disequilibrium ($r^2 = 1.0$) across the human genome using ~1.58 million SNPs genotyped by Perlegen in three diverse populations of European, Asian and African descent. We show that by matching pairwise SNP combinations based on allelic frequency, LD (r^2) values range from 0 to 1, whereas r^2 between SNPs is always limited to values much less than 1 ($LD_{max} \sim 0.6$) when averaging across the entire frequency distribution. Therefore, frequency matching SNP pairs for the calculation of r^2 provides a more sensitive measure for assessing the decay of LD. Using this LD metric, we demonstrate an increased extent of LD, and a significantly higher fraction of perfectly correlated SNPs in genic regions compared to intergenic regions at distances ranging from 20 kb to more than 400 kb throughout the human genome. In addition, these results were not caused by the effects of increased recombination rates because, compared to intergenic regions, perfectly correlated SNPs in genic regions were more likely to occur in regions of increased recombination. SNP pairs exhibiting perfect LD also showed a significant bias for derived, non-ancestral alleles, which may be indicative of positive natural selection. In addition, we estimated the effect of LD in designing optimal SNP sets for whole genome association studies. We demonstrate that SNP marker selection based on allele frequency matching leads to a dramatic reduction (3 - 10 fold) in the number of SNPs needed for association mapping and could require as few as 100,000 SNPs genome-wide.

Identification of TUB as a novel gene associated with body weight regulation in man. *M. Hofker[1], R. Shiri-Sverdlov[1], A. Custers[1], J.V. van Vliet-Ostaptchouk[1], P.J.J. van Gorp[1], P.J. Lindsey[2], J. van Tilburg[3], A. Zhernakova[3], B.P.C. Koeleman[3], E.J.M Feskens[4], C. Wijmenga[3].* 1) Dept Molecular Genetics, Cardiovascular Inst, Maastricht, Netherlands; 2) Dept Population Genetics NUTRIM, Maastricht, Netherlands; 3) Division of Medical Genetics, University Medical Center Utrecht, Netherlands; 4) Center for Nutrition and Health, RIVM, Bilthoven, Netherlands.

Previously, we identified a genomic locus on 11p harboring quantitative trait loci influencing obesity in families with type II diabetes (T2D) from the Breda cohort. In the current study, we selected TUB as a functional candidate gene from this locus and performed association studies to determine whether this gene has an effect on T2D and /or obesity. TUB is the founding-member of the tubby-like proteins and is conserved among vertebrate genomes. The tubby mouse which arises from a loss-of-function mutation, presents a syndrome that is characterized by late onset obesity. In a case-control design 443 T2D patients from the Breda cohort and 356 controls were genotyped for 13 single nucleotide polymorphisms (SNPs) along this gene. Although no significant association to T2D was identified, linear regression analysis revealed that a combination of 3 SNPs (SNPs 8, 10 and 2) has a marked effect on BMI (+0.9, +1.8, +1. 2 kg/m2 respectively, p=0.007). We replicated this study in an independent cohort, using 664 individuals that were not selected for T2D. This independent cohort confirmed our initial findings as a significant effect on BMI was found for SNP 2 (+1.5 kg/m2, p=0.008). Combined analysis of both cohorts revealed that the effect of this allele on BMI was +1.2 kg/m2, p=0.004. Importantly, this allele was found to be more common in obese subjects (OR=1.32, p<0.02). The associations observed for SNPs in this gene indicate clearly the influence of TUB on body weight, independent of T2D. Moreover, the minor allele of SNP 2, which has a frequency of 0.28, was found to be more common among obese patients within both study populations, indicating the contribution of this gene to obesity.

Human mitochondrial SNP genotyping in large cohorts of European ancestry. *B.J. Klanderman[1,2], S. Mazza[1], B.A. Raby[1,2,3], S.T. Weiss[1,2].* 1) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Beth Israel Deaconess Medical Center, Boston, MA.

It is well established that particular rare mutations in the mitochondrial genome can lead to severe maternally-inherited disorders; however, there is growing interest in exploring the mitochondrial genome for its contribution to common, complex diseases. To this end, we are developing a panel of mitochondrial single nucleotide polymorphisms (mtSNP) for haplotype tagging of the mitochondrial genome, with the goal of establishing a reliable set of mtSNP TaqMan Genotyping Assays for complete characterization of all common European haplotypes (frequency at least 1%). To construct this set of SNP assays, we are genotyping SNPs from the MITOMAP human mitochondrial genome database (www.mitomap.org). Primer and probe sequences are aligned against mitochondrial and autosomal genomic sequence to ensure their unique binding to one mitochondrial locus, without overlapping other known mtSNPs. All SNPs are genotyped in three large cohorts of self-reported European ancestry: 1030 adult women participating in the Nurses' Health Study, 432 men participating in the Normative Aging Study, and 948 individuals of European descent collected from eight North American cities. To assess population specificity, these SNPs are also typed in 134 African Americans and 128 Mexican Americans. Haplotype tagging SNPs are selected using the BEST algorithm (Sebastiani et al. 2003), and common haplogroup distributions are compared to those previously described by Torroni et al. (1996). These assays will be available as TaqMan Genotyping Assays from Applied Biosystems, Inc., and we anticipate that this set of mitochondrial haplotype-tagging polymorphisms will serve as a useful tool for genetic association studies of common traits.

An Oceanian lineage of mtDNA is associated with the lower BMI in Solomon men. *R. Kimura[1], J. Ohashi[1], I. Naka[1], T. Furusawa[2], T. Yamauchi[2], K. Natsuhara[2], M. Nakazawa[3], T. Ishida[4], R. Ohtsuka[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo; 2) Department of Human Ecology, Graduate School of Medicine, The University of Tokyo; 3) Socio-Environmental Health Sciences, Graduate School of Medicine, Gunma University; 4) Department of Biological Sciences, Graduate School of Science, The University of Tokyo.

It is recently suggested that regional variation in human mtDNA was shaped not only by stochastic factors such as genetic drifts, bottlenecks, and founder effects but also by adaptation to regional difference in climate. In the Austronesian-speaking people who colonized Pacific islands within the last 6,000 years, the adaptation in energy expenditure to long voyage and life in isolated islands may influence their mtDNA variation. In this study, we examined association between mtDNA variation and physical indices such as BMI in Solomon Islanders. Sample collections and physical examinations were performed in three villages (Munda, Paradise, and Ravaki). The people living in the Ravaki village are immigrants from Kiribati in Micronesia. For typing of mtDNA, the D-loop region was sequenced and used as markers. We carried out stepwise multiple regression analyses considering sex, age, village, and mtDNA polymorphisms as variables. In the analyses, we found that sex, age, and village are significantly associated with BMI both in males and in females. In addition, an Austronesian-specific variant, 16247G, was significantly associated with lower male BMI ($P = 0.0282$). When only males under 40 years were considered, a stronger association was observed ($P = 0.0071$). Our results were unexpected since the 16247G is a major variant in Polynesian populations which have a high prevalence of obesity. Genetic adaptation of the Austronesians may be more complicated than we could expect.

Mitochondrial and Y-chromosomal analysis of an indigenous Mexican population, the Filomeno Mata, to investigate admixture with the Spanish. *K.H. Ritchie[1], S. Harmon[1], R. Wiskirchen[1], J.E. Gomez[1], N.M. Myres[1], U.A. Perego[1], J.E. Ekins[1], L.A.D. Hutchison[1], L. Layton[1], M.L. Lunt[1], S.S. Masek[1], A.A. Nelson[1], M.E. Nelson[1], K.L. Pennington[1], J.L. Peterson[1], T.A. Tolley[1], S.R. Woodward[1,2].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; 2) Department of Microbiology, Brigham Young University, Provo, UT.

According to oral tradition, the Filomeno Mata population of eastern Mexico has remained in relative isolation since its initial encounters with Spanish conquers during the Conquistador era. Genetic analysis can support the legitimacy of such historical accounts as they are reflected in the extant genetic composition of a population. We report the estimated degree of European admixture present in the Filomeno Mata population based on concurrent analysis of Y-chromosome (Y-ch) and mitochondrial DNA (mtDNA). The differential histories of the maternal and paternal genetic records are also examined. Samples were collected from 141 females and 69 males from the Filomeno Mata village. All samples were typed for the characteristic Native American mtDNA haplogroups, A-D and X. Males were also tested using the Y-ch specific SNPs, DYS199, M242 and RPS4Y711. To further assess the degree of admixture, Y-ch haplogroups were then resolved into individual paternal lineages with 36 STR loci and compared with published Spanish and Portuguese datasets. The combination of mtDNA and Y-ch data demonstrate a complex genetic history of the Filomeno Mata.

MOLECULAR ANALYSIS OF DUCHENE MUSCULAR DYSTROPHY AND SPINAL MUSCULAR ATROPHY GENES IN SAUDI PATIENTS. *M. Albalwi[1,3], M. Aljumah[2,3], I. Alabdulkareem[2,3].* 1) Division of Molecular Path & Genetics, Department of Pathology and Laboratory Medicine (1122); 2) Dept. of Medicine (#2216) Neurogenetics unit; 3) King Abdulaziz Medical City-Riyadh King Fahad National Guard Hospital P O Box 22490 Riyadh 11426 Saudi Arabia.

Molecular studies on neurological disorders among Arabs are scattered. In our laboratory, we have tested 483 Saudi patients referred for Duchene Muscular Dystrophy (DMD) or Spinal Muscular Atrophy (SMA). Our database of 124 patients referred because of suspected diagnosis DMD, gene deletion was detected in about 46 % (39/124). The DMD deletion was common in exons 4, 6, 12,13,17,19, 34, 41, 42, 43, 44, 45, 46, 48, 49, 50, 51, 52 and muscle promoter (Pm). No deletion was detected in exons 3, 32 and Brain promoter (Pb) as described in current protocols of human genetic (1994). However, 46.1% (18/39) had deletions in the know hot-spot region for both exons 51 and 52. Among 359 patients referred because of suspected diagnosis of SMA, homozygous deletion of exon 7 was detected in about 47% (115/244). On the other hand, our initial data showed that 3% of Saudis (3024 individuals were screened with an equal gender ratio) are carriers of SMA exon 7 gene deletion, a figure comparable to that of other international studies. However, the exact prevalence of SMA cases in Saudi Arabia is unknown but we expect it to be higher than international figures due to the high rate of consanguineous marriages.

Accurate Polymorphism Detection in DNA Resequencing Data. *A. Quinlan, G. Marth.* Biology, Boston College, Boston, MA.

The discovery of sequence variants in individuals requires complete resequencing. This process typically uses PCR products from genomic DNA and results in diploid sequencing traces. Polymorphisms that appear as heterozygous bases must be detected within individual traces. Extant heterozygote detection tools such as POLYPHRED are useful, but have a high false positive rate, and do not provide reliable accuracy measures. As a result, laborious manual review is necessary.

Building upon our existing software POLYBAYES, we have devised a novel method of diploid polymorphism detection. Our design first detects heterozygous positions within each trace (diploid base calling), and then evaluates homologous base positions across every aligned trace. Diploid base calling is achieved with a support vector machine that allows us to classify unseen trace positions as either polymorphic or monomorphic. This determination and an associated probability of correctness are based on indicative features (e.g. peak height drop, secondary peak ratio) in appropriate training examples. We augment the usual features, which are provided by PHRED, with novel features of the peak shape from the binary trace files.

To determine whether a given position within the trace alignment represents a polymorphic site, we have modified the original Bayesian statistical scheme in POLYBAYES. This scheme takes into account the diploid base calls and corresponding probabilities calculated for each aligned trace, together with prior information such as the genomic or regional polymorphism rate, and the expected transversion/transition ratio to calculate the probability that the site in question is polymorphic.

Our initial results show that we are able to reduce both false positive and false negative rates significantly, as compared to existing software, and that the confidence scores for our calls are accurate. This is an important initial step in the redesign of POLYBAYES as a full-scale polymorphism discovery tool.

Formalization of matching strategies for duplicated loci. *L.A.D. Hutchison[1], N.M. Myres[1], K.H. Ritchie[1], J.E. Ekins[1], J.B. Ekins[1], L. Layton[1], M.L. Lunt[1], S.S. Maesek[1], A.A. Nelson[1], M.E. Nelson[1], K.L. Pennington[1], U.A. Perego[1], J.L. Peterson[1], T. Tolley[1], S.R. Woodward[1,2].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; 2) Dept. Micro and Molecular Biology, Brigham Young University, Provo, UT, USA.

Several commonly-used Y chromosome STR loci (including DYS385, DYS459 and YCAII) are referred to as duplicated, because PCR using the standard primers amplifies two different regions of the chromosome, potentially producing two alleles rather than one. As a result, it is not generally possible to unambiguously assign either allele to a locus copy, making it difficult to reliably compare the correct allele copies between two genotypes. Nevertheless, various strategies have been used in the literature to analyze data containing these these loci; for example, the total number of allele copies that match between two genotypes are sometimes counted as zero, one or two out of two matches. The various matching strategies in use do not technically capture the real properties of the data, and are therefore not completely accurate. Additionally, different matching strategies are not completely comparable, and error rates for the different strategies have not previously been determined. We present here a formalization of the matching of duplicated loci, and compare the theoretical error rates of different matching strategies from empirical data. We show that in certain situations, alleles can be compared unambiguously, and we derive a new matching strategy for duplicated loci from this result. We compare the accuracy of this new matching strategy to those used previously, and show we are able to significantly reduce error in matching duplicated loci. We discuss the impact of this improved matching strategy on the accuracy of calculations in forensics and population statistics. Extension of the method to matching of autosomal loci is discussed.

Mutation spectrum of type I collagen genes in Korean OI patients. *K.S. Lee[1], T.M. Lee[1], H.S. Jin[1], H.Y. Park[1], S.C. Jung[2], S.K. Koo[1].* 1) Division of Genetic Disease, Department of Biomedical Sciences, National Institute of Health, Seoul, Korea; 2) Department of Biochemistry, College of Medicine, Ewha Womans University, Seoul, Korea.

Mutations in the type I collagen genes, *COL1A1* and *COL1A2*, are responsible for the dominantly inherited connective tissue disorder, osteogenesis imperfecta (OI). The severity of OI is diverse, ranging from perinatal lethality to a very mild phenotype with no deformity and normal stature. Although there are several studies of the mutational spectra of *COL1A1* and/or *COL1A2* in Western populations, only a few cases have been reported from Asia. In this study, we investigated 67 unrelated Korean probands with OI and used nucleotide sequence analysis to detect *COL1A1* and *COL1A2* mutations. Thirty-five different mutations in the two genes were identified, including 25 novel mutations. Among the 25 novel mutations, eight were glycine substitutions (G16R, G64D, G544S in COL1A1, and G235E, G268S, G586D, G730S, G766R in COL1A2), four were frameshift mutations in *COL1A1*, two were in-frame duplications in *COL1A2*, and eleven were splice-site mutations (six in *COL1A1*, five in *COL1A2*). The c.982 G to A mutation in *COL1A2* was found repeatedly, and was the causative mutation in 5 independent OI probands. The collagen gene mutation spectrum in Koreans may be representative of those in eastern Asian populations and its elucidation should broaden our understanding of the relationship between genotype and phenotype in OI patients.

***CYP2D6* allele frequency in the Portuguese population.** *P. Santos[1], C. Correia[1], A.M. Coutinho[1], G. Oliveira[3], A.M. Vicente[1,2].* 1) Instituto Gulbenkian Ciência, Portugal; 2) Instituto Nacional Saude Dr Ricardo Jorge, Portugal; 3) Hospital Pediátrico Coimbra, Portugal.

Cytochrome P450 2D6 plays a critical role in the metabolism of about 20% of all prescribed drugs. The *CYP2D6* gene is highly polymorphic, with more than 80 allelic variants showing interpopulation differences. Alleles are classified, based on protein activity, into four different phenotypes: Poor (PM), Intermediate (IM), Extensive (EM) and Ultrarapid Metabolizers (UM). Determination of *CYP2D6* PM alleles *3, *4, *5, *6 and the UM gene duplication allows a correct prediction of enzyme activity, providing clinicians with a useful tool in drug prescription. The frequency of *CYP2D6* alleles *3, *4, *5, *6, and gene duplication was determined in 110 and 43 healthy Portuguese individuals, respectively. Allele frequencies were 0.014 (*3), 0.133 (*4), 0.028 (*5), 0.018 (*6) and 0.035 for the gene duplication, with five individuals classified as PM (4.9%) and three as UM (6.9%). Our results agree with previous studies in European populations: in Southern Europe frequencies for alleles *3, *4, *5, *6 and gene duplication vary between 0.007-0.03, 0.12-0.21, 0-0.034, 0-0.03 and 0.01-0.058, respectively, with 5-10% classified as PM and up to 7% as UM, while in Northern Europe the duplication is much rarer and the frequency of PM alleles is higher (0.23 for allele *4 and 0.04 for allele *5). The frequencies in Portugal reinforce the previously suggested north/south gradient of PM allele frequencies, which likely results from a North Africa anthropological influence in Southern Europe, especially in the Iberian Peninsula, as suggested by the low frequency of these alleles in African populations. Because the PM phenotype may result in toxic concentrations of CYP2D6 substrates with an increased risk of side effects, while the UM phenotype induces sub-therapeutic drug levels and thus lack of clinical effect, *CYP2D6* genotyping should be considered for drug prescription. Given the interpopulation *CYP2D6* heterogeneity, the determination of allele frequencies in specific populations is required for useful application of *CYP2D6* genetic information in clinical settings and in pharmacogenetic studies.

The Construction of The Genetic Diversity Database of Chinese Populations. *J. Chu[1], T. Shi[2].* 1) Medical Genetics, Inst Med Biology, CAMS, Kunming, Yunnan, China; 2) Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, Shanghai, 200031.

China is a country with a long history; it has over 13 billion people and 56 different ethnic groups. China offers abundant human genetic resources. To collect and reserve those resources for analyzing the genetic characteristics will push forward the study of disease genes and pharmacogenomics to a new level. From this point of view, China has the great unsubstituted advantages. Genetic diversity between different groups has long been an important part in Chinese human genome research. Under the support of the government and the efforts that the scientists have made, the genetic diversity research in China has achieved great success. A lot of information and data have been gathered. In order to collect these data and information regularly, and give a convenient way to future search and comparison and present information for related research fields, the Genetic Diversity Database has been constructed, which includes STR, mitochondrion DNA, HLA and SNP, as well as the information of the cell lines, the history of the populations and the information on each sample. At the same time, the database is linked to other related databases rich in related information, such as OMIM, dbSNP, HGMD, MITOMAP etc., and forms a knowledgeable database about the human genetic diversity. The users can retrieve a lot of information through the database. Beside that, the system has the interface for the data input and management. There are three different levels for the data to be shared in the database. According to the data owner's selection, the data can be shared in a lab, among the collaborating labs or released to the public. Each lab can set up the data sharing criterion by itself. The database can be reached through the web site: http://www.chgd.org.

Using Single Nucleotide Polymorphisms (SNPs) to quantitate selection against nonsense, missense and silent mutations in humans. *I. Gorlov*[1], *M. Kimmel*[2], *C. Amos*[1]. 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Department of Statistics, Rice University, Houston, TX.

A large body of evidence suggests that point mutations in coding regions of the human genome are under purifying selection. If natural selection acts against point mutations in coding regions, then population frequencies of point mutations should be at equilibrium between a decrease in the frequency by purifying selection and an increase due to new mutations. According to an elegant population genetics formula, the equilibrium frequency of deleterious mutations depends on the selection coefficient and the mutation rate. Given reliable estimates of mutation rates we can estimate selection coefficients against different types of mutations if we know their equilibrium frequencies. To estimate equilibrium frequency of different types of point mutations in coding regions we have used NCBI dbSNP database on Single Nucleotide Polymorphisms (SNPs) in the human populations. We have adjusted proportions of SNPs for difference in codon usage and in mutation rates. We estimated selection coefficients against nonsense mutations, conservative missense, radical missesne, silent, and all missense mutations combined. We found that the average selection coefficient against missense mutations is ~12% of that against nonsense mutations. There are 3.5 fold differences in strength of selection against radical and conservative missense mutations. Surprisingly, we have found considerable selection against silent mutations - the selection coefficient is ~5% of that for nonsense mutations. Based on the estimated selection coefficients against nonsense, missense and silent mutations and mutation rate per nucleotide/per generation, we predict that average fitness drops ~5% each generation due to de novo point mutations in coding regions of human genome.

Association of bone mineral density with a dinucleotide repeat polymorphism at the calcitonin (CT) locus in mexican population. *J. Magana Aguirre[1, 2], R. Gomez Ortega[2], L. Casas Avila[2], G. Suastegui[3], P. Diez Garcia[3], B. Cisneros Vega[1], M. Valdes Flores[2].* 1) Department of Genetics and Molecular Biology, CINVESTAV-IPN,07360 Mexico city, Mexico; 2) Department of Genetics, Centro Nacional de Rehabilitacion-SSA, 14389 Mexico city, Mexico; 3) Osteoporosis Clinic, Centro Nacional de Rehabilitacion-SSA, 14389 Mexico city, Mexico.

Osteoporosis is a multifactorial and poligenic disease, which is characterized by a generalized reduction in bone mineral density (BMD), and microarchitectural deterioration of bone tissue that results in an increased risk of bone fractures. Calcitonin (CT) may play a role in the pathogenesis of osteoporosis, genetics variations in or adjacent to the CT gene may be associated with variations in bone mineral density (BMD). The present study examined the correlation between a dinucleotide (cytosine-adenine) repeat polymorphism at the CT locus and BMD in 60 osteoporotic women, 60 non-osteoporotic women and 500 subjects of a Mexican general population. Nine alleles were present in the Mexican population. Alleles containing 10, 11, 12, 15, 16, 17, 18, 19 or 20 CA repeats. Thus, we designated the alleles as A, B, C, F, G, H, I, J and K respectively. We found that the A allele frequency was 63% in osteoporotic women, with a value significantly higher than that observed in non-osteoporotic women (35%) ($p<0.05$) and the AA genotype frequency was 45% in osteoporotic women, which was significantly higher than that found in non-osteoporotic women (18%) ($p<0.05$). For these reasons, the A allele and the AA genotype were related to the presence of osteoporosis (odds ratio 1.97 and 3.64 respectively). The loss of BMD and T scores (a parameter representing deviation from gender, race-adjusted average BMD) were compared between individuals that possessed one or two A alleles and those that did not posses the A allele. Subjects who possessed one or two A alleles had lower BMD and T scores than those who did not present any A allele (lumbar loss DMD: 26% vs 12% and T score: -2,3 vs -0.9). The significant association observed between BMD and genetic variation at CT locus implies that this polymorphism may be useful marker for the genetic study of osteoporosis.

Comparison of two ancestral MHC DR3 haplotypes as a resource with which to examine common disease association. *A.N. Roberts[1], J.A. Traherne[2], R. Horton[3], M.M. Miretti[3], M.E. Hurles[3], J.L. Ashurst[3], P. Coggill[3], L.G. Wilming[3], J.A. Todd[1], J. Trowsdale[2], S. Beck[3].* 1) JDRF/WT DIL, CIMR, University of Cambridge, Cambridge, CB2 2XY, UK; 2) Dept Pathology, University of Cambridge, Cambridge, CB2 1QP, UK; 3) WT Sanger Institute, Genome Campus, Hinxton, Cambridge CB10 1SA, UK.

The major histocompatibility complex (MHC) is a highly duplicated and polymorphic region of the human genome on chromosome 6p21.31 and its core spans ~4 Mb including > 150 expressed genes. The aim of this project is to sequence and analyze the total DNA content and polymorphisms of the MHC region from eight consanguineous HLA-homozygous cell lines (http://www.sanger.ac.uk/HGP/Chr6/MHC/). Here, we present 4.25 Mb of the third haplotype, QBL (HLA-A26, -B18, -Cw5, -DR3, -DQ2) and compare the findings with that from the first two haplotypes, PGF (HLA-DR2(15)) and COX (HLA-A1, -B8, -Cw7, -DR3, -DQ2), (http://vega.sanger.ac.uk). Both QBL and COX share the classical serological determinant, DR3, and, therefore, some commonality in their origin. We have defined this shared segment of DNA identical-by-descent to only a 158 kb-region between *HLA-DRB3* and *HLA-DQB3* which contains the DR3 serological determinants *HLA-DRB1*, *HLA-DQA1* and *HLA-DQB1*. The time to the most recent common ancestor (MRCA) is estimated to be less than four thousand years. Outside this segment, the divergence between QBL and COX is as extensive as we found previously between PGF and COX: we identified ~15,000 SNPs, of which 6,159 were novel to this QBL project and ~2,000 DIPs. Most of the SNP variation was concentrated in peaks overlying the classical class I and class II loci. The heterozygosity per nucleotide site () between any two MHC haplotypes in this study falls in the range of 2.7 - 3.6 x 10^{-3}, which is 4-7 fold higher than typical genomic wide diversity. Delineation of the boundaries of the hypervariable *HLA-DRB* region is defined using genomic repeat elements as handles. The sequences of the remaining haplotypes will not only reveal further polymorphisms for genetic dissection of the MHC in disease but also define ancestral relationships between haplotypes.

An unusual haplotype structure at inversion polymorphic region on human chromosome 8p23. *L. Deng[1], T. Liu[2], H. Zhao[1], J. Kang[3], H. Zhao[1], T. Niu[4], H. Yang[1], C. Zeng[1], BGI HapMap Group.* 1) Beijing Genomics Institute, Chinese Academy of Sciences, Beijing, China; 2) Institute of Biophysics, Chinese Academy of Sciences, Beijing, China; 3) Department of Mathematics, Beijing Normal University, China; 4) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Using population genotype data of 1072 single nucleotide polymorphisms (SNPs) generated by the HapMap project, we delineated genomic structure of a previously reported 3.8-Mb inversion polymorphism region at chromosome 8p23 (Giglio et al. 2001). Analysis of molecular variance and pairwise FST comparison of individual SNPs revealed great genetic differentiation among populations. Divergent population subgroups were resolved in CEU samples under the ¡admixture model¡ of the structure. Considering this inversion segment as a specific polymorphism frame, three distinct haplotype clades, named as Clade_1, Clade_2, and Clade_3, were detected based on the phylogenetic clustering analysis. The distribution of these clades among geographic populations was considerably different. Clade_2 was mainly detected in CEU samples and Clade_3 was only seen in YRI samples. Clade_3 was identified as the ancestral type evident by its co-clustering with chimpanzee haplotype in phylogenetic analysis. For future larger-scale studies of genetic association and human evolution in this region, tag SNPs were also selected based on principal component analysis and greedy-discard method. Further analysis regarding the large dissimilarity of genetic background among geographic populations resulted from different inversion frequency, as well as cytogenetic localization of this inversion polymorphic region by fluorescent in situ hybridization, would also be presented. Taken together, our results provide a panoramic view on structural and population features of the inversion polymorphism on 8p23, as well as a primary tool to detect and deduce the orientation of chromosomal arrangement.

Linkage Disequilibrium and haplotype structure in the *DC-SIGN* gene in Caucasians and Afro-Caribbeans. *J. Martinson[1,2], Y. Li[2], R. Bosko[1], R. Ferrell[2].* 1) Inf Diseases & Microbiology, Univ Pittsburgh, GSPH, Pittsburgh, PA; 2) Human Genetics, Univ Pittsburgh, GSPH, Pittsburgh, PA.

The Dendritic Cell protein DC-SIGN plays a pivotal role in the early stages of the immune response, as it is involved in both pathogen peptide processing and Dendritic Cell motility. Many pathogens exploit DC-SIGN, either as an adhesion receptor in the infection of Dendritic Cells, or as a means of escaping the host immune response. The *DC-SIGN* gene is a member of the *CD209* gene family: genes in this family are heavily alternately spliced, generating variant forms of their protein products that differ in cell tropism and cellular localization. Genetic variation in *DC-SIGN* may therefore be of importance in disease resistance and immune function.

In an earlier study, we reported initial data on nucleotide variation in *DC-SIGN* in Caucasians, and here present results of a more extensive survey of SNPs and haplotypes in this gene in Caucasians and in sub-Saharan African-descended inhabitants of the Caribbean island of Tobago. We used a combination of DHPLC and resequencing to obtain SNP data on coding, non-coding and regulatory sequences averaging 6.0kb per person for 120 Caucasians and 96 Tobagans.

We observed a high degree of LD in Caucasian samples. Although we identified 48 SNPs in Caucasians, 34 of these were rare (minor allele frequency <10%). Determination of the likely haplotypes present, using the PHASE software package, showed a total of 74 haplotypes based on 48 SNPs, but only six of these haplotypes accounted for 50% of the samples. Analysis of LD parameters using the ldmax and GOLD packages showed high LD extending across the whole of the gene. In contrast, LD in Tobagans was very patchy, with small blocks of LD in the promoter and downstream regions, but no LD between these blocks. Tobagans were also characterised by a higher level of haplotype diversity than Caucasians, including haplotypes based on SNPs not observed in Caucasians. The differing demographic histories of these populations has had a profound effect on LD and haplotype structure at the *DC-SIGN* gene.

Evidence for Constraint in Telomere Stability Genes. *S.A. Savage[1], M. Yeager[2,3], J. Liao[1], S.J. Chanock[1].* 1) Pediatric Oncology Branch, CCR, NCI, NIH, Bethesda, MD; 2) SAIC-Frederick, Bethesda, MD; 3) OD, DCEG, NCI, NIH, Bethesda, MD.

Telomeres, nucleotide repeats at the ends of chromosomes, are essential for chromosomal integrity. An ordered protein complex at the telomere protects chromosomes from end to end fusion. Previously, we reported that the pattern of genetic variation in 7 key telomere genes, *POT1, TERT, TERF1, TERF2, TINF2, TERF2IP* and *TNKS*, showed limited nucleotide diversity, a paucity of nonsynonymous single nucleotide polymorphisms (SNPs) and variability in linkage disequilibrium (LD) in 4 ethnic groups (n=118 individuals divided between AA-African/African-American, CA-Caucasian, HI-Hispanic, PR-Pacific Rim). In this study, the analysis was extended to include SNPs in *POT1, TERT, TERF1*, and *TINF2* in an additional set of 280 individuals from the CEPH Human Diversity Panel (76 AA, 66 CA, 49 HI and 89 PR), which is large enough to effectively estimate haplotype diversity. Overall, SNP frequencies were comparable and limited haplotype diversity was again observed. LD in *TERT* is particularly limited whereas there is strong LD across *POT1*. Population specific SNPs were observed in *TINF2*. Bi-directional sequence analysis was performed in two additional genes, *PTOP* and *PINX1*, in 24 individuals from 3 ethnic groups to identify common variants. Sequence analysis included all exons, 5 and 3 UTRs as well as regions of homology between human and mouse sequences. Haplotypes were inferred and LD was estimated. This analysis suggests that common variants are rare in *PTOP* and *PINX1*. Haplotype structure was restricted and slightly more complex in AA than CA, HI and PR and LD was variable. Studies are underway to characterize the extent of variation and LD in *PTOP* and *PINX1* in larger sets of individuals. In summary, telomere stability genes appear to be constrained; most likely due to the role they play in chromosomal stability. Thus, genetic variation in telomere stability genes suggests that they could be suitable candidate genes for study in autoimmune, cancer and hematologic disorders.

Gene Copy Number Quantitation in Drug Metabolism Genes by Real-Time Quantitative PCR. *S. Liew, K. Lazaruk, L. Wong, J. Stevens, K. Livak.* Applied Biosystems, Foster City, CA.

Polymorphisms in drug metabolism genes have been classically identified as SNPs, indels and STRs. Gene deletion and gene duplication are genomic variations that can also affect enzyme function or phenotype. Deletions and duplications in drug metabolism genes have been associated with phenotypic variation, for example, they can characterize a phenotype as poor (PM), intermediary (IM), extensive (EM), and ultrarapid metabolizer (UM). Gene copy number, or gene dosage, can be accurately determined using real-time quantitative PCR. The method involves relative quantification of the gene of interest versus a reference gene known to be single copy. Relative gene copy number is determined by the Ct method, a well-established relative quantitation method used in mRNA quantitation studies. We have developed assays to measure gene dosage in a variety of genes, including drug metabolism genes such as CYP2D6 and GSTM1.

Y-CHROMOSOM POLYMORPHICS MARKERS IN INDIGENOUS GROUPS Of THE ZULIA STATE. *T.C. Pardo[1], L. Borjas[2], W. Zabala[2], G. Portillo[2], J. Marquez[2], A. Aranguren[3].* 1) Laboratorio de Genética Molecular. Unidad de Genética Médica. university of zulia, Maracaibo, Venezuela; 2) Instituto de Investigaciones Biológicas, university of zulia, Maracaibo, Venezuela; 3) Cátedra de Genética. Facultad de Ciencias Veterinarias. Universidad del Zulia, Maracaibo, Venezuela.

The first natives that populated Zulia state, derived from three main linguistic groups: Arawacos (Wayúu), Caribbean (Yukpa) and Chibchas (Barí). The Wayúu were the first ones accepting the European colonization, assimilating some of their customs and having marriages among them, contrary to the observed in Barí and Yukpa, culturally closed groups, geographically isolated, where the endogamy prevailed. To characterize the genetic structure of three indigenous groups through the analysis of DYS385a/b, DYS389I, DYS389II, DYS287 and DYS199 in human Y chromosome. Four loci Y-STRs, the DYS199 and the insert Yap Alu were analyzed by PCR in a sample of 71 individuals belonging to the 3 mentioned groups. Thirty two (32) different haplotype was observed; twenty-seven (27) in Wayúu and five (5) in Barí, the Yukpa presented an only haplotype that repeated in the Wayúu. For each locus, the levels of genetic diversity varied between 0 and 0.72 and those of haplotipc diversity between 0 and 0.96. the AMOVA test showed a bigger intra-population variation (66.95%) that inter-populations (33%). DYS389II presented high frequencies for different groups, showing that there is a genetic difference among these groups. As for the assessment of mixture degree, Barí and Yukpa showed an Amerindian mono-parental contribution while in the Wayúu the Amerindian component was followed by the European one. The Y-STRs haplotypes constitute a very useful tool for the molecular anthropology studies, since it allows to study the genetic relationships and composition of different populations.

Application of a DNA microarray based comparative genomic hybridization (Array-CGH) method to the study on the genetic effects of atomic bomb radiation. Results from a pilot study. *N. Takahashi[1,4], K. Sasaki[1], M. Kodaira[1], Y. Satoh[1], Y. Kodama[1], K. Sugita[2], H. Katayama[2], N. Tsuyama[3].* 1) Dept Genet, Radiation Effects Res Fdn, Hiroshima, Japan; 2) Dept Inf Tech, Radiation Effects Res Fdn, Hiroshima, Japan; 3) Dept Bio-Signal Anal, Grad Sch Med Yamaguchi Univ, Ube, Japan; 4) CREST, Kawaguchi, Japan.

[Purpose] We have studied the effects of A-bomb radiation on human germ cells, that is, whether the mutation rate has increased significantly in the offspring of A-bomb survivors compared with controls at the genomic DNA level. To enable genome-wide detection of these mutants, we have been introducing a microarray based comparative genomic hybridization (array CGH) method. Before starting a large-scale study, we conducted a pilot study to examine the feasibility of this method. [Experiments] We constructed an array where about 2400 Bac-clones were printed onto three different slide glasses as one set. These clones are distributed about every 1.2 Mb across human autosomes. After preliminary studies for establishing good experimental conditions, we did a population study on 40 offspring of A-bomb survivors and 40 members of a control group. [Results and discussion] Fourteen variants were observed once in this population, termed rare variants, and the results from family studies revealed that these variants were inherited from at least one parent. Thus, until now, no de novo mutant was identified. We characterized these rare variants by Southern blot analysis using pulse field gel electrophoreses, quantitative PCR, FISH method, and sequencing. These results demonstrated that our array CGH system can reliably detect the variants larger than 50 kb. Moreover, 18 kinds of variants were recurrently identified in this population, and they were termed polymorphic variants. Southern analyses conducted for these polymorphic variants demonstrated that many showed various complicated patterns. From our data, we consider that array CGH is one of the most useful techniques for our research purposes. Now, we are planning a larger population study.

Sequence variation at the GABA transporter-1 gene (*SLC6A1*) in five populations. *R. Hirunsatit[1,2], R.L. Malison[1], P. Räsänen[4], A. Sughondhabirom[2], N. Thavichachart[2], S. Tangwonchai[2], A. Mutirangura[2], H. Kranzler[5], J. Gelernter[1,3], J. Lappalainen[1,3].* 1) Psychiatry, Yale University, New Haven, CT; 2) Chulalongkorn University, Bangkok, Thailand; 3) VA Connecticut Healthcare System, West Haven, CT, USA; 4) University of Oulu, Department of Psychiatry, Finland; 5) University of Connecticut, School of Medicine, Department of Psychiatry.

The *SLC6A1* gene encodes the -aminobutyric acid (GABA) transporter-1, which participates in the regulation of synaptic GABA levels via re-uptake of GABA. GABA transporter-1 is the selective therapeutic target of tiagabine, a novel anticonvulsant medication. The goal of this study was to identify sequence variation and the haplotype structure of *SLC6A1* in different populations, representing three of the major continental groups, in anticipation of pharmacogenetic studies of tiagabines therapeutic and adverse effects. Approximately 11.6 kb of the *SLC6A1* locus were sequenced, including the 5promoter region, all 16 exons, and large segments of the flanking intronic regions, in eight samples from Finnish, Thai, Hmong, European-American (EA), and African-American (AA) subjects (n=40). A total of 55 SNPs were found in these samples; 20 were present in more than one population studied. Population-specific SNPs were rare in the Finnish, Thai, and EA samples. Common population specific SNPs were discovered only in the AA sample (p>0.25). Twenty seven SNPs were novel (not reported in the NCBI SNP database). No non-synonymous SNPs were identified. Nucleotide diversity () in *SLC6A1* was highest in the AA population. There were no marked differences in between the EA, Finnish, Thai and Hmong populations. To evaluate the linkage disequilibrium (LD) structure of *SLC6A1*, 11 SNPs were genotyped in 47 Finnish, 41 Hmong, 46 EA, 46 AA, and 46 Thai subjects using the 5 nuclease (Taqman) method. Preliminary analysis indicated that the LD structure of *SLC6A1* is similar in the five populations we studied. These findings from extensive resequencing and haplotype analysis of the *SLC6A1* gene will be useful for pharmacogenetic studies focusing on the therapeutic and adverse effects of tiagabine and other medications that influence GABA transporter-1 function.

Association of TNF alpha gene -308 GG genotype with post operative infections in esophageal cancer patients. *K. Azim, K. Brophy, R. McManus, D. Kelleher, J.V. Reynolds.* Inst Molecular Medicine, Trinity Col Dublin and Dublin Molecular Medicine Centre, Dublin, Ireland.

Purpose: To find the effect of TNF alpha gene biallelic single nucleotide polymorphism (SNP) at -308 position on post operative infections in Esophageal Cancer patients. Methods: In a retrospective case-control study design, we selected 197 Esophageal Cancer patients who underwent surgery in St. Jamess hospital, Dublin Ireland. The patients were divided in three groups; 1) Post Operative (PO) Infections (55); 2) No PO complication (114); and 3) Other PO complications (28). DNA was extracted and genotyping was done using Taqman chemistry and PCR/RFLP. Relevant clinical data was obtained for all study subjects and possible confounding patient characteristics were taken into account during statistical analysis. The study had local Ethical Committee approval and informed consent was obtained from all study subjects. Results: The distribution of GG homozygotes was significantly higher in the Post operative infection group ($P = 0.021$), and G allele was significantly higher in post operative infection group as compared with no complication group ($p = 0.017$) and other complication group ($p = 0.013$). No significant difference was observed in the three groups as regards preoperative chemotherapy, tumor stage, differentiation, location and histology, though there was a significant difference in the age of the patients, the post operative infection group being older. Conclusion: TNF alpha gene -308A allele has been shown to be associated with higher circulating levels of TNF alpha and the -308 G allele is a comparative low secretor allele. Many recent studies have reported a higher incidence of infections in patients under anti TNF alpha therapy (infliximab or etanercept). We propose that the polymorphism in the promotor region of TNF alpha gene may lead to altered expression and a possible suboptimal activity of TNF alpha in GG genotypes, predisposing them to a higher risk of developing infections.

P-gene variability in North Eurasian human populations. *M.A. Perkova, B.A. Malyarchuk, M.V. Derenko.* Genetics Laboratory, Institute of Biological Problems of the North, Magadan, Russian Federation.

To estimate the level of variation of the P-gene, the human homologue to the mouse pink-eye dilution locus, polymorphism at three loci (R305, A355, and R419) was studied in 350 normally pigmented individuals representing different populations of North Eurasia. These samples were grouped into four ethnogeographic areas: Europe (the Russians), Southwest Asia (the Iranians), South Siberia (the Buryats), and Northeast Siberia (the Chukchi, Koryaks and Evens). We found that the heterozygosity level ranges from 54 per cent in Europe and 53 per cent in Southwest Asia to the lower values of 49 and 30 per cent in South Siberia and Northeast Siberia, respectively. Differences among regional groups account for 1.7 per cent of the total variation ($p = 0.003$); however, in pairwise comparisons significant Fst-differences were revealed only between Northeast Siberians and other regional groups studied. In addition, the results of the present study show that there are significant differences between distribution of R419G variant in Russian populations ? the 419G allele frequency is much higher in the northwestern Russians (6.2 per cent in Velikij Novgorod sample) than in southwestern ones (3.6 per cent in Belgorod sample). Interestingly, previous studies have indicated that increased proportion of 419G alleles appears to be characteristic for individuals with green/hazel eyes compared with others (Rebbeck et al. 2002). Thus, the results of our study suggest that allelic variation in the P-gene may be associated with normal variability in pigmentation of the eyes, hair and skin at the population level. This work was supported by the grant from the Far-East Branch of the Russian Academy of Sciences (05-3--06-096).

Association of Uteroglobin related protein (UGRP)1 gene polymorphism with Asthma in African Americans and Caucasians. *K. Yanamandra, E. Chen, D. Napper, P.B. Boggs, S.A. Ursin, H. Chen, J.A. Bocchini Jr., R. Dhanireddy.* Dept Pediatrics, LSU Medical Ctr, Shreveport, LA.

Asthma is a multifactorial, polygenic disorder involving the contribution of many genes and the environment. Because of its polygenic inheritance, many investigators studied the role of several genes including those of interleukins and non-interleukins. One of the genes studied in the Japanese population was Uteroglobin related protein (UGRP)1 gene, encoding the UGRP1 protein which was thought to be an anti-inflammatory agent. A polymorphism in the promoter region of the gene, carries a SNP transition from G to A at position 112 which results in 24% reduction in the promoter activity compared to the wild type. UGRP1 is a secretory protein mainly expressed in the lung and trachea and has recently been implicated in asthma. Although Niimi T, et al. in 2002 have shown an association of -112A allele with asthma in Japanese population, Jian Z, et al. in the following year in 2003, contradicted the association, in another Japanese population with childhood atopic asthma. And, the findings of Jian Z, et al. were confirmed by Batra J, et al. in 2005, in the Indian asthmatic population. We, at the Molecular Genetics Laboratory at LSU Health Sciences Center in Shreveport, Louisiana, have been studying the role of several genes in asthma for the past several years. In the present investigation, we began to study the role of UGRP1 gene in the etiology of asthma by genotyping 120 asthmatic individuals and 250 control individuals, from Northwest Louisiana population. The -112A allele frequency was same in both patients and controls at 0.16, among the Caucasians. Similarly, the -112A allele frequency was 0.35 in patients and 0.30 in controls among the African Americans. Our data does not indicate an association of UGRP1 polymorphism with asthma in either African Americans or in Caucasians. This is the first report in the literature to show the role of this polymorphism in asthmatic patients in the African American community. Data, statistics, and distribution of genotypes with ethnic break down of patients and controls will be presented.

The -globin recombinational hotspot reduces the effects of strong selection around HbC, a recently arisen mutation providing resistance to malaria. *E.T. Wood[1,2], D.A. Stover[2], M. Slatkin[3], M.W. Nachman[1], M.F. Hammer[1,2].* 1) Department of Ecology & Evol Biology; 2) Division of Biotechnology, University of Arizona, Tucson AZ; 3) Department of Integrative Biology, University of California, Berkeley, CA.

Recombination is expected to reduce the effect of selection on the extent of linkage disequilibrium (LD), but the impact that recombinational hotspots have on sites linked to selected mutations has not been investigated. We empirically determine chromosomal linkage phase for 5.2-kb spanning the -globin gene and hotspot. We estimate the HbC mutation, which is positively selected due to malaria, originated less than 3,000 years ago and that selection coefficients are 0.04-0.09. Despite strong selection and the recent origin of the HbC allele, recombination (crossing-over or gene conversion) is observed within 1-kb 5 from the selected site on more than one third of the HbC chromosomes sampled. The rapid decay in LD upstream of the HbC allele demonstrates the large effect the -globin hotspot has in mitigating the effects of positive selection on linked variation.

An Updated World-Wide Characterization of the Cohen Modal Haplotype. *J.E. Ekins[1], E.N. Tinah[2], N.M. Myres[1], K.H. Ritchie[1], U.A. Perego[1], J.B. Ekins[1], L.A.D. Hutchison[1], L. Layton[1], M.L. Lunt[1], S.S. Masek[1], A.A. Nelson[1], M.E. Nelson[1], K.L. Pennington[1], J.L. Peterson[1], T. Tolley[1], S.R. Woodward[1,2].* 1) Sorenson Molec Genealogy Fndn, Salt Lake City, UT; 2) Department of Micro and Molecular Biology, Brigham Young University, Provo, UT.

Since the definition of the Cohen Modal Haplotype (CMH) in 1998, the 6 SNP-6 STR genetic motif has been utilized to infer connections of contemporary individuals and communities to the ancient Hebrew population. The elucidation of the YCC SNP Phylogeny has allowed cataloguing of chromosomes compatible with the original CMH definition into several different Y-SNP subclades. Haplogroup membership was determined for 266 samples matching at 5 of the CMH STR alleles, defined as the Cohen Modal Haplogroup (CMHg). The bulk of the CMHg chromosomes were observed in J1 (53.0%) and J2 (43.2%), with a small portion falling outside of haplogroup J (3.8%). Members of the CMHg were observed throughout the world, with significant frequencies in various Arab populations: Oman (20.1%), Iraq (15.2%), Palestine (9.5%). Coalescent simulations were performed for CMH chromosomes within each SNP haplogroup using 24 STR loci. Estimates within J1 [6.5kybp(4K-12K)] and J2 [13kybp(7K-27K)] were substantially deeper than previous figures obtained from a heavily weighted Jewish sampling, indicating a likely origin of the compound haplotype prior to the establishment of the Hebrew population. The significant presence of CMH chromosomes in deeply divergent clades J1 and J2 (>20kybp), indicates the present CMH definition is not sufficient to distinguish lineages that likely arose by parallel IBS mutations. An expanded STR definition is proposed which allows differentiation between CMH-compatible chromosomes in J1 and J2. The inference of Jewish ancestry based on the original CMH definition should be performed with caution as subjects may be falsely categorized into the eponymous CMH lineage when the true origin is in the deeply divergent IBS branch. These observations underscore the importance of using updated SNP classifications when utilizing the CMH to infer ancestry in Jewish populations, or the use of the expanded STR definition.

Genomic regions exhibiting positive selection identified from dense genotype data. *C. Carlson[1], D. Thomas[2], M. Eberle[1], R. Livingston[1], M. Rieder[1], D. Nickerson[1].* 1) Dept Genome Sci, Univ Washington, Seattle, WA; 2) University of California, Santa Cruz, CA.

Patterns of nucleotide diversity can be used to test for signatures of natural selection in sequences that depart from the expected distribution of nucleotide diversity under the neutral theory. We observed a significant ($p<0.001$) correlation between the Tajima's D test statistic in full resequencing data and Tajima's D in a dense, genome wide data set of genotyped polymorphisms for a set of 178 genes. Based on this, we used a sliding window analysis of Tajima's D across the human genome to identify regions putatively subject to strong, recent selective sweeps. This survey identified seven Contiguous Regions of Tajima's D Reduction (CRTRs) in African Americans (AD), 23 in European Americans (ED), and 29 in Chinese Americans (XD). Only four CRTRs overlapped between populations, three between ED and XD, and one between AD and ED. Full resequencing of six genes within four CRTRs demonstrated patterns of nucleotide diversity inconsistent with neutral expectations for at least one gene within each CRTR. Identification of the functional polymorphism (and/or haplotype) responsible for the selective sweeps within each CRTR may provide interesting insights into the strongest selective pressures experienced by the genome over recent evolutionary history.

How frequently is common variation shared among US populations? An unbiased assessment based on 3,873 resequenced genes. *S. Guthery[1], B. Salisbury[2], M. Pungliya[2], C. Stephens[3], M. Bamshad[1,4].* 1) Dept of Pediatrics, Univ of UT, SLC, UT; 2) Genaissance Pharmaceuticals, New Haven, CT; 3) Motif BioSciences, NY, NY; 4) Dept of Human Genetics, Univ of UT, SLC, UT.

The common variant/common disease hypothesis posits that genetic susceptibility to complex diseases is influenced mainly by variants that are shared among populations. Analyses of allele sharing have shown that most common (ie, 10% in a given group) variants are shared among African-, Asian-, and European Americans. In most of these studies, alleles were measured by genotyping variants ascertained as common in one or a few populations, which can upwardly bias estimates of allele sharing among groups. To obtain an unbiased estimate of allele sharing, we examined resequencing data from the regulatory and coding regions of 3,873 genes in individuals self-identified as Hispanic (n=17), African- (20), Asian- (19), and European Americans (20). A total of 63,012 variants were found. Six pairwise population comparisons of variants with frequencies 10% showed that 71-96% of variants common in one population were present in both populations, though only 44-72% of such variants were common in both populations. Correlation of the frequency of common variants between populations ranged from 0.23 in African Americans vs. Hispanics to 0.83 in European Americans vs. Hispanics. Correlations were consistently lower in comparisons with African-Americans. Approximately 60% of variants common in at least one population were present in all populations, but only 32% of them were common in all populations. These results indicate that a variant common in one population is, in general, present in other populations but not necessarily common in other populations. Moreover, common variants are frequently not shared between African Americans and non-African populations. These findings suggest that a sizable fraction of genetic factors that influence common health-related traits might vary substantially between populations, particularly Africans vs non-Africans. It would therefore be prudent to develop more initiatives to identify common variation and risk variants in non-European populations, particularly African Americans.

Ethnic admixture in Maracaibo, Venezuela: Analysis based on biparental and uniparental DNA markers. *L.M. Pineda Bernal, L. Borjas, W. Zabala, C. Castillo, M.G. Portillo, M. Mendt, E. Fernández, M.A. Sánchez.* Laboratorio de Genética Molecular.Unidad de Genética Médica. Facultad de Medicina. Universidad del Zulia, Maracaibo, Zulia, Venezuela. Apartado Postal 4002.

According with historical records the population of Maracaibo, at the northwest of Venezuela, is considered to be a result of the mating of European and African derived people with the local Amerindians, but the precisely contribution of each one is needed to be established with a several DNA markers. Objective: We analyzed in this study several DNA polymorphisms to clarify about the genetic structure and ethnic admixture of the contemporary Maracaibo population. Material and methods: DNA was extracted from blood samples of individuals born and living in Maracaibo after signing an informed consent. The blood samples were analyzed by PCR, capillary electrophoresis and/or PAGE for the following genetic markers: VNTR D1S80 and fifteen autosomal STRs, two biallelic polymorphisms of Y chromosome, twelve Y-STRs and the Amerindian mt-DNA haplogroups. Intra and interpopulations parameters were obtained with ARLEQUIN, DISPAN, and ADMIX3 softwares. We used as parental groups the published data from European, African and Amerindian populations. Results: The results with biparental polymorphism and Y-markers reveal that Maracaibo sample has a main European genetic contribution (more than 80%), followed by Amerindian and African contribution. However, in data derived from mt-DNA haplogroups showed an important Amerindian component in the sample (50%). These results suggest the presence of an asymmetric patterns of mating with a predominant contribution of European males with Amerindian females. These results are in accordance with historical records about the predominance of colonizer males, the almost extermination of the males natives and limited entrance of African people into Maracaibo population.

Investigation of YSTR haplotype clustering among Caucasians in the US. *D. Garvey[1], P. Berdos[2], L. Sims[2], J. Ballantyne[2].* 1) Department of Physics, Gonzaga University, Spokane, WA; 2) Center for Forensic Science, University of Central Florida, Post Office Box, 162367, Orlando, FL 32816-2367.

An analysis was conducted of 17 YSTR haplotypes for 298 randomly sampled Caucasian men in the US. The approach used was to treat each of the 17 alleles as a coordinate in a 17 dimensional space, so that each haplotype was represented as a lattice point in that 17 dimensional space. This analysis found that 85% of the haplotypes were grouped into one of three isolated clusters, with the population density at lattice points outside those clusters being nearly zero. SNP genotyping identified these three clusters as being separately composed of men belonging to haplogroups R-M269, I-M253, and R-M17 (in order of decreasing cluster membership). The highest population density of each haplogroup cluster occurred at the lattice point at the center of the cluster, and all three clusters were seen to have more than 50% of the cluster member haplotypes differing from the central lattice point by three or fewer repeat unit steps. This clustering of haplotypes means that the forensic usefulness of YSTRs must be evaluated based on intra-cluster variation, as opposed to evaluating the diversity seen in the whole population. The most extreme example of this was DYS438. DYS438 showed a whole population variance of 0.90, but was seen to be nearly monomorphic inside each cluster.

mtDNA diversity and the settlement of the Peruvian Andean Altiplano. *N.M. Myres[1], J.E. Myres[1,2], M. Malan[2], J. Fuller[2], M. McNairy[2], M.J. Rowe[2], R.T. Matheny[2], H.A. McCammon[1], S.R. Woodward[1,2].* 1) Sorenson Molec Genealogy Fndn, Salt Lake City, UT; 2) Department of Microbiology, Brigham Young University, Provo, UT.

A more adequate understanding of New World settlements and biologic history is accessible within the context of selected population studies. Examination of regional populations will more completely address the nature of New World settlement within the framework provided by broader studies. Selected regional studies can yield a more refined assessment of settlement scenarios that include intra-continental migration because of the different developmental history of each group. The current study examines the population structure of Andean Altiplano populations from the Lake Titicaca Basin within the context of South American populations. We report the mtDNA haplogroup distribution of 454 samples from island and mainland populations of the Lake Titicaca region and identify control region sequence polymorphisms of 58 individuals. A selectively dispersed mtDNA control region motif is also presented as a diagnostic marker for tracing gene flow and founding events within the Lake Titicaca region and surrounding areas.

Genetic admixture, phenotype, and perceived admixture in Hispanics and Native Americans in New Mexico. *Y. Klimentidis.* Anthropology, University of New Mexico, Albuquerque, NM.

Examining admixed populations is useful for disease mapping, characterizing inter-population differences, and for exploring interactions between genetic admixture and various personal, social, and phenotypic outcomes such as BMI, % body fat, and skin pigmentation. This study considers a population of Hispanics and Native Americans from the state of New Mexico. A panel of AIMs (Ancestry Informative Markers) is used to classify individuals along the European-Native American ancestry spectrum. Measurements of skin pigmentation, height, weight, % body fat as well as facial photographs are obtained from each individual. In addition, various data on self-identified ethnicity, self-perceived admixture proportions, social environment, and familial history is obtained. Relationships between genetic ancestry and self-perceived ancestry/ethnicity are examined as well as the perception of others degree of shared ancestry as judged from facial photographs where both respondent and photographed individual have known degrees of genetic admixtures. Results generally show that genetic admixture is a moderately good predictor of a variety of traits, and that these are influenced by social and cultural factors. Implications concerning human evolutionary ecology and human diversity are discussed.

Evidence of Overdominant Selection for IL-10 Receptor (IL10RB) and IFN- Receptor 2 (IFNGR2) in European Americans but not in African-Americans. *N. Wang[1], X. Sheng[2], R. Chakraborty[2].* 1) Divs. of Allergy/Immunology and Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Recent studies have indicated that human disorders mediated by T-helper 1 (TH1) and T-helper 2 (TH2) pathways, such as type-1 diabetes and asthma, could down-regulate each other. IL-10 receptor (IL10RB) and IFN- Receptor 2 (IFNGR2) are required for IL-10 and IFN- to active the receptor complex, respectively. IFN- is mainly responsible for the TH1 response; IL-10 plays an important role by suppressing TH1-dependent but supporting TH2-dependent immune response. Overdominant selection (heterozygote advantage) suggests that heterozygous individuals at particular loci have a higher fitness than homozygotes. Our analyses of the resequence of IL10RB and IFNGR2 genes in 24 European Americans (EA) and 23 African-Americans (AA) show that the allele frequency and heterozygosity distributions of polymorphisms in these two genes are considerably different from those of selectively neutral genes in EA. A large proportion of the single nucleotide polymorphisms (SNPs) in IL10RB and IFNGR2 have intermediate frequencies; approximately 65% and 52% of the heterozygosity of IL10RB and IFNGR2, respectively, are contributed by such intermediate SNPs. These results suggest that IL10RB and IFNGR2 genes might be influenced by overdominant selection in EA. Since the evidence for overdominant selection could be confounded by population demographic history, such as population bottleneck, we conduct coalescence simulation for these two genes. Our simulation results rule out population bottleneck as the explanation, and support that overdominant selection is the primary cause. Interestingly, the evidence for overdominant selection of these two receptors is not observed in AA, suggesting that those SNPs with intermediate frequencies in IL10RB and IFNGR2 might be maintained after human moved out of Africa as an adaptation to local surroundings. The results obtained from our study provide new clues and emphasize the importance of these two gene receptors in diseases related to TH1 and TH2 pathways.

The efficiency and transferability of tagSNPs in six populations from three tagSNP selection algorithms. *S. Gu*[1], *N. Liu*[2], *H. Zhao*[1,2], *K.K. Kidd*[1]. 1) Department of Genetics; 2) Department of Epidemiology & Public Health, Yale University School of Medicine, New Haven, CT.

The HapMap project is focused on three continental groups, Yoruba from Africa, Mixed Europeans from Utah, and two Asian populations. However, there are few data that address how useful tagging SNPs selected on one population will be in another population from the same continent. Our analyses to test the generalizability of tagging SNPs across populations have used samples of two African populations (Yoruba and Hausa), samples of two European populations (Irish and Danes), and samples of European Americans and African Americans. The data consisted of 247 SNPs in six genomic regions totaling 2.5 Mb typed in all six populations. Three different tagSNP selection algorithms (based on haplotype diversity, haplotype entropy and linkage disequilibrium) were compared with each other and to see how well tagSNPs derived from one population sample would apply to other populations. For each algorithm, the resulting tagSNP sets from different populations were compared through the similarity measure (Liu et al. 2004, Genetic Epidemiology 27). The haplotype diversity based algorithm is most cost effective in tagSNP selection by preserving tagSNP transferability among regional populations with the minimum number of tagSNPs. However, it is dependent on block structure, an overly simplistic view of LD. Indeed, block patterns differ significantly among all populations, both within and between regions. However, the tagSNP sets show good transferability among populations within regions. The best tagSNP transferability among regional populations is achieved from pairwise LD tagging algorithm at a cost of 30~60% more tagSNPs per gene, and it is independent of block definition. In those instances in which Yoruba or Hausa tagSNPs did not suffice for African Americans (the diversity and LD based algorithms for two of the genomic regions) the union of tagSNPs from an African and European population included most of the tagSNPs selected directly for African Americans. We conclude that tagSNPs are usually generalizable within geographic regions but not exactly so. Supported in part by NIH GM57672.

Positive Selection of a Pre-expansion CAG Repeat of the Human SCA2 Gene. *F. Yu[1], P. Sabeti[2], P. Hardenbol[3], Q. Fu[1], B. Fry[2], X. Lu[1], S. Ghose[1], R. Vega[1], A. Perez[1], S. Pasternak[1], S. Leal[1], T. Willis[3], D. Nelson[1], J. Belmont[1], R. Gibbs[1].* 1) Baylor College of Medicine, Human Genome Sequencing Center, 1 Baylor Plaza, Houston, TX, 77030, USA; 2) Broad Institute of MIT and Harvard, 1 Kendall Square, Cambridge, MA 02319, USA; 3) ParAllele Bioscience, Inc., 7300 Shoreline Court, South San Francisco, CA, 94080, USA.

A region of approximately one megabase of human Chromosome 12 shows extensive linkage disequilibrium (LD) in Americans with ancestry from northern and western Europe. This strikingly large LD block was analyzed with statistical and experimental methods to determine whether natural selection could be implicated in shaping the current genome structure. Extended Haplotype Homozygosity and Relative Extended Haplotype Homozygosity (EHH/REHH) analyses on this region mapped a core region of the strongest conserved haplotype to the exon 1 of the Spinocerebellar ataxia type 2 gene (*SCA2*, locusID: 6311). Direct DNA sequencing of this region of the *SCA2* gene revealed a significant association between a pre-expanded allele ($(CAG)_8CAA(CAG)_4CAA(CAG)_8$) of CAG repeats within exon 1 and the selected haplotype of the SCA2 gene. A significantly negative Tajima's D value (-2.20, $P < 0.01$) on this site consistently suggested selection on the CAG repeat. This region was also interrogated in the three other populations, none of which showed signs of selection. These results suggest that a recent positive selection of the pre-expansion *SCA2* CAG repeat has occurred in Europeans.

Further evidence for a correlation of variation of CYP3A5*3 and AGT-M235T allele frequencies with distance from the equator: inclusion of Asian Indian populations. *T.J. Pemberton[1], D. Witonsky[2], C. Gonzales[1], J.W. Belmont[3], A. Di Rienzo[2], P.I. Patel[1].* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Department of Genetics, University of Chicago, Chicago, IL; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Large inter-ethnic variation in prevalence is known for a number of common conditions, such as hypertension. This variation may be due in part to large differences in risk allele frequencies between human populations which result either from the history of population structure and migration or from the action of natural selection on the risk variants themselves. Because selective pressures may vary with geography and other environmental variables, detectable patterns of geographic variation may be observed. Recently, allele frequencies at two single nucleotide polymorphisms within the CYP3A5 and AGT loci that have been shown to influence salt homeostasis were reported to correlate with distance from the equator (Thompson et al. AJHG 75:1059, 2004). Asian Indian populations have been largely excluded from the majority of large scale studies on genetic variation in populations, primarily because the Human Genome Diversity Panel does not include Asian Indian natives. This is despite their displaying a high prevalence of diseases linked to changes in diet and environment that have arisen as their lifestyle has become more westernised. The high prevalence of endogamy and relatively low admixture present in the population distinguishes Indian populations from most other populations presently used in population genetic studies. We have analysed these SNPs within a large Indian cohort of 577 individuals speaking 15 different Indian languages to determine the relative correlation in these populations with that of previously studied populations. Our data shows that these SNPs exhibit the same trend within our Indian population and that their inclusion in the analysis of the global population improves the correlation of the data. These results support the inclusion of an Indian population in future analysis of global population genetics.

Detecting population stratification using 100K Affymetirx Mapping Array. *X. Mao[1], I. Halder[1], M. Bauchet[1], R. Mei[2], C. Shweta[4], E. Burchard[4], E. Ziv[4], M. Shriver[4], N. Schork[3].* 1) Department of Anthropology, Penn State University, State College, PA; 2) Affymetrix, Inc., 3380 Central Expressway, Santa Clara, California 95051, USA; 3) Department of Psychiatry, University of California, San Diego, CA; 4) Dartment of Medicine, University of California, San Francisco.

DNA microarray platforms have increased the efficiency of biomedical research substantially. Likewise, greater analytical effect is required to summarize the information and interpret the results. We have typed the 100K Affymetrix Mapping Array on 267 individuals from five major groups (85 African Americans and West Africans, 115 European Americans, 17 South East Asians, 20 East Asians and 30 Indigenous Americans) and use the resulting multilocus genotypes to explore two methods of detecting population structure, a principle coordinate-based method and a pairwise distance-based method. Correlation of principle coordinates estimates from unlinked subsets of SNP markers is one way to explore the pattern of population structure. Populations with higher correlations have more stratification while populations with insignificant correlations have no stratification. In our analysis, African Americans and European Americans show the highest levels of correlation indication, while the East Asian group shows the smallest amount of correlation. The pairwise allele sharing distance estimates of individuals is an analogous approach to study substructure. Correlations of pairwise distance measure from unlinked subsets of markers (even vs. odd chromosomes) not only have the same trend as principle coordinates correlations, but also can be used to pinpoint the causation of population heterogeneity to certain individuals. Importantly, we can test for correlations between locus specific pairwise distance and overall pairwise distance measured across the genome as a method of quantifying the informativeness of previously unselected markers to facilitate the identification of ancestry informative markers.

Population differentiation of a SE Asian isolate from major Asian populations using 36 microsatellites. *J. Listman[1], R.T. Mailson[2,3], A. Sughondhabirom[4], N. Thavichachart[4], S. Tangwonchai[4], A. Mutirangura[4], T.R. Disotell[1], J. Gelernter[2,3].* 1) Dept Anthropology, New York Univ, New York, NY; 2) Dept Psychiatry, Yale Univ Sch Medicine, New Haven, CT; 3) VA CT, West Haven, CT; 4) Chulalongkorn Faculty of Med, Bangkok, Thailand.

The ability to differentiate between populations is valuable for admixture detection in case-control association studies and for inferring interpopulation relationships in anthropological studies. This is easy to achieve for major continental populations. We investigated whether this could be accomplished with more closely related populations. Unrelated samples of self-identified Thai (N=53) and Chinese (N=37) obtained in Bangkok, Thailand and Hmong (N=45) obtained from a village in northern Thailand were genotyped with 36 unlinked autosomal microsatellite markers. These markers were previously demonstrated to collectively differentiate between African Americans and European Americans. The mean delta for this panel was 0.25 (between Hmong and Chinese), 0.24 (between Hmong and Thai), and 0.17 (between Chinese and Thai). The program, STRUCTURE, which implements Bayesian clustering was used to assess the ability of this marker set to differentiate between the three Asian populations. The program MER was used to detect and remove any related individuals who may not have identified themselves as such. The Hmong were allocated into a distinct cluster with 91.4% estimated ancestry (K=2). Thus, we were able to differentiate an Asian tribal population from larger Asian populations. It was not possible to differentiate between the Thai and Chinese with this marker set irrespective of the presence of the Hmong in the analysis. Success in differentiating within these continental populations demonstrates that population structure is detectable at this level. This could be due to genetic drift shaping the gene pool of an endogamous population or the effects of sampling Hmong from a village in contrast to Thai and Chinese from an urban population. The results also suggest that superficial phenotype (i.e., continental origin) may mask population history and support the possibility of admixture mapping in closely-related populations.

Founder effects and diversity for hereditary eye diseases in Newfoundland and Labrador. *J. Green[1,2,3], J. Whelan[2], D. Bautista[2], S. Moore[3], K. Grewal[1], M. O'Driscoll[1], B. Younghusband[1], P. Parfrey[3], S. Murphy[3].* 1) Disc of Genetics; 2) Disc of Ophthalmology; 3) Disc of Medicine, Memorial Univ, St. John's, NL, Canada.

PURPOSE: Newfoundland and Labrador (NL) has been described as a genetic isolate with founder effect and increased prevalence of certain hereditary diseases. Ancestors were English (protestant) or Irish (catholic). Settlements were coastal remaining isolated until recently, and family size was large. Both geographic and religious isolation occurred. We were interested in the proportion of blindness in NL attributable to hereditary eye disorders, and in the genetic epidemiology of hereditary eye disease. **METHOD:** Records of the Canadian National Institute of the Blind (CNIB) were reviewed, patients seen in local and outreach clinics, and affected and unaffected members of families with unusually frequent conditions were recruited and consented for clinical and molecular genetic analysis. **RESULTS:** At least 24% of CNIB registrants had a single gene disorder as a cause of blindness including retinal dystrophies, ocular and oculocutaneous albinism, and anterior segment anomalies. A cluster of patients with a distinctive early-onset retinal dystrophy (Newfoundland Rod-Cone Dystrophy (NFRCD)) was identified. Families with NFRCD live within a 10 mile radius. Surprisingly there were two different mutations of the *RLBP1* gene in these 27 individuals from one genetic isolate. Bardet-Biedl Syndrome (BBS), a complex condition involving a severe retinal dystrophy, obesity, polydactyly, learning difficulties, renal and endocrine abnormalities, is unusually prevalent. Although one founder mutation was expected, seven different mutations in five BBS genes have been identified. There is as much intra-familial as interfamilial variability in these families, and no genotype/phenotype correlation is apparent. **CONCLUSIONS:** NL has multiple genetic isolates rather than being one homogenous genetic isolate. This knowledge is important as current and future studies focus on blindness caused by complex traits including high myopia, cataracts, glaucoma, and age-related macular degeneration.

Variation of individual admixture within and between populations follows continuous distributions. *I. Halder[1], C. Nievergelt[2], R. Ferrell[3], C. Gu[4], D. Arnett[5], S. Kardia[6], R. Cooper[7], X. Zhu[7], N. Risch[8], C. Hanis[9], N. Schork[2], M.D. Shriver[1].* 1) Pennsylvania State University; 2) University of California, San Diego; 3) University of Pittsburgh; 4) Washington University; 5) University of Alabama; 6) University of Michigan; 7) Loyola University; 8) University of California, San Francisco; 9) University of Texas, Houston.

Admixture stratification is a well documented cause of confounding in association studies. We have estimated individual ancestry and tested for presence of admixture stratification in the populations that are part of the Family Blood Pressure Program. Individuals studied are from several African-American (AA) and European-American (EA) populations and one Mexican-American (MA) population. All individuals were typed for a common panel of 311 microsatellite markers. Individual ancestry estimated using Maximum Likelihood and a separate Bayesian method implemented in the program STRUCTURE, show a continuum of ancestry proportions with substantial variation within different self identified race/ethnicity groups and some degree of overlap between two of the groups. We have tested for and observed admixture stratification in all of the AA and MA samples, but not in any of the EA samples. We have additionally observed correlations between admixture proportions and some phenotypes. We conclude that since categorical descriptions of individuals are non-overlapping and do not describe within group variation, they are suboptimal for describing human genetic variation within and among populations and metapopulations. Continuous expressions of genetic variation such as individual admixture provide more detailed descriptions of the genetic structure of a population.

Woodward[1,2].* 1) Sorenson Molecular Genealogy Foundation (SMGF), Salt Lake City, UT, USA; 2) Dept. of Microbiology, Brigham Young University, Provo, UT, USA.

Genetic data as well as anthropological and linguistic evidence suggest that modern inhabitants of Oceania could have originated in a variety of world locations, including Asia. A large amount of the genetic data studied is based on either Y chromosomal or mitochondrial analysis (e.g. the Polynesian Motif), however, few of these studies have incorporated the X-chromosome (X-chr) as evidence of population origins. Herein we characterize a novel private allele on the X chr for the Oceanic region and East Asia. We have identified a 1-bp mutation in the STR locus DXS1041. 176 of 18,065 samples genotyped at that locus have this mutation, giving a frequency of 0.974% in the SMGF database. Of these samples, 172 have X line genealogies deeply rooted in Asia or Oceania: 66.9% of these are Polynesian, 22.1% Asian, 4.1% of New Zealand origin, 2.3% Filipino, 2.3% Melanesian, and 2.3% are mixed from both Asian and Oceanic populations. Herein we propose that this allele could be used to identify membership in Asian/Oceanic populations.

Population bottlenecks and neutral evolution as major shaping forces of human genome architecture. *N. Katsanis[1], P.E. Chen[1], T.M. Teslovich[1], P. Stankiewicz[2], C.S. Kashuk[1], S.P. Zack[3], J.M. Organ[3], M. Withers[2], A. Chakravarti[1], J.R. Lupski[2], D.J. Cutler[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Center for Functional Anatomy and Evolution, Johns Hopkins University, Baltimore, MD.

The neo-Darwinian view of human evolution proposes that the fixation of novel mutations is driven by the selective advantage they proffer to reproductive fitness. When considering the global architecture of the human genome, a similar model has been evoked to explain the rapid acquisition and proliferation of exogenous DNA. To understand the evolutionary forces that have morphed human genome architecture, we investigated the origin, composition, and functional potential of *numts* (nuclear mitochondrial pseudogenes), partial copies of the mitochondrial genome found abundantly in chromosomal DNA. Our data indicate that these elements are likely to be evolutionarily neutral or deleterious, since they possess no gross positional, transcriptional, or translational features that might indicate functionality subsequent to integration. Using sequence analysis and fossil data, we also show a burst of integration of *numts* in the primate lineage that centers on the prosimian-simian split and mimics closely the temporal distribution of Alu and processed pseudogene acquisition. We suggest that the gross architecture and repeat distribution of the human genome can be largely accounted for by a population bottleneck early in the simian lineage and subsequent neutral fixation of repetitive DNA, rather than positive selection or unusual insertion pressures.

Haplotype diversity and population histories in the CEPH Human Genome Diversity Panel based upon variation in four cytochrome P450 genes and COMT. *W. Modi[1], H. Sicotte[1], D. Garcia-Ross[1], M. Yeager-Jeffery[1], R. Welch[1], L. Burdette[1], H. Cann[2], G. Thomas[2], S. Chanock[3].* 1) SAIC, NCI-ATC, Bethesda, MD; 2) CEPH, Paris, France; 3) NCI-Core Genotyping Facility, Bethesda, MD 20892.

Central to the mission of ascertaining the importance of genetic variation in human health and disease is understanding patterns of variation in different populations throughout the world. Assessing geographic variation enables us to evaluate the relative contributions of selection, drift and admixture in molding the architecture of the human genome. This study is estimating nucleotide and haplotype diversity, times to most recent common ancestory through coalescent simulations, and migration patterns among nearly 1500 individuals belonging to over 55 populations from the CEPH Human Genome Diversity Panel, and the HapMap and SNP500 reference populations, based upon variation in cytochrome P450 genes and COMT. The cytochrome P450 proteins are monooxygenases which catalyze many reactions involved in drug metabolism and synthesis of cholesterol, steroids and other lipids. Catechol-O-methyltransferase (COMT) catalyzes the transfer of a methyl group from S-adenosylmethionine to catecholamines, including the neurotransmitters dopamine, epinephrine, and norepinephrine. Data collection includes: 1) the resequencing of all coding and adjacent flanking regions in 102 individuals assigned to four ethnic groups. This has identified about 300 SNPs from 60 kb of sequence revealing a frequency of one SNP every 200 bp. 2) Genotyping common SNPs every 2 kb throughout each gene in 1500 individuals: CYP1A1 and CYP1A2 (22 SNPs covering 62 kb), CYP1B1 (18 SNPs covering 22 kb), CYP3A4 (18 SNPs covering 49 kb) and COMT (31 SNPs covering 59 kb). Preliminary results indicate extensive intergenic variability in nucelotide diversity and interpopulation variation in allele and haplotype frequencies suggesting varied selective pressures and/or population histories.

Single molecule recovery of human L1 insertions from sperm DNA. *R.M. Badge[1], A.J. Jeffreys[1], J.V. Moran[2].* 1) Dept Genetics, Univ Leicester, Leicester, United Kingdom; 2) Dept Human Genetics, Univ Michigan Medical School, Ann Arbor, Michigan, USA.

L1 is our most successful and currently only autonomous transposable element. As such it contributes to mutational load directly through insertional mutagenesis and indirectly through ectopic recombination, and likely mobilises all other dispersed repeats currently remodelling the human genome. Thus L1 drives genome fluidity in humans, but the rate at which this process occurs in germline cells is not known. Cell culture retrotransposition assays have revealed our genome contains highly active elements that show presence/absence polymorphism. These assays are also powerful tools to study the mechanism of L1 retrotransposition but cannot estimate the rate of retrotransposition of endogenous human elements. ATLAS (Badge *et al*, 2003) is a genomic display technique that can selectively display full-length L1 terminus/genomic DNA junctions from the most active L1 subfamilies. Simultaneous display of full-length L1s from many human genomes makes the isolation of low allele frequency, and thus likely young and still active elements, relatively trivial. In addition the application of ATLAS to very small numbers (pools) of sperm genomes can potentially enable the display of *de novo* insertions by gel electrophoresis, despite their origin as unique L1/genomic junctions within individual sperm genomes. Here we describe the development of an ATLAS variant, Small Pool (SP) ATLAS that can demonstrably recover molecularly unique events from human sperm DNA and that shows levels of reproducibility and specificity that are compatible with the recovery of *de novo* L1 insertions. Dilution of display inputs to the single molecule level allows estimation amount of DNA scanned per reaction, thus placing an upper limit on the rate. Importantly these rates are specific for insertions of intact L1s and thus enable us to quantify the most relevant evolutionary parameter- the rate at which retrotransposition competant elements are inserted into our genome. Badge RM, Alisch RS, Moran JV. ATLAS: a system to selectively identify human-specific L1 insertions. Am J Hum Genet. 2003 Apr;72(4):823-38.

Hybridisation enrichment recovery of *de novo* human L1 insertions from sperm DNA. *P.J. Freeman, R.M. Badge, A.J. Jeffreys.* Dept Genetics, Univ Leicester, Leicester, UK.

The most important class of mobile DNA in humans is L1, an autonomous non-LTR retrotransposon. L1 retrotransposition has contributed to the remodeling of the human genome through insertional mutagenesis, transduction, pseudogene formation, and ectopic recombination. There is strong evidence that L1s have played an important role in changing human DNA, and also that they are still doing it today. However L1 retrotransposition dynamics are little understood in the human germline due to the lack of stable human germline cell culture techniques and the fact that *de novo* insertions occur at approximately one event genome-wide per 50 - 100 haploid genomes. Hybridisation enrichment can be used to directly access *de novo* L1 insertions in human sperm genomic DNA, from targeted loci. L1 specific biotinylated oligonucleotides (bio-oligos) are used to enrich specific DNA sequences that are under-represented in an aliquot of DNA. Enrichment is achieved by binding bio-oligos to the target sequence and physical retrieval of the bio-oligo bound single stranded DNA using streptavidin-coated paramagnetic beads. Successive rounds of PCR and enrichment can be used to increase yield. The use of the bio-oligos directly on sperm DNA would be futile due to the amount of L1 sequence dispersed throughout the genome. In order to detect *de novo* insertions in sperm DNA, the search area has to be limited to genomic sections (~ 5kb in length) that are devoid of L1 sequences. An important technical challenge is that the PCR amplification of *de novo* insertions (up to 12kb in length) has to be efficient at the single molecule level. A *de novo* insertion will appear once in a pool of sperm DNA, and thus must be amplifiable even in the presence of an overwhelming majority of empty target sites. Also to screen sufficient DNA to be sure to recover many *de novo* L1 insertions multiple target loci must be simultaneously amplified requiring long-range multiplex PCR. Here we demonstrate that these technical challenges have been overcome and in principle that even at the lowest estimated rate of insertion (1 insertion in 2 X 10^8 kb) at least 10 *de novo* insertions should be recovered per ejaculate.

Substantial variation in retrotransposition potential generated by many alleles of young human L1 retrotransposons. *M.dC. Seleme, M.R. Vetter, H.H. Kazazian.* Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Even though they are rare in the human genome(0.02%), young active L1 retrotransposons can generate large variation among individuals through various molecular events such as insertional mutagenesis, exon shuffling, and mediating the dispersion of processed pseudogenes, Alu, and SVA elements. Here, in four populations (160 genomes) we have investigated a type of variation generated by active L1s that is based on the natural substitutions that occurred along their full-length sequence after insertion. Interestingly, we have found a large number of alleles at each of 3 L1 loci analyzed. Roughly 1 new allele was found for every 3 full-length sequences analyzed at each locus. For example, among 73 genomes containing a particular L1, 25 alleles were identified. Among the various nucleotide changes, we found nonsense mutations, insertions and deletions. Assuming a neutral mutation rate, the polymorphism data suggested that the insertions occurred from about 356.000 years ago for the oldest to about 80.000 years ago for the youngest. Along with the allelic description of these three L1 loci, we studied the allelic retrotransposition capacity ex-vivo. We grouped the alleles according to their average retrotransposition capacity and found that many single or combined nucleotide changes dramatically affected the retrotransposition efficiency of the elements, generating an unsuspected high degree of individual variation in retrotransposition potential. For instance, one element presented variants with activity as low as 5% and as high as 180% as compared to a reference element; another element presented inactive alleles and alleles with activity as high as 100%. This is the first large-scale analysis on the polymorphism of single, potentially active L1s at specific genomic locations and provides new insights into 1) how quickly recently inserted L1s can become inactivated by mutation and 2) the extent of individual variation in retrotransposition capability.

Identification of proteins that bind galectin-2, encoded by a gene associated with myocardial infarction using tandem affinity purification method. *K. Ozaki[1], K. Inoue[2], K. Odashiro[2], M. Nobuyoshi[2], Y. Nakamura[1,3], T. Tanaka[1].* 1) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 2) Department of Cardiology, Kokura Memorial Hospital, Kitakyushu, Japan; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Myocardial infarction might result from the interactions of multiple genetic and environmental factors, none of which can cause disease solely by each of themselves. We have previously identified galectin-2 protein as a binding partner of lymphotoxin- (LTA) whose functional single nucleotide polymorphisms (SNPs) conferred susceptibility to myocardial infarction. The association study further revealed that a functional SNP in *LGALS2* encoding galectin-2, which led to altered secretion of LTA, was also indicated a risk of myocardial infarction. To clarify detailed function of galectin-2 protein, we searched for its binding partners by using a tandem affinity purification method and identified several molecules. Toll like receptor 2 (TLR2) was one of them, which plays an important role in immune systems. Combined with previous results that LTA and tubulins also bind with galectin-2 and that tubulins have been reported to be used in the intracellular transport of membrane protein, we hypothesized galectin-2 plays a pivotal role in the transport of various membrane/secreted protein that constitute immune system including inflammation.

A novel DFNA9 mutation in the vWFA2 domain of COCH alters a conserved cysteine residue and intrachain disulfide bond formation resulting in progressive hearing loss and site-specific vestibular and central oculomotor dysfunction. *V.A. Street[1], J.C. Kallman[1], N.G. Robertson[2], S.F. Kuo[2,5], C.C. Morton[2,3,4], J.O. Phillips[1].* 1) V.M. Bloedel Hearing Research Ctr, Otolaryngology - HNS Department, University of Washington, Seattle, WA; 2) Department of Obstetrics, Gynecology and Reproductive Biology; 3) Department of Pathology, Brigham and Women's Hospital; 4) Harvard Medical School, Boston, MA; 5) Speech and Hearing Bioscience and Technology Program, Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA.

Statement of Purpose: Hearing and balance impairment are common clinical complaints. However, the number of single gene mutations known to precipitate both sensory problems in one individual or family is small. It is unclear whether auditory and vestibular dysfunction generally represent separate entities or whether the presence of vestibular symptoms is not fully appreciated without formal vestibular assessment in human pedigrees segregating hearing loss. In this abstract, we report the characterization of a large American pedigree (referred to as the HL3 family) that self-reports inherited hearing loss. Methods Used: Audiologic evaluations consisted of immittance testing and establishment of pure-tone air and bone conduction thresholds. Vestibular assessment included oculomotor testing, computerized dynamic posturography, rotational testing, vestibular evoked myogenic potentials, and caloric testing. Genetic linkage, haplotype analysis, and mutation scanning was performed on DNA samples from HL3 individuals. Transient transfections and Western blot analysis were used to characterize the identified mutation. Summary of Results: Autosomal dominant hearing loss in the HL3 pedigree was mapped genetically to the long arm of chromosome 14 in band q12. A maximal pairwise LOD score of 7.08 was obtained with marker D14S1021. A mutation within exon 12 of the COCH gene (encoding the cochlin protein) was identified in affected HL3 family members. The mutation results in a predicted substitution at an evolutionarily conserved cysteine residue in the C-terminus of cochlin. This COCH exon 12 alteration represents the first reported mutation outside of the cochlin LCCL domain which is encoded by exons 4 and 5. The exon 12 mutant cochlin is translated and secreted by transfected mammalian cells. Western blot analysis under non-reducing and reducing conditions suggests that this exon 12 mutation alters intramolecular cochlin disulfide bond formation. In the vestibular system, a progressive horizontal canal hypofunction and a saccular otolith crisis were detected in HL3 family members with the COCH alteration. Abnormal central oculomotor test results in HL3 family members with the COCH alteration imply a possible central nervous system change.

Auditory and vision phenotype of waltzer *Cdh23$^{v\text{-}6J}$* and Ames waltzer *Pcdh15$^{av\text{-}Jfb}$* double mutant mice: no evidence of retinitis pigmentosa or digenic inheritance of progressive hearing loss. *Z. Ahmed[1], R.J.L. Haywood-Watson II[1,2], S. Riazuddin[1], S. Kjellstrom[1], R.A. Bush[1], L.L. Hampton[3], J.F. Battey[1,3], P.A. Sieving[1,4], G. Frolenkov[1], T.B. Friedman[1].* 1) Lab Molecular Genetics, NIDCD, National Institutes of Health, Rockville, MD; 2) Molecular and Cellular Biology Program, Tulane University, New Orleans, LA; 3) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 4) National Eye Institute, National Institutes of Health, Bethesda, MD.

Mutations of *CDH23* or *PCDH15* are associated with Usher syndrome type I. Recently, a digenic interaction between these two genes was reported to be responsible for progressive hearing loss in doubly heterozygous mice (+ *Cdh23$^{v\text{-}2J}$* / *Pcdh15$^{av\text{-}3J}$* +) and for Usher syndrome type I in humans (Zheng et al. 2005). Here, we provide evidence that mice (n = 44) which are double heterozygotes for both *Cdh23$^{v\text{-}6J}$* and *Pcdh15$^{av\text{-}Jfb}$* alleles in cis or in trans on a uniform C57BL/6J background do not exhibit progressive hearing impairment beyond the age related hearing loss seen in control mice (n = 51). No stereocilia defects were observed in P2 *Cdh23$^{v\text{-}6J}$ Pcdh15$^{av\text{-}Jfb}$* double heterozygotes (P120) and neither the *Cdh23$^{v\text{-}6J}$* nor *Pcdh15$^{av\text{-}Jfb}$* homozygotes were more affected by the presence of one mutant copy of *Pcdh15$^{av\text{-}Jfb}$* or *Cdh23$^{v\text{-}6J}$*, respectively. We also document the auditory and visual phenotype of mice that are double homozygotes for *Cdh23$^{v\text{-}6J}$* and *Pcdh15$^{av\text{-}Jfb}$* mutations. Although, there is no retinal abnormality detected in the double homozygous mutant mice, scanning electron microscopic studies revealed, as expected, prominent abnormalities of inner ear hair cell stereocilia bundles.

State Space Methods for Studying Dynamic Behavior of Gene Regulation. *X. Sun[1], L. Jin[1], J. Qian[1], M. Xiong[2].* 1) Genetics, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas Health Scince Center.

Gene regulation is a complex system that requires accomplishing complex tasks with high accuracy. A very powerful approach to modeling complex systems is the state-space approach. Mechanisms for using RNA interference and artificial genetic networks as target gene therapy are systematical control of the state of the cell to minimize malfunctions of the cells. Their successful applications to the development of smart drugs require state-space representation of dynamics of gene regulation and genetic networks and applications of modern control theory to design and analysis of regulatory systems. State-space approach provides a general framework and a powerful tool for application of control theory to analysis of gene regulation. The purpose of this report is to develop state-space models for gene regulation, study transient response of gene expression under environment stimuli and classify genes according to their transient response to external perturbation. To achieve this goal, State-space representation of regulation of a gene and study second order systems for gene regulation will be presented. Interpretation of coefficients in the second order systems as resistance, capacitance and inductance will be studied. Mathematical methods for transient response analysis of gene regulation will be developed. The proposed methods will be applied to cell cycle of yeast gene expression data. Classification of genes in terms of their transient response behavior for the yeast gene expression data set will be performed.

Idenfitication of ABCA4 regulatory mutations in recessive Stargart families. *C.M. Zaremba[1], W. Wiszniewski[1], R.A. Lewis[1,2,3,4], E.H. Marguiles[5], E.D. Green[5], J.R. Lupski[1,2].* 1) Department of Molecular and Human Genetics; 2) Department of Pediatrics; 3) Department of Medicine; 4) Department of Ophthalmology; 5) Genome Technology Branch and NISC, National Human Genome Research Institute.

Stargart disease (STGD1) is an autosomal recessive retinal dystrophy caused by alterations in *ABCA4*. Mutational analysis of recessive STGD has been limited to direct DNA sequencing of the exon coding regions, in which 66-80% of mutant alleles have been identified; thus leaving a significant fraction of mutant alleles unaccounted for. In an effort to identify the remainder of the causative alterations, we employed a method to elucidate highly conserved sequences by comparative sequence analysis in a 300-Kb region surrounding *ABCA4* followed by direct DNA sequencing and functional analysis of these conserved fragments. Initial prediction of potential functional elements in the 5 UTR of *ABCA4* was implemented using a comparative genomic strategy across eight vertebrate species (human, chimpanzee, armadillo, cat, dog, mouse, pig, and opossum). Using this approach we identified 32 conserved fragments (39.59 bp average) in a 10-Kb interval just upstream of the 5 UTR of *ABCA4*. Furthermore, we screened for alterations in these conserved sequences in two groups of STGD families with multiple (greater than two) affected siblings possessing either zero (16 families) or one (40 families) *ABCA4* coding region alterations. Presently, we have identified four potentiialy significant SNPs: -1439 A>T (12.0%), -1086 A>C (29.2%), -900 A>T (34.9%), and -761 C>A (1.7%). Ongoing experiments are addressing whether these represent functional SNPs. Collectively, these data support the contention that a fraction of mutations are undetected in patients with recessive STGD and may reside in the non-coding, potentially regulatory regions of *ABCA4*.

Evaluating dependency among three systems: analysis of the relationships between a pair of transcriptional regulatory elements and tissue specific gene expression using the double and triple mutual information in humans. *M. Tanino[1,2], M. Watanabe[3], Y. Takahashi[3], T. Tamura[4], T. Imanishi[2], T. Gojobori[2,5].* 1) Integrated Database Group, JBIRC, JBIC, Tokyo, Japan,; 2) Integrated Database Group, BIRC, AIST, Tokyo, Japan; 3) Fujitsu Co. Ltd, Tokyo, Japan; 4) BITS Co., Ltd, Shizuoka, Japan; 5) Center for Information Biology and DNA Data Bank of Japan, National Institute of Genetics, Shizuoka, Japan.

To date, there have been many reports investigating the relationship between transcriptional factors and their tissue-specific regulatory mechanisms. However, few reports have discussed or evaluated the combinatorial effects of transcriptional factors on regulatory mechanisms. Transcriptional regulation, especially in multi-cellular eukaryotes, is a complex system in which different types of transcriptional factors work together through DNA binding sites (cis-acting elements). Thus, the analysis of the relationship between a pair of cis-acting elements in the upstream regions of genes and the expression patterns must be effective for understanding the transcriptional regulatory mechanism in multi-cellular eukaryotes. The double (usual) mutual information gives a general measure of correlation between two systems and this index is useful as long as we consider only two systems. However, in the case of three systems, even when two systems seem to be independent, for example the relationship between a cis-acting element and expression pattern, if we consider another cis-acting element together with these, we may observe a mutual dependence among these three systems. We present here a method of evaluating inter dependency among three systems, a pair of cis-acting elements and an expression pattern, using the double and triple mutual information. Our method should be very useful in unraveling the transcriptional regulatory mechanism where not a single factor but multiple factors cooperate to govern the mechanism. We scored all pairs of cis-acting elements stored in the TRANSFAC database and found several novel pairs of cis-acting elements which may regulate tissue-specific expression under normal conditions in adult humans.

In Vivo Functional Study of a Unique Polyglutamine Stretch in RUNX2. *P. Fonseca[1], G. Zhou[1], Y. Chen[1], B. Lee[1,2].* 1) Dept Molecular Human Genetics, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Chevy Chase, MD.

RUNX2 is a non-redundant transcriptional activator involved in osteoblast differentiation and chondrocyte maturation. It contains a unique N-terminal polyglutamine-alanine (Q/A) domain consisting of a stretch of 23 residues of glutamine and 17 residues of alanine. Mutations in RUNX2 cause an inherited skeletal malformation syndrome, cleidocranial dysplasia (CCD). Until now, only one expansion in the alanine tract has been reported in an individual with CCD, while contractions of the tract are benign polymorphic variants. Polyglutamine expansions are known to cause several neurodegenerative diseases, but the function of the QA tract in RUNX2 is still unclear. In this study, we generated a series of mutant forms of RUNX2 with a deleted (7QE2A-RUNX2) or expanded (72QE23A-RUNX2) QA domain. In vitro studies show that polyglutamine deletion (7QE2A-RUNX2) decreases transactivation of the osteocalcin reporter, while expansions only reduce transactivation when they exceed 70 repeats. Mice over expressing the deletion mutation 7QE2A-RUNX2 under the osteoblast-specific Col1a1 promoter present with short stature at birth. Skeletal preparations revealed delayed closure of fontanel while clavicles appeared normal. Radiographic analysis of transgenic mice suggests lower bone mass. Transgenic mice also show absence of upper teeth and overgrown lower teeth with malocclusion suggesting this mutant was able to interfere with RUNX2 function during intramembranous ossification thereby phenocopying CCD in the skull. Interestingly, a fragment containing only the QA domain exhibited a stronger dominant-negative effect on full-length RUNX2 in RUNX2 transactivation assay in ROS17 cells. In vivo, transgenic mice over expressing only the QA domain in osteoblasts exhibited dwarfism and lower bone density. These data suggest that over expression of normal length Q/A domain may have dominant negative effects on osteoblast function independent of the RUNT domain. The analysis of these different transgenic mice will lead to a better understanding of the function of the Q/A tract in RUNX2 and potentially identify novel human phenotypes that might be allelic to CCD.

Two novel point mutations in the long-range Shh enhancer in three families with triphalangeal thumb and preaxial polydactyly. *C.A. Gurnett[1], A.M. Bowcock[2], F.R. Dietz[3], J.A. Morcuende[3], J.C. Murray[4], M.B. Dobbs[5].* 1) Dept Neurology, Washington Univ, St Louis, MO; 2) Dept Genetics, Washington Univ, St Louis, MO; 3) Dept Orthopaedics, University of Iowa Carver College of Medicine, Iowa City, IA; 4) Dept Pediatrics, University of Iowa Carver College of Medicine, Iowa City, IA; 5) Dept Orthopaedics, Washington Univ, St Louis, MO.

Spatio-temporal expression of Shh is driven by a regulatory element (ZRS) that lies 1 Mb upstream from Shh. Point mutations within the highly conserved ZRS have been described in the hemimelic extra toes mouse and in four families with preaxial polydactyly (Lettice et al., 2003). Four North American Caucasian families were identified with autosomal dominant triphalangeal thumb. DNA from 20 affected and 36 unaffected family members was evaluated by sequence analysis of a 774 bp highly conserved ZRS contained within Lmbr1 intron 5. Mutations within ZRS were identified in three of four families. In pedigree A and C, a novel A/G transition was identified near the 5' end of ZRS at bp 739 that segregated with disease or carrier status. Pedigree A, described previously (Dobbs et al., 2000), is a large family with 19 affected members who exhibit a milder phenotype, including predominantly triphalangeal thumbs and low penetrance relative to other families (82%). Pedigree C is a small family with two affected family members with triphalangeal thumb, and one affected with both triphalangeal thumb and preaxial polydactyly. A novel C/G mutation at bp 621 was identified in pedigree B that segregated with the disease in all four affected individuals who manifested both preaxial polydactyly and triphalangeal thumb. Mutations within ZRS appear to be a common cause of familial triphalangeal thumb and preaxial polydactyly. A genotype/phenotype correlate is suggested by pedigree A, whose mutation lies near the 5' end of ZRS; this family demonstrates a higher rate of nonpenetrance and milder phenotype. However, modifier genes may be contributing to the milder phenotype in this family.

Expression of sarcoglycans in brain reveals potential role of -SG in myoclonus dystonia. *H. Cai, L. Zweier, W. Shi, J. Chen, Y.M. Chan.* The Henry Hood Research Program, Sigfried and Janet Weis Center for Research, the Geisinger Clinic, Danville, PA 17822.

Sarcoglycans are a group of transmembrane proteins predominantly expressed in skeletal and cardiac muscle. Currently, six sarcoglycans have been identified (,,,,,-SG). In muscle, , , , and -SG form a tetra-meric complex on the sarcolemma. The proper assembly and targeting of sarcoglycans to the plasma membrane are dependent on the formation of a central /-SG core. Mutations in muscle sarcoglycans have been shown to cause autosomal-recessive limb-girdle muscular dystrophies (LGMD) and dilated cardiomyopathy. On the other hand, mutations in -SG are responsible for a movement disorder called myoclonus dystonia. In this study, we compared the expression of sarcoglycans in brain with other tissues. Previously, we have demonstrated that sarcoglycans form a distinct complex in Schwann cells consisting of -SG, -SG, -SG and -SG. They are localized to the outermost membrane of the Schwann cell and their expression correlates with peripheral nerve development. In this report, we provided evidence that and -SG are abundantly expressed in brain. However, -SG and -SG are barely detectable while -SG and -SG are not present in brain as demonstrated by both protein and RNA expression studies. Co-immunoprecipitation experiment indicated that -SG does not tightly associate with -SG. Our data suggested that -SG and -SG could have different functions in brain. Although no mutation has been associated with -SG, mutation screening in -SG should be included for myoclonus dystonia or other neurological disorders in the future.

A Novel De novo Missense Mutation on the Grandpaternal X Chromosome in the JmjC Domain of the *JARID1C* Gene in an XLMR Family Linked to Xp11.3. *F.E. Abidi[1], L. Holloway[1], L.M. Wolf[2], R.E. Stevenson[1], C.E. Schwartz[1].* 1) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, South Carolina, USA; 2) Department of Pediatrics/ Human Development, Michigan State University, East Lansing, Michigan, USA.

Mutations in the *JARIDIC/SMCX* gene were recently found to cause X-linked mental retardation. As a part of our XLMR candidate gene testing, mutation analysis of the *JARIDIC* gene was done in the probands from 24 XLMR families linked to Xp11.2. We identified a novel missense mutation (p.V504M) in one of these families (K8835). The family consists of three affected males in two generations with mild - moderate MR. All three exhibited developmental delay as well as delayed speech and short stature (~10-15 % tile). The alteration, c.1510G>A, changes a conserved valine residue at position 504 to a methionine (p.V504M) and segregates with the phenotype. The analysis of markers flanking the *JARIDIC* gene indicates that this mutation is a de novo event arising on the grandpaternal X chromosome. The p.V504M mutation was not observed in 609 X chromosomes from normal individuals (239 males and 185 females) which would rule out the mutation being a rare polymorphism. This mutation falls in the JmjC domain of the *JARIDIC* gene where no previous mutations have been reported. Out of the 4 missense mutations previously reported only one was found to be present in the C5HC2 zinc finger domain, whereas the three other mutations were not located in any conserved domains of the gene. It has been postulated that the *JARIDIC* gene may have a role in histone modification because of the presence of the JmjC domain. Functional studies using the above mutation may help us understand the function of this domain in the *JARIDIC* gene. Our finding further confirms the hypothesis that this gene may play an important role in human brain function.

Protein composition of the intranuclear inclusions of FXTAS. *P.J. Hagerman[1], C.K. Iwahashi[1], D.H. Yasui[1], H.J. An[2], C.M. Greco[3], F. Tassone[1], K. Nannen[1], B. Babineau[1], C.B. Lebrilla[2], R.J. Hagerman[4].* 1) Dept Biochem & Molec Med, UC Davis, Davis CA; 2) Dept Chem, UC Davis, Davis CA; 3) Dept of Path, UC Davis, Sacramento CA; 4) MIND Inst, UC Davis, Sacramento CA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurodegenerative disorder involving progressive intention tremor, gait ataxia, parkinsonism, and progressive memory loss. The selectivity of FXTAS for carriers of transcriptionally active, premutation alleles, coupled with the elevated levels of *FMR1* mRNA in the premutation range, led us to propose an RNA toxic gain-of-function model for FXTAS (Neurology 2001 57:127). The pathologic hallmark of FXTAS is the ubiquitin-positive intranuclear inclusion, found in neurons and astrocytes in broad distribution throughout the brain. A central prediction of the RNA toxicity model for FXTAS is that one or more RNA binding proteins is necessary to transduce the effect of the abnormal *FMR1* mRNA. Consistent with this hypothesis, we previously reported that the inclusions do contain *FMR1* mRNA.

Using a combination of nuclear isolation and preparative particle sorting protocols, we have now successfully isolated highly purified intranuclear inclusions from post-mortem brain tissue of FXTAS patients. Determination of the identities of the proteins comprising the inclusions has been greatly facilitated by the use of modern mass spectrometry approaches. Further analysis of the purified inclusions has enabled us to identify more than twenty proteins in the inclusions, including two RNA binding proteins, hnRNP A2 and MBNL1 (a homologue of *Drosophila* muscleblind), which are potential mediators of the RNA toxicity. FMRP itself appears to be absent from the inclusions. The inclusions also appear to contain several intermediate filament (IF) proteins, including lamins A/C, -internexin, and other neurofilament (NF) proteins. Although the role(s) of the A-type nuclear lamins is only beginning to emerge, they may be involved with the regulation of RNA synthesis and processing. Thus, the lamins could also be involved in mediating the effects of the expanded-repeat *FMR1* mRNA.

NF-B Mediates TNF- Inhibitory Effect on Human COMT Gene Expression. *I.E. Tchivileva[1], R. Sitcheran[2], A.S. Baldwin[2], W. Maixner[1], L. Diatchenko[1].* 1) Center for Neurosensory Disorders, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, NC.

Catechol-O-methyltransferase (COMT) is a ubiquitous enzyme that catabolyzes catecholamines. Recent studies documented that reduction in COMT activity results in increased pain sensitivity in animal models, and human genetic variants coding for low COMT activity are associated with heightened pain sensitivity. Increased pain sensitivity is one of the characteristics of both the acute and chronic inflammation. We thus hypothesized that regulation of COMT expression under inflammatory conditions could contribute to development of inflammatory pain. In present study, we cloned a distal promoter of human COMT (P2-COMT) into a luciferase reporter vector and transiently transfected the construct into PC-12 cell line. COMT expression is controlled by two promoters, but only the P2-COMT is active in the human brain tissues. We demonstrated that proinflammatory cytokine tumor necrosis factor- (TNF-) down-regulated the activity of P2-COMT. RT-PCR and Western analyses of cell lysates confirmed decreased level of endogenous COMT after TNF- treatment at both mRNA and protein levels. Our findings showed that transcription factor NF-B, which plays a pivotal role in inflammation, mediated this TNF- effects. Specifically:(i) an optimal NF binding site was found by TFSearch analysis of P2-COMT sequence; (ii) cotransfection of p65 (RelA) inhibited expression of the P2-COMT reporter construct; (iii) TNF-/p65-induced repression of P2-COMT reporter construct could be reversed by the inhibitor of NF-B (IB) thus confirming the specific involvement of NF-B. The mechanism of NF-B suppression was assessed using electrophoretic mobility shift assay (EMSA) and P2-COMT mutants with impaired NF binding site. These results represent a first demonstration of COMT regulation by the NF-B pathway and suggest that inflammation can lead to enhanced pain sensitivity through decreased COMT expression.

Long range PCR facilitates the identification of *PMS2* specific mutations. *M. Clendenning[1], H. Hampel[1], J. La Jeunesse[1], A. Lindblom[2], J. Lockman[1], M. Nilbert[3], K. Sotamaa[1], A. de la Chapelle[1].* 1) Human Cancer Genetics Program, Comprehensive Cancer Center, The Ohio State University, Columbus, OH; 2) Karolinska Institute, Department of Molecular Medicine, Stockholm, Sweden; 3) Department of Oncology, Clinical Sciences, Lund University, Lund, Sweden.

Mutations within the DNA mismatch repair gene, *PMS2* (postmeiotic segregation increased 2), have been associated with a predisposition to hereditary non-polyposis colorectal cancer (HNPCC; Lynch syndrome). Unlike the other members of the DNA mismatch repair family, accurate mutation detection within this gene has proved very difficult due to the presence of a large family of highly homologous *PMS2* pseudogenes. Here, we describe a novel method that utilizes long range PCR as a means to preferentially amplify *PMS2* and not the pseudogenes. A second, exon-specific, amplification from diluted long range products enables us to obtain good clean sequence that shows no evidence of pseudogene contamination. This method has been successfully utilized to screen a cohort of HNPCC-like patients (colorectal and endometrial cancers), whose tumors were negative for the PMS2 protein by immunohistochemistry, and had not shown any mutations within the *MLH1* gene. Sequencing of the *PMS2* gene from 30 colorectal and 9 endometrial patients identified 9 novel sequence changes as well as 16 sequence changes that had previously been identified. In total, putative pathologic mutations were detected in 9 of the 39 families. Among these were four novel mutations, c.705+1G>T, c.736_741del6ins11, c.1688G>T and c.2113G>A. The indel mutation within exon 7 was identified in two Swedish national patients and one American citizen who is of Swedish descent, and may potentially represent a Swedish founder mutation.

ABCA1 mediated lipid transport from both the liver and the periphery are essential for maintenance of plasma HDL levels in vivo. *R. Singaraja[1], M. van Eck[2], C. Fievet[3], N. Bissada[1], M. Kang[1], L. Brunham[1], M. Hayden[1].* 1) CMMT,Univ British Columbia, Vancouver,Canada; 2) Leiden/Amsterdam Center for Drug Research, Leiden University, The Netherlands; 3) INSERM, Institut Pasteur de Lille, Lille, France.

Mutations in ABCA1 underlie Tangier disease and familial hypoalphalipoproteinemia which are characterized by low plasma HDL-C. ABCA1 is expressed widely and its function in various tissues has not been ascertained. Until the discovery of ABCA1 as a gene essential for regulating plasma HDL-C homeostasis, cells in the periphery were considered critical for the regulation of HDL. This was challenged by recent data overexpressing ABCA1 specifically in the liver via adenoviral delivery, and also by selective deletion of ABCA1 in the liver (hepatic ABCA1-/-) which highlighted the primary role of the liver in maintenance of HDL levels. Mice with complete deletion of ABCA1 (TKO) and with selective deletion of ABCA1 in the liver (LSKO) allowed us to examine the discrete roles of ABCA1 in the liver and periphery and their relationship to HDL levels. Adenoviral delivery of ABCA1 resulted in selective expression of ABCA1 in the liver of both TKO and LSKO mice. Expression of ABCA1 in the liver of LSKO mice resulted in a significant increase in plasma HDL-C levels to that seen in wild-type mice (pre-infection:3.61.4, post-infection:38.31.3, wt:37.61.2, all mg/dL). However, expression of ABCA1 in the liver of TKO mice resulted in plasma HDL-C levels that were significantly lower than wild type levels (pre-infection:1.40.2, post-infection:19.24.3, wt:37.61.2, all mg/dL). The HDL particles from the ABCA1 expressing LSKO mice were larger than those from TKO mice (LSKO:11.90.4, TKO:10.30.5, nm, p=0.006). In addition, a significant increase in the concentration of large HDL particles was observed in the ABCA1 expressing LSKO mice (LSKO:52.47.1, TKO:19.28.9,mg/dL,p=0.003). These data indicate that ABCA1 expression in the liver is essential but insufficient to maintain normal plasma HDL, and indicate that the contribution of both liver and extrahepatic ABCA1 are essential for the regulation of plasma HDL levels.

Molecular pathogenesis of mutations causing X-linked heterotaxy. *S.M. Ware, J. Purnell.* Cincinnati Children's Hospital Medical Center, Department of Pediatrics, Cincinnati, OH.

Members of the ZIC family of C2H2 zinc finger transcription factors are important mediators of patterning during development. Mutations result in a variety of brain, limb, cardiac, and visceral organ anomalies in humans and animal models. We have identified ZIC3 point mutations in patients with X-linked heterotaxy and also in patients with isolated congenital heart defects. Analyses of all known ZIC3 mutations demonstrate that loss of function results not only from impairment of transactivation ability but also from aberrant subcellular localization, suggesting that the pathogenesis of a subset of ZIC3 mutations results from failure of appropriate nuclear localization. The nucleocytoplasmic shuttling and transactivation properties of ZIC3 have been identified using a combination of in vivo nuclear export and nuclear localization assays, and GAL4-ZIC3 fusion domain mapping analyses. Zinc fingers 2-5, encompassing amino acids 290-420, are responsible for nuclear localization, nuclear export, DNA binding and physical interaction with GLI superfamily members. A cryptic CRM1-dependent nuclear export signal is present between amino acids 290-350 of ZIC3. The missense mutation T323M results in the unmasking of this nuclear export signal such that the mutant protein is cytoplasmic. Correction of aberrant ZIC3 cytoplasmic localization does not restore transactivation potential, highlighting the complex functions of this protein domain. Mapping of the nuclear localization domain of ZIC3 indicates it spans a relatively large region from amino acids 290-420, and overlaps with the GLI binding region. ZIC3 and mutant ZIC3 co-localize with GLI3 but not GLI2 in subcellular localization assays, suggesting that ZIC3-GLI3 may shuttle to the nucleus as a complex. These results provide the first evidence that ZIC3 is a nucleocytoplasmic shuttling protein and indicate that aberrant shuttling underlies a subset of X-linked heterotaxy cases. Given that this region is highly conserved among ZIC family members, defects of nucleocytoplasmic shuttling may contribute to a broader spectrum of congenital anomalies.

Exaggerated Blood Pressure Response to Exercise in Epinephrine-Deficient Mice. *X. Bao[1], C.M. Lu[2], Y. Gu[1], F. Liu[1], J. Chen[1], P.C. Simpson[3], M.G. Ziegler[1].* 1) Dept. of Medicine, University of California at San Diego, CA; 2) Dept. of Labratory Medicine, VA Medical Center at San Francisco, CA; 3) Dept. of Medicine, VA medical Center at San Francisco, CA.

Epinephrine (E) release increases during exercise along with elevated heart rate (HR) and blood pressure (BP). To better understand the role of E in the cardiovascular adaptation to exercise, we generated a mouse model whereby the E biosynthesizing enzyme phenylethanolamine n-methyltransferase (PNMT) has been knocked out (KO). The E levels in various tissues including plasma and urine were undetectable in PNMT KO mice. Mean arterial blood pressure (MAP) and heart rate (HR) in KO (n=12) and wild type (WT, n=11) mice were telemetrically monitored at rest and during graded treadmill exercise, initiated at 0.06 m/s, followed by 0.03 m/s increase every 2 min for 12 min. Although 24-hour MAP and HR were maintained at normal levels in resting PNMT KO mice, their MAP responses to initial exercise at 0.06 m/s were significantly increased by 37.9% to 137.93.8 mmHg compared to WT controls (increase by 12.3% to109.77.2 mmHg, P=0.002). This excessive increase in MAP remained through exercise session at nearly every speed. However, there was no difference in increase in heart rate responses to exercise between KO and WT mice. Furthermore, the exercise capacity was significantly reduced in KO mice compared to WT (4.11.63 versus 0.270.1 breaks/min at 0.21 m/s,P<0.05; maximum speed 0.170.01 versus 0.210.01 m/s, P<0.05). Our data suggest that E is required to offset exaggerated BP response to exercise but not required for the increased HR during exercise.

Reproducing the haplotype; the role of the 5-lipoxygenase activating protein in ischaemic heart disease in Ireland. *P.G. Horan[1], A.R. Allen[2], A.E. Hughes[3], C.C. Patterson[4], M.S. Spence[1], P.G. McGlinchey[1], C. Belton[2], P.P. McKeown[1 2].* 1) Regional Medical Cardiology Centre, Royal Victoria Hospital, Grosvenor Road, Belfast, BT12 6BA, Northern Ireland, UK.United Kingdom; 2) Department of Medicine, Queens University Belfast, Institute of Clinical Science, Grosvenor Road, Belfast, BT12 6BJ, Northern Ireland, UK; 3) Department of Medical Genetics, Queens University Belfast, Royal Victoria Hospital, Grosvenor Road, Belfast, BT12 6BJ, Northern Ireland, UK; 4) Department of Epidemiology and Public Health, Queens University Belfast, Mulhouse Building, Grosvenor Road, Belfast, BT12 6BJ, Northern Ireland, UK.

Introduction. Low-density lipoprotein (LDL) oxidation by leukotrienes and the 5-lipoxygenase activating protein (FLAP) plays a central role in atherosclerosis. A four single nucleotide polymorphism (SNP) haplotype (HapB) in the gene encoding FLAP has been shown to be associated with myocardial infarction (Helgadottir et al. Nature Genetics, 2004). Within HapB, SNP SG13S114 has been shown to be associated with stroke (Lohmussaar et al. Stroke, 2005). We investigated HapB in an Irish study group with premature ischaemic heart disease (IHD) (males 55 years, females 60 years). Methods. 1494 individuals (580 families) were included. 10 individuals (3 families) were excluded due to insufficient DNA, leaving 799 discordant sib-pairs and 62 parent-child trios. Linkage disequilibrium between HapB and IHD was tested using the combined transmission disequilibrium test and pedigree disequilibrium test. Results. SNP SG13S377 was excluded as it showed no heterogeneity in our study group. The numbers of informative families for SG13S114, SG13S41 and SG13S35 were 271, 79 and 127, respectively. A significant association between the informative SNPs of HapB and IHD was detected (p=0.032) due to the preferential transmission of the T allele of SG13S114 (p=0.015). Conclusions. Using family-based association tests we have shown association between the FLAP gene (particularly SG13S114) and IHD. Replication of previous work suggests an important role for FLAP in the pathogenesis of atherosclerosis.

Alternative splicing appears to be not responsible for the appearance of protein isoforms of eukaryotic elongation factor-2 (EEF2) in human heart. *S. Schulz[1], C. Glaeser[2], J. Holtz[3], K. Werdan[1], U. Mueller-Werdan[1].* 1) Departm Internal Med, Univ Halle, Halle, Germany; 2) Inst Human Genetics, Univ Halle, Halle, Germany; 3) Inst Pathophysiology, Univ Halle, Halle, Germany.

The eukaryotic protein biosynthesis is catalyzed by a variety of interacting enzymes. In the healthy heart the last step of the elongation cycle catalyzed by the eukaryotic elongation factor 2 (EEF2), a 95 kDa monomeric G-protein, is considered to play a major regulatory role. In previous studies it could be shown that this enzyme occurs in various protein variants showing different biological activity under physiological conditions. Up to now, posttranslational modifications including phosphorylation and ADP-ribosylation are considered to be the main cause for the different isoforms of EEF2 and its regulation under varying metabolic circumstances. The aim of the present study was to investigate, whether possible modifications in the processing of the mRNA may also account for the existing isoforms. Therefore, we isolated RNA from heart samples obtained from 8 human donors using TriStar-reagentTM. EEF2 mRNA was reversibly transcribed using specifically designed primers. For investigating the size of EEF2 transcripts four overlapping PCRs were performed using primer combinations suitable to span the complete mRNA. However, for none of the 8 tissue samples of human heart any variant mRNA fragment was detected. This result supports the thesis, that not differences in the splicing procedure but posttranslational modifications are responsible for the appearance of EEF2 isoforms at least in the human heart.

The establishment of a predictive mutational model of the Forkhead domain through the analyses of FOXC2 missense mutations identified in patients with hereditary lymphedema with distichiasis. *M.A. Walter[1,2], Y. Tamimi[2], M. Carle[2], O.J. Lehmann[1,2], F.B. Berry[2].* 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Depart Ophthalmology, Univ Alberta, Edmonton, AB, Canada.

The FOX family of transcription factor genes is an evolutionary conserved, yet functionally diverse class of transcription factors that are important for regulation of energy homeostasis, development and oncogenesis. The proteins encoded by FOX genes are characterized by a conserved DNA-binding domain known as the Forkhead domain. To date disease-causing mutations have been identified in eight human FOX genes. Many of these mutations result in single amino acid substitutions in the Forkhead domain. We analyzed the molecular consequences of two disease-causing missense mutations (R121H and S125L) occurring in the Forkhead domain of the FOXC2 gene that were identified in patients with hereditary lymphedema with distichiasis to test the predictive capacity of a forkhead domain structure/function model. Based on the FOXC2 solution structure, both FOXC2 missense mutations are located on the DNA-recognition helix of the forkhead domain. A mutation model based on the parologous FOXC1 protein predicts that these FOXC2 missense mutations will impair the DNA-binding and transcriptional activation ability of the FOXC2 protein. When these mutations were analyzed biochemically, we found that both mutation did indeed reduce the DNA-binding and transcriptional capacity. In addition the R121H mutation affected nuclear localization of FOXC2. Together these data indicate that these FOXC2 missense mutations are functional nulls, that FOXC2 haploinsuffeciency underlies hereditary lymphedema with distichiasis, and validates the predictive ability of the FOXC1-based Forkhead domain mutational model.

Epigenetic silencing of retrotransposed L1s in cultured mammalian cells. *J.L. Garcia-Perez[1], K.S. O'Shea[2], J.V. Moran[1].* 1) Human Genetics and Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 2) Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI.

L1s are abundant retrotransposons that comprise ~17% of human DNA. The average human genome is estimated to contain ~80-100 retrotransposition-competent L1s (RC-L1s) and their mobility can result in disease. The proteins encoded by RC-L1s also are responsible for the mobilization of Alu elements and the formation of processed pseudogenes, which comprise at least 10% of human DNA. Thus, L1 retrotransposition has had a tremendous impact on human genome evolution. Despite these findings, little is known about the host mechanisms that act to promote or restrict L1 retrotransposition. Using a series of engineered L1s, we have demonstrated that human and mouse embryonic stem cells (hES and mES) as well as human ovarian teratocarcinoma cells can accommodate L1 retrotransposition. L1 retrotransposition in these cell types appears to be relatively inefficient when compared with other human cultured cells (i.e., HeLa cells). In addition, our data indicate that the new L1 retrotransposition events in both ovarian teratocarcinoma and ES cells undergo epigenetic silencing either during or soon after integration, and that this silencing can be reversed by treating the cells with histone deacetylase inhibitors (HDAC). Further experiments in ovarian teratocarcinoma cells revealed the following: 1) silencing can be reversed with several HDAC inhibitors; 2) silencing does not depend on the promoter or poly (A) signal used to express the retrotransposed reporter gene; 3) silencing also occurs for retrotransposition events derived from a synthetic mouse L1. Thus, we hypothesize that epigenetic silencing might represent a host mechanism to restrict the number of retrotransposition-competent LINE-1 sequences in mammalian cells.

Functional Characterization of the *Hind*III Polymorphism in the Lipoprotein Lipase Gene. *Q. Chen, W.J. Xu, H. Razzaghi, M.I. Kamboh.* Human Gen, Grad Sch Pub Hlth, Univ Pittsburgh, Pittsburgh, PA.

Lipoprotein Lipase (LPL) plays a pivotal role in lipid metabolism by hydrolyzing triglyceride (TG) rich liporprotein particles. Abnormalities in normal LPL function are associated with the risk of coronary artery disease (CAD). A number of genetic variants have been identified in the LPL gene that affect different functions of the LPL protein. A common *Hind*III polymorphism in intron 8 (T/G) of the LPL gene has been found to be associated with altered plasma TG and HDL-cholesterol, and CAD risk in several studies, but its functional significance is unknown. It has been shown that certain intronic sequence contain regulatory elements that are important for transcription and translational regulation of a gene. In this study we tested the hypothesis that the T/G polymorphism at the *Hind*III site affects the binding site of a transcription factor that regulates the transcription of the LPL gene. Electrophoretic mobility shift assays indicated that the *Hind*III site binds to a transcript factor and that the wild type allele has higher binding affinity than the mutant allele. For transcription assay, entire intron 8 DNA (1,392 kb) fragment containing the wild type (T) or mutant type (G) *Hind*III site was subcloned upstream of the luciferase gene in pGL3-basic vector and cotransfected COS-1 cells along with *Renila* Luc control vector (pRL-TK). Full-length LPL promoter (1,537 bp) was also inserted upstream of the intron 8 fragment in the expression vector to enhance the gene transcription. Transfected cells were harvested after 48 hours and lysed in the lysis buffer followed by measurement of luciferase activities using the dual luciferase assay system. Data were obtained from three independent experiments, each performed in triplicates. Our results showed that the mutant allele at the *Hind*III site significantly decreased the luciferase expression level compared to the wild type allele (3.38 ¡À 1.21 vs. 4.30 ¡À 1.31; p = 0.037). This study demonstrates that the polymorphic *Hind*III site in the LPL gene is functional because it affects the binding of a transcription factor and it also has impact on LPL expression.

Mutations in the MTO2 related to tRNA modification impair mitochondrial gene expression and protein synthesis in the presence of a paromomycin resistant mutation in mitochondrial 15S rRNA. *M.X. Guan, Q. Yan, X. Li.* Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

Nuclear gene(s) has been show to modulate the phenotypic expression of mitochondrial DNA mutations. We report here the identification and characterization of the yeast nuclear gene MTO2 encoding an evolutionarily conserved protein involved in mitochondrial tRNA modification. Interestingly, mto2 null mutants expressed the respiratory deficient phenotype when coexisting with the C1409G mutation of mitochondrial 15S rRNA, at the very conservative site for human deafness-associated 12S rRNA A1491G and C1409T mutations. Furthermore, the overall rate of mitochondrial translation was markedly reduced in a yeast mto2 strain under the wild type mitochondrial background, while the mitochondrial protein synthesis was almost abolished in a yeast mto2 strain carrying the C1409G allele. The other interesting feature of mto2 mutants is the defective expression of mitochondrial genes, especially in CYTB and COX1, only under the coexistence of the C1409G allele. These data strongly indicate that a product of MTO2 functionally interacts with the decoding region of 15S rRNA, particularly at site of C1409G or A1491G mutation. In addition, we showed that yeast and human Mto2p localize in mitochondria. The isolated human MTO2 cDNA can partially restore the respiratory deficient phenotype of yeast mto2 cells carrying the C1409G mutation. These functional conservations imply that human MTO2 may act as a modifier gene, modulating the phenotypic expression of the deafness-associated A1491G or C1409T mutation in mitochondrial 12S rRNA.

The Effects of d337T Thyroid Hormone Receptor (TRb) and Peroxisome Proliferator Actived Receptor (PPARa) on Early Responding Cardiac Gene Expression. *N.E. Buroker[1], M.E Young[2], C. Wei[3], K. Serikawa[4], M. Ge[1], X-H. Ning[1], M.A. Portman[1].* 1) Department of Cardiology, Seattle Childrens Hospital & Regional Medical Center, 4800 Sand Point Way N.E., Seattle, WA 98105; 2) Brown Foundation Institute of Molecular Medicine, University of Texas Health Science Center at Houston, Houston, TX 77030; 3) Department of Biostatistics and Applied Mathematics, University of Texas M.D.Anderson Cancer Center, Houston, TX 77030; 4) Center for Expression Arrays, Department of Microbiology, University of Washington, School of Medicine, Seattle, WA 98195.

In this study we used the d337T TRb transgenic mouse that has been created to reproduce the human genetic disease known as resistance to thyroid hormone(RTH)as a model to determine if the d337T TRb mutation would have an effect on PPARa activation. A single amino acid deletion(d337T) abrogates thyroid hormone(T3)binding and transforms the thyroid hormone receptor(TRb)into a constitutive repressor. The principle goal was to determine if T3 regulates myocardial energy metabolism through its nuclear receptors. We introduced a known PPARa activator(WY14,643)into control and d337T TRb mice then examined cardiac gene expression using Affymetrix 430_2 GeneChips and RT-PCR. We compared the gene expression of PPARa,RXRb & TRa,b and 3 PPARa target genes among 4 studies groups [cont, cont+WY14,643,d337TTRb,& d337TTRb+WY14,643]. Microarray analysis revealed that these genes responded to the WY14,643 treatments of control and d337T TRb mice. Analysis of the array and RT-PCR data indicates that mRNA expression levels of PPARa and mRXRb decrease after a 6 hour drug treatment in both control and d337T TRb mice ($P<0.01$) as did the array mRNA expression levels for TRa & b($P<0.025$). Three target genes (AMPD3, PDK4 and UCP3) of PPARa were up regulated in control and down regulated in the d337T TRb mouse,indicating a direct action on these metabolic genes when the TRb becomes a repressor. In conclusion, PPARa activation by WY14, 643 has a positive effect on control mice and a negative effect on the TRb transgenic mice which supports our hypothesis that T3 regulates myocardial energy metabolism through its nuclear receptors.

Visualization of functional human gene domains in nuclear chromatin. *P. Sabo[1], S. Kuehn[2], W. Noble[3], M. Dorschner[1], J. Stamatoyannopoulos[1].* 1) Dept of Molecular Biol, Regulome, Seattle, WA; 2) Div. of Medical Genetics, University of Washington, Seattle, WA; 3) Dept. of Genome Sciences, University of Washington, Seattle, WA.

The functional organization of the human genome is reflected in the topology of nuclear chromatin. We recently described a high-throughput chromatin accessibility assay - Quantitative Chromatin Profiling (Nature Meth. 1:219-25, 2004) - that permits large-scale quantitative determination of chromatin structure in vivo. We have now applied this approach to define at high resolution the chromatin architecture of several human multi-gene loci including the beta-globin locus (Chr11); IL3/4/5/13 locus (Chr5); CFTR locus (Chr7); ApoA1/A4/A5/C3 locus (Chr11); alpha-globin locus (Chr16); IGF2/H19 locus (Chr11); HoxA2 locus (Chr11); and the Down Syndrome critical region (Chr21). These studies reveal a vibrant patchwork of interleaved 'open' and 'closed' chromatin domains that organize functionally related genes. Surprisingly, these domains only loosely correspond with gene expression status and appear to dominate more localized patterns of histone acetylation and methylation. In many cases functional domains in chromatin parallel long-range patterns of evolutionary conservation, and frequently display a striking inverse correlation between chromatin accessibility and the density of conserved non-coding sequences. This suggests that many of the functional elements regulating chromatin accessibility - and hence the access of critical transcriptional regulatory factors to the genome - are of recent evolutionary vintage.

Gene profile analysis of typical and atypical disease states in Friedreich's Ataxia. *D. McDaniel[1], S.H. Subramony[2], L.S. McDaniel[3].* 1) Surgery, University of MS Medical Center, Jackson, MS; 2) Neurology; 3) Microbiology.

Since the discovery of the Friedreichs Ataxia gene known as X25, located on chromosome 9 numerous progress have been made towards the identification of the elements associated with the pathogenesis of the disease. It is well established that a majority (97%) of patients with Friedreichs ataxia (FA) carry a mutation associated with expansion of GAA.TCC trinucleotide repeats in the first intron of the X25 gene. The mutation is associated with defects in the FA gene coding for the iron storage protein frataxin. Multiple models have been proposed regarding to the dynamic formation of DNA triplexes (referred to sticky DNA) and its association with the reduction in mRNA transcription. In this study we investigate the scope of the mRNA and signal pathways affected by FA gene in typical and atypical disease states using focus microarrays. Patients were identified by their clinical presentation and size of GAA expansion. The PBMCs were used for evaluation of gene expression of neurotrophin and receptors signaling pathways in GEAarrays. We performed gene expression profiling of 4 samples, 2 typical FA with expansion repeat size of equal or greater than 800 and 2 atypical patients with expansion size approximately 130 repeats. Signal values were normalized by dividing by the relative expression level of the housekeeping gene in the same sample. Using the normalization criteria at least 9% of the transcripts showed significant reduction in typical FA samples as compared with atypicals. Activating transcription factor 2 (ATF-2), nerve growth factor receptor (TNFR), neurotrophic tyrosine kinase receptor, type 1 and 2, signal transducer and activator of transcription 3 (STAT3), STAT5 and TAC1 were expressed higher in atypical FA as compared with typical FA patients. In summary, this study might generate new diagnostic parameters to test transcriptional differences between disease states and level of gene mutation.

ATM splicing mutation 5932 G > T decreases SRp40 binding to an ESE motif. *S.E. Arroyo, H. Feng, R. Gatti.* The David Geffen School of Medicine at UCLA, Department of Pathology and Laboratory Medicine, Los Angeles, CA, 90095-1732, USA.

Ataxia Telangiectasia (AT) is a progressive, neurodegenerative disease caused by mutations in the ATM gene. Over 400 unique mutations have been identified, none with a frequency greater than 3%. Of these unique mutations, approximately 85% result in truncated protein created by premature termination codons. An interesting subset of these mutations are splicing defects that can appear as nonsense, missense, or even silent mutations. One such splicing mutation is the nucleotide substitution 5932 G > T, 14 nucleotides from the beginning of exon 42. Although the mutation encodes for a primary termination codon - GAA (Glu) TAA (ter) - the mRNA transcript reveals that the consequence is in fact the skipping of exon 42. While it is unlikely that the mutation disrupts a splice junction motif because of its nested position within the exon, analysis of exonic splicing enhancer (ESE) motifs reveals that a binding site for SRp40 is also impacted by this mutation. We designed a protein pull-down assay to test whether this mutation affects the binding of SRp40. Small biotinylated RNA oligonucleotides were made for both wild type and mutant sequences with the substitution near the midpoint. The oligonucleotides were then fixed onto streptavidin-coated magnetic beads and incubated in nuclear lysates. Eluates from these beads were run on SDS-PAGE gels, probed with antibodies to SR proteins, and compared for differential band intensities. Our results show that the SRp40 band, seen clearly in eluates from wild type oligonucleotides, was diminished or absent in eluates from mutant oligonucleotides. We conclude that the primary disease-causing mechanism in this ATM mutation is the disruption of the splicing function of an ESE motif.

Functional study of a novel 5 bp deletion mutation located in a putative insulin response element in exon 10 of human lipoprotein lipase gene. *L.-X. Yang[1], H. Razzaghi[2], M.I. Kamboh[1].* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Preventative Medicine, Univ Colorado, Denver, CO.

Lipoprotein lipase (LPL) plays a pivotal role in lipid metabolism and abnormalities in LPL function are associated with coronary heart disease. LPL gene is sensitive to hormonal regulation of insulin, but the insulin response element (IRE) has not been identified. Previously we identified a 19 bp putative IRE in non-coding exon 10 of LPL and a 5 bp naturally occurring deletion within the putative IRE. The purpose of this study is to determine if the proposed IRE is indeed a functional motif, to identify transcriptional factor that binds to it and to test if the 5 bp deletion affects LPL gene expression and mRNA stability. Competitive Gel shift assay demonstrated that a nuclear protein binds to the putative IRE in non-coding exon 10 in a sequence-specific manner. To identify the nuclear factor binding to the putative IRE, we performed antibody supershift assay with the transcription factor antibodies. When using human aorta smooth muscle cell nuclear extract instead of Hela cell nuclear extract, a supershifted DNA-protein-antibody complex was found in the presence of Elk-1 antibody. These results indicate that transcription factor Elk-1 specifically binds to the putative IRE or evolutionarily conserved sequence in LPL gene. To clarify the functional significance of the 5 bp deletion, the mutant and wild type cDNA expression plasmids were transfected into COS-1/human muscle cells, treated with or without insulin and followed by TaqMan real-time RT-PCR to quantitatively measure the changes of LPL gene expression. We did not see significantly reduced mRNA in the deletion mutant expressions. Further in vitro experiments testing the influence of the deletion on mRNA stability are in progress. We also constructed the luciferase expression vectors containing the human LPL promoter and full-length cDNA with or without the 5 bp or 19 bp deletion in the putative IRE to examine LPL promoter activities. We are performing Western blot analysis to determine if the mutation affects LPL gene expression in response to insulin at the translational or post translational (phosphorylation) level.

Interaction between IL1B gene promoter polymorphisms in determining susceptibility to Helicobacter pylori associated duodenal ulcer. *M. Chakravorty, A. Choudhury, S. Roychoudhury.* Human Genetics and Genomics, Indian Institute of Chemical Biology, Kolkata, West Bengal, India.

The variability in the clinical outcome of the host upon *Helicobacter pylori* infection is attributed to both bacterial as well as host genetic factors. It has been proposed that single nucleotide polymorphisms present in the cytokine genes are responsible for the alteration in expression of these genes.The pro inflammatory cytokine IL1B plays a key role because of its strong inhibitory role towards gastric acid secretion in the gastric mucosa, upon infection with *H.pylori*. Thus to understand the contribution of host immunogenetics towards *H.pylori* mediated duodenal ulcer,310 individuals from Eastern India were subjected to a case control study to determine the *IL1B*and *IL1RN* risk genotypes to *H.pylori* mediated duodenal ulcer.Analysis of genotype frequency revealed significantly higher frequency of *IL1B*-511T/T, OR=4.22 (95% CI 1.8-9.5) and -31 C/C, OR=2.16 (95% CI 1.12-4.16) genotypes in *H.pylori* infected individuals with duodenal ulcer compared to infected individuals with normal mucosa. Quantitative analysis of the mucosal IL1B mRNA revealed that among *H.pylori* infected individuals, carriers of the -31C/C genotype, had significantly lower IL1B transcript levels than carriers of C/T and T/T genotypes. To dissect the role of these allelic polymorphisms in an in vitro model we carried out IL1B promoter assay, which showed that promoter with -31C, had a 10-fold lower activity when compared to the -31T. Moreover, IL1B promoter bearing the different combinations of both the polymorphic loci showed interaction between the -511 and -31 loci. The effect of allelic variation of IL1B upon acid secreting gene gastrin was studied in detail, which suggested that the allele conferring lower transcriptional ability also led to lesser inhibition of gastrin. Our results show that *H.pylori* infected individuals with -31C/C genotype secrete less amount of IL1B, which in turn leads to lesser inhibition of gastrin, and hence are susceptible to duodenal ulcer. We also propose that allelic interaction between the -511 and -31 polymorphic sites determines the overall strength of the IL1B promoter.

A splicing variant of the human lysyl oxidase-like gene 3 (*LOXL3*) functions as an amine oxidase with distinct tissue-specificity from *LOXL3*. *Y. Kim[1, 2], J.E. Lee[2], S.Y. LEE[2], J.Y. Park[2].* 1) Asan Institute for Life Sciences, Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Diseases, University of Ulsan College of Medicine, Seoul, Korea.

The lysyl oxidase-like gene 3 (*LOXL3*) encodes a member of the emerging family of lysyl oxidase (LOX) that functions as a copper-dependent amine oxidase catalyzing lysine-derived cross-links in extracellular matrix. The LOXL3 protein contains four scavenger receptor cysteine-rich (SRCR) domains in the N-terminus in addition to the characteristic domains of the LOX family such as the copper-binding domain, the cytokine receptor-like domain and the residues of the lysyl-tyrosyl quinine cofactor in the C-terminus. Using a BLASTN search with the *LOXL3* cDNA sequence, we identified an EST clone that contained the cDNA sequence of *LOXL3* from exons 4 to 14 but lacked the sequence corresponding to exon 5. This *LOXL3* splicing variant (*LOXL3*-ex5) showed a distinct exon-intron structure from *LOXL3*, containing a 90 bp sequence corresponding to intron 3 of *LOXL3* in the 5 UTR and a 561 bp sequence corresponding to the 3 proximal genomic region of exon 14 in the 3 UTR. *LOXL3*-ex5 was predicted to encode a protein of 393 amino acids, containing the C-terminal domains required for the amine oxidase activity but lacking the N-terminal SRCR domains 1 and 2 of *LOXL3*. To assess its amine oxidase activity, we expressed the LOXL3-ex5 protein as a recombinant form attached with hexa-histidine residues at the C-terminus, using an *Escherichia coli* expression system. The purified LOXL3-ex5 protein showed -aminopropionitrile-inhibitable activity of amine oxidase toward collagen type I. As analyzed by RT-PCR assays with various human tissues, *LOXL3*-ex5 was predominantly expressed in the pancreas, spleen, thymus, and liver, while *LOXL3* was more specifically expressed in the heart, placenta, liver and lung. Luciferase reporter assays revealed an orientation-dependent promoter element in the 5 proximity of intron 3. These findings indicate that the differently spliced mRNAs of *LOXL3*, showing distinct tissue specificity, arise as a consequence of alternative promoter activation.

Gene expression profiling of murine spermatogenesis leads to the identification of mArd2, a novel mouse Ard1 homolog that is preferentially expressed starting from meiosis. *A.L.Y. Pang[1], W. Johnson[1], D.H. Bear[1], O.M. Rennert[1], W.Y. Chan[1,2].* 1) Lab of Clinical Genomics, NICHD/NIH, Bethesda, MD; 2) Cell Biology and Pediatrics, Georgetown University, Washington, DC.

Spermatogenesis is a tightly regulated developmental process of the male germ cells. The concomitant change in morphology during germ cell differentiation highly suggests an underlying global change in gene expression pattern. We profiled the transcriptomes of different stages of male mouse germ cells to elucidate their functional differences. From that, an EST showing preferential expression in meiotic germ cells was chosen for characterization. Subsequent RACE experiment led to the identification of a 3.4-kb transcript encoding a putative homolog of N-acetyltransferase subunit mArd1, which is named mArd2. In silico analysis revealed the existence of three highly conserved Ard1 homologs in the mouse genome. Interestingly, differential expression patterns were observed for these Ard1 homologs in various tissues and different stages of germ cells, with mArd2 showing a testis-specific expression pattern. The use of alternative transcriptional start sites and polyadenylation signals in mArd2 transcripts was observed in different stages of spermatogenesis. A mArd2-specific antibody preparation was generated. Preliminary Western blotting and immunohistochemistry analyses verified the germ cell-specific expression pattern of mArd2. However, the highest level of mArd2 was detected only in post-meiotic germ cells, indicating the mArd2 transcript was translationally active only after meiosis. We also predicted the presence of specific regulatory motifs, which were recently shown to be miRNA binding sites, on the 3 untranslated region of mArd2. Our results suggest that mArd2 is responsible for a germ cell-specific function and its expression may be regulated at both transcriptional and post-transcriptional levels. The yeast ARD1 has been implicated in functions such as cell cycle regulation, DNA repair/recombination and histone acetylation. Further characterization experiments are underway to elucidate the functional role of mArd2 in germ cell development.

Common Human Catechol-O-methyltransferase Haplotypes Modulate RNA Stability, Protein Expression, and Enzymatic Activity. *A.G. Nackley[1], S.A. Shabalina[2], W. Maixner[1], L.B. Diatchenko[1].* 1) Ctr for Neurosensory Disorders, University of North Carolina, Chapel Hill, NC; 2) National Center for Bioinformatics, NIH, Bethesda, MD.

Catechol-O-methyltransferase (COMT) has recently been implicated in the modulation of persistent pain. The COMT gene encodes two proteins: the soluble form (S-COMT), expressed mainly in peripheral tissues, and the membrane-bound form (MB-COMT), the exclusive form expressed in the central nervous system. We demonstrated that three common haplotypes of the human COMT gene are associated with pain sensitivity and the risk of developing temporomandibular disorder (TMD)(Diatchenko et al., HMG 2005). Based on subjects pain ratings, COMT haplotypes were designated as low (LPS), average (APS), or high pain sensitive (HPS). Individuals with HPS and APS haplotypes were ~2.5 times more likely to develop TMD. Furthermore, reductions in COMT activity result in elevated pain sensitivity in rats (Nackley et al., SfN 2004). Thus, a clear link exists between COMT and pain. The present study was conducted to elucidate the mechanism whereby COMT haplotypes modulate pain sensitivity. The relationship between S- and MB-COMT haplotype, RNA stability, protein expression, and COMT enzymatic activity was evaluated in the lysate of HEK 293 cells transiently transfected with identical full-length cDNA clones corresponding to the three haplotypes. COMT RNA stability, protein expression, and enzymatic activity were measured using Real-Time PCR, western blotting, and normetanephrine ELISA, respectively. Total S- and MB-COMT RNA were significantly greater in cells expressing the LPS haplotype relative to the APS and HPS haplotypes. Similarly, cells expressing the LPS haplotype exhibited the highest amount of S- and MB-COMT enzymatic activity and protein, while those expressing the APS or HPS haplotype displayed significantly lower levels. Taken together, these results suggest that HPS and APS COMT haplotypes produce heightened pain sensitivity by coding for reduced total RNA which ultimately results in decreased levels of the corresponding protein and enzyme activity. Ala and Glu are the amino acids at 360 and 654 sites of the PDEB in Mexican population. Until now considered regions in conflict. *C. Córdova, R.A. Lara, I.C. Núñez, C. Medina.* Genética, CIBO (IMSS), Guadalajara, Guadalajara, Mexico.

Introduction. The beta subunit of the cGMP phosphodiesterase (PDE6B) participates in the processes of transmission and amplification of the visual signal in rod cells. PDE6B has two cGMP-binding sites (GAF-I and GAF-II) in the N-terminal half and a catalytic domain (PDEase) in the C-terminal portion. The PDEB gene (4p16.3) presents seven regions in conflict. Regions in conflict are those with more than one version of the nucleotide sequence encoded by a specific DNA region. The conflict at site 360 in the protein PDE6B is caused by putative assignment of the amino acids alanine (Ala) and arginine (Arg) coded by GCT and CGT triplets, respectively, it located in the exon 8 from GAF-II domain. The conflict at site 654 is caused by assignment of the amino acids glutamic acid (Glu) and aspartic acid (Asp) coded by GAG and GAT triplets, respectively, it located in the exon 16 from PDEase domain. Material and Method. We analyzed PCR products of the 8 and 16 exons from 50 healthy individuals, using the BsmI and BssSI restriction enzymes that recognize to GAATGCNNN and GTGCTC complementary of GAG. Results. The GCT and GAG triplets were present in the 100 chromosomes, showing that Ala and Glu are universally present at 360 and 654 sites of the protein PDE6B. Discussion and Conclusion. Ala and Arg are amino acids with dissimilar polarity that would involve different function in the protein. Ala 360 is an amino acid higher conserved in the PDEB of other species. The 654 site shows several amino acids with different biochemical properties, It is probably that 654 site is not important for PDE6B protein function. We showed that Glu is the 654 amino acid present in the PDEB of Mexican population studied. Therefore, the 360 and 654 sites of PDEB must be not considered regions in conflict on the human PDEB appointment.

Large-scale identification of transcription start sites and splicing of human genes using full-length cDNAs constructed by oligo-capping method. *T. Isogai[1], A. Wakamatsu[1], K. Kimura[2], J. Yamamoto[1], N. Nishikawa[1,2], Y. Suzuki[3], S. Sugano[3].* 1) Reverse Proteomics Res Inst, Kisarazu, Chiba, Japan; 2) Central Research Laboratory, Hitachi Ltd., Tokyo, Japan; 3) Department of Medical Genome Sciences, Graduate school of Frontier Sciences, University of Tokyo, Tokyo, Japan.

Human gene number was estimated to be 20-25 K. However number of human mRNA variety was predicted to be about 100 K. The varieties are thought to be caused by variations of transcription start site (TSS) and splicing. In our NEDO human cDNA project, about 30 K of human full-length sequenced cDNAs (FLJ cDNAs) were deposited to DDBJ/GenBank/EMBL, and we obtained about 1.4 million of 5'-onepass sequences (5'-onepass) of full-length cDNAs from about 100 kinds of cDNA libraries consist of human tissues and cells constructed by oligo-capping method. About 500 bp of all 5'f-end of the cDNAs were obtained. The majority of the insert cDNA sizes were over 2 kb and the full-length rate of 5'-end was 90%. And about 19 K of full-length sequenced FLJ cDNAs was newly obtained, major part of which were selected focusing on TSS and splicing variations. In this study we estimated TSS variations of human genome using our 5'-onepass cDNA sequences. We obtained 54,723 loci which 5'-onepass sequences of our cDNAs completely match to human genome sequences (Build 35). Firstly, using this we clustered cDNAs based on first exons to predict TSSs roughly. 45,907 of the reliable first-exon variations were obtained in 19,194 loci of human genome. Secondly, we clustered cDNAs under the conditions which permit even the difference in one base to predict TSS in detail. 70,529 of the reliable TSSs were obtained in 19,194 loci. From these results, the number of TSS was predicted to be approximately 50,000-70,000. This result was supported efficiently by 1.4 million of our 5'-onepass sequences. Then we also predicted TSSs of 2,094 clusters of multiple variable first exons. Furthermore, we found some TSS and splicing variations which had specific expression or motif. This work was supported by a grant from New Energy and Industrial Technology Developmental Organization (NEDO) project of the Ministry of Economy, Trade and Industry of Japan.

Gene expression analysis in amplification/deletion region detected by array CGH method. *Y. Satoh[1], T. Tsuyama[2], M. Kodaira[1], N. Takahashi[1].* 1) Dept. Genetics, RERF, Hiroshima, Japan; 2) Appl. Med. Eng. Sci., Yamaguchi Univ., Ube, Japan.

We have studied the effects of atomic bomb radiation on human germ cells. Using the array CGH(comparative genomic hybridization) method to detect mutations occurring in the children of A-bomb survivors due to radiation, a number of amplification/deletion regions transmitted from parents to offspring were detected (Takahashi et al., present at this meeting). Realtime PCR assay was used to analyze whether expression levels of genes residing in such a genomic amplification/deletion region were correlated with genome amplification/deletion. A variant mapped to 18q23 was a 150 kb amplification with a structure of two 75 kb tandem duplicate sequences. AK056304 is a gene whose full length is included in the amplification region. PARD6G and KIAA0863 are genes whose partial length is included in the amplified region. Gene expression of AK056304 was increased in mother and child with this variant form compare with father with a normal form of the gene. Whereas KIAA0863 showed no difference in expression among father, mother and child regardless of the presence or absence of this variant form, PARD6G showed a significant decrease of mRNA expression in mother and child with amplified region. In this region, gene expression may be amplified by genome amplification. As we perform analysis of gene expression in other amplification/deletion regions, we are continuing the analysis of PARD6G, a gene whose expression level decreased despite the genome amplification.

Identification and characterization of a novel transcript embedded in the *HNF4A* gene. *A.B. Lehtinen, F. Segade, J.C. Mychaleckyj, D.W. Bowden.* Wake Forest Univ Sch Med, Winston-Salem, NC.

The transcription factor *HNF4A* plays a key role in glucose, cholesterol, and fatty acid metabolism, and has been implicated in type 2 diabetes (T2DM) susceptibility. Control of *HNF4A* expression is complex, with two promoters separated by 45.5 kb driving transcription in a tissue-specific manner. While the promoter elements have been identified and characterized, little is known about the impact the intervening genomic sequence has on gene expression. Bioinformatic evaluation of the 45.5 kb of genomic sequence suggests that a transcript is embedded in the region between the two *HNF4A* promoters, and that this transcript and *HNF4A* are transcribed in opposite directions from opposing strands. We verified the expression of the embedded transcript in HepG2 human hepatoma cells by RT-PCR; however, we were unable to experimentally verify the direction of transcription in those cells. In an effort to isolate and characterize the novel transcript, we screened a human liver cDNA library using a 218 bp genomic DNA probe specific for a predicted exon of the transcript. We identified a 564 bp transcript, which contains two transcribed transposable elements, has no polyadenylation signal, has no open reading frame,is continuous on the genomic DNA, and is not homologous to any known protein coding sequence. These features are strikingly similar to the characteristics of noncoding RNAs, particularly antisense RNA. Secondary structure predicitions also suggest that the embedded gene resembles a noncoding RNA. In addition, the novel transcript and *HNF4A* are transcribed in opposite directions from opposite DNA strands. Gene profiling of the novel transcript and *HNF4A* indicate that they are expressed in many of the same tissues (kidney, liver, fetal liver, colon, small intestine, and adrenal gland), some of which are important in the development and progression of T2DM. The location and direction of transcription of this possible noncoding RNA suggests that it may play a role in regulating *HNF4A* gene expression. Further experiments are underway to fully characterize the transcript and investigate its involvement in the regulation of *HNF4A* expression.

Characterization of the Region of 4q Associated with Hereditary Benign Intraepithelial Dyskeratosis. *B. Layfield[1], W. Lambert[1], M. Bembe[1], J. Clapp[2], J. Hewitt[2], K. Bastress[1], R. Lemmers[3], S. van der Maarel[3], R. Allingham[4], M. Hauser[1,4].* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Institute of Genetics, Queens Medical Center, University of Nottingham, United Kingdom; 3) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Hereditary benign intraepithelial dyskeratosis (HBID) is an autosomal dominant cell proliferation disorder characterized by opaque epithelial plaques of the conjunctiva and oral mucosa. This disorder has been linked to a near-telomeric DNA duplication on 4q that includes a partial duplication of the D4Z4 repeat. The D4Z4 region has been reported to be a transcriptional silencer. We used real time PCR to analyze the expression of 19 genes near or within the HBID duplication in conjunctival cell lines and tissue. First strand cDNA was synthesized from primary cell lines from a HBID ocular lesion and control conjunctiva. No consistent pattern of expression as a result of the duplication was observed. One of the 4q genes analyzed was FAT, a member of the cadherin superfamily that functions in cell-cell adhesions, and whose expression level was decreased in HBID patients. FAT is an attractive candidate for the causative HBID gene: it is expressed in ocular tissues, and mutations in the fat locus in Drosophila cause defects in epithelial cell proliferation control and morphogenesis. Transcriptional silencing of the copy of the FAT gene located on the chromosome carrying the duplication, followed by somatic mutation of the second FAT allele in the conjunctival epithelium of HBID patients could give rise to abnormal cell-cell junctions and/or communication, thus leading to uncontrolled cell proliferation. To test this potential two-hit mechanism, we sequenced the FAT gene in DNA from peripheral blood from a HBID patient and from a cell line generated from lesion tissue removed from the same patient. No novel lesion-specific somatic mutations were observed, suggesting the hypothesis that FAT is the causative HBID gene via a two-hit mechanism is not valid.

Mannose binding lectin haplotypes are not associated with recurrent spontaneous abortion. *D. Berger[1], W. Hogge[2], R. Ferrell[1].* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Ob/Gyn, Univ Pittsburgh, Pittsburgh, PA.

Recurrent spontaneous abortion (RSA) affects up to 5% of all pregnancies and is likely to be of multifactoral etiology, with both genes and environment contributing to risk. Several infectious agents are known to cause late term pregnancy loss and an infectious etiology for RSA has been proposed. Mannose binding lectin (MBL) is a C-type lectin that plays an important role in innate immunity and low plasma levels of MBL are a known cause of severe infantile infection. Plasma levels of MBL are largely genetically determined and can be predicted by examining single nucleotide polymorphisms (SNPs) in the proximal promoter and exon 1 of the MBL2 gene. To test the hypothesis that MBL haplotypes leading to reduced levels of circulating MBL are significantly associated with idiopathic RSA, we conducted a case/control study of RSA. Cases (n=273) and controls (n=236) were drawn from the obstetrical population served by Magee-Womens Hospital, Pittsburgh, PA and the Center for Reproductive Medicine, Minneapolis, MN. RSA was defined as having two or more clinically recognized spontaneous abortions of unknown etiology prior to 22 weeks gestation. Subjects were genotyped for missense mutations in exon 1 (R52C, G54D and G57E) and functional promoter SNPs at -550 CG and -221 GC by standard methods. Allele frequencies were estimated by gene counting and compared to the expectations of Hardy-Weinberg equilibrium by chi square analysis. Haplotypes were estimated by maximum likelihood using the EM algorithm and single-locus tests. Allele and haplotype frequencies were compared in cases and controls using chi square contingency table analysis. Finally, subjects were classified by haplotypes based on predicted MBL levels (high, intermediate, low). No significant association was observed between MBL genotypes, haplotypes or predicted plasma MBL levels and increased genetic risk of recurrent pregnancy loss among women whose pregnancy loss is not associated with chromosomal abnormalities. Despite prior smaller studies reporting an association between RSA and variation at the MBL2 locus, we conclude that the MBL2 locus is not a significant determinant of risk of RSA.

Regulation of Adrenergic Receptor $_2$ by C/EBP and cAMP Pathways. *T. Higgins, I. Tchivileva, C. Downey, W. Maixner, L. Diatchenko.* Neurosensory Disorders Unit, School of Dentistry, University of North Carolina, Chapel Hill, NC 27599.

Adrenergic receptor $_2$ (ADRB2) is a primary target for epinephrine. It plays a critical role in mediating physiological responses to environmental stressors and affects a complex array of psychological and physiological characteristics: including psychological distress, blood pressure and pain sensitivity. However, on immune cells ADRB2 functions as an inflammatory mediator. Increased pain sensitivity is one of the characteristics of both acute and chronic inflammation. We thus hypothesized that regulation of ADRB2 expression under inflammatory conditions would mediate inflammation-induced pain. We first searched the ADRB2 promoter region for putative binding sites of pro-inflammatory mediators, which revealed CREB (cAMP response element binding protein) and C/EBP (CCAAT/enhancer binding protein) binding sites. We constructed a luciferase reporter vector containing three major polymorphic variants haplotypes) of a 1.9kb human ADRB2 promoter region, and transiently transected the constructs into neuronal and immune cell lines. These variants showed different basal activity in all assessed cell lines. We measured promoter response to various treatments; modulating inflammatory state. Cells were stimulated with epinephrine and forskolin and co-transfected with an expression vector containing C/EBP or C/EBP. In the neuronal cells, reporter activity decreased significantly below baseline upon stimulation, and increased upon co-transfection with C/EBP and C/EBP. Stimulation with forskolin in the immune cells increased reporter activity. In summary, we demonstrated; i) different levels of basal promoter activity related to three major human haplotypes; ii) tissue specific regulation of ADRB2 promoter at the basal level and upon treatment; iii) haplotypes exhibited similar response patterns, demonstrating haplotype-independent transcription regulation by C/EBP and cAMP. These results are the first to demonstrate regulation of ADRB2 by C/EBP and cAMP pathways, and suggest a mechanism by which inflammation modulates pain sensitivity. Supported by NIH grants DE016558 and NS045685.

Efficient gene transfert into normal human B lymphocytes with the chimeric adenoviral vector AD5/F35. *D. Jung[1,2], S. Néron[1,2], M. Drouin[1], A. Jacques[1].* 1) Dept Research & Development, Hema Quebec, Sainte-Foy, PQ, Canada; 2) Department of Biochemistry and Microbiology,Laval University, Québec, PQ, Canada.

The failure to efficiently introduce genes into normal cells such as human B lymphocytes limits the characterization of their function on cellular growth, differentiation and survival. Recent studies have shown that a new adenoviral vector Ad5/F35 can efficiently transduce human haematopoietic CD34+ progenitor cells. In this study, we compared the gene transfer efficiencies of the Ad5/F35 vector to that of the parental vector Ad5 in human B lymphocytes. Peripheral blood B cells obtained from healthy individuals were cultured in vitro using CD40-CD154 system. Normal B lymphocytes were infected with replication-defectives Ad5 and Ad5/F35, both containing the GFP reporter gene, and transduction efficiencies were monitored by flow cytometry. Ad5 was highly ineffective, infecting only about 5 % of human B lymphocytes. In contrast, Ad5/F35 transduced up to 60% of human B lymphocytes and GFP expression could be detected for up to five days post infection. Importantly, physiology of B lymphocytes such as proliferation, viability and antibodies secretion were unaffected following Ad5/F35 transduction. Finally, we observed that memory B lymphocytes were more susceptible to Ad5/F35 infection than naïve B lymphocytes. Thus, our results demonstrate that the adenoviral vector Ad5/F35 is an efficient tool for the functional characterization of genes in B lymphopoiesis.

Identification of novel exons and different isoforms for VSX1. *S.M. Hosseini*[1,2], *E. Heon*[1,2,3]. 1) Program in Genetics & Genomic Biology, The Hospital for Sick Children Research Institute, Toronto, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Canada; 3) Department of Ophthalmology and Vision Sciences, University of Toronto, Toronto, Canada.

Background: VSX1 is a homeobox transcription factor important for terminal differentiation of the retina. Mutations in *VSX1* have been found in patients affected with two distinct types of corneal dystrophies: Posterior Polymorphous Corneal Dystrophy (PPCD) and Keratoconus. Both conditions are genetically heterogeneous. However, the family originally used for mapping of PPCD to chromosome 20, did not show any coding sequence change in *VSX1*. Putative disease causing mechanisms include either the involvement of unsequenced regulatory sequences, uncharacterized isoforms, splicing defects or the involvement of a neighboring gene.

Purpose: To investigate alternative splicing events in *VSX1* and to characterize the possible isoforms of VSX1.

Methods: ECgene v1.2 gene prediction was used for exon prediction. Total RNA was extracted from the human retina using a phenol-chloroform based method (TRIzol). 3 RACE (Rapid Amplification of cDNA Ends) was performed on human retinal RNA using two different gene specific primers in the known exons 2 and 4. Second round of PCR were performed using nested primers. PCR product was run on either 4% polyacrylamide gel or 1.2% agarose gel. All observed bands were cut, gel purified, cloned into pGEM-T vector and sequenced.

Results: We identified novel downstream exons and characterized at least 8 different isoforms with the evidence of alternative splicing events.

Conclusion: Different isoforms of proteins are known to be associated with disease causing mutations in other diseases such as Retinitis Pigmentosa and Usher syndrome. Our data shows the existence of multiple VSX1 isoforms and warrants further investigation into their potential pathologic role in PPCD.

5 triphosphate of *in vitro* transcribed siRNAs induce antiviral response in cell culture. *M. Grippo[1], T. Campos-Pereira[1], V. B. P. Pascoal[1], P. A. R. Aguiar[1], M. S. Silva[1], R. Gilioli[2], I. Lopes-Cendes[1].* 1) Medical Genetics, UNICAMP/FAC CIENCIAS MED, Campinas, Brazil; 2) Laboratory of Animal Quality Control, CEMIB,UNICAMP, Campinas, Brazil.

RNA interference(RNAi)is a technique for specific and gene silencing by double stranded RNA molecules(dsRNAs).The objective of this study was verify the efficiency of this new technique in the combat of the MHV-3 virus (hepatitis murine type 3).MHV-3 is the most frequently found pathogen in laboratory mice. It is an enveloped virus with a large plus-stranded RNA genome belonging to the Coronaviridae family and codifies structural proteins such as: S(spike); M(transmembrane) ,E(membrane)and N (nucleocapsid) .The N protein was chosen as the target for siRNA mediated silencing in our experiments.Design of the siRNA molecules was based on the MHV-3 genome sequence available(GenBank AF 201929).We obtained 2 siRNA molecules,named 634 and 910, based on RNA messenger position. Molecules were produced by in vitro transcription through a T7 RNA polymerase.We used L-929 cell culture placed in 24 wells plates and 270 ng/well of each siRNA molecule, separately, in each experiment. Cultured cells were transfected with lipofectin.After transfection, cells were infected with 1 TCID50 of the MVV-3 virus, and cultures were observed up to 48 hours. We found that siRNAs synthetized with T7 RNA polymerase system can trigger a potent induction of IFN in L929 cell.This effect was subsequently eliminated by siRNA treatment with calf intestine phosphatase prior to transfection. In addition, we observed a significant reduction of the citopatic effect of the MHV-3 virus in cell cultures treated with siRNA 910 but not with siRNA 634.In conclusion, we were able to demonstrate a potential therapeutic application for iRNA in the treatment of *in vitro* MHV-3 viral infection. In addition, our data show that although cost-effective and efficient, *in vitro* transcribed siRNAs must be dephosphorylated before *in vitro* use.

The quantification of the allelic variations of gene expression by real-time TaqMan PCR. *K. Kobayashi[1], A. Suzuki[1], Y. Kochi[1], R. Yamada[2,1], K. Yamamoto[1,3].* 1) Laboratory for Rheumatic Diseases, SNP Research Center, RIKEN, Yokohama, Japan; 2) Center for Genomic Medicine, Kyoto University, Kyoto, Japan; 3) Dept. of Allergy and Rheumatology, University of Tokyo, Tokyo, Japan.

Recently, multiple studies have shown that human single nucleotide polymorphisms (SNPs) affect gene regulation, resulting allelic imbalance of gene expression. The finding of these regulatory SNPs leads to understanding phenotypic diversity and the identification of alleles that modify disease risks. Therefore, it is important to quantify the allelic difference of gene expression in vivo to identify regulatory SNPs. We applied TaqMan assay on cDNA from heterozygous cells to quantify transcripts in allele-specific manner. We validated applicability of the method as follow. Initially the calibration curve was obtained by assaying mixture of genomic DNA samples from known homozygous individuals with various mixture ratio ranging from 4:1 to 1:4. Then we estimated mixture ratio of genomic DNA samples from known SNP genotypes including heterozygozes. After correction with the calibration curve, the estimates were corresponded well with the given ratio. After validation of the method, we examined allele-specific gene expression in peptidylarginine deiminase 4 (PADI4) and Fc receptor-like (FCRL3) genes, which were reported to be associated with rheumatoid arthritis (RA), and of which allelic imbalances of gene expression were observed. We used TaqMan probes, rs11203366 (G/A) and rs945635 (G/C) as markers, located in exonic region of PADI4 and FCRL3, respectively. We measured the signal intensity using cDNA and DNA which were isolated from peripheral blood leukocytes of healthy heterozygous individuals, and we calculated allele-specific gene expression ratio. We showed that RA susceptible allele-specific PADI4 expression mean ratio '} SD was 1.21 '} 0.33 in 7 heterozygous individuals, and RA susceptible allele-specific FCRL3 expression mean ratio '} SD was 1.99 '} 0.50 in 5 heterozygous individuals. These data supported the hypothesis that expression levels of PADI4 and FCRL3 are associated with RA susceptibility[1, 2]. 1) Nat. Genet. 2003, 34:395-402, 2) Nat. Genet. 2005, 37:478-485.

Real-time PCR as a tool in the identification of functional oncology target genes. *S. Rhodes, P. Culp, E. Tom, S. Tanlimco, W. Schneider, A. Sharp, H. Li, T. Anderson, R. DuBridge.* Protein Design Labs, Fremont, CA.

For RNAi assays to give a clear indication of the functional activity of an oncology target gene, a reduction in protein and mRNA levels upon siRNA treatment must be seen to correlate with a reduction in the growth rate of cells expressing the target. At the same time siRNA treatment of cells not expressing the target should have no effect on tumor cell growth. This requires an accurate knowledge of the expression levels of the target gene in each cell line in the study. Expression data from a wide variety of human tumor cell lines was accumulated using proprietary custom designed Genechips (Hu03) made by Affymetrix . We used Taqman real-time PCR for selected oncology targets in these cell lines to determine absolute expression levels. This allowed positive and negative cell lines to be chosen for cell growth assays using three different siRNAs (Dharmacon) directed against each target gene. We found it necessary to design our taqman assays such that they measured sequences 5 to the siRNA cleavage site to generate an accurate assay for mRNA down modulation. SiRNAs, which showed an apparent reduction in growth in at least some of the positive cell lines, but no effect in the negative cell lines, were assumed to be specific. These transfectants were then screened by FACS for protein down-modulation and/or real-time PCR for mRNA down-modulation. Functional targets were then defined as those genes that showed specific growth effects that were proportional to their degree of down modulation.

Knockdown of SMN expression in NSC34 motor neuron cell line: Insights into the pathogenesis of spinal muscular atrophy (SMA). *M. Ganta, S.M. Grzeschik, C.H. Wang.* Dept Neurology, Stanford Univ, Stanford, CA.

Spinal muscular atrophy (SMA) is an autosomal recessive motor neuron disease affecting approximately 1/10,000 live births. SMA is characterized by degeneration of spinal cord motor neurons and muscular atrophy. SMA is caused by decreased levels of the survival of motor neuron (SMN) protein as a result of mutations in the SMN1 gene. Although SMN is ubiquitously expressed in all cells, motor neurons are selectively vulnerable to decreased amounts of SMN. The reason for the selective vulnerability of motor neurons in SMA is still unclear. Recently it has been suggested that SMN may play a role in neurite outgrowth and formation and maintenance of neuromuscular junctions. To gain a further understanding into the role of SMN in these motor neuron functions, we used RNA interference (RNAi) to knockdown SMN expression in immortalized mouse motor neuron cells (NSC34 cells). NSC34, a hybrid spinal cord motor neuron-neuroblastoma cell line, possesses properties of primary motor neurons, including generation of action potentials, acetylcholine production, expression of neurofilament proteins, and innervation of myotubes in vitro. A shRNA (short hairpin RNA) targeting SMN was cloned into a plasmid expression vector also expressing coral GFP (cGFP). Expression vector without the shRNA targeting SMN was used as a control. NSC34 cells were transiently transfected using Lipofectamine 2000 reagent. Cells were fixed at 24, 48, 72, 96 and 120h after transfection and stained with a monoclonal antibody against SMN. At least 15 cells in each group and at each time point were visualized by confocal microscopy. All cGFP positive cells transfected with plasmid containing shRNA targeting SMN showed a decrease in the intensity of SMN staining, indicating a knockdown in SMN levels, compared to controls and untransfected cells. Reduction in levels of SMN was observed as early as 72h and extended up to 120h post transfection. In conclusion, we have created a novel cell culture model to study the function of SMN in a relevant cell type.

Retinal Dystrophin isoform Dp260 expression is induced by steroids and the up-regulation is likely mediated by glucocorticoid receptors (GRs) and two glucocorticoid response elements (GREs) in an internal promoter of the Duchenne (DMD) gene. *D.M. Pillers, B. Malmin, J.S. Pang.* Dept Pediatrics,Ophthalmology, and Molecular & Medical Genetics, Oregon Health & Sci Univ, Portland, OR.

Background: Duchenne muscular dystrophy (DMD) is an X-linked disorder leading to severe myopathy and early death. The DMD gene encodes dystrophin, which in muscle, is expressed as a 427 kDa protein. Non-muscle manifestations include abnormal electroretinograms (ERGs) and defects in cognition. Dp260 is the predominant isoform expressed in retina, and is implicated in normal retinal electrophysiology. Objective: To determine how Dp260 expression is regulated, and whether manipulation of the regulatory elements could lead to expression of Dp260 in muscle or retina. Methods: A human genomic fragment from a cosmid containing the promoter of Dp260 was subcloned into the pGL2 luciferase reporter vector. The vector was transfected into cell lines (Y79, C2, HeLa) and exposed to methylprednisolone. Site-directed mutagenesis was used to determine the contributions of elements in the promoter region. A gel shift assay was performed using HeLa cell extract and a super-shift using anti-GR. A potential role of a glucocorticoid receptor (GR) was investigated by transfection into the COS-7 GR-defective cell line, and by exposure to the glucocorticoid antagonist, RU486. Results: Sequence analysis identified two glucocorticoid response elements (GREs. Both elements are important in the steroid response, but the proximal GRE has the greatest effect on gene expression. The importance of GRs in mediating the response was demonstrated by a lack of stimulation of Dp260 expression in the COS-7 cell, by a super-shift in the presence of anti-GR, and by the ability of the glucocorticoid antagonist, RU486, to block the response. Conclusions: Upregulation of Dp260 expression by methylprednisolone is mediated by the interaction of DNA-binding GR proteins with GREs in this internal promoter region of DMD. Use of the GR/GRE system by Dp260 is unique for genes expressed in retina. Novel opportunities to manipulate dystrophin expression in vivo may lead to new pharmacogenetic approaches to the therapy of DMD.

The Extent and Functional Consequences of Mutation at the *PRODH* locus. *A.S. Willis[1,2], H.U. Bender[1,2], G. Steel[1,2], A. Pulver[3], D. Valle[1,2].* 1) Institute of Genetic Medicine, Johns Hopkins Univ School of Medicine, Baltimore, MD; 2) Howard Hughes Medical Institute, Johns Hopkins Univ School of Medicine, Baltimore, MD; 3) Dept Psychiatry, Johns Hopkins Univ School of Medicine, Baltimore, MD.

PRODH maps to 22q11 within the critical region for 22q11 deletion syndrome and encodes proline oxidase (POX), a mitochondria inner membrane enzyme that catalyzes the first step in proline catabolism. Severe loss of function mutations in *PRODH* cause Type I hyperprolinemia while mild mutations have been implicated as possible susceptibility alleles for schizophrenia. Additionally, alterations in the level of POX expression have been shown to influence apoptosis and to play a role in certain cancers.

To better understand the extent and functional consequences of *PRODH* mutations, we determined the exonic and flanking intronic sequences of *PRODH* in a group of 25 individuals with 22q11 deletion syndrome including several with hyperprolinemia. We found 12 missense and 7 synonymous mutations in the coding exons as well as 2 - 5UTR and 51 intronic variations. We have recently reported the functional consequences of 9 of the missense mutations and are in the process of testing the remainder (Bender et al, *Am J Hum Genet* 76:409-420, 2005).

Additionally, to better understand the pathological mechanisms of the *PRODH* missense mutations, we conducted studies to determine the oligomerization state of POX. We produced cDNA clones of *PRODH* tagged with C-terminal HA or myc as well as analogous cDNA clones for hydroxyproline oxidase (HPOX), which shares 31% amino acid identity with POX. Co-immunoprecipitation experiments showed that POX subunits can oligomerize with themselves or with HPOX subunits. Studies are in progress to determine the stoichiometry of and domains involved in the oligomerization and the functional consequences of variation on the homo- or hetero-oligomerization of POX.

TAB2, TRAF6 and TAK1 mediate NF-kB activation induced by the TNF-receptor Edar. *A. Morlon, A. Munnich, A. Smahi.* INSERM U393, Hopital Necker, France.

Activation of NF-kB by the TNF receptor Edar and its downstream adaptator Edaradd is essential for the development of hair follicles, teeth, exocrine glands and other ectodermal derivatives. Dysfunction of the Edar signalling pathway cause hypohidrotic/anhidrotic ectodermal dysplasia, a disorder characterized by sparse hair, lack of sweat glands and malformation of teeth. By virtue of a two-hybrid screening, we isolated TAB2 as a binding partner of Edaradd. Here we show that TAB2 and also TRAF6 and TAK1, two partners of TAB2 in IL-1/TLR and RANK signalling, coimmunoprecipitate with Edaradd in mammalian cells. Moreover, our results show that dominant-negative forms of TAB2, TRAF6 and TAK1 inhibit Edaradd-induced NF-kB activation in 293 cells. These results support the involvement of the TAB2/TRAF6/TAK1 complex in Edar signalling. These findings have important implications for our understanding of NF-kB activation pathways and pathophysiology of ectodermal dysplasia.

The Mechanism of degenerative muscle defects in myotonic dystrophy. *P.S. Sarkar, T. Ashizawa, R. Gao, W. Xu.*
Department of Neurology, University of Texas Medical Branch, Galveston, TX.

Myotonic dystrophy type1 (DM1) is characterized by the dysfunction of the muscle structure and function (1). Delayed muscle differentiation and hypotonia are the predominant features in congenital DM1 whereas myotonia, atrophy and weakness are the features in adult onset DM1 (1). DM1 genetic mutation is the expansion of CTG repeat in the 3 UTR of DMPK on chromosome 19q13.3 and massive expansion is associated with dystrophic muscle defects(1). The mechanism by expanded CTG repeat causes dystrophic muscle defects is not established. Transgenic mice expressing ~250 units of CTG repeats in skeletal muscle develop myotonia and structural defects reminiscent of DM1 (2). Sequestration of muscle-blind proteins by expanded CUG RNA was found to be the pathogenic mechanism in the CUG mice (3). Subsequent studies with muscle-blind (Mbnl1) knockout mice confirmed that the loss of muscle-blind function is one of the important mechanistic steps required to cause myotonia (2,3). Neither Mbnl1 knockout nor the CUG transgenic mice develop dystrophic muscle defects, hallmark DM1 features(4). Our goal is to understand the mechanism by which massive expansion of CTG repeats causes dystrophic muscle defects in DM1. Our ability to clone longer repeats allows us the advantage of not only in developing appropriate mouse models but also identifying a novel zinc-finger protein, sequestered by expanded CUG RNA. Our studies show that the novel protein is sequestered in nuclei and co-localizes with CUG-RNA. We will present evidences to show that multiple proteins are sequestered by expanded CUG RNA and sequestration of proteins in addition to muscle-blind proteins is the major pathogenic mechanism underlying the complex dystrophic muscle defects DM1. 1)Harper PS. Genetic Analysis of Nonstop mRNA Decay in *Caenorhabditis elegans*. *J. PARVAZ, C. SCHARTNER, P. ANDERSON.* DEPARTMENT OF GENETICS, UNIVERSITY OF WISCONSIN-MADISON, MADISON, WI.

Degradation of messenger RNAs (mRNAs) is a fundamental aspect of gene expression. Nonstop decay (NSD) is an mRNA degradation pathway that selectively degrades mRNAs lacking an in-frame stop codon. NSD occurs in the cytoplasm of yeast and human cells and requires active protein synthesis. NSD in yeast is distinct from the major pathways of mRNA turnover, because it functions in the absence of factors required for the deadenylation-dependent 5' decay pathway or for nonsense-mediated mRNA decay (1). Instead, yeast NSD occurs via an exosome-dependent 3' pathway (2). The mechanisms of NSD in other organisms are not well understood.

We present evidence that NSD exists in the nematode, *Caenorhabditis elegans*. The steady-state abundance of mRNAs expressed from a nonstop reporter gene, is greatly reduced relative to controls containing an in-frame stop codon. We have mutagenized worms expressing a nonstop reporter mRNA, and identified seven mutants that elevate reporter gene expression. We are investigating these mutants both genetically and molecularly to determine whether they encode factors needed for *C. elegans* nonstop decay.

Analysis of conserved regulatory elements in the glucocerebrosidase gene locus. *K.S. Hruska[1], M.E. LaMarca[1], S.G. Ziegler[1], M.E. Portnoy[2], NISC Comparative Sequencing Program[2], E.D. Green[2], E. Sidransky[1].* 1) Section on Molecular Neurogenetics, NIMH and Medical Genetics Branch, NHGRI; 2) Genome Technology Branch, NHGRI; NIH, Bethesda, MD.

Delineating the mechanisms that coordinate gene expression has become one of the primary goals of the post-genomic era of biology. Regulatory elements in the promoter and first exon of the human glucocerebrosidase gene (GBA) have been reported previously, but the availability of sequenced genomes has simplified functional analyses and greatly expanded their scope. The comparison of orthologous sequences from multiple species in parallel can be used to detect evolutionarily conserved regions that may reflect functional elements. MultiPipMaker alignments of the 58.5 kb genomic region comprising the genes clorf2, GBA, metaxin 1 (MTX1) and thrombospondin 3 (THBS3) from human and ten mammals demonstrated strong conservation of exons in all four genes, especially THSB3. Therefore, we performed a WebMCS analysis focused on mammalian sequences aligning with the 39.4 kb segment of human genomic sequence that encompasses MTX1, GBA and their respective pseudogenes. At the 95% threshold, 46 multi-species conserved sequences (MCSs) were detected with an average length of 43 bp. Two MCSs were identified in the 3'-UTR region of GBA that did not correspond to exonic sequence of the metaxin pseudogene; one 25-bp MCS represents the THBS3 enhancer previously described within intron 6 of MTX1, while a second 25-bp MCS appears to be novel. No MCSs were identified in the 4 kb region upstream of GBA. When the aligned multi-species sequences were inspected for consensus regulatory motifs using the Genomatix Suite applications, however, a shared framework of transcription factor binding sites was identified upstream of GBA in human, chimp, galago, cow, dog and fruit bat. This potential regulatory module was not detected in murine GBA or human GBA pseudogene (psGBA) sequences. The regions containing these conserved motifs are being tested *in vitro* for their effects on the transcriptional regulation of GBA.

Molecular characterisation of the aminopeptidase P gene regulatory region. *A.L. Jones, A.M. Carter, P.J. Grant, N.M. Hooper.* The LIGHT Laboratories, University of Leeds, Leeds, UK.

Aminopeptidase P (APP) degrades des-arg9-bradykinin and decreased APP has been linked to ACE inhibitor-induced angioedema. We hypothesised polymorphisms in the APP 5 regulatory region influence APP expression. The aims of this study were to (1) characterise 3kb of the 5 regulatory region of APP (2) identify novel polymorphisms (3) determine the contribution of polymorphisms to variance in APP in the Leeds Family Study (4) determine the influence of polymorphisms on reporter gene expression. Key regulatory regions were identified by ligating 3kb of APP regulatory region upstream of the luciferase gene in pGL3 and generating nested deletion constructs using Erase-a-Base. Luciferase was analysed in HepG2 cells transiently transfected with the nested deletion constructs. The Transgenomic WAVE system was used to identify polymorphisms. The polymorphisms were genotyped in the family study (537 individuals) and plasma AP-P activity was measured using the substrate Lys(Abz)-Pro-Pro-pNA. The influence of polymorphisms on luciferase activity was determined by site directed mutagenesis of the APP-pGL3 construct and transient transfection of HepG2s. Statistical analyses were carried out using SPSS and SOLAR. Nested deletion analysis identified a putative enhancer region between -2310bp and -2046bp and a minimal promoter located in the first 146bp upstream of the +1 site. Three common SNPs (-201GA, -1512GT, -2207CA) and 2 rare (+27CT, -1078GA) were identified. The -201GA and -2207CA SNPs were significantly associated with plasma AP-P activity (-201GA: GG=1.97 [1.76, 1.98]; GA=2.27 [1.98, 2.60]; AA=2.32 [1.96, 2.74] mol/ml/min, p0.001) and (-2207CA: CC=2.16 [2.04, 2.29]; CA=1.75 [1.57, 1.95]; AA=1.06 [0.89, 1.26] mol/ml/min, p0.001) and SOLAR analyses indicated that the -2207CA and -201GA SNPs contributed to 7.36% and 1.43% of the phenotypic variation in AP-P respectively (age and sex adjusted). These associations were supported by luciferase reporter gene analyses. These data suggest that both the -2207CA and -201GA polymorphisms, which are located in the vicinity of the 2 key regulatory regions, are functional and contribute to variance in plasma APP levels.

Transcriptional repression of WEE1 by Kruppel-like factor 2 is involved in DNA damage-induced apoptosis. *F. Wang[1], Y. Zhu[1], Y. Huang[1], S. McAvoy[1], W.B. Johnson[2], T.H. Cheung[3], T.K. Chung[3], K.W. Lo[3], S.F. Yim[3], M.M. Yu[4], H.Y. Ngan[3], Y.F. Wong[3], D.I. Smith[1].* 1) Division of Experimental Pathology, Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, 200 First Street SW, Rochester, MN 55905, USA; 2) Departments of Molecular Pharmacology & Experimental Therapeutics, Mayo Clinic College of Medicine, Rochester, MN, USA; 3) Department of Obstetrics and Gynecology, The Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong, People's Republic of China; 4) Department of Anatomical and Cellular Pathology, The Chinese University of Hong Kong, Hong Kong, People's Republic of China.

Human Kruppel-like factor 2 (KLF2) is a Cys2/His2 zinc-finger-containing transcriptional factor, which is involved in multiple cellular pathways. Utilizing gene expression profiling to identify aberrantly expressed genes in ovarian cancer, we found that KLF2 was significantly and specifically downregulated in ovarian tumors. After reintroducing KLF2 into ovarian cancer cell lines, we observed decreased cell growth and increased sensitivity to DNA damage-induced apoptosis. Analysis of genes that could be potential targets of KLF2 revealed that KLF2 negatively regulated WEE1 expression. WEE1 encodes a tyrosine kinase that regulates the G2/M cell cycle transition. Expression of KLF2 markedly repressed the transcription of WEE1 by directly binding to an SP1/CPBP motif located between -252 bp and the start codon of the WEE1 promoter. Both activation and zinc-finger domains of KLF2 were required for this suppression of Wee1 expression. In addition, we demonstrated that Wee1 expression prevents cancer cells from undergoing apoptosis in response to DNA damage; however, this resistance was abolished by coexpression of KLF2, which inhibits WEE1 transcription. Thus, the level of WEE1 is regulated by KLF2 and enhanced KLF2 expression sensitizes cells to DNA damage-induced apoptosis.

SUMOylation of the SOX10 transcription factor modulates its transcriptional activity with different functional consequences. *M. Girard, M. Goossens.* Dept Genetics, INSERM U654, Creteil, France.

SOX10 is a transcription factor of the SOX family that is expressed in the neural crest by the time of its emergence, and then in neural crest derivatives forming sensory, sympathetic and enteric ganglia, melanocytes and glial cells of the nervous system. Heterozygous SOX10 mutations cause Waardenburg syndrome type IV (WS4), associating Hirschsprung disease (intestinal aganglionosis) and Waardenburg syndrome (pigmentation defects and sensorineural deafness). Some WS4 patients also present with a neurological phenotype, leading to PCWH syndrome (Peripheral neuropathy, Central leukodystrophy, Waardenburg syndrome and Hirschsprung disease). A two-hybrid screen revealed an unsuspected aspect of SOX10 regulation: sumoylation. Sumoylation is a highly dynamic post-translational modification consisting of attachment of a small peptide, SUMO, to a target protein. This modification has various functional consequences on target proteins and affects stability, activity and localisation of specific transcription factors. Sumoylation occurs on a KXE consensus sequence where indicates a hydrophobic amino acid, K is the lysine of attachment of SUMO and E is a glutamate. The SOX10 protein has three potential SUMO consensus sites, all of them are functional and lead to SOX10 sumoylation in vivo. Sumoylation does not affect SOX10 sub-cellular localisation, but modulates its transcriptional activity. Indeed, mutation of the three SOX10 sumoylation sites significantly increases its transcriptional activation of two of its target genes, GJB1 (encoding connexin 32) and MITF. Interestingly, sumoylation of SOX10 appears to have different consequences on its function depending on the site that is used for SUMO attachment. Sumoylation modulates SOX10 protein interactions, including its own dimerization and interaction with its cofactors EGR2 and PAX3. Sumoylation is the first post-translational modification described for SOX10 and leads to a fine regulation of its function, in agreement with the multiple roles of this factor. This work allows a better understanding of SOX10 function in development and enlightens a new aspect of its regulation.

A 300 bp of Mouse *Col10a1* Distal Promoter Element is Sufficient to Mediate its High-level Tissue-specific Expression in Hypertrophic Chondrocytes *In Vivo*. *Q. Zheng[1], B. Keller[1], G. Zhou[1], D. Napierala[1, 2], Y. Chen[2], A. Parker[3], B. Lee[1, 2].* 1) Molec & Human Genetics, Baylor College Med, Houston, TX; 2) Howard Hughes Med Inst. Houston, TX; 3) Respiratory and Inflammation Res. Area, AstraZeneca , Cheshire U.K.

Type X collagen gene (*Col10a1*) is specifically expressed in hypertrophic chondrocytes. Identification of the cis-regulatory element and its binding factors for tissue-specific mouse *Col10a1* expression is essential for understanding the mechanisms that specify endochondral ossification and underlie the molecular pathogenesis of skeletal dysplasia. We have previously reported that 4kb *Col10a1* promoter containing Runx2 elements can specifically drive weak reporter gene (*LacZ*) expression in the lower hypertrophic zone of transgenic mice. Here we report generation of additional transgenic mouse lines harboring various *Col10a1* promoter/intronic fragment (Tg-10 kb) or distal *Col10a1* element (Tg-6kb and Tg-4.6kb) driving *LacZ* as reporter. High-level tissue-specific reporter expression was observed in these transgenic mice. To clarify the contribution of this *Col10a1* distal element to its tissue-specific expression, transgenic mouse lines using two copies of the 700 bp putative enhancer element (-4.6 to -3.9 kb) upstream of the *Col10a1* basal promoter driving *LacZ* as reporter (Tg-2xEnh) have been established and showed similar tissue-specific expression pattern. More recently, we have generated transgenic founder mice carrying reporter construct containing four copies of highly conserved 300 bp fragments within this region (-4.3 kb to -4.0 kb) upstream of the same *Col10a1* basal promoter. These Tg-4x300 founder mice show similar hypertrophic chondrocyte-specific expression pattern to that of the Tg-4.6 kb, Tg-6 kb, Tg-10 kb and Tg-2xEnh mice. These data together suggest that this 300 bp highly conserved element contains cis elements sufficient for tissue-specific *Col10a1*/reporter expression throughout hypertrophic zone. Further dissecting of the cis regulatory element within this region and its binding factors will ultimately help to identify signaling pathways relevant to skeletal development, especially chondrocyte maturation.

An SVA element in the 3UTR of the fukutin gene impairs transcriptional elongation in Fukuyama-type congenital muscular dystrophy. *F. Wang[1], Y. Nagai[1], H. Kurahashi[1,2], K. Kobayashi[1], H. Kano[1], T. Toda[1].* 1) Division of Clinical Genetics, Department of Medical Genetics, Osaka University Graduate School of Medicine, 2-2-B9 Yamadaoka, Suita, Osaka 565-0871, Japan; 2) Division of Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Aichi 470-1192, Japan.

Fukuyama-type congenital muscular dystrophy (FCMD) is a severe autosomal recessive muscular dystrophy accompanied by brain malformation. We previously isolated the responsible gene for FCMD, fukutin, through positional cloning, and found that 87% of FCMD chromosomes contain a 3 kb SVA-type retrotransposal insertion in the 3UTR of the fukutin gene. We also showed that the fukutin mRNA is greatly reduced in patient lymphoblasts, skeletal muscle and brain. However, the molecular mechanisms by which the SVA insertion influences fukutin mRNA expression have not been elucidated. In this study, we confirm that the retrotransposal insertion significantly decreases fukutin mRNA expression both in transiently transfected cells and in patient fibroblast culture. Analysis of mRNA stability using actinomycin D shows only a slight shortening of the half-life of fukutin mRNA by the insertion. On the other hand, induction of fukutin mRNA expression is greatly impaired by the insertion in an inducible cell line, suggesting transcriptional disruption. Chromatin immunoprecipitation analyses reveal that histone modifications in the promoter region of fukutin is not affected by the insertion in the fibroblasts. Further analysis of transcription by the nuclear run-on assay shows that transcriptional elongation is impaired by the insertion whereas transcriptional initiation is unaffected. We conclude that the SVA element in the 3UTR of the fukutin gene impairs transcriptional elongation. As SVA elements are thought to be currently active in the human genome, the SVA element inserted in the 3UTR of the fukutin gene may function through epigenetic mechanisms to down-regulate the host gene expression.

A conserved splicing enhancer identified by alignment of intronic sequences. *I. Aznarez[1,2], D. He[1,2], G. Deng[1], J. Cheung[1], L.-C. Tsui[1,2,3], J. Zielenski[1], J. Parkinson[1,2], B.J. Blencowe[4].* 1) Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Molecular & Medical Genetics, University of Toronto, ON, Canada; 3) University of Hong Kong, Hong Kong; 4) Banting and Best, University of Toronto, ON, Canada.

Splicing requires accurate selection of splice sites (ss) promoted by elements that are bound by splicing factors. Intronic splicing enhancers in particular are not well characterized. Using CFTR as a starting point we performed multi-species alignments of genomic sequences. Intronic sequences showing high conservation near exon boundaries were considered as candidate splicing elements. Results showed that the intron sequences downstream of the 5'ss of 12 of the 26 CFTR introns contained conserved segments of 20-40 nucleotides. We screened these conserved segments for motifs and 9 out of 12 contained T-rich hexamers (5Ts/6). Conversely, T-rich motifs were found in only 2 out of 14 non-conserved sequences (p=0.004). To assess whether the T-rich motifs were present in other genes proximal to 5'ss, we scanned 26,555 protein-coding, intron-containing genes. Results showed a significant increase of T-rich motifs compared to compiled intronic nucleotide content (p=0.015). Pools of intronic sequences downstream of alternative and constant exons were analyzed independently, revealing a higher incidence of T-rich motifs downstream of alternatively spliced exons. To assess the distribution of T-rich hexamers, 1000 bp from +1 of all introns were analyzed revealing a cluster within the first 20 bp of intronic sequences starting at position +5. In addition, sequences downstream of pseudo 5ss (n=78) located in all exons and the first 150 nucleotides of each intron of CFTR were scanned for T-rich motifs. Results showed that these motifs occur less frequently downstream of pseudo 5ss (p=0.04). A candidate splicing factor, T-lymphocyte inducer of apoptosis (TIA-1) that promotes 5'ss selection, may be involved in the recognition of the identified T-rich motif based on previous analyses of three independent genes. Altogether, these results suggest that the T-rich motifs could function as an intronic splicing enhancer.

Expression of Normal and Abnormal CPSI Transcripts Using a Eucaryotic-Replicating-CPSI containing BAC Expression System. *A. Eeds[1], L. Hall[1,3], R. Wade-Martins[2], A. Putnam[1], R. Price[1], D.. Mortlock[1], M. Summar[1,3].* 1) Center for Human Genetic Research, Vanderbilt Univ, Nashville, TN; 2) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) Dept of Pediatrics, Vanderbilt Univ, Nashville, TN.

RNA processing defect mutations are now known to be one ,if not the, most common causes of defective gene expression. We have found that 1/3 of the mutations in carbamyl phosphate synthetase I (CPSI) are of this nature. It has been difficult to study exact effects of these changes in patients without an expressing tissue source. We have previously reported the creation of a BAC expression system that replicates in eucaryotic cells and contains a selective agent. We have tested this construct containing a full copy of the CPSI gene and found that it produces normally spliced CPSI RNA. We have used homologous recombinant engineering to incorporate a mutation near the intron/exon boundary of intron 10, suspected of causing nonsense mediated decay, into this system. We have found that the transcript from this clone produces an abnormally spliced CPSI transcript with abnormal message levels compared to the control construct. This system provides a rapid and reliable method for assessing the affect of suspect RNA processing defects using a whole gene construct. This system can also be used to test the effects of mutations and polymorphisms on most aspects of a gene product and should prove to be a valuable tool in assaying functional significance.

Human and mouse retinal alternative RNA splicing (AS) of a set of genes that are implicated in retinal degenerations. *F.Y. Demirci[1], B.W. Rigatti[1], M.B. Gorin[1, 2].* 1) Dept. of Ophthalmology, UPMC Eye Center, Ophthalmology and Visual Science Research Center, Univ. of Pittsburgh SOM, Pittsburgh, PA; 2) Dept. of Human Genetics, Univ. of Pittsburgh GSPH, Pittsburgh, PA.

Alternative RNA processing generates functionally diverse isoforms or provides a regulatory mechanism by modifying the elements that control RNA stability, localization, and translation. According to recent genome-wide analyses, ~75% of human and ~60% of mouse multi-exon genes are predicted to be alternatively spliced. The retina is among the top 3 tissues with the highest levels of tissue-specific AS and a number of human retinal disease genes are known to undergo AS. We used human and mouse databases to identify the known and/or predicted AS events for a set of retinal disease genes and we sought to experimentally confirm them as well as discover novel forms. Initially, 5 genes (*UNC119, RGR, NR2E3, NRL, CRB1*) were evaluated. Total RNA was isolated from retinas of 8-12 week-old mice and human retinal RNA was commercially obtained. The brain and spleen RNA samples were also obtained to determine the tissue-specificity of AS events. RT/PCR was performed to amplify the transcript fragments that are known or predicted to undergo AS. PCR fragments were gel-purified and directly sequenced. We identified some previously unreported retinal AS and alternative termination events in the set of transcripts that we investigated. Observed AS events included exon skipping, alternative exon inclusion, different splice site usage, and intron retention. Some of the murine variants were found to be different than the human variants, while others were confirmatory for the corresponding human forms. Conserved splicing events warrant particular consideration for their functional significance. AS appears to occur in retinal transcriptome more frequently and in a wider spectrum than previously thought. Identification and characterization of retinal transcript splice forms will guide further studies toward understanding the functional diversity created by these variants and/or their contribution to regulatory mechanisms, effect on retinal disease, and factors regulating retinal alternative RNA processing.

Protein-protein interaction of the intracellular loops and NBD domains in CFTR. *S.J. Potts[1], M.J. McGinniss[2], F.M. Hantash[2], W. Sun[2], C. Strom[2].* 1) Advanced Diagnostics IT, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) Genetic Testing Center, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Mutations in the human ATP-binding cassette (ABC) transporter, Cystic Fibrosis Transmembrane Regulator (CFTR), cause cystic fibrosis by either disruption of biosynthetic processing or by production of a functionally defective protein. From structures of other ABC transporters and biochemical experimental evidence, activity in each nucleotide binding domain (NBD) is coupled to transmembrane helices through two intracellular loops. Along with others, we have observed functionally impacting mutations in cystic fibrosis patients in both these intracellular loops and the putative areas of the NBDs that interact with these loops. With the recent crystal structure of NBD1 (Lewis, et al EMBO J 2004; 23:282-293) and a homology model for NBD2, further insight into the likely impact of these mutations on protein function is now possible. Using protein-protein docking software, ab initio modeling and threading algorithms (Simons et al. J Mol Biol 1997;268:209-225) for alignment with other solved protein structures, we are investigating the possible interactions of these loops with the two NBD domains in order to predict the functional significance of novel point mutations in CFTR. We include known biochemical assay data, sequence conservation across human CFTR orthologs and paralogs, and the available data on functional implications of mutations in these domains in other human ABC-transporters. From our predicted interaction of these loops with NBD domains we can restrict the potential topology arrangements of the transmembrane helices.

ELOVL4 distribution in mouse, monkey and human eyes. *Y. Chen, D. Cameron, Z. Yang, G. Karan, K. Howes, Z. Tong, S. Hamaya, A. Azimi, Y. Zhao, K. Zhang.* Ophthalmology, University of Utah, Salt Lake City, UT.

Purpose: Stargardt-like macular dystrophy (STGD3) is an autosomal dominant form of early onset macular degeneration. The disease causing gene ELOVL4 encodes a protein that belongs to a family of proteins functioning in elongation of long chain fatty acids. The purpose of this study is to characterize ELOVL4 protein distribution in mouse, monkey and human eyes. Methods: We raised polyclonal antibody againt ELOVL4 bacterial fusion proteins. The Affinity-purified ELOVL4 antibody was used to perform immunohistochemistry in retinas from mutant and normal ELOVL4 transgenic mice, monkey and human along with the specific outer and inner segment marker antibodies. Results: Elovl4 expression is predominantly enriched in inner segments of photoreceptor from normal mouse, monkey and human. However, ELOVL4 expression in photoreceptors of mutant ELOVL4 transgenic mice had a tendency to follow an aggregated pattern. Conclusions: Our in vivo ELOVL4 expression data are consistent with that of our reported in vitro studies. ELOVL4 transgenic mice will aid our understanding of underlying pathogenetic mechanism of maculae degeneration.

Chromatin Immunoprecipitation - Microarray Analysis Identifies Transcriptional Targets of the Speech and Language Gene, FOXP2. *E. Spiteri[1], Z. Luo[1], J. Ou[1], B. Ren[2], D.H. Geschwind[1,3].* 1) Department of Neurology, Program in Neurogenetics, UCLA School of Medicine, Los Angeles, CA; 2) Department of Cellular and Molecular Medicine, University of California, San Diego School of Medicine; 3) Department of Psychiatry and Center for Autism Research, UCLA School of Medicine, Los Angeles, CA.

FOXP2 became the first gene identified as the genetic cause for an inherited speech and language disorder when a mutation was identified in individuals of the KE family affected with verbal dyspraxia and language deficiencies. The forkhead binding domain family of proteins, to which FOXP2 belongs, is a group of transcriptional regulators known to be active in development. In the mouse lung, FoxP2 is important for the development of the epithelium and in drosophila FoxP2 is important in the development of the gut. The expression patterns of the FOXP2 mRNA and protein in the brain is becoming well defined. FOXP2 expression starting in post-mitotic neurons is consistent with a role in the development and maintenance of mature neuronal phenotypes. However, the functional role of FOXP2, especially the nature of its transcriptional targets, remains unclear. To better understand the functional role of FOXP2 in brain development, we performed chromatin immunoprecipitation followed by hybridization to a promoter rich microarray (ChIP-chip). To ensure specificity, we made a new polyclonal FOXP2 antibody based on a region with high sequence divergence between FOXP2 and FOXP1. Three replicate experiments were performed in SY5Y cells following peak FOXP2 induction. The targets were confirmed using RT-PCR in SY5Y cells before and after over expression of FOXP2, demonstrating transcriptional regulation by induction of FOXP2. These targets include genes from varying gene ontology categories such as transcriptional activators involved in organogenesis, signal transduction and cell adhesion. Through their relationship with FOXP2 these genes themselves become candidates for evolutionary selection, autism and other speech and language disorders as well as important genes in the development of the brain.

Humanized xenobiotic response in trans-chromosomic mice containing the human CYP3A cluster. *Y. Kazuki[1], T. Oshima[2], Y. Kai[1], S. Abe[1], M. Takiguchi[1], H. Yamada[1], K. Tomizuka[2], M. Oshimura[1].* 1) Departmentof Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, 86 Nishimachi, Yonago, Tottori 683-8503, Japan; 2) Pharmaceutical Research Laboratory KIRIN Brewery CO. Ltd., 3 Miyabara-cho, Takasaki, Gunma 370-1295, Japan.

Human CYP3A4 is the most abundant P450 isozyme present in human liver and small intestine and participates in the oxidative metabolism of approximately half of all commercially-available drugs, and the CYP gene has clear species-specific inducibility. In order to investigate the role of cis-elements of the human CYP3A cluster and to generate humanized Tc mice that are responsive to a human specific CYP3A inducer, a human artificial chromosome (HAC) containing the CYP3A cluster (CYP3A-HAC) was constructed using the Cre/loxP-mediated chromosome-cloning system. The CYP3A-HAC was then introduced into mouse embryonic stem (ES) cells via Chinese hamster ovary (CHO) cells using microcell-mediated chromosome transfer (MMCT), and healthy chimeric mice containing the CYP3A-HAC were generated from the ES cells. CYP3A4, CYP3A5, and CYP3A7 on the CYP3A-HAC were expressed only in Tc chimeric liver and small intestine, consistent with the expression profile in humans. To investigate whether expression of the human CYP3A genes can be induced in mouse genetic background through trans-regulatory factors, Tc chimeric mice containing the CYP3A-HAC were treated with the human-specific inducer, rifampicin. The CYP3A cluster, particularly CYP3A4 gene expression in the liver of Tc mice with the CYP3A-HAC, was induced by rifampicin. The present data suggest that the endogenous mouse trans-acting factors trans-activated the human CYP3A gene in the Tc mice without human nuclear receptor, hPXR/SXR. In conclusion, the Tc chimeric mice containing the full CYP3A cluster are the first model mice showing interspecific expression differences by introducing cis-acting element rather than trans-reguratory factor. These mice may provide a useful model in which to test novel drugs that induce the CYP3A genes or to identify a novel cis-element in CYP3A4 activation.

Changes in Molecular Conformation of Expanded Ataxin-3: Experimental Evidence from Small Angle X-ray Scatering (SAXs) Technique. *M.C.C. Garcia[1], C.L.P. Oliveira[2], I. Torriani[2], C.E. Benedetti[3], I. Lopes-Cendes[1].* 1) Medical Genetics, Fac. Ciencias Med / UNICAMP, Campinas, SP, Brazil; 2) Physics Institute GLEB WATAGHIN, UNICAMP, Campinas, SP, Brazil; 3) Synchrotron Light National Laboratory, CAMPINAS, SP, Brazil.

Several dominant inherited human neurodegenerative diseases are caused by expansion of a polyglutamine (polyQ) domain within the respective proteins. This confers a putative dominant toxicity leading to dysfunction and neuronal loss. Expanded polyQ proteins form aggregates within neurons but precisely how it causes neuronal dysfunction and cell death remains unclear. Machado-Joseph disease (*MJD*) is one of the most frequent forms of a neurodegenerative disorder caused by this type of molecular defect in the protein ataxin-3, which physiological and biochemical functions are unknown. Since the function of a protein is closely related to its structure, information on its conformation is very useful for function prediction. Small-Angle X-ray scattering (SAXS) technique is a valuable tool for studying protein conformation in solution, at conditions close to the native state. Recombinant human ataxin-3 with normal (18Q) and expanded repeats (71Q) were expressed in *E. coli* and purified by affinity chromatography. SAXS measurements were performed in samples containing at least 1mg/mL of protein and revealed a value for the molecular weight close to the expected for both isoforms, increasing the reliability of the data obtained. Our results indicated an elongated conformation and the presence of loose parts in the structure. Ab initio calculations allowed the construction of low-resolution three-dimensional (3D) models. Comparison of both isoforms showed that the expanded polyQ tract significantly changes the 3D conformation of the protein and this could be related to the pathogenic effect. Our results showed, for the first time, conclusive evidence of conformational changes related to the pathogenicity of expanded polyQ tracts in human proteins.

The aggregative properties of proteins with polyalanine domains. *A. Klein, C. Alexander, M. Ebihara, M.J. Dicaire, B. Brais.* Neurogenetique, CHUM - Hopital Notre-Dame, Montreal, QC, Canada.

Oculopharyngeal muscular dystrophy (OPMD) is an autosomal dominant disease caused by an expansion of triplet (GCN) encoding a polyalanine domain in the poly(A) Binding Protein Nuclear 1 (PABPN1). PABPN1 is a polyadenylation factor which allows the elongation of the poly(A) tail of each mRNA. The main characteristic of the disease is the formation of intranuclear inclusions in the skeletal muscle fibers. To date, eight other diseases caused by mutations in a polyalanine-coding sequences have been described. Recently several studies showed that seven of the eight proteins involved in the polyalanine diseases form nuclear or cytoplasmic inclusions when overexpressed in cellular models. These results suggest that the polyalanine proteins share a tendency to aggregate. To establish if this is a general property of proteins with polyalanine domains, we chose to study some that have not been implicated in diseases. We selected six transcription factors with variable size (7 to 17 alanines) and position of the polyalanine domain in the protein: TBX2, ID4, BHLHB3, TLE3, PUM2 and ZNF358. We also selected PHOX2B which possess the larger polyalanine domain in human (20 alanines). Immunofluorescence studies allowed us to confirm the localization of the exogenous protein and the eventual inclusions formation in the transfected cells. Our results showed that five of the seven proteins tested form nuclear inclusions when overexpressed, while one formed cytoplasmic inclusions. Size and position of the polyalanine domain do not seem to influence greatly the general aggregation properties. Co-expression studies with PABPN1 showed that even if the proteins form inclusions, they do not co-aggregate. These results confirm the aggregative properties of proteins with polyalanine domains while suggesting that specific sites of nuclear aggregation do not exist.

Ocular expression profiling and co-localization of Optineurin with its interacting proteins of RAB8, Myosin VI, and FOS in Rhesus Monkey. *T. Rezaie, M. Sarfarazi.* Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT.

Previously, we reported that mutations in the Optineurin (*OPTN*) gene are involved in the etiology of adult-onset primary open angle glaucoma (Science 2002; 295:1077). Recently, we determined expression pattern of this protein in various ocular tissues of human and mouse (Genomics 2005; 85: 131-138). In this study, we aimed to study the endogenous OPTN and its known interacting proteins of RAB8, Myosin 6 (MYO6), and FOS in ocular tissues of Rhesus monkey. Direct interaction of OPTN with these proteins has previously been documented in the yeast two-hybrid system. For OPTN, an anti-peptide antibody previously raised in chicken was used but specific antibodies to OPTN-interacting proteins of RAB8, MYO6 and FOS were obtained commercially. Immunohistochemistry analyses revealed a high expression of OPTN in anterior segment, trabecular meshwork, non-pigmented ciliary epithelium, ciliary muscle, iris constrictor muscle, endothelial cells of blood vessels and Schlemm's canals. Additionally, prominent immunolabeling was observed in retinal ganglion cells, inner and outer plexiform and in the photoreceptor layers. Interestingly, a very high degree of co-localization was observed in ocular tissues of Rhesus monkey between OPTN and its interacting proteins of RAB8, MYO6, and FOS, particularly in the retinal ganglion cells and photoreceptors rods and cones. In silico analyses revealed that for Rhesus monkey, *RAB8b* encodes for 207-aa, *MYO6* for 1285-aa, and *FOS* for 380-aa polypeptide that are, 100%, 98% and 97% identical to their human counterparts, respectively. In summary our study, in addition to OPTN, elucidates specific ocular expression of RAB8, Myosin 6, and the FOS proteins in various ocular tissues of Rhesus monkey. Biological processes in which normal and abnormal copies of OPTN interact with RAB8, MYO6 and FOS still remain to be determined. Further studies also needed to determine if mutations in any of these OPTN-interacting proteins would have a direct involvement in glaucoma optic neuropathy. Supported By: EY-009947 and EY-014959.

Usher syndrome, audiological and vestibular finding.14 Mexican patients. *F. Castillo-Lorca[1], C.F. Martinez-Cruz[2,3], R. Baez-Reyes[4], L. Gomez-Hernandez[5], A. Garcia-Huerta[1], S.G. Juarez-Garcia[6], G. Garcia-Sanchez[1].* 1) Servicio de Genética, Departamento de Cirugía y Medicina Interna. Instituto de la Comunicación Humana/Instituto Nacional de Rehabilitación; 2) Servicio de Comunicación Humana, Departamento de Seguimiento Pediátrico, Instituto Nacional de Perinatologia, Mexico, D.F; 3) Servicio de Pediatría, Hospital General de Zona no. 53 IMSS Los Reyes la Paz. Estado de México; 4) Departamento de Genetica. Instituto Nacional de Perinatologia, Mexico, D.F; 5) Servicio de Audiologia.Instituto de la Comunicación Humana/Instituto Nacional de Rehabilitación. E-mail gsanchezg@yahoo.com.mx; 6) Servicio de Neuropsicologia Infantil.Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación.

Usher syndrome is the most common condition that involves both hearing and vision problems. Although the syndrome was first described by Albrecht Von Graefe in 1858, it was named for Charles Usher, a British eye doctor, who believed that the condition was inherited or passed from parents to their children. The major symptoms of Usher syndrome are hearing impairment and retinitis pigmentosa. Some people with Usher syndrome also have balance problems. There are three general types of Usher syndrome. The three types of Usher syndrome are Usher syndrome type 1 (USH1), Usher syndrome type 2 (USH2), and Usher syndrome type 3 (USH3). USH1 and USH2 are the most common types. Together, they account for approximately 90-95 percent of all cases of children who have Usher syndrome..Approximately 3-6 percent of all deaf children and perhaps another 3-6 percent of hard-of-hearing children have Usher syndrome. In developed countries such as the United States, about 4 babies in every 100,000 births have Usher syndrome.In this report we studied the type/ grade of hearing impairment, vestibular function and clinic type of Usher, so we could classify them. Material and methods: We evaluated 14 patients with Usher syndrome. They underwent tonal audiometry, caloric tests and posturography by conventional techniques. Results: We studied 14 patients with different types of Usher syndrome: 8 males (57.1%) and 6 females (42.9%). The youngest was 16 years old and the oldest: 47, with a media of 29 years old; 9 patients (64.3%) had USH1, 4 (28.2%) USH2 and l patient (7.1%) USH3. All patients with USH1 showed profound sensorineural hearing impairment with abnormal caloric and posturographic tests. Patients with USH2 had severe sensorineural hearing loss with normal vestibular tests, and patient with USH3 showed severe progressive deafness with normal vestibular tests. Conclusions: The clinical findings of Usher syndrome are enough to classify each type. Patients with Usher syndrome do not come for an audiologic evaluation at first instance that is why our approach was difficult. In spite of this is a small sample, USH1 was the most frequent type seen.

Instituto de la Comunicación Humana/Centro Nacional de Rehabilitación.E mail gsanchezg03@yahoo.com.mx.

Syndrome characterized by total oculocutaneous albinism and congenital severe hearing loss was found in tour children in two sibships in a kindred and described by Ziprkowski and Adam, in 1964. The characteristics of ibis syndrome include (1) autosomal recessive inheritance: (2) albinism of the entire body, including, optic fundí and irides: (3) deficient media eyebrows; and (4) congenital severe sensorineural hearing loss. However, Smith (3) has examined the kindred once again and attests to the validity of a condition now termed oculocutaneous albinism and congenital sensorineural hearing loss, autosomal dominant. We report mother and son with oculocutaneus albinism and sensorineural hearing loss. CASE 1: Male child 4-year-old, is the third child, of young, non consanguineous parents. Hearing loss onset at 3 months of age. Oculocutaneous albinism is observed since birth. ABR performed at 2 years old reported bilateral response at 90dB. Audiometric test showed sensorineural bilateral severe hearing loss. CASE 2: female patient 29-year-old, probandos mother, hearing loss onset at 4-year-old. Oculocutaneus albinism. Audiometric test showed sensorineural bilateral severe hearing loss. Vestibular test were normal.

***GJB2/GJB6*testing for infant hearing loss from a diverse US population.** *L. Schimmenti[1], A. Martinez[2], M. Teletar[2], N. Shapiro[2], M. Fox[2], B. Crandall[2], Y. Sininger[2], C-H. Lai[2], W.W. Grody[2], C.G. Palmer[2].* 1) Dept Peds/Inst Human Gen, Univ Minnesota, Minneapolis, MN; 2) Dept of Psychiatry and Biobehavioral Sci,Lab Medicine and Pathology, Pediatrics, Otolaryngology, Human Genetics, UCLA, Los Angeles, CA.

Mutations in the genes *GJB2/GJB6* are associated with up to half of the cases of non-syndromic hearing loss in some populations. We are in the third year of a longitudinal study in a diverse California population to determine the feasibility and impact of introducing testing into newborn hearing screening protocols with the hypothesis that genetic testing will enhance diagnostic efforts and intervention. To date, 74 infants and toddlers with non-syndromic hearing loss are enrolled in the study. For all infants, buccal cell derived DNA is used to sequence both exons of *GJB2* and to assay for del(*GJB6*-D13S1830). Using these methods, hearing loss can be explained in 19 infants. (26%) by the presence of biallelic mutations in *GJB2/GJB6*. The three most common genotypes are 35delG/35delG (8), 35delG/167delT(3) and V37I/V37I (3). We also identified 5 infants with various biallelic *GJB2* hearing loss associated variants (35delG/311del14, 235delC/235delC, 35delG/K168X) including two with double heterozygosity for del(GJB6-D13S1830)(167delT/delGJB6, 35delG/delGJB6). In the remaining 55 infants, 4 infants are identified with only one hearing loss associated allele (35delG/wt(2), Y152X/wt(1) and S139N/wt(1)), 15 with known polymorphisms (V27I/wt (9), V27I/V27I(2), V153I/wt(1), M34T/wt(2), V27I,E114G/wt(1)), and 36 with only wildtype alleles. When the bialleic data was broken down by ethnic group (where both parents are of the same ethnic group), mutations are identified in 10/24 (41%) of non-Hispanic Caucasian infants, 4/9 (44%) of Asian infants and 2/29(7%) of Hispanic infants. In infants of mixed heritage, (non-Hispanic Caucasian/Hispanic), we find 3/9 with bialleic mutations in *GJB2*. We show that mutation testing in infants from a diverse Los Angeles population is feasible and robust. However, the low rate of *GJB2/GJB6* mutations warrants further study to identify causes of hearing loss in infants of Hispanic heritage.

The frequency of the *GJB2* V27I polymorphism in the Los Angeles Mexican American population. *M. McCarra[1], A. Martinez[2], M. Teletar[2], N. Shapiro[2], M. Fox[2], B. Crandall[2], Y. Sininger[2], W.W. Grody[2], C.G. Palmer[2], L.A. Schimmenti[1].* 1) Pediatrics, Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 2) Psychiatry and Biobehavioral Sci, Lab Med Pathology, Pediatrics, Human Genetics, Otolaryngology, UCLA, Los Angeles, CA.

Recessive mutations in *GJB2* are the most commonly identified genetic cause of non-syndromic hearing loss and are associated with up to half of all autosomal recessive non-syndromic hearing loss in Caucasian populations. In a longitudinal prospective study of infants in Los Angeles with apparent non-syndromic hearing loss, it was noted that the V27I (79G>A) variant was commonly identified in a number of Mexican-American infants but rarely observed in non-Hispanic Caucasian infants. Of 18 infants with sensorineural hearing loss who had both parents of Mexican heritage, the V27I polymorphism occurred as the only sequence variant in 8 of 36 chromosomes (22%); four being heterozygous and two being homozygous. As a control for this group of infants and to find the population frequency of V27I, one hundred DNA samples from Mexican American individuals from Los Angeles were obtained from the Coriell Institute. In the control group, at least 3 grandparents were born in Mexico. Ninety-nine samples were amplified with *GJB2* specific primers, and assayed by restriction digest for the presence of the 79G>A. We determined that the V27I variant occurred in 46 of 198 chromosomes (23.2%); 36 being heterozygotes and five being homozygotes, confirming that V27I is a polymorphic variant with very high frequency (0.23) in the Mexican American control population and is not a hearing loss-causing allele.

Correlation of acute GVHD with HLA sequence and structural dissimilarity after unrelated hematopoietic stem cell transplantation. *S. Hwang[1], Y.S. Heo[2], J.J. Seo[3], J.W. Lee[4], H.B. Oh[1].* 1) Laboratory Medicine; 2) CrystalGenomics, Inc; 3) Pediatrics; 4) Internal Medicine, Univ. of Ulsan, College of Medicine, Asan Medical Ctr, Seoul, Korea.

High-resolution HLA mismatch is known to be major cause of acute graft-versus-host disease (aGVHD) after hematopoietic stem cell transplantation (HSCT). Direct allorecognition of T cell is the major mechanism for aGVHD. Hypothesis of this study was that the severity of aGVHD would increases according to structural difference between HLA alleles. To estimate the difference between a donor/recipient pair, we used two dissimilarity score matrixes of amino acids. One was Risler's distance matrix (Bone Marrow Transplant 2004:165-9) which is based on evolution. The other was invented to access structural dissimilarity in aspect of space-electrostatic bonding and hydrogen bonding. Mismatches occurred in the region of peptide-binding and TCR-contact were given more penalties (score). We developed a web-based system to get dissimilarity score (www.koreanhla.net). The system was designed to be tailored by users, which meant that nearly all parameters could be changed easily on the web with administrator's permission. Correlation between the dissimilarity score and the grade of aGVHD after HSCT was analyzed in thirty-eight donor/recipient pairs. The sequence and structural dissimilarity scores of HLA-A, -B and - DR loci correlated significantly with the grade of aGVHD ($r = 0.460$, $r = 0.356$, respectively; $p = 0.004$, $p = 0.031$, respectively). It was also found that substitution at residue 99 of HLA -A significantly related to the prevalence of aGVHD. It could be suggested that the dissimilarity scores which reflect HLA difference in aspect of sequence or structure correlate well with the severity of aGVHD. Larger sample size is necessary to confirm our result. Web-based system will give researches chance to use our system, by which our system will be further refined.

Genetics Home Reference: translating genetic data into educational materials. *J.A. Mitchell[1], C. Fomous[2], J. Fun[2], S. Morrison[2].* 1) Med Informatics, Univ Utah Sch Medicine, Salt Lake City, UT; 2) Nat Library Medicine, NIH, Bethesda, MD.

The Genetics Home Reference (GHR) website (**http://ghr.nlm.nih.gov**) fills a unique niche by using plain language to interpret the health implications of the Human Genome Project. Prior to GHRs launch in April 2003, online genetic resources focused on the needs of genetics professionals. Consumers seeking information about inherited disorders, however, reported that genetics websites were often confusing, difficult to navigate, and hard to understand. GHR was developed to address the growing need for online genetics information in lay language. GHR uses innovative strategies developed through informatics research to manage the large and expanding body of genetics information. Automated techniques integrate information across data sources, assist data interpretation, and increase the accuracy of search results. GHRs architecture collects information as structured data with embedded relationships and presents this data in a simple, document-based format. Fields in the structured data can be mapped to other databases, controlled vocabularies, and ontologies. For example, condition names are mapped to Medical Subject Headings (MeSH) to improve the accuracy of search results. Mining databases, such as Entrez Gene, OMIM, and Gene Ontology streamlines content development by automatically extracting information for content developers to use. The marriage of bioinformatics data and consumer-oriented content has been fruitful. Content on the GHR site doubled over the past year; currently, information is available for more than 200 conditions and 250 genes. Site traffic has increased fourfold over the past 2 years. Tracking data show that all features of the site are used. Initial evaluation found very high overall user satisfaction. GHR is a successful example of using informatics tools to produce an educational resource that meets consumers needs. Continued growth of the site will guide the application of informatics techniques and drive new research to assist content development, ensure accuracy, and help consumers navigate the complex world of genetics.

Fetal Aqueductal Stenosis: Prenatal diagnosis and postnatal outcome/autopsy findings. *E. Ying[1], M. Sgro[1], S. Keating[3], D. Chitayat[2].* 1) Pediatrics, St. Michael's Hospital, Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology; 3) Department of Pathology, Mount Sinai Hospital. University of Toronto, Toronto,Ontario, Canada.

Background: Aqueductal stenosis is a rare finding. Prenatal diagnosis of aqueductal stenosis is defined by the ultrasound finding of enlargement of both lateral and third ventricles with a normal sized 4th ventricle. Objectives: To report and describe our experience of the etiology and outcomes of fetuses prenatally diagnosed with aqueductal stenosis on ultrasound. Methods: Over a 15 year period (1992-2005), all pregnancies with the finding of aqueductal stenosis seen at a tertiary regional prenatal diagnosis centre were obtained through a database. The outcomes including laboratory (serologies, platelet antibodies, L1CAM gene mutation, and chromosome analysis), delivery records, autopsies and neonatal follow up were gathered by chart review. Results: 29 patients with fetal ultrasound findings of aqueductal stenosis were seen at the Prenatal Diagnosis Program. The mean gestational age at diagnosis was 20.2 weeks (range 15-39.7 weeks). Follow-up was available in 26 cases. Four (14%) had chromosomal abnormalities (2- trisomy 21; 1- trisomy 18 and 1- 45,X). In 4 cases (14%) L1CAM gene mutation was detected. Multiple anomalies, including renal and cardiac, were found in 10 cases including one with Walker-Warburg syndrome and one with 3C syndrome. 5 had additional central nervous system abnormalities including cerebral dysgenesis, myelomeningocele and lissencephaly. 23 pregnancies were terminated. One child who is alive (45, X) is severely delayed. Conclusions: Our report highlights the etiological hetegeneity of aqueductal stenosis detected prenatally and the need for a thorough autopsy, chromosome analysis and mutation analysis of the L1CAM gene in males and 45,X females to try and delineate the diagnosis and thus provide accurate genetic counseling.

Still lumping after 14 years: OFD-VI, Hydrolethalus and Pallister-Hall syndromes. A diagnostic dilemma for recurrence risk counseling. *D.M. McDonald-McGinn[1], N. Unanue[1], S. Saitta[1], S. Halbach[1], S. Purandare[1], M. Muenke[2], H. Honkala[3], L. Biesecker[2], W.B. Dobyns[4], E.H. Zackai[1].* 1) Children's Hospital of Philadelphia and The University of Pennsylvania School of Medicine; 2) NIH; 3) NPHI of Helsinki; 4) U of Chicago.

We previously reported a fetus with overlapping features of OFD-VI, Hydrolethalus (HYL) and Pallister-Hall (PH) syndromes (Muenke 1991). Fourteen years later we describe another such patient with significant overlap including: ocular colobomas and an occipital keyhole defect as seen in HYL, a molar tooth and multiple frenula as described in OFD-VI, a hypothalamic hamartoma consistent with OFD-VI and PH, and cerebellar vermis hypoplasia, epiglottal abnormalities and lower extremity pre-axial polydactyly as reported in all three. In 1991, there was no definitive way to distinguish the above syndromes. Because of this insolvable overlap Verloes suggested a phenotypic classification called the multiplex syndrome. This impacted recurrence risk counseling though, as PH is dominant while HYL is recessive. Progress has been made, however, as mutations have now been identified in PH (GLI3-Johnston 2005) and HYL (HYLS1-Mee 2005) and these studies are pending in our patient. Since many of our probands features overlapped with OFD-VI (presumed recessive) we reviewed the brain findings in 3 of our patients with OFD-VI (Patients 1 and 2 - Muenke 1990) and their long-term outcome. All had a molar tooth, hypothalamic hamartoma and vermis hypoplasia. The prognosis correlated with the severity of the brain findings: the 18 year old is non-verbal/non-ambulatory, the 28 year old is normal intellectually and the 4 year old has significant delays. Based on our probands brain and airway findings, the long-term prognosis, regardless of the classification is considered poor. However, the outcome of mutational analysis may offer definitive recurrence risk counseling. Thus, this report emphasizes the importance of CNS abnormalities in this spectrum of disorders as a prognostic indicator, whereas the specific mutations will ultimately determine the recurrence risk.

Evaluation of unclassified DNA sequence variants of the BRCA1 and BRCA2 genes. *R.K. Schmutzler[1], B. Wappenschmidt[1], M. Brosig[2], A. Meindl[3], German Consortium for Hereditary Breast and Ovarian Cancer (GCHBOC).* 1) Dept. Ob/Gyn, University of Cologne, Germany; 2) Institute for Medical Informatics, Statistics and Epidemiology, University of Leipzig, Germany; 3) Dept. Ob/Gyn, Technical University of Munich, Germany.

Purpose We aim to categorize unclassified DNA variants (UCVs) i.e. missense mutations of the BRCA1 and BRCA2 genes according to a multifactorial likelyhood-ratio (LR) model (Goldgar et al., AJHG 75:535-544, 2004). **Material and Methods** Within the GCHBOC 91 unique BRCA1 and 143 unique BRCA2 UCVs have been detected in 3081 independend index cases. Provided that a UCV does not exert an intermediate risk we perform co-occurrence, co-segregation, biochemical, interspecies variability and loss of heterozygosity (LOH) analysis. Calculation of LOH LRs is performed under the assumption that 95% of hereditary breast cancers but only 20% of sporadic breast cancers reveal LOH of the BRCA chromosomal regions. **Results** We first evaluated the model by analysing the BRCA2 UCV S384F by co-occurrence, co-segregation and LOH analysis and revealed a combined LR of $1.4x10^{-8}$ in favour of neutrality. Subsequent analysis of co-occurrence revealed highly significant LRs of <0,001 in favour of neutrality for 5 UCVs in BRCA1 (L6V, R7C, I15L, E23Q, P1099L) and 3 in BRCA2 (N289D, L1019V, V2969M). In additional 5 cases exclusion of LOH of the BRCA wildtype allele in 1 breast carcinoma per family (BRCA1: L668F, R866C; BRCA2: R2108C, R3052W, F3065L) led to an uncertain LR of 0.0625. In 1 family with the BRCA2 UCV I1446T located in the Rad51 binding domain, 2 breast carcinomas revealed maintenance of the wildtype allele leading to a LR of 0.0039 in favour of neutrality. Biochemical and interspecies analysis of these UCVs were of uncertain significance. **Conclusions** The Goldgar model provides a valuable approach for the evaluation of UCVs and so far 6 UCVs could be classified as being neutral. As co-occurence is the single most informative factor large data sets strongly promote clarification of UCVs. The remaining UCVs require additional material from the families for co-segregation and LOH analysis and are currently under investigation.

MRI fails to detect invasive breast cancer in a BRCA2 positive patient. *J.S. Wilbur, T.R. Sousa, R.D. Legare.*
Cancer Risk Assessment and Prevention Program, Program in Women's Oncology, Women & Infant's Hospital, Providence, RI.

Introduction: Breast magnetic resonance imaging (MRI) is a relatively novel screening method for women with a familial or genetic predisposition to breast cancer. Since 2000, six noteworthy publications have supported the fact that breast MRI is significantly more sensitive in detecting breast cancer in women at hereditary risk. Case Study: A heathly 44-year-old woman was referred to the Cancer Risk Assessment and Prevention Clinic because she was found to have inherited the BRCA2 deleterious mutation, R2520X. Following comprehensive cancer genetic counseling, which included the option of annual breast MRI screening, the patient decided to pursue prophylactic bilateral mastectomy (PBM). Prior to her PBM, a bilateral mammogram and breast MRI were performed, both of which were negative. The mammogram, performed five months prior to surgery, showed scattered fibroglandular densities in both breasts with no significant masses or calcifications. This mammogram was interpreted by a Board Certified Radiologist as well as a digitized computerized mammography reading program. The breast MRI was performed using standard breast protocol following intravenous administration of gadolinium three months prior to surgery. There was no evidence of mass-like or nonmass-like enhancement or lymphadenopathy. There were scattered areas of enhancing fibroglandular parenchyma with no evidence of malignancy and a BIRADS score of one. Despite her negative mammogram and MRI, the proband pursued prophylactic bilateral skin sparing mastectomy with immediate tram flap reconstruction. Post operatively, pathology identified a right breast TIcN1MX stage II ductal carcinoma, having extensive lymph-vascular invasion. The tumor was estrogen receptor (ER) positive, progesterone receptor (PR) positive, and Her-2/Neu negative by FISH. The patient is currently undergoing chemotherapy treatment. Conclusion: Current publications support breast MRI screening to be an extremely valuable tool in high risk popultations. However, while breast MRI sensitivity is considered superior to other screening modalities, it too has limitations and is worthy of further study.

Empiric recurrence risks for congenital solitary kidney. *E. McPherson.* Department of Medical Genetics, Marshfield Clinic, Marshfield, WI.

Congenital solitary kidney (CSK) affects about 1/1000 persons while bilateral renal agenesis (BRA) affects about 1/5000. Because CSK is significantly increased in the parents of infants with bilateral renal agenesis (BRA) and in the mothers of fetuses with non-lethal renal anomalies on ultrasound, there is reason for concern that the offspring of CSK patients may be at risk for both unilateral and bilateral renal anomalies, but no empiric data exist. The aim of the current study was to gather empiric data concerning the risks of CSK and BRA in close relatives of individuals with CSK.

Through a computerized review of records from 1979 to the present in a large multispecialty clinic, 206 subjects with CSK (defined as presumably congenital absence or severely reduced function of one kidney) were identified and 82 agreed to participate. They completed a questionnaire regarding renal and related urogenital anomalies in relatives. The numbers affected were as follows:

offspring 14/144(10%); parents 5/164(3%); siblings 4/234(2%)

Because subjects are unlikely to be aware of all non-lethal renal anomalies in their relatives, actual risks may be greater. The subjects report no cases of BRA among their relatives. Significant under-diagnosis of lethal renal anomalies is unlikely because the incidence of stillbirth was only slightly increased (1.8%) and the incidence of miscarriage was comparable to the general population (12%).

The minimum empiric risk for CSK and related anomalies in offspring of CSK patients is 10%, which is slightly less than the reported incidence of CSK in parents of fetuses with non-lethal renal anomalies. Lower risks in parents and siblings may represent underascertainment, but this mirrors the situation when family histories are obtained by interview. The incidence of BRA in relatives of CSK probands is apparently low, suggesting that either CSK is usually a separate disorder or the incidence of BRA relative to CSK is too low to be detected in the current study.

Y Chromosome long arm (Yq) Microdeletions in Idiopathic Male Infertility. *E. Fernández[1], F. Alvarez-Nava[2], L. Borjas[2], J. Osuna[3], W. Zabala[2], M. Zambrano[4], MG. Portillo[2].* 1) Inst de Inv Clínicas, Universidad del Zulia, Maracaibo, Maracaibo/Zulia, Venezuela; 2) Unidad de Genética Médica, Facultad de Medicina Universidad del Zulia (LUZ); 3) Unidad de Endocrinología del Hospital universitario de Mérida; 4) Cátedra de Bioquímica Clínica, Escuela de Bioanálisis, Facultad de Medicina-LUZ.

Today infertility is a major health problem affecting about 10-20% of couples. Male factor is assumed to be responsible in about 50% of the infertile couples. Both qualitative and quantitative abnormalities in sperm production are responsible in 40% of the infertile population. The origin of reduced testicular sperm function is unknown in about 60-70% of cases. Micro-deletions in the Yq are known to represent the pathogenic mechanisms for infertile males. Four differents non-overlapping regions designated as AZFa, AZFb, AZFc and AZFd are located in interval 5-6 of Yq, and are associated with impaired spermatogenesis in humans. To determine the prevalence and distribution of Y chromosomal microdeletions in venezuelan males with idiopathic infertility, chromosomal, Y-microdeletion, seminal and histological analyses were carried out in 30 venezuelan males with idiopathic azoospermia or oligoospermia. Yq Microdeletions were tested by mutiplex PCR, and were detected in 2 patients (6.7%). One patients had Yq microdeletions on AZFc-d and other had almost the entire AZF region with undetectable mosaicism (45,X/46,XY) on a first cytogenetic analysis. Affected patients had azoospermia and the histological findings the SCOS type I in one patient. The frequency and distribution of AZF microdeletions in venezuelan patients were similar to other populations with different ethnical or geographical origin. Patient selection criteria seem to be showed most important factor on the prevalence of microdeletions. Genetic evaluation in azoospermic men is recommended before to realize other diagnostic tests because of a high frequency of cytogenetic and genetic abnormalities among these patients with Yq microdeletions. Carrying patients of microdeleciones Yq can present an increase in the incidence of cellular lines 45, X in his karyotype.

Pyridoxine responsive seizures: phenotypic and pathogenic variability of febrile seizures, hypophosphatasia and hyperphosphatasia with neurologic defect. *P. Hwang[1], M. Thompson[2].* 1) Neurology, North York General Hospital, Toronto, Ontario, Canada; 2) Dept. Pharmacology, University of Toronto.

We present a series of paediatric cases with pyridoxine responsive seizures of variable aetiology. In the context of the more common pridoxine responsive neonatal seizures (infantile spasms in Japan), and the hypophosphatasia syndromes, we present data collected from families affected by pyridoxine responsive hyperphosphatasia with neurologic deficit or HND (MIM#239300). Considerable clinical heterogeneity within these disorders belies the fact that they are commonly responsive to pyridoxine. The genetic and physiological basis of the pyridoxine responsive hypophosphatasia syndromes contrasts with that proposed to explain hyperphosphatasia with neurologic deficit. In addition, the hyperphosphatasia seen in HND is not accompanied by abnormalities of bone, liver metabolism, or altered skeletal architecture. As in the other disorders, affected siblings and/or consanguinity suggest autosomal recessive inheritance. Unlike the hypophosphatasias and neonatal spasms, the underlying pathogenesis of HND is unknown. We describe a series of cases with heterogeneity and review the clinical features in the context of the other pyridoxine responsive diseases. Electroencephalographic (EEG) assessment is used to contrast the pyridoxine responsive syndromes. Whether or not febrile seizures or hyophosphatasia are evident, we suggest that phenotypic delineation of epileptic encephalopathy in infancy, childhood and adolescence should involve assays for: 1) alkaline phosphatase; 2) pyridoxine-EEG challenge. We contrast the genetic disruptions that underlie the metabolic errors in these disorders and suggest strategies for isolating the genes that contribute to the heterogeneity of HND and other pyridoxine responsive disorders.

Maternal reports of family history from the National Birth Defects Prevention Study, 1997-2001. *R.Fisk Green[1], R. Olney[1], J. Reefhuis[1], L. Botto[1], P. Romitti[2].* 1) NCBDDD, CDC, Atlanta, GA; 2) Dept Epidemiology, Univ Iowa, Iowa City, IA.

Enhancing family history (FH) use in pediatrics, in which parents provide most information, requires exploring what FH data could be obtained. We analyzed FH responses from the National Birth Defects Prevention Study (NBDPS) using data from completed interviews of mothers of children with birth defects (n=9331) and of control children (n=3390) with 1997-01 delivery dates. Mothers were asked if they, the father or other relatives had a birth defect or health problem at birth and, if so, what it was. We could not confirm FHs, so differences in accuracy or FH risk could not be determined. Of respondents with completed interviews, 17% reported an FH of birth defects, 5% genetic disorders, 10% developmental disabilities and 24% other conditions. Reports of birth defects in mothers and fathers were nearly equal in number, and defects were reported more for 1st and 2nd degree relatives than 3rd. Further analyses included only 1st and 2nd degree relatives. Univariate analyses indicated that, as expected, case mothers were nearly twice as likely as control mothers to mention an FH of birth defects (OR=1.9 [95% CI 1.7, 2.2]). White, non-Hispanic maternal race compared with all other races and ethnicities was associated with more reports of an FH of birth defects (OR=1.7 [1.5, 2.0]), as was maternal education of >12 years (OR=1.2 [1.1, 1.4]), English spoken at home (OR=2.8 [2.3, 3.3]) and an annual family income >$20K (OR=1.3 [1.2, 1.5]). Other factors associated with reporting an FH of birth defects included the father contributing to the interview (OR=1.4 [1.1, 1.6]) and the mother reporting factors she thought might cause birth defects (OR=1.6 [1.4, 1.7]). We assigned a level of detail (high, medium, low) to responses indicating a birth defect FH and found that a high level of detail was associated with being a case mother (OR=1.7 [1.1, 2.6]) and speaking English at home (OR=1.5 [1.1, 2.1]) but not with maternal race, education or family income. Our results suggest that demographic factors might affect reporting of FH, which could be considered in developing pediatric FH tools.

NIPBL Mutational Analysis in a Cornelia de Lange Syndrome Family with Two Affected Siblings and Normal parents. *D.M. Niu[1], N.C. Lee[1], J.Y. Wu[2], K. Kosaki[3].* 1) Pediatrics, Taipei Veteran General Hosp, Yang-Ming University, Taipei, Taiwan; 2) Department of Medical Research, China Medical College Hospital, Taichung; 3) Division of Medical Genetics, Keio University School of Medicine, Japan.

Cornelia de Lange syndrome (CdLS [MIM 122470]), is a clinically heterogeneous developmental disorder characterized by facial dysmorphia, upper-extremity malformations, hirsutism, cardiac defects, growth and cognitive retardation, and gastrointestinal abnormalities. Mutations in NIPBL have recently been reported to cause CdLS. Mutations in this gene can cause autosomal dominant inheritance. Recently, we found a family in which a boy and a girl in the same sibship show variable manifestations of CdLS. The brother had severe congenital heart disease and expired at age of one. The sister only had a mild patent ductus arteriosus (PDA) with spontaneous closure. Both parents are healthy and phenotypically normal. Mutational analysis of NIPBL gene was performed for the affected sister and both parents. A missense mutation (D2433G) at exon43 was identified at the affected sister, but not in both parents. This study reminds us that germline mosaicism should be considered for CdLS even in the parents who have normal phenotype.

A Survey of the Genetic Information Needs of Clients and Clinicians at Clinics in Washington, DC. *K. Christensen, E. Alfano, J. Martin, R. Caligiuri, R. van der Riet, N.T. Robinson, L. Wise, S.F. Terry.* Genetic Alliance, Washington, DC.

Purpose: To determine what information individuals from underserved and underrepresented communities need in the course of general medical care, what their health providers consider important and in what form that information is accessible.

Methods: We surveyed the literature, conducted surveys and focus groups of individuals who access Washington DC clinics for services. In addition, we surveyed clinicians who serve these underserved and underrepresented individuals. We qualitatively analyzed this information.

Results: Individuals receiving information in these clinics need consumer friendly, accessible materials. The literacy level of these materials must be appropriate for a wide range of clients. Consumer perspectives of what constituted critical information differed from clinician perspectives. Consumers achieved a high level of conceptual understanding when materials were made accessible.

Conclusions: In addition to understanding the socioeconomic and cultural attributes of clients in health clinics that serve underserved and underrepresented communities, material development for these communities must also integrate complex genetic information in an accessible manner. As a result, we developed a manual for clinicians to share genetic information with their patients.

Utilization of genetic counseling services by surgical oncologists: education a must. *D.M. Agnese, H. Hampel, C. Eng.* Internal Med/Human Genetics, Ohio State Univ, Columbus, OH.

Genetic counseling services are available at many institutions, however referral patterns differ among medical professionals. Perhaps the most widely used is cancer genetic counseling. The purpose of this study was to determine basic knowledge of and utilization of cancer genetic counseling services by surgeons specializing in oncology. Prior to the annual meeting in March 2004, where an educational session on cancer genetics was planned, a questionnaire was sent to the membership of the Society of Surgical Oncology. This survey evaluated the type and volume of practice, and basic information about knowledge of genetic consultation availability and genetic testing. The survey was electronically sent to 1512 members of the Society of Surgical Oncology. It is unknown how many were unopened or not received. There were 364 responses. The majority (71.3%) were academic surgeons. The majority saw more than 50 new cancer cases annually, and 31.8% saw more than 200 new cancer cases annually. Nearly all (98.1%) collected family history on these patients. Genetic consultation services were available in the majority of centers (82.6%). Despite this availability, only 56.1% referred frequently, while 38.3% referred occasionally and 5.6% rarely referred. In addition, 60% of those surveyed had ordered genetic testing on their patients. Members of the Society of Surgical Oncology, a predominantly academic group of surgeons with a particular interest in cancer surgery, do collect family history information when evaluating new cancer patients, although the extent of this history and its accuracy are not known. Surprisingly, although genetic consultation services are available in the majority of institutions, many surgeons have ordered genetic testing on their own patients. The non-respondents may represent a group even less likely to refer, and as such, our estimate of the frequency of counseling usage may be even lower. Further education is necessary in this group to reinforce the importance of genetic counseling prior to ordering testing.

The use of Concept Mapping to assess genetic counseling needs of prenatal patients. *A. Cronister[1], S. Bhatt[1], D. Cutillo[1], T. Cousineau[2].* 1) Genzyme Genetics, Phoenix, AZ; 2) Inflexxion, Inc, Newton, MA.

Purpose: Integral to the successful delivery of prenatal genetic services is providing patients with information they deem relevant. The study was designed to assess what patients perceive as important information in a routine prenatal genetic counseling session and compare this to what health experts consider most relevant. **Methods**: A structured program planning procedure called Concept Mapping (CM), was used to systematically analyze qualitative information generated from patients who had received genetic counseling (n=11), Genzyme genetic counselors (n=12) and perinatologists (n=8). This technique allowed for a direct and quantifiable comparison of differences among these various groups. **Results**: 61 statements were generated and sorted into 7 distinct cluster maps: Prenatal diagnostic testing, Prenatal screening, Genetic counseling information, Personalized genetic risk assessment, Carrier and ethnicity screening, General genetics information, Follow-up information and resources. A pattern match was generated using The Concept System software (Concept Systems, Inc, Ithaca, NY), allowing a comparison of how groups rated the content statements. Results demonstrated a high level of agreement between genetic counselors and physicians (r=.81). Moderate though strong agreement was noted between genetic counselors and patients (r=.58), which was greater than agreement between physicians and patients (r=.48). While all three groups rated information on testing and procedures as highly important, patients gave high importance ratings to most items overall and to wanting specific contact information from Genzyme, suggesting a consumer need for easy access to information. Data regarding all aspects of the CM process will be presented. **Conclusion**: CM allowed for direct and quantifiable comparison between patients and providers. Overall, there was high correlation between groups suggesting that patients, genetic counselors and physicians agree on the most important aspects of prenatal genetic counseling. Concept Mapping is a useful tool in the endeavor to discover efficient and effective ways to both educate patients and provide personalized risk assessment.

Psychosocial health service implications for genetic testing: A clinical and training needs assessment. *M. Cappelli[1], M.J. Esplen[2], J. Bottorff[3], B. Wilson[4], J. Allanson[1], J. Carroll[5], M. Dorval[7], C. Shuman[5], J. Millar[9], M. Bell[6], P.J. McGrath[8], M. Mullen[1], E. Humphreys[1], E. Wouterloot[1].* 1) Children's Hospital of Eastern Ontario & University of Ottawa, Ottawa, ON; 2) Toronto General Research Institute & University of Toronto, Toronto, ON; 3) University of British Columbia, Vancouver, BC; 4) University of Ottawa, Ottawa, ON; 5) University of Toronto, Toronto, ON; 6) Credit Valley Hospital, Mississauga, ON; 7) University of Laval,Laval, QC; 8) Dalhousie University, Halifax, NS; 9) Nova Scotia Dept of Health, Halifax, NS.

There is wide consensus that implementation of any new genetic services should be accompanied by a complementary psychosocial framework to ensure that patients understand as fully as possible the information they are being given and to enhance psychological adjustment to the implications of such information. Despite the acknowledged importance, an environmental scan and review of the literature identified no reports specifically addressing this issue. We conducted a Canadian national clinical and training needs assessment to determine the level of psychosocial need, as perceived by clinicians in direct contact with patients, identify the types and level of psychosocial services currently available, determine if these sufficiently meet current and projected future needs, and identify options for meeting needs. A survey was conducted(mail-out questionnaires and semi-structured interviews) of all Canadian geneticists (n=47) and genetic counselors (n=78) (total clinician response rate 64%;), medical directors of regional genetic centres and their satellite sites (16/21; 76%), genetic residency programs chairs (4/6), fellowship chairs (3/6), and directors of university genetic counseling training programs (3/3). Across all groups, the findings showed that there is a need for additional training in assessing and screening for psychosocial distress, more knowledge on how and when to triage for more specialized mental health care, and also, additional training for front-line staff on initial psychosocial interventions. A follow-up national study is now in progress addressing these issues.

Family History Tools for Underserved and Underrepresented Communities. *N.T. Robinson[1], S.F. Terry[1], P. Kyler[2], M. Lloyd-Puryear[2], Family Health History Coalition.* 1) Genetic Alliance, Washington, DC; 2) Genetic Service Branch, Maternal and Child Health Bureau, HRSA, HHS.

Purpose: To develop a toolkit to make family health history tools accessible to underserved & underrepresented communities (UUCs).

Methods: We convened a Family Health History Coalition - composed of major organizations working on family history tools. These included: the Genetics Services Branch of the Maternal & Child Health Bureau, Office of the Surgeon General, Centers for Disease Control and Prevention, National Institutes of Health, American Society of Human Genetics, American Folklife Center, Institute for Cultural Partnerships, National Society of Genetic Counselors, Genetic Alliance, UUC nonprofits, biotech companies & others. These organizations analyzed existing family history tools; conducted research, including focus groups, to create a guide to match UUCs with the best tool for them and refine that tool to meet their needs; & developed a plan to disseminate this information to UUCs and the field.

Results: A comprehensive survey of UUC needs in taking family health history; a thorough analysis of the strengths & weaknesses of tools in meeting those needs; & the outline of a resource to aid UUCs in taking better family health histories.

Conclusions: UUCs have unique needs in taking a family health history. These tools should be adapted to allow greater access, thereby reducing health disparities.

Project funded by the Genetics Services Branch of the Maternal & Child Heath Bureau, HRSA, HHS, though cooperative agreement #U33MC00214-04-00.

What do patients want: Informed consent models for genetic carrier testing. *K. Ormond, M. Iris, S. Banuvar, J. Minogue, S. Elias.* Northwestern Univ, Chicago, IL.

Recently, there has been an increase in the number of conditions for which patients can undergo genetic carrier testing. This raises the question of how best to provide patients with pre-test informed consent. Clinical approaches vary from a minimalist model (where patients are told various tests exist, with details provided if they test positive) to a model where patients are given data about all conditions to aid in decision-making. Little data exists as to patient preferences, or the impact on decision-making. This study assessed the knowledge and preferences of pregnant patients and male partners surrounding informed consent for carrier testing, and reactions towards two models of informed consent. Seven high-literacy focus groups were conducted to date, including 24 women and 13 men, from Caucasian, Latino and African American Backgrounds. Groups were moderated by non-genetics social scientist, transcribed and analyzed using ATLAS. Many groups agreed that carrier testing is perceived as relevant to the babys health, and minimized the focus on ones own genetic material. Overall, most groups felt that some balance between details and brevity was optimal, recognizing that anxiety can occur when patients are provided with too much information and that the wide range of tests offered during pregnancy often led to confusion. Women also felt that it was useful to have time to discuss carrier testing with their partners. Carrier testing was seen as different from other routine blood tests conducted in pregnancy. Critical areas for the informed consent process included (1) details about the conditions and risk of being a carrier (2) logistics of testing, (3) next steps if test positive, and (4) prognosis, options and resources if child was affected with disease. A list of reasons why people decide to have or not have testing was also proposed. While more data needs to be collected from low literacy groups, it will be useful to develop model consent programs and prospectively assess their impact on informed consent and patient satisfaction, both when positive and negative results are received. Funded by Friends of Prentice.

Attitudes on fragile X mutation carrier testing from women identified in a general population survey. *A. Anido[1], L.M. Carson[2], S.L. Sherman[1].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Emory Transplant Cetner, Emory Univ, Atlanta, GA.

Fragile X syndrome (FXS) is primarily due to a CGG repeat expansion found in the FMR1 X-linked gene. In a previous study, we conducted focus groups with women to assess their attitudes towards FXS carrier screening. In this follow-up study, we conducted in-depth interviews of general population reproductive-age women who were identified as carriers. We explored their attitudes toward testing for carrier status of the fragile X mutation. These women underwent screening primarily to participate in a research project rather than in search of a diagnosis. As such, these women were wholly unprepared for positive carrier results. Their responses about their results and carrier screening, in many cases, were being worked out over the course of the interview itself. The most salient finding of this work is the apparent lack of relevance of carrier status to these women. Many expressed that although the information could be relevant in the future, it is not relevant at this stage of their lives in terms of family planning (either with respect to having unaffected offspring or to premature ovarian failure) and personal relationships. Although issues of abortion seemed prominent in the focus groups, we found that carrier status did not have an apparent effect on womens attitudes about termination. We hypothesize this may be related to the fact that women had not processed their new carrier status and had not related it to previously-formed personal opinions. The findings of this work have significant implications for genetic counseling and population screening. Genetic counselors should be mindful that general population women may not recognize the immediate importance of their carrier status even when literature is discussed prior to providing a sample. In addition to standard counseling, counselors should identify the reproductive life stage of the women receiving the new information, help identify when this information would be useful, and personalize a flow sheet of specific services that will be more relevant to the women as their carrier status becomes more relevant.

How are Minnesota parents informed about newborn screening? *K.J. Johnson[1], S. Berry[2], D. Bartels[2], B. Leroy[2], L.A. Schimmenti[2].* 1) Genetics, Mayo Clinic, Rochester, MN; 2) Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

Newborn screening (NBS), performed in the United States since the early 1960s,remains one of the largest public health-based disease prevention programs. Since the emergence of NBS there have been no clear guidelines to explain testing to parents. Parents require information regarding NBS to minimize anxiety and improve compliance in the event of a positive screen (Newborn Screening Task Force). To examine how Minnesota parents are informed about blood spot and hearing screening, a phone/e-mail survey of 31 questions was conducted. The survey targeted the top 90% of birthing hospitals. Of 50 hospitals contacted, 35 responded (70%). We identified several differences in how hospitals provide information about blood spot and hearing screens. We found that for blood spot screening, 25 hospitals provided verbal information, 34 provided written information and 25 provided both. For hearing screening, 28 provided verbal information, 32 provided written information and 26 provided both. We also asked when informing occurred and found that 54% (verbal and written) informed prior to blood spot screen and 42% (verbal), 31% (written) informed prior to hearing screening. We reviewed copies of written information given to families and found that sometimes parents were given out-of-date materials lacking information on expanded NBS or referred to NBS as PKU screening. For hearing screening, we found parents were given a hospital made pamphlet providing up-to-date information. We also asked what was said and did not find evidence of consistent informing practices between hospitals. Through this survey, we identified areas that need improvement. We suggest that verbal information be scripted to ensure accurate conveyance of information and written information to be consistent and up-to-date, while informing parents about screening more than once using both verbal and written methods. Further educational efforts are needed to standardize the provision of newborn screening information to Minnesota parents.

Cystic fibrosis newborn screening: a pilot study to maximize carrier screening. *E. Lagoe, S. LaBella, G. Arnold, P.T. Rowley.* University of Rochester, Rochester, NY.

Newborn screening for cystic fibrosis (CF) is expanding because early diagnosis results in improved nutrition and growth. Most newborns identified by a mutation panel have a single detected mutation and require sweat testing to exclude an additional undetected mutation. The resulting identification of CF carrier newborns, though not the primary purpose of screening, has three potential benefits, (1) the detection of trait x trait couples, (2) presymptomatic testing of these couples previously born children who may have undetected CF, and (3) a carrier parent alerting extended family members to the chance of being a CF carrier. Reaping each benefit requires genetic counseling and acceptance of carrier testing by parents. The purpose of this study was to utilize the sweat testing visit to educate parents about the value of carrier testing for themselves and their blood relatives. We compared *special care* (communicating their newborn's sweat test result, providing genetic counseling, and offering carrier testing to parents, all on the sweat test visit) vs. *standard care* (sweat test result reported by phone to the parent by the newborns physician the next day, ideally with the recommendation to arrange genetic counseling and parental carrier testing). In the first year of NYS CF screening, 64 newborns with one detected mutation were reported in the nine-county region that includes Rochester. Of these, parents of 39 agreed to participate in the study and to be randomized to *special* or *standard* care. Of 61 participating parents, 23 had carrier testing after the birth of the baby. The frequency of such parental testing was significantly higher in the *special* care group (17/34 or 50%) than in the *standard* care group (6/27 or 22%)(p0.05).

This is the first evidence from a randomized trial that parental genetic counseling and carrier test offered on the sweat test visit increases identification of carrier parents. Such identification detects trait x trait parents and facilitates carrier testing of relatives.

Evaluation of informativeness of microsatellite markers for carrier testing of dystrophic epidermolysis bullosa in Tunisia. *H. Ouragini[1], W. Daoud[2], F. Cherif[2], S. Chakroun[1], C. Charfedine[1], S. Boubaker[3], A. Ben Osman-Dhahri[2], S. Abdelhak[1].* 1) Molecular Investigation of Genetic Orphan Diseases Institut Pasteur de Tunis, Tunis, Tunisia; 2) Dermatology department, Hôpital de La Rabta, Tunis, Tunisia; 3) Anatomo-Pathology service, Institut Pasteur de Tunis, Tunisia.

Dystrophic Epidermolysis Bullosa (DEB) is a clinically heterogenous blistering disorder of the skin and mucous membranes characterized by abnormalities in the anchoring fibrils (AF) and loss of dermal-epidermal adherence. It is inherited in either autosomal dominant or recessive mode. Mutations within the *COL7A1* gene (3p21) which encodes collagen VII, the major component of the AF, have been shown to be responsible for DEB. *COL7A1* is composed of 118 exons overlapping 32Kb. More than 200 mutations have been identified and most of them correspond to private mutations. Mutation screening is hampered by the size of the *COL7A1* gene and by the mutation heterogeneity. Analysis of polymorphic markers may provide a rapid and relatively easy method to identify carriers for genetic counselling. Our aim is to evaluate the informativeness of polymorphic markers for carrier testing of DEB in Tunisian families at risk. For this purpose, six consanguineous Tunisian families with at least one affected child have been analysed. Transmission of the disease within these families follows an autosomal recessive mode. All family members were genotyped with five microsatellite markers overlapping the *COL7A1* gene. The genetic map of this region is: cen-D3S1568, D3S3629, (*COL7A1*), D3S643, D3S1478, D3S3582-tel. For the two closest markers to *COL7A1*, D3S643 was fully informative in the six families and D3S3629 was fully informative in 5 families and partially in 1 family. Taking into consideration the informativeness and distance of these 2 markers to *COL7A1* (10Kb and 80Kb respectively), we propose the use of their use for carrier testing of DEB in North African population.

High frequency of familial cardiovascular risk in a cancer genetics clinical population suggests the need for genetics services for adult-onset cardiovascular disorders. *A. Sturm, E. Varga, C. Eng.* Division of Human Genetics, The Ohio State University, Columbus, OH.

Cardiovascular disease (CVD) is the number one killer of men and women in the United States and other developed countries. Substantial evidence exists that genetic factors play a role in the risk for CVD. Previous studies have shown that up to 10% of individuals have a high familial risk and could benefit from risk factor modification, biochemical screening, early detection strategies, and genetic counseling. Family history has been shown to be a comprehensive and overall accurate initial method for the identification of high-risk individuals. This study was undertaken to assess the number of individuals attending a cancer genetics clinic who were also at high familial risk for coronary artery disease and/or thrombosis. Genetic counselors received inservice training regarding the clinical presentation and risk factors associated with CVD and collected pedigree data during the initial consultations for patients seen in the Clinical Cancer Genetics Program at The Ohio State University over a six-month period. Following initial consultation, two adult cardiovascular genetic counselors independently reviewed family history data and assigned high familial risk status based on published criteria. The proportion of high familial risk individuals in this clinical population was determined. Preliminary data over two months indicates that 31% (12/39) of patients referred for clinical cancer genetics consultation are also at high familial risk for CVD. These individuals require more aggressive management, including the assessment of biochemical and genetic risk factors and markers, the potential for early detection of subclinical disease, and the provision of a personalized prevention plan. Genetics professionals in various subspecialties who routinely obtain family history information will identify high risk for CVD in a considerable proportion of their patients. Because the opportunity for prevention of CVD in high risk individuals exists, the number of cardiovascular genetics programs whose focus is prevention of adult-onset disease should increase.

Knowledge of CanMEDS 2000 roles and competencies among medical genetics residents. *M. Capelli[1,2], G.E. Graham[1,2].* 1) Depts of Genetics, Pediatrics and Psychology, Children's Hospital of Eastern Ontario; 2) University of Ottawa, Ontario, Canada.

Medical Genetics has been a primary specialty of the Royal College of Physicians and Surgeons of Canada (RCPSC) since 1989 and requires 5 years of clinical training beyond medical school. Like all specialty programs, Medical Genetics adheres to a national framework approved by the Royal College in 1996. CanMEDS (Canadian Medical Education Directives for Specialties), explicitly describes 7 essential roles common to Canadian specialist physicians, each with their own set of specialty-specific competencies. Specialty programs are required to incorporate these roles and competencies into their accreditation standards, objectives of training, in-training evaluations and final exam blueprints. CanMEDS was divided into phases: Framework Development (1990-96), Pilot Projects (1996-97), Implementation (1997-2002) and Faculty Development (2003-). This framework is now extensively implemented in Canada and has attracted international attention from medical educators. We surveyed 20 of 22 (91%) English-speaking Canadian Medical Genetics residents outside the province of Quebec between March and May 2005. All were from programs that had implemented the CanMEDS framework. None were able to correctly expand the acronym CanMEDS. The percentage of residents able to name the individual CanMEDS roles was: Medical Expert (15%), Communicator (10%), Collaborator (10%), Manager (10%), Health Advocate (10%), Scholar (5%) and Professional (15%). On a 5-point Likert scale (1=none and 5=heavy), residents reported the following mean emphasis in their programs: Medical Expert (4.15), Communicator (3.8), Collaborator (3.45), Manager (2.75), Health Advocate (2.9), Scholar (3.4) and Professional (3.65). When provided with the CanMEDS roles, the percentage of residents able to correctly match descriptors with their respective roles varied with the descriptor: Medical Expert (35%-80%), Communicator (35%-45%), Collaborator (60%-75%), Manager (20%-85%), Health Advocate (75%-80%), Scholar (50%-75%) and Professional (70%-95%). Is CanMEDs truly changing postgraduate medical education?

Video self-assessment in the acquisition of CanMEDS competencies in medical genetics. *G. Graham[1,2], M. Capelli[1,2].* 1) Departments of Genetics, Pediatrics and Psychology, Children's Hospital of Eastern Ontario; 2) University of Ottawa, Ontario, Canada.

Medical genetics residencies and clinical genetics fellowships focus on the acquisition of consultancy skills for a large variety of patient presentations, including those requiring prenatal counselling, cancer genetic counselling, the diagnosis and management of genetic syndromes (dysmorphology) and the diagnosis and management of inborn errors of metabolism. In Canada, the training of geneticists is almost exclusively based on traditional approaches. In both inpatient and outpatient clinic settings, all programs routinely use one-on-one teaching by a staff geneticist before, during and following a patient encounter. Practice OSCEs (Objective Structured Clinical Exams) with standardized patients are regularly used in four of the seven residency programs. Video recording is not regularly used in any program. A search of the PubMed database using various combinations of genetics, counselling, training and video produced no publications addressing the use of video recording in the training of genetics residents or fellows. Following REB approval and with informed consent, 20 of 22 Canadian medical genetics residents and clinical genetics fellows have agreed to participate in a research project involving a 30 minute video-recorded OSCE scenario using a single standardized patient and a single staff geneticist observer. Using a CanMEDS assessment tool, we are measuring concordance between the residents self-assessments before and after video review of their performance; concordance between residents self-assessments and those of the staff geneticist; and concordance between the assessments of the resident, standardized patient and staff geneticist. All residents and fellows are also completing pre-and post-OSCE surveys examining their attitudes and preferences regarding the use of OSCE scenarios, physician observers and videotaping in clinical training. Data collection will finish in July 2005 and data will be summarized using descriptive statistics. Concordance and pre-post data will be analyzed using Chi-square analysis or paired t-tests.

Long-term follow-up of "Genetics in Primary Care", a faculty development intiative for primary care providers.

A.M. Laberge[1], K. Fryer-Edwards[1], P. Kyler[2], M. Puryear[2], W. Burke[1]. 1) University of Washington, Seattle, WA; 2) Health Resources and Services Administration, Dept of Health and Human Services, Rockville, MD.

The Genetics in Primary Care (GPC) project, a national faculty development initiative, offered train the trainer workshops for primary care providers (PCP) with teaching responsibilities, using case-based teaching modules. Between October 2000 and April 2001, 79 participants from 20 U.S. medical training programs participated in the workshops. In 2004-2005, follow-up interviews were conducted by phone with 27 individuals from 10 sites. Among PCP, all respondents had made changes to their teaching practices following their participation in GPC, and 86% also reported changes to their clinical practice. Over four years later, 55% report a greater interest in genetics than before GPC. The most appreciated aspect of the project was the interdisciplinary collaboration (55%). Most commonly cited difficulties were maintaining the level of enthusiasm over time (36%), finding time (27%) and convincing other PCP of the relevance of genetics in their practice (23%). All of the PCP respondents have used the GPC materials for teaching purposes. Among genetics experts, all reported making changes to their teaching practices since their involvement in GPC, but only 20% reported changes in their clinical practice. 60% had little or no contact with PCP before GPC, but all showed interest in working with PCP in the future. For the genetics experts, maintaining enthusiasm over time was the hardest part of the project (40%), and interdisciplinary collaboration the most interesting (80%). 60% of the genetics experts used the GPC materials for teaching purposes. Of all respondents, 22% spontaneously reported that their participation in GPC was the launching point to getting a new position or participating in other projects. All would recommend a similar project to their colleagues. GPC has had lasting effects on participants' teaching and clinical practices, and has encouraged interdisciplinary collaboration. Future efforts will need to address sustainability issues.
Supported by HRSA Contract No.240-MCHB-20(1)MJS.

Medical school use of "Genetics in Clinical Practice: A Team Approach". *W.A. Faucett[1,2], H. Smith[3], N. Lamb[1], D. Waggoner[4].* 1) Dept of Human Genetics, Emory Univ Sch of Med, Atlanta, GA; 2) Center for Disease Control (CDC)and ORISE, Atlanta, GA; 3) Un of Arkansas Med Schl Library, Little Rock, AK; 4) Dept of Human Genetics, Univ of Chicago, Chicago, IL.

Introduction:*Genetics in Clinical Practice: A Team Approach*is an interactive cd-rom/web educational tool originally designed to provide 10+ hours of genetic education for practicing physicians. Developed by Dartmouth Medical School and the CDC it simulates a clinical rotation in genetics using current medical conditions (CF, colon cancer, hemochromatosis, Fragile-X). This educational tool was incorporated into the curriculum of the University of Arkansas Medical School(UAMS), Emory University School of Medicine(EUSM) and the Pritzker School of Medicine at University of Chicago(PSMUC). **Methods:** At each school the program was introduced to first or second year students. UAMS students were required to complete one patient scenario followed by a 36 question survey. EUSM students completed 6 of the 7 patient scenarios over 4 weeks, with weekly assignments and small group discussion sessions, followed by an optional 7 question survey. PSUMC students completed one of the patient scenarios and a 5 question survey to receive credit. Use of the cd-rom consitituted 5% to 10% of the student's grades. **Results:**Surveys found that 95% of the PSMUC students felt the program was a useful part of the class. Similarly, 90% of the UAMS and 89% of the EUSM students found the "patient encounters" useful. 92% of the PSMUC students felt that the cases augmented their class learning. 81% of UAMS and 87% of EUSM students felt the program contained "just the right amount" of information. Over 60% of UAMS and EUSM students felt the material was relevant to practicing physicians and 79% of the UAMS and 71% of the EUMS students felt they learned more than or the same amount that they could have learned in a real clinical setting. 89% of the PSMUC students recommended using the program in future classes. **Conclusion:**This educational tool is highly rated by medical students and can be successfully utilized in both medical school and healthcare training programs to simulate patient experiences in a genetic context.

Constructivist Learning Theory in Genetics Education. *K.U. King, J. DeLuca, R. D'Aoust, J. Clements.* Univ Rochester, Rochester, NY.

Background: Inclusion of genetics curriculum in health education is essential to the clinical care of individuals, families and communities throughout the lifespan. Cognitive learning takes place in social interactions; the quantity and quality of these interactions impact the acquisition of critical thinking. Application of this theory is pedagogically consistent with educational needs of adult-learners. Purpose: To explore the implementation of constructivist learning theory conceptualized as collaborative, problem-based-learning in genetics education. Intervention: For 60 students, we designed and implemented group-based, social and adult learning activities that incorporate relativism or value of learning, bridging knowledge from previous-to-new in directed-problem-based learning. We anticipated that students would acquire higher order thinking skills to further apply genetics knowledge in novel situations encountered in clinical practice through complex thinking and collaboration. Individual students explored one genetic entity in-depth and collaborated in group projects and later prioritized findings for group presentations. Half of the groups developed expertise in Mendelian entities and half developed expertise in multifactorial entities. Assessment of this strategy consisted of student and faculty appraisal of individual and group projects and compilation of formal course evaluations. Findings/Outcomes: Students reported overall satisfaction with individual and group-based learning activities; they expressed that the groups were too large, and that they would have benefited from exploring more than one entity. Because students represent diverse backgrounds, they expressed satisfaction with the mutual development of skills as compared to traditional unidimensional learning. Faculty reported satisfaction with the process and outcomes of group learning projects. Interpretation/Discussion: Implementation of constructivist learning theory is a novel approach to genetics education. More follow-up is needed in to determine the application and generalizability of complex social and collaborative learning in clinical settings post-graduation as well as the specific application of genetics knowledge and principles to clinical care.

Sharing Cx26/Cx30 genetic test information with family members. *T. Blase[1], A. Martinez[2], W.W. Grody[2], L.A. Schimmenti[3], C.G. Palmer[2].* 1) California State University Northridge, Northridge, CA; 2) University of California Los Angeles, Los Angeles, CA; 3) University of Minnesota, Minneapolis, MN.

Although clinical genetic testing for Connexin26/Connexin30 (Cx26/Cx30) is available, there is limited information regarding the sharing of test results and the effects of this genetic test information on families. A qualitative study was conducted to elucidate if, how, and why parents of children with hearing loss who have had Cx26/Cx30 genetic testing share the genetic test results with relatives. Parents of a child with hearing loss who had Cx26/Cx30 testing (n=7 positive results, n=4 negative results, n=1 inconclusive result) participated in a semi-structured interview. All participants shared their childs genetic test result with at least one relative. The reasons for sharing were diverse and differed as a function of the test result. *Duty to inform* was a common reason given by participants who received positive test results, but never voiced by participants who received a negative or inconclusive test result, suggesting that only those parents who receive positive Cx26/Cx30 test results feel that this information has a meaningful impact on their family members. Family members learning of a positive Cx26/Cx30 result were reported to express *surprise* while relatives learning of a negative test result were *unsettled* by this result. While a variety of reactions of relatives to the genetic test results were reported, relatives of individuals with positive test results expressed a wider range of emotions compared to those with negative or inconclusive test results. Similar to the disclosure process of genetic information to relatives for other conditions such as cystic fibrosis and hereditary breast/ovarian cancer, individuals whose child had Cx26/Cx30 genetic testing share genetic test information with close relatives, however, the etiologic heterogeneity of hearing loss affects the reasons for disclosure and responses of family members to Cx26/Cx30 test information. These differences suggest that hearing loss may have unique attributes that influence responses to genetic test information.

Real Time PCR Strategy for Newborn Screening in Spinal Muscular Atrophy. *T.W. Prior, R.E. Pyatt.* Pathology, 121 Hamilton Hall, Ohio State Univ, Columbus, OH.

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disease characterized by degeneration and loss of the anterior horn cells and associated progressive muscle weakness. 95% of affected individuals will have a homozygous deletion of exon 7 in the SMN1 gene. While a number of potential therapies are currently in clinical trials, their success may depend on identifying individuals as early as possible to begin treatment before potentially irreversible neuronal loss. Thus we have investigated the utilization of newborn blood spots for the early detection of SMA. Any potential screening protocols for SMA must demonstrate no overlap between affected individuals and carriers, utilize a minimum of target DNA, and most importantly distinguish the SMN1 gene from the SMN2 centromeric copy which has greater than 98% sequence homology. We have developed an assay for the detection of homozygous deletions in SMN1 exon 7 from neonatal blood spots using the Real Time PCR system. To specifically detect levels of SMN1, each reaction contained a competitive, non-extending oligo for SMN2 exon 7 in addition to a primer/probe set specific for SMN1 exon 7. 156 DNA samples extracted using a standard salting out method including 85 affecteds and 67 carriers were used to validate the assay specificity. Regardless of SMN2 copy number (0-5), normal individuals and carriers were distinguished from affected individuals in all cases based on amplification curves and cycle thresholds. Finally, we tested a series of 63 samples extracted from 50ul whole blood spots using a rapid purification protocol from Gentra which included 24 carriers and 16 affecteds. In all cases, affected samples were distinguished from carriers and normals regardless of their SMN2 copy number and with no amplification failures. Thus we have developed an automated and sensitive assay for the detection of SMN1 homozygous deletions with a potential application in newborn screening programs.

One of six founder mutations account for nearly 75% of all BRCA1/2 mutations in French Canadian women attending two McGill University high-risk clinics. *K.V. Kotar[1,2,4], K. Osczevski[3], L. Yamani[1], M. Galvez[1,4], N. Hamel[1,4], E. Ferrara[1], P. Tonin[1,3,4], W.D. Foulkes[1,2,3,4].* 1) Div. Medical Genetics, Dept Medicine, McGill Univ. Health Centre, Montreal, QC, Canada; 2) Cancer Prevention Centre, Sir M.B.Davis-Jewish General Hospital, McGill Univ., Montreal, QC, Canada; 3) Dept Human Genetics, McGill Univ., Montreal, QC, Canada; 4) Research Institute, McGill Univ. Health Centre, Montreal, QC, Canada.

The identification of founder mutations in the French Canadian (FC) population of Quebec has simplified genetic testing. Oros et al (2004) found that in cancer-dense FC breast/ovarian cancer families (FCBOCF), one of five founder mutations accounted for 84% of all BRCA1/2 mutations. We set out to determine the proportion of BRCA1/2 mutations in a clinic population of FC women eligible for BRCA1/2 testing that are attributable to six identified founder mutations [BRCA1: (4446C>T, 2953del3+C); BRCA2: (8765delAG, 6085G>T, 6503delTT, 3398del5)]. FC probands were defined as francophone individuals having at least three grandparents born in Quebec. Of tested probands, 35/219 (15.9%) carried founder mutations [4446C>T (n=11), 2953del3+C (n=3); 8765delAG (n=14), 6085G>T (n=5), 6503delTT (n=1), 3398del5 (n=1)]. Two had non-founder BRCA1 mutations, (1135insA and 3875del4) identified serendipitously. Of 182 probands left, 125 were not tested further. The remaining 57 probands were sent to Myriad Genetics for further testing where nine (15.8%) were positive for a BRCA1 mutation (one each for 3875del4, 241C>T, 5641A>C, 4160delAG, two for 3773delTT, and three for 1061G>A), one had a BRCA2 mutation (2558insA) and 47 had no mutation detected. Thus 12/47 (25.5%) BRCA1/2 mutations were non-founder mutations. By haplotype analysis, the 1061G>A mutation has a common origin in the FC population but was not seen in other FCBOCF. As BRCA1/2 genomic deletions are rarely seen in this population (Moison et al, 2003), these 6 founder mutations account for ~75% of all BRCA1/2 mutations in the FC population. Hence, we conclude that pre-screening of all clinic-based FC patients for these six mutations is recommended prior to large-scale mutation analysis of both cancer susceptibility genes.

Quality Management and Quality Assurance in Molecular Genetic Testing Laboratories. *E. Dequeker[1], S. Berwouts[1], J.J. Cassiman[1], M.A. Morris[2].* 1) Human Gen/Gasthuisberg O&N 6, Univ Leuven, Leuven, Belgium; 2) Medical Genetics Service, Geneva University Hospital, Switzerland.

Genetic testing services in Europe have substantially increased their activity in the past few years. Testing for genetic diseases has rapidly moved from the laboratory into medical practice and, in this process, issues of quality require adequate attention. The organization of annual external quality assessment schemes in Europe, complemented by regional workshops on quality, has demonstrated that quality assurance is essential in order to minimize errors in genetic services. It has been conclusively shown that errors and deficiencies can occur everywhere during the processes of sampling, genetic testing, interpretation, and reporting of results. The introduction of international standards for quality and competence in laboratories, together with a growing interest in accreditation of laboratories, has increased the need for a better understanding of quality management and quality assurance. The International Organization for Standards (ISO) defines quality as the degree to which a set of inherent characteristics fulfils requirements. The EUROGENTEST* network aims to help and guide medical genetic laboratories in order to better understand this type of standards language that is used by accreditation bodies. An educative website will be constructed with links for each EU country to relevant information on accreditation bodies, contact persons, coordinates of the national standardization institutes, and explanations of terminologies. Furthermore, a database will be prepared to publicize with relevant information on quality assurance in European laboratories. Finally, a study is planned to calculate the real cost for implementing and maintaining a quality management system in a genetic service laboratory. *EUROGENTEST is an EU project of 6th framework - Genetic Testing in Europe - Network for test development, harmonization, validation and standardization of services.

Applicability and cost-effectiveness of the genetic test of adult-type hypolactasia in diagnosis of gastrointestinal symptoms in Finnish adults. *H. Rasinperä[1], S. Tikkakoski[2], A. Kotamies[3], H. Komu[1], I. Järvelä[1,4], K-L. Kolho[2].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland; 3) Helsinki Center of Economic Research, Helsinki, Finland; 4) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland.

Gastrointestinal symptoms are common in everyday clinical practice. In this study we have evaluated the applicability and cost-effectiveness of the genetic test of adult-type hypolactasia by genotyping the single nucleotide polymorphism C/T_{-13910} associated with this trait. DNA of 1916 Finnish patients aged 18 to 64 years with or without gastrointestinal symptoms in outpatient clinics in capital area of Helsinki, were analysed by PCR-minisequencing. The participants filled in structured questionnaires concerning consumption of milk products and gastrointestinal problems. The frequency of the C/C_{-13910}-genotype associated with lactase non-persistence was 18%. Subjects with the C/C-genotype drank significantly less milk than those with the C/T- or T/T-genotypes associated with lactase persistence: 18% of the C/C-genotypes drank milk with meals compared to 38% and 36% of the C/T- and T/T-genotypes ($p< 0.01$). Based on preliminary analysis the C/C-genotype (84%) was related to gastrointestinal problems during the last three months more often than the C/T- or T/T-genotypes of lactase persistence (79% and 78 % respectively; $p< 0.05$). Bloating and flatulence was experienced by 53% and 79%, respectively, of those with the C/C-genotype (OR: 1.20 and 1.19, compared to the T/T-genotype). Moreover, our preliminary results in this population demonstrate that lactose tolerance test (LTT) in diagnosis of lactose malabsorption is even more inaccurate than earlier suggested. In conclusion, the genetic test for hypolactasia is a cost-effective method for primary screening of unspecific gastrointestinal symptoms in populations where the use of dairy products is common. The genetic test has been well accepted in the Finnish health care by the patients.

Metylenetetrahydrofolate Reductase Polymorphism as maternal risk for Down Syndrome among Venezuelan Women. *W. Zabala, Z. Butron, S. Gonzalez, L. Borjas, MG. Portillo, K. Urdaneta, A. Morales-Machin.* Medical Genetic Unit, Univ Zulia, Maracaibo, Venezuela.

Down syndrome (DS) is the most commonly identified chromosome abnormality in humans attributed to the presence of three copies of chromosome 21 and is a major cause of pregnancy loss and mental retardation. Several studies indicated that the origin of the extra chromosome is maternal in about 80-90% of cases. Advanced maternal age is yet the only well-documented risk factor for nondisjunction, while the underlying mechanism remains unexplained. Recently, the C677T polymorphism in the methylenetetrahydrofolate reductase (MTHFR) gene has been related to maternal risk for DS. The hypothetical effect of C677T into maternal no-disjunction was liked to an altered DNA methylation pattern on the oocyte, secondary to reduced MTHFR activity of folate metabolism. In order to, determine the relation between the presence of the polymorphic variant 677T in MTHFR gene and the increased risk to have children with DS, we examined the C677T in 50 mothers of children with SD (MSD) and 50 mothers studied control (MC). Following DNA isolation, the MTHFR C677T polymorphism was analyzed by polymerase chain reaction and allele specific restriction digestion with Hinf I. Allele frequencies were calculated for each genotype, and the differences in allele frequencies between MSD and MC were determined using chi-square test. Odds ratios for both the heterozygous and homozygous mutant genotypes, was compared with the wild types, as a measure of association between the MTHFR genotypes and the maternal risk of SD. Genotype frequencies in the MSD were CC: 54%, CT: 34% and TT: 12%, and in the MC were 36%, 58% and 6% respectively, whereas the calculation of the relative risk (OR) was CC/CT OR: 0,39 [0,16- 0.90]; CC/TT OR: 1,33 [0.29 - 6.02]; CT + TT OR: 0,48 [0,21- 1.06]. The data presented in this study fail to support the relationship between MTHFR C677T polymorphisms and risk of having a child with DS.

The complete reversion of a FRAXA premutation to a normal allele: implications for Fragile X genetic testing. *R. Polli, A. Casarin, L. Anesi, M. Martella, E. Leonardi, A. Murgia.* Dept Pediatrics, Univ Padua, Padua, Italy.

Fragile X Syndrome is the most common form of inherited mental retardation. The underlying molecular mechanism is the expansion of a series of (CGG)n repeats in the 5 untranslated region of the FMR1 gene. Expansions beyond 200 repeated elements are associated to methylation of the entire region, which is responsible of transcriptional silencing and loss of FMR1 protein. Rare cases have been reported in which the alteration was a point mutation or deletion of FMR1. Abnormal repeat expansions cause instability and lead to complex conditions of mosaicism in which Fragile X pre and full mutations, and even deletion/reversion patterns, are seen in the same individual. We report the case of a Fragile X family in which two independent events of complete reversion of a premutation to normal allele have occurred. A mother carrier of a Fragile X premutation with more than 70 CGG triplets, and a normal allele of 31 repeats was referred to our center for prenatal diagnosis in her second pregnancy. The molecular analysis was performed with PCR amplification and Southern blot on DNA on DNA from CVS sampling at the 13th week of gestation. The female fetus carried two normal X alleles: the paternal one with 24 repeats and a second one with 38 CGG trinucleotides; no evidence of mosaicism was detected. The first child, who was referred as mildly mentally retarded, was also tested. The Southern blot analysis showed a single fragment, corresponding to an apparently normal X allele and failed to detect the presence of other Fragile X expanded fragments. This allele was then characterized by PCR which obtained the amplification of a main product with 34 CGG repeats but also showed the presence of other, extremely underrepresented products suggesting a condition of instability in the Fragile X region. This finding has important consequences in the evaluation of appropriate strategies for Fragile X molecular analysis. The known frequency of somatic mosaicism, and the possible occurrence of complete reversions of FRAXA mutations strongly argue for a very careful evaluation even of normal-size alleles, particularly in Fragile X families.

Identification of -galactosidase A mutations in females at-risk for Fabry disease: correlation of mutation status with clinical manifestations. *J. Wiszniewska[1], E. ORourke[2], K. Hoon[1], S.A. Darilek[1], A. James[1], M.J Darilek[1], J.A. Barranger[2], B.B. Roa[1], C.M. Eng[1].* 1) Dep of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Genetics, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Fabry disease (FD) is an X-linked lysosomal storage disorder caused by deficiency of -galactosidase A (-GalA), leading to progressive deposition of glycosphingolipids, primarily globotriaosylceramide (GL-3) in the vascular endothelium and cells throughout the body. The phenotype in heterozygous females ranges from being asymptomatic, to manifesting some symptoms with age, to females with clinical symptoms as severe as classic male patients. Identification of heterozygous females by enzymatic determination of -GalA activity is unreliable as the sole diagnostic test and current recommendations advise molecular testing for all at-risk females with a family history and/or symptoms compatible with the disorder. In a series of 92 females studied for GLA gene mutations, GLA mutations were identified in 30 of 65 (46%) females who were referred for DNA testing solely due to having a family history of the disease and 16 of 16 females (100%) who had a positive family history as well as reporting some symptoms consistent with FD. Enzymatic activity in these females fell into a broad range, from normal to severely decreased. There was no apparent correlation between degree of enzyme activity and clinical manifestations in these females. GLA mutations were found in three of eleven females (27%) referred for symptoms consistent with FD, but with no known family history. All three women with GLA mutations had decreased -GalA activity and renal manifestations, while the females without identified GLA mutations were referred for indications such as possible acroparesthesias and angiokeratoma. Our experience demonstrates the value of GLA mutation analysis in female patients for whom a diagnosis of Fabry disease is being considered. Presence of symptoms in females with a family history and renal manifestations in females with no family history were strong predictors of mutation status.

Evaluation of a new microfluidics format for the detection of cystic fibrosis (CF) mutations using crudely prepared DNA lysates. *K.G. Monaghan, D. Bluhm.* Dept Medical Genetics, Henry Ford Hosp, Detroit, MI.

InPlex (Third Wave Technologies, Inc.), is a new method for CF mutation detection using multiplex Invader reactions. The assay involves target amplification of a DNA template, followed by standard Invader reactions performed within the channels of a plastic card. The assay tests for 41 CF mutations (including the 23 ACMG recommended mutations), I148T, F508C and the 5T, 7T and 9T alleles. The turn-around time from sample preparation to result is approximately 3.5 hours, with less than 30 minutes of hands-on time required to analyze up to 93 samples. To further decrease time and costs related to DNA extractions, we evaluated this assay using crudely prepared DNA lysates. The only difference in the method used for the crude lysates compared to highly purified DNA template was an increase in the number of amplification cycles from 14 to 15. Amplified DNA was then mixed with buffer and Cleavase, loaded onto an InPlex card and incubated. Cards were analyzed using a fluorescent plate reader. Samples were scored as either wild type, heterozygous, homozygous mutant or equivocal for each mutation analyzed. We ran a total of 87 lysates over the course of 3 independent assays, each with a normal control, positive control and no DNA control. Each lysate used was previously analyzed for CF mutations by another method. Of the 87 samples, 83 were negative for mutations previously screened (ACMG 25 plus 7 additional mutations). One sample was a known 3120+1GA heterozygote and 3 were known F508 carriers. All lysates derived from samples known to be positive for a CF mutation yielded the expected result. Of the 83 samples negative for the previously tested mutations, we identified 2 that were heterozygous for a mutation included in the InPlex assay (D1152H and D1270N) but not included in the original genotyping performed in the laboratory. Of the remaining 81 samples, 6 were called as equivocal and 3 yielded a low signal with uninterpretable results. There were no false positive or false negative calls using crude lysates with the InPlex assay. We are working to decrease the equivocal calls and low signals by adjusting cycling and incubation conditions.

Identification of female carriers of DMD/BMD using real-time PCR and fluorescence gene dosage PCR. *E.K. Ra[1], M.W. Seong[1], S.I. Cho[1], S. Hong[1], J.Y. Kim[2], S.S. Park[1].* 1) Laboratory Medicine, Seoul National University Hospital, Seoul, Seoul, Korea; 2) Central Blood Laboratory Center, Korean Red Cross, Seoul, Korea.

Duchenne/Becker muscular dystrophy (DMD/BMD) is a severe X-linked myopathy, of which two thirds are caused by exon deletions within the dystrophin gene. Carrier detection is very important for the prevention of the disease, but deletion assay is affected by the presence of one normal X chromosome in the carrier. Although several methods such as Southern hybridization, quantitative PCR with radioisotope and FISH have been developed for carrier test, each has several disadvantages. We developed simple and rapid carrier test using real-time quantitative PCR and fluorescence gene dosage PCR, and performed on 14 female relatives (8 carriers and 6 non-carriers) of 10 DMD patients who had confirmed to have exon deletion. Dosage of deleted exon for each subject was determined by calculating ratio of deleted to non-deleted exon and followed by comparing this value to the ratio of normal control for both methods. Real-time PCR was done using primers and probes specific for each deleted or non-deleted exon and ABI Prism 7700 sequence detector. The fluorescence gene dosage PCR was carried out by 18-cycle amplification with fluorescence labeled primers and followed by analyzing on ABI 3100 genetic analyzer. Carrier status was accurately identified in all cases by both methods. The gene dosage range in carriers was 0.40 to 0.56 (0.450.05) with real-time PCR, 0.42 to 0.55 (0.500.05) with fluorescence gene dosage PCR, and, in non-carriers, 0.81 to 1.00 (0.910.08) with real-time PCR and 0.95 to 1.14 (1.020.07) with fluorescence gene dosage PCR. The coefficient variations of gene dosage determined by fluorescence gene dosage PCR were 2.4 to 4.1% in carriers and 2.4 to 5.9% in non-carriers. In conclusion, real-time PCR and fluorescence gene dosage PCR were simple, rapid and accurate method to identify female carriers of DMD/BMD and could be applied to determine gene dosage in other diseases with gene duplication or deletion.

National CF Program in Chile: analysis of common CFTR mutations in 190 patients. *G.M. Repetto[1], A. Puga[1], M.L. Boza[2], M.A. Perez[3], O. Fielbaum[4], M. Betancourt[5], C. Pierry[6], M. Linares[7], M. Mendez[7], M. Oelcker[8], J. Silva[8], P. Astudillo[9], and members of the National CF program, Chile.* 1) Dept Genetics, Clinica Alemana-Univ Desarrollo, Santiago, Chile; 2) H. San Borja Arriaran; 3) H Exequiel Gonzalez Cortes; 4) H Luis Calvo Mackenna; 5) H Regional de Temuco; 6) H San Juan de Dios; 7) H Padre Hurtado y Sotero de Rio; 8) H. Regionales de Concepcion y Talcahuano; 9) Ministerio de Salud de Chile.

A National Cystic Fibrosis (CF) Program was initiated in Chile in 2000 to improve access to diagnosis and therapy for known patients in the country. Three hundred individuals have been registered, accounting for more than 90% of known patients. The Program has included access to molecular diagnosis for the registered patients since 2004. We report the findings of 191 unrelated patients with CF that were analyzed for the presence of 32 common mutations by PCR-OLA using Cystic fibrosis v3.0 ASR (Celera Diagnostics, USA). The overall detection rate was 40.1%, similar to other Latin American countries. Ten mutations were found: deltaF508 in 29% of alleles, G542X, R334W, 3849+10kb C>T, W1282X, R1162X with frequencies between 1 and 3% each, and G553X, G85E, 1078delT and G551D with less than 1% each. The polymorphic extragenic markers XV-2c and KM.19 were evaluated in twenty families of individuals with no mutation identified. There was no difference in haplotype distribution between the mutant alleles compared with the alleles not transmitted by the unaffected carrier parents. These results emphasize the need to improve the mutation detection rate in the country.

Detection of glycine substitutions in the amino end of type I collagen by biochemical screening of fibroblast collagen requires supplementation by direct sequencing for osteogenesis imperfecta probands. *W.A. Cabral, S. Milgrom, E. Moriarty, J.C. Marini.* BEMB/NICHD/NIH, Bethesda, MD.

The biochemical test for osteogenesis imperfecta detects structural abnormalities in the helical region of type I collagen as delayed electrophoretic migration of alpha chains synthesized by cultured fibroblasts on SDS-Urea-PAGE. The sensitivity of this test is based on overmodification of alpha chains in helices with a substitution of an invariant glycine residue in a Gly-X-Y triplet. Substitutions delay helix folding locally, allowing excess glycosylation of OH-lysine residues. Biochemical testing is most sensitive for substitutions in the carboxyl end of a chain because helices fold in the carboxyl to amino direction. Although the standard biochemical test has been used for 2 decades, the limits of detectability are unreported. We compared the electrophoretic migration of normal fibroblast collagen from 30 patients with clinical OI (types III or IV) and known mutations in the amino half of the 1(I) and 2(I) chains of type I collagen and found that sensitivity differed for each chain. Sensitivity was enhanced on 5% rather than 6% PA gels, and by examination of intracellular as well as secreted collagen. In 1(I), substitutions in the first 100 residues were not electrophoretically detectable; 7% of cases in the current Mutation Consortium database are in this region. 1(I) substitutions between residues 100-230 were variably detectable while those after residue 232 were all detected. In 2, variability of electrophoretic detection extended through residue 436. About a third of cases in the Consortium database are located in the variable detection region. There was no correlation of substituting residues and biochemical sensitivity. Complete testing of probands with normal type I collagen biochemical results requires supplementation by direct sequencing of cDNA or gDNA in the amino regions of the alpha chains. Mutation detection in OI remains important for genetic counseling, reproductive decisions, exclusion of child abuse and genotype-phenotype correlations. In addition, identifying OI patients without collagen mutations will help define non-collagenous causes of OI.

A new concept in mutation scanning. *R. Cotton[1,2], T. Tabone[1], G. Sallmann[1], E. Webb[1].* 1) Genomic Disorders Res Ctr, Fitzroy, VIC 3065, Australia; 2) The University of Melbourne, Parkville, VIC 3010, Australia.

We describe here a new approach for the detection of mismatched DNA in patient and control DNA samples. Mutation scanning is an important technique for research and diagnostic laboratories. Identification of unknown mutations has proved expensive by means of sequencing or laborious and less sensitive by means of alternative scanning techniques.

The detection of mutations as mismatched PCR amplicons is a well-established technique exploited by other mutation detection methods such as CCM and DHPLC. We have developed a simple mutation scanning method accurately and reproducibly detecting mismatched DNA in heteroduplex PCR amplicons without the use of toxic chemicals or separation techniques. The technology exploits potassium permanganate oxidation of mismatched bases to detect a mutation in a PCR amplicon, when present as a heteroduplex or by hybridising the test sample to a reference sample. The rate of modification is measured by the change in absorbance of the sample over time and compared against a known control. This assay is capable of analysing 96- to 384-well microplates in 2 hours. The initial set up cost of the assay requires a basic UV/Vis microplate reader and the ongoing cost for analysing each amplicon is less than AU$0.30 per sample.

Using this technique for genotyping, we have been able to successfully detect the 9 mutant samples in a set of 72 mitochondrial DNA samples from Melas syndrome patients using a range of PCR fragment sizes from 200-280 bp. In addition the assay, whilst not fully optimized for this application, has also proven 70% efficient in a blinded test to discover new mutations. This new approach to mutation scanning will provide a much needed alternative to the current and expensive mutation scanning methods and those suited to high-throughput applications that are not feasible for smaller diagnostic and research laboratories. The next phase will be to track-test the assay in collaboration with a diagnostic laboratory in order to evaluate the performance against currently established and more widely used mutation scanning methods.

Study of MEFV mutations in the Iranian population by means of reverse-hybridization teststrips. *C. Oberkanins[1], S.H. Amini[2], B. Moghimi[3], A. Ghamari[4], N. Almadani[2], K. Kahrizi[4], G. Kriegshaeuser[1], H. Najmabadi[2,4].* 1) ViennaLab Labordiagnostika GmbH, Vienna, Austria; 2) Kariminejad/Najmabadi Genetic and Pathology Center, Tehran, Iran; 3) Medical School, Tehran University of Medical Sciences, Tehran, Iran; 4) Genetics Research Center, Social Welfare and Rehabilitation Sciences University, Tehran, Iran.

Familial Mediterranean Fever (FMF) is a hereditary inflammatory disorder caused by mutations in the MEFV gene. Carrier rates are known to be high among Turks, Armenians and Arab populations, whereas no data on the frequency and the spectrum of MEFV mutations were so far available from neighbouring Iran. We have applied reverse-hybridisation teststrips (FMF StripAssay) to simultaneously analyse twelve common MEFV mutations in 208 asymptomatic Iranians from different regions and ethnic groups. The overall frequency of mutant alleles in our study population (15.6%) was moderate compared to Armenia, but exceeded the values known from Turkey and Iraq. The most common variant E148Q was identified in 9.6% of MEFV genes. Five other mutations (P369S, M694V, V726A, A744S, R761H) were observed with lower prevalence. In addition, we studied the case of an 8 year old boy with short recurrent fever attacks and abdominal pain from a small village in the northwest of Iran. He turned out to be homozygous for MEFV mutation M694V. His parents were M694V/N and M694V/R761H. Several other members of this large family were found to be affected by typical symptoms of FMF and to carry MEFV mutations. Among 30 asymptomatic inhabitants of this village, who consented to participate in our study, we identified six different variants (E148Q, P369S, M680I(G/C), M694V, V726A, R761H) in a total of 13 mutant MEFV genes. Given the high frequency of MEFV mutations in Iran, the awareness for FMF and the availability of testing needs to increase significantly. (oberkanins@viennalab.co.at).

Evolution of Ashkenazi Jewish Carrier Screening: Towards Comprehensive Reproductive Risk Assessment. *C. Oddoux, L. U, K. Hoang, N. Hayes, M. Banerjee, H. Ostrer.* Div Human Genetics, New York Univ Sch Medicine, New York, NY.

Recent advances in the understanding of the population genetics of Ashkenazi Jews (AJ) have identified increasing numbers of genes with founder mutations occurring at appreciable frequencies in this population. The genes include those encoding early-onset fatal and chronic diseases, late-onset diseases, and disabilities. This complexity represents a challenge to the development of consistent clinical services making use of this information and has led to the haphazard introduction of tests. We therefore applied similar strategies as those used by the ACMG for development of the policy statement on cystic fibrosis population-based carrier testing, to the development of a comprehensive carrier screening panel for AJ for implementation in our laboratory. Criteria for inclusion included: 1. Significant morbidity, whether severe or chronic; 2. Availability of an accepted intervention; 3. 100% penetrance; 4. Carrier frequency of 1% or more among AJ, 5. Mutation frequency of 1% or more among AJ affecteds. Tests for presymptomatic disease identification, or to screen for disabilities rather than diseases, were not included in the carrier testing panel. Based on these criteria, the following 16-disease AJ test panel was developed: cystic fibrosis, Canavan disease, Bloom syndrome , Fanconi anemia type C, Tay-Sachs disease, Gaucher disease, Niemann-Pick disease, familial dysautonomia, Glycogen storage disease, type 1A, Mucolipidosis, type 4, Usher syndrome, types 1 and 3, Familial hyperinsulinism, Maple syrup urine disease, Lipoamide dehydrogenase deficiency, and fragile X syndrome. In order to provide the benefits of multiplexing of tests while still allowing the patient the option of individual informed consent for each disease, a novel allele-specific oligonucleotide hybridization strategy was devised. The development of an extended AJ panel provided to the patient as individual tests provides the benefits of comprehensive carrier risk assessment without imposing testing for disorders the patient may not choose and eliminates the unopened window dilemma of the geneticist having access to information not available to the patient.

Detection of African American and Hispanic Population-Specific Cystic Fibrosis Mutations in a Single-Tube Assay. *C.R. Novak, R. Saberi, J.T. Brown, A.G. Hadd.* Ambion Diagnostics, 2130 Woodward, Austin, TX 78744 USA.

PURPOSE: Molecular screening for cystic fibrosis mutations requires methods that are rapid, accurate and inexpensive. Improving risk assessment within ethnic populations is an important aspect of CF carrier screening. The purpose of our study was to develop a single-tube assay that incorporated Hispanic and African American population-specific alleles into the current ACMG recommended CF panel. METHODS: The assay combined single-tube multiplex PCR and a liquid bead array to query 90 alleles along the CFTR gene. Biotin-modified PCR products were directly hybridized to allele-specific capture probes, eliminating the need for secondary amplification or purification. Following the addition of fluorescent reporter, samples were analyzed for available genotypes in 15 seconds per patient using a Luminex platform. Results were automatically processed for allele ratio and genotype using Signature Script software. This data management software enabled selective revealing of ACMG recommended and ethnic specific alleles on a per patient basis. RESULTS: A single-tube multiplex PCR was optimized for 10-500 ng of input genomic DNA purified from whole blood. Using liquid bead-array hybridization followed by Luminex-based detection, a set of 23 CF mutations was expanded to 45 with detection of normal genomic DNA and respective mutant at 10 times signal-to-noise. In a direct-hybridization assay for 90 alleles, concordant mutation detection was demonstrated. The assay was completed in 4.5 hours with 50 minutes of hands on time (18% of total workflow). CONCLUSION: A multiplex PCR and direct-hybridization procedure was adapted for liquid bead array detection of an expanded CF carrier screening panel. Concordant results demonstrated that direct-hybridization screening assays could be modified to increase the number of alleles tested from a single patient sample. The addition of Hispanic and African American alleles as an adjunct to the current ACMG panel will provide expanded coverage to better address screening requirements for individual ethnic populations.

The Genetic Testing Quality Control Materials Program (GTQC)- A sustainable community process to improve availability of appropriate, verified quality control (QC) materials for genetic testing. *L. Kalman, B. Chen, D.J. Boone.* NCHM, CDC, Atlanta, GA.

The expansion of molecular genetic testing in clinical and public health practice has increased the need for appropriate, verified quality control (QC) materials for quality assurance, test validation, proficiency testing (PT), and development of new genetic tests. However, despite the growing test volume and the rapidly increasing number of tests being offered, the necessary QC materials are not available for many tests.

The Centers for Disease Control and Prevention (CDC), in collaboration with members of the genetic testing community, has developed a program to improve public availability of QC materials and facilitate information exchange and communication on QC materials development, contribution, verification, distribution, and needs assessment. This CDC based Genetic Testing Quality Control Materials Program (GTQC) will provide continuing support and coordination to improve QC material availability. The GTQC will 1) facilitate the identification, procurement, development, verification and distribution of needed QC materials; 2) facilitate exchange of QC-related information; and 3) explore collaborative efforts for ongoing needs monitoring and materials development.

The GTQC is currently developing cell lines and genomic DNA QC materials for fragile X, Huntington disease, cystic fibrosis and disorders on the Ashkenazi Jewish Panel (Bloom, f. dysautononia, Canavan, Niemann-Pick, Tay-Sachs, Gaucher, Glycogen storage). More information about the program and available QC materials is available at the GTQC website, http://www.phppo.cdc.gov/dls/genetics/qcmaterials/default.aspx.

Exploring community views regarding population fragile X carrier testing in a non-pregnancy health setting. *S. Metcalfe[1,2], A. Henry[1], S. Wake[3], L. Sheffield[3], J. Cohen[4].* 1) Genetics Education, MCRI, Royal Children's Hosp, Parkville, Australia; 2) Dept Paediatrics, The University of Melbourne, Parkville, Australia; 3) Genetic Health Services Victoria, Royal Children's Hospital, Parkville, Australia; 4) Fragile X Alliance Clinic, N. Caulfield, Australia.

Fragile X is the most common familial cause of intellectual disability. Since the identification of the gene in 1991 it has been possible to offer accurate carrier testing for fragile X. To date in, Australia, carrier testing has been confined to individuals with a family history of fragile X, however, testing at a population-wide level has not been explored. We have conducted focus groups of staff and female clients of a family planning clinic (a publicly-funded womens health care organisation) in Victoria, Australia, to assess their interest and concerns about offering population-based testing for fragile X carriers in this setting. In general, both staff and the clients were positive about the possibility of offering the program, although there were some concerns: the importance of up-skilling staff regarding counselling in offering the test; ensuring that women receive appropriate education prior to being tested and that genetic counselling be available for test-positive women; and that cost should not be a prohibitive factor. Staff were also concerned that offering such testing in a pre-pregnancy consultation was not the most ideal time, but this view was not echoed by the women. Information obtained from the focus groups are now being used to inform the development of a testing protocol and educational resources, for a pilot study to assess the feasibility and acceptability of offering population-based testing for fragile X carrier females.

Multiplex PAP: Application to the detection of heterozygous deletions. *V.Q. Nguyen, Q. Liu, X. Li, S.S. Sommer.*
Dept Molecular Genetics, City of Hope Medical Ctr, Duarte, CA.

Large heterozygous chromosomal deletions and gene duplications are important classes of mutations that are generally missed by standard PCR amplification and sequencing. Multiplex dosage pyrophosphorolysis-activated polymerization (MD-PAP), a derivative of PAP, was utilized to detect these types of mutations. PAP is a method for nucleic acid amplification in which 3 blocked oligonucleotides (P*) are activated by pyrophosphorolysis when annealed to the target template and subsequently extended. A key advantage to this technology is that PAP reactions produce little or no primer-dimer or false priming. As a result of this enhanced specificity, MD-PAP is easy to optimize. Herein, we utilize MD-PAP to determine gene dosage of each exon of the human factor IX gene by comparison with one endogenous internal control from the ATM gene. Estimated dosage is proportional to the actual template copy number over a minimum dynamic range from one to sixteen copies. A blinded analysis detected 100% of 43 heterozygous deletions of exons in the human factor IX gene.

Pseudomonas infection in a Delta F508/I148T compound heterozygote negative for the 3199del 6 mutation; Implications for predicting CF phenotype in the prenatal genetic counseling setting. *J. Follmer.* Genzyme Genetics, Weston, FL.

A forty-year-old, gravida 1 para 0 presented for genetic counseling due to AMA. She and her husband were also Delta F508 and I148T (-3199del 6) CF mutation carriers, respectively. Amniocentesis revealed a normal male karyotype positive for both Delta F508 and I148T. Based on a limited number of case reports, this couple was counseled that classical CF symptoms were not expected when the I148T mutation (-3199del 6) is present in conjunction with a severe (i.e., Delta F508) mutation. It was also explained that non-classical symptoms of CF, however could not be ruled out due to lack of available data regarding the genotype/phenotype correlation of the I148T mutation. At six months of age this infant male presented to a pediatric pulmonologist because of a persistent cough. Sweat chloride tests had previously been negative. Pneumonia was ruled out, however a sputum culture was positive for *Pseudomonas aeruginosa*. To date, this male is one-year-old and thriving. He has no clinical manifestations of CF, however pancreatic function tests have not been performed. *Pseudomonas aeruginosa* is a gram-negative respiratory tract bacterium that is present in the lungs of 70% of CF patients and is one of the most serious complications of CF. It is a rare cause of infection in healthy individuals. No other case reports of Delta F508/I148T compound heterozygotes who have tested positive for *Pseudomonas aeruginosa* have been located.

CONCLUSION: This case study challenges the recent suggestions that the I148T mutation (-3199del 6) is only a benign polymorphism. Several studies have also suggested that the I148T be removed from genetic testing panels. However, this report emphasizes the complexity of providing accurate genetic counseling and raises the possibility of non-classical CF manifestations for I148T compound heterozygotes.

Classic Congenital Myopathies Presenting with Lethal Neonatal Phenotypes. *L. Medne[1], J. Golden[1], R. Finkel[1], J. Ming[1], K. Ciprero[1], J. Lunardi[2], N. Monnier[2], C. Wallgren-Petterson[3], C. Bonnemann[1].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Centre Hospitalier Universitaire De Grenoble, Grenoble, France; 3) Haartman Institute, University of Helsinki, Helsinki, Finland.

We report two cases of classic congenital myopathies that presented with an unusually severe phenotype at birth and novel clinical features. Patient 1 presented with decreased fetal movements, IUGR, generalized severe hypotonia, distal arthrogryposis, fractures and respiratory distress requiring mechanical ventilation. Central cause of hypotonia was ruled out. Respiratory support was withdrawn at 24 days of age. Post-mortem muscle biopsy was consistent with central core disease (CCD). Compound heterozygosity of the Asn759Asp and Phe4808del mutations in the *RYR1* gene was found. Both asymptomatic parents were identified as carriers. Patient 2 presented with decreased fetal movement, polyhydramnios, severe hypotonia, fractures and poor respiratory effort requiring ventilation at birth. He was found to have absent suck and swallow, virtual lack of any movement and complete ophthalmoplegia. Family history showed that the parents were consanguineous; half first cousins from Ecuador. Muscle biopsy was consistent with nemaline myopathy (NM). Ventilatory support was withdrawn given the grave prognosis. *ACTA1* sequencing did not identify any mutations. Nebulin gene (*NEB*) sequencing is in process. Classic congenital myopathies are important differential diagnoses in neonatal akinesia. This is the second report of a rare lethal case of CCD, typically a non-life threatening autosomal dominant myopathy. While both of the *RYR1* mutations are novel, Phe4808del occurs in the functionally important and highly conserved transmembrane domain (seen in autosomal dominant CCD) of the calcium channel and Asn759Asp is in the highly conserved N-terminal domain. Autosomal recessive cases of severe NM have been reported; however, none have had complete ophthalmoplegia as observed in patient 2. Muscle biopsy was crucial in establishing the correct diagnosis in both cases allowing for appropriate genetic counseling.

Diverse single- and multi-exon NF1 copy number changes represent two percent of the germ-line mutations in neurofibromatosis type 1 patients. *K. Wimmer[1, 2], S. Yao[1], K. Claes[3], H. Kehrer-Sawatzki[4], S. Tinschert[5], T. De Raedt[6], E. Legius[6], T. Callens[1, 3], H. Beiglböck[2], O. Maertens[3], L. Messiaen[1, 3].* 1) Laboratory Medical Genomics, Dept Genetics UAB,USA; 2) Abteilung für Humangenetik, Medizinische Universität Wien, Vienna, Austria; 3) Centre for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Dept of Human Genetics, University of Ulm, Germany; 5) Institut für Klinische Genetik, Medizinische Fakultät Carl Gustav Carus Universität, Dresden, Germany; 6) Centre for Human Genetics, Catholic University Leuven, Belgium.

Comprehensive mutation analysis achieves mutation detection rates of approximately 95% in NF1 patients fulfilling the NIH criteria. The vast majority of mutations are minor lesions and ~5% are total gene deletions. We found 13 single and/or multi-exon deletions/duplications using our RNA-based approach in a cohort of 1100 NF1 patients. We confirmed these copy number changes using a recently developed technique: multiplex ligation-dependent probe amplification (MLPA). Using MLPA, we further analyzed 55 NF1 patients for which thorough analysis was unable to uncover a pathogenic NF1 mutation. A novel multi-exon deletion/duplication was found in 12 of them. Thus, we have identified and/or confirmed by MLPA a total of 25 single- and/or multi-exon deletions/duplications. At least 19 of these deletions/duplications were unique. The extent of the 22 deletions and 3 duplications varied greatly and there was no clustering of breakpoints. We also evaluated the sensitivity of MLPA to identify multi-exon deletions present in a mosaic state and tested the ability MLPA P122-NF1 area assay, designed to identify total gene deletions, to distinguish between type I and type II deletions. Our study shows that intragenic deletions and duplications represent ~2% of all NF1 mutations. Due to this low percentage these copy number changes MLPA is not substantially increasing the mutation detection rate in NF1 patients. However, it may become a useful first step in a comprehensive mutation analysis scheme as it can quickly pinpoint patients with intragenic deletions/duplications as well as patients with total gene deletions.

Performance of the Verigene System for multiplexed array-based mutation detection. *W. King, S. Haymond, T. Patno, W. Cork.* Applications Development, Nanosphere, Northbrook, IL.

The Verigene System (Nanosphere, Inc.) is a multiplex platform for direct detection of mutations and polymorphisms using unamplified human DNA. The patient sample is detected in a single-well microarray hybridization reaction. The method is based on hybridization of the target by allele-specific, surface-immobilized capture probes and oligonucleotide-functionalized gold nanoparticle probes, followed by a proprietary signal amplification process for target detection. The use of microarrays in molecular diagnostics allows multiplex detection of several genetic loci simultaneously in a single sample. It can be used to detect SNPs, and small insertions or deletions directly from genomic DNA. This platform is ideally suited for rapid detection of mutations without the complexities associated with PCR-based target amplification. In the present study, we assessed the analytical performance of the Verigene System for multiplex SNP detection of specific nucleotide sequences that are important for familial thrombophilia. The Factor V Leiden (1691 G->A, FVL) and Prothrombin (20210 G>A, PT) mutations were assessed in normal and mutant DNA. The following genomic DNA samples obtained from Sigma and Coriell Cell Repositories were investigated: Wild Type, homozygous PT mutant, homozygous FVL mutant and heterozygous PT and FVL. The Verigene System processed each of the samples and determined a genotype for each. The System demonstrated a 100% call accuracy and a 92.5% call rate. In additional studies aimed at measuring the reproducibility of call accuracy, 53/53 DNA samples isolated from peripheral blood of 9 normal donors were detected as WT PT (n=27) or WT FVL (n=26). In a similar set of experiments, feasibility was demonstrated for 24 of the ACMG recommended mutations for CF carrier screening. The CF assay results indicate that the Verigene System is capable of true multiplex mutation detection beyond single base changes. This low-complexity Verigene System array-based nanoparticle technology is also adaptable for use in a large variety of other clinical applications.

Identification of a 45 X; 46 XX mosaic DMD carrier. *J.S. Parboosingh[1], T. Gillan[1], J.M. Miller[1], L.M. Graham[1], C. Davies[1], S. Merchant[2], A.M. Innes[1], S. Bamforth[2], J. Chernos[1], P.J. Bridge[1].* 1) Dept. Medical Genetics, Alberta Children's Hospital and University of Calgary, Calgary, AB, Canada; 2) Dept. Medical Genetics, University of Alberta, Edmonton, AB, Canada.

In 1988, a year after identification of the dystrophin gene, carrier testing was performed on a woman with a deceased affected son and her two daughters; no DNA was available from the affected son. Southern hybridization using a cDNA probe indicated that the woman had a reduced signal approximately equivalent to the signal strength of a male and that her daughters had normal female dosage. The interpretation of the results was that the woman carried a deletion of the dystrophin gene but that the daughters had not inherited the deleted chromosome. Recently, a grandson was diagnosed with DMD. Current molecular testing, consisting of MLPA analysis, revealed the presence of a duplication of exons 3 - 8 in both the grandson and the daughter. MLPA analysis on the woman suggested mosaicism for the duplication. Genotyping of X-linked markers revealed apparent homozygosity with apparent lack of transmission of a portion of the X chromosome to one daughter. Upon closer analysis of the genotyping data, the apparently non-transmitted alleles were present at very low levels. This data, together with the original Southern hybridization data, suggested that the woman was a mosaic with a major 45,X cell line lacking the DMD duplication and minor 46,XX cell line which carried the DMD duplication. This was confirmed molecularly by MLPA using a subtelomeric kit and the MECP2 kit for X chromosome dosage and cytogenetically; karyotyping revealed that 45/50 cells were 45,X and 5/50 cells 46,XX. Thus, what was originally interpreted as a dystrophin deletion is explained by the mosaicism for monosomy X. The degree of mosaicism observed in blood and buccal cells will be compared. This case illustrates the need to revisit molecular results in DMD families where carrier testing was performed in the absence of an affected, as well as, the power of molecular testing to detect mosaicism.

Mutation detection in the *ATM* gene by haplotype analysis and Denaturing High Performance Liquid Chromatography (DHPLC) in A-T Italian patients. *S. Cavalieri[1], R. Gatti[2], P. Pappi[3], A. Funaro[1], N. Migone[1,3], A. Brusco[1,3].* 1) Genetics Biol & Biochem, Univ Torino, Torino, Italy; 2) Department of Pathology and Laboratory Medicine, The David Geffen School of Medicine at UCLA, Los Angeles, California, USA; 3) Medical Genetics Unit, San Giovanni Battista Hospital, Torino, Italy.

The mutation screening of the *ATM* gene in A-T patients is hampered by the large size of the transcript (9 Kb), the high number of exons, and the lack of mutational hot spots. In Iberian, Polish, Russian, and Brazilian populations SNPs and STRs haplotypes within ATM gene have been shown to be helpful in identifying recurrent mutations. Twelve Italian A-T patients (10 unrelated and 2 sisters), lacking ATM protein at Western blot, were pre-screened by SNP/STR haplotype analysis: we identified 3 homozygotes (2 sisters and one patient) and 9 heterozygotes. Three haplotypes were associated to known mutations: 3576GA mutation recurred in three patients and the two sisters; 7517_7520delGAGA was found in two patients (one heterozygote and one homozygote); 2250GA mutation was found in a single heterozygote. All are mutations already reported in Italian patients. A total of nine mutated alleles out of 22 were identified by SNP/STR analysis (40.9%). By DHPLC screening of the coding exons of the gene we detected additional 13/22 different mutated alleles. Eight of them are novel mutations. These combined techniques enhanced the efficiency of the mutation screening to a detection rate of 91% (20/22). Among the micro-mutations identified, 5 are nonsense, 5 cause a frameshift due to small insertions or deletions, 2 are missense(s) and four affect splice sites. A large deletion spanning exons 32-36 was identified in one patient by cDNA analysis and Southern Blot. This study confirms the importance of SNP/STR haplotyping to improve ATM mutation analysis, and shows that mutations missed by DHPLC may involve large genomic rearrangements in the ATM gene.

Mutations in the ectodysplasin-A receptor gene *EDAR* in dominant and recessive hypohidrotic ectodermal dysplasia. *A.H. van der Hout, G.G. Oudesluijs, A. Venema, B. Mol, A.J. van Essen, Y.J. Vos.* Dept Clinical Genetics, University Medical Centre Groningen, The Netherlands.

Hypohidrotic ectodermal dysplasia (HED) is a congenital disorder characterized by the absence or hypoplasia of hair, teeth, and eccrine sweat glands. HED usually shows X-linked recessive inheritance but in a minority of cases it is inherited as an autosomal dominant or recessive trait. The X-linked form is caused by mutations in the ectodysplasin-A gene *ED1*. Boys are severely affected, women can show only some missing or malformed teeth and thin hair. Mutations in the ectodysplasin-A receptor gene *EDAR* were found in autosomal and recessive HED, one autosomal recessive case was described with mutations in the EDAR-Associated Death Domain gene *EDARADD*. We analyzed *ED1* in 38 independent patients as part of genetic counselling in their families. A causative mutation was found in 21 cases (55%). In the remaining 17 cases also *EDAR* and *EDARADD* were analyzed. Mutations in *EDAR* were found in five families (29%), no mutations were found in *EDARADD*. In four of these families which all show an autosomal dominant inheritance pattern the mutations, three nonsense mutations and one missense, are located in the Death Domain in the 3 end of the gene, supposed to be involved in protein-protein interactions. The phenotype in carriers of these dominant mutations is milder than in boys with a mutation in *ED1*. In the fifth family two affected boys were compound heterozygous for two missense mutations in a more 5 part of the gene. They have a phenotype comparable to X-linked cases. Both parents each carried one of the mutations. The father is unaffected, the mother, however, is affected but less severe than her sons. Until now only six families with mutations in *EDAR* were published, four with recessive inheritance and two dominant. Three of the five different mutations we found were also found in these studies. Therefore, although the numbers are small, the spectrum of mutations in *EDAR* seems limited. In all cases of HED negative for a mutation in *ED1* analysis of *EDAR* should be considerd, even though the pedigree is totally compatible with X-linked inheritance.

A large pedigree with mitochondrial 1555AG mutation: Genetic counseling and point-of-care genetic testing by CASSOH for prevention of aminoglycoside-induced deafness. *S. Kure[1], J. Kanno[1], F. Kamada[1], T. Niihori[1], Y. Narumi[1], Y. Aoki[1], M. Hiratsuka[2], Y. Matsubara[1].* 1) Dept Medical Genetics, Tohoku Univ Sch Medicine, Sendai, Japan; 2) Dept Clinical Pharmacoceutics, Tohoku Pharmaceutical Univ, Sendai, Japan.

Recent studies in pharmacogentics have revealed various genetic polymorphisms that regulate drug responses. Individualization of the drug treatment based on this information would potentially maximize the effectiveness of medication and minimize its risks. Clinical application of the genetic information to individual healthcare has been hampered by a lack of a simple point-of-care genetic test that can be performed in an outpatient clinic or at bedside. Recently, we have developed a simple and raipd genotyping method, CASSOH, which utilizes immunochromatographic test strips. CASSOH method allows us to determine SNP within two hours (Matsubara and Kure, Hum Mutat; 2003:22:166, Hiratsuka et al, Drug Metab Pharmacokinet, 2004;19:303). We encountered a large deaf pedigree with maternal inheritance. Since streptomycine had been used for treatment of bacterial infections in deaf family members, we suspected that hearing loss was caused by mitochondrial 1555A>G mutation. The analysis of mitochondrial 1555A>G mutation by the CASSOH method revealed that two asymptomatic individuals were positive for the 1555A>G mutation. Additional four family members at risk were also tested. For prevention of further exposure to aminoglycoside antibiotics we issued the mutation-positive individuals with a medical alert card to warn doctors of the risk for hearing loss by aminoglycoside administration. The present case indicates that pharmacogenetic evaluation of clinically valuable SNP at genetic clinics would facilitate personalized medicine.

Fragile X testing: Is it indicated in cases of premature ovarian failure? *M. Thangavelu, S. Bhatt.* Genzyme Genetics, Orange, CA.

Premature ovarian failure (POF) occurs in approximately 1% of women and is characterized by amenorrhea and elevated levels of serum gonadotropins before age 40. Etiologically POF is heterogeneous with involvement of different environmental and genetic factors. X-linked genes have been hypothesized to play a role in POF, one of them being the fragile X (FRAXA) gene. In particular POF is seen in carriers of the FRAXA premutation. Literature suggests that among fragile X premutation carriers 16%-33% experienced POF and in two fragile X families, 60% and 67% of premutation carriers experienced POF. On the other hand, among females experiencing POF only 4.1% to 6.8% were found to be carriers of the FRAXA premutation. Fragile X carrier testing results on 108 specimens received in our lab for the specific indication of POF were reviewed retrospectively. Of the 108 samples, 4.6% of patients (n= 5), were identified to have a premutation in the FRAXA gene, with repeats ranging from 64 to 80. Interestingly, 2 patients were identified to have alleles in the gray zone with 47 and 52 repeats. In an additional patient, only one normal allele was identified suggesting presence of only one X chromosome (possibly a 45,X karyotype). The incidence of permutation carriers in this cohort of patients with POF is similar to that previously observed. Interestingly all our patients identified to have premutation were referred from infertility practices. In view of the association between POF and fragile X, it is important that evaluation for fragile X premutation is part of the laboratory work up for POF. Although the clinical significance of observations in the grey zone is as yet unclear from the perspective of the classic fragile X syndrome, the observations in this cohort suggests the need for further evaluation for possible correlation with POF. Based on the emerging data on the association between POF and fragile X premutation, it is important that in addition to other clinical facets of fragile X syndrome, implications of POF and related fertility issues are discussed with the premutation carriers.

Educational priorities in genetics for GPs, Paediatricians and Gynaeco-Obstetricians in 5 European countries: the Gened survey. *C. Julian-Reynier[1], JM. Calefato[1], I. Nippert[2], H. Harris[3], AM. Plass[4], L. Ten Kate[4], U. Kristofferson[5], J. Schmidtke[2], C. Benjamin[3], K. Challen[3], R. Harris[3], and the GenEd group.* 1) INSERM UMR379, Inst Paoli-Calmettes, Marseille, France; 2) Institut Fuer Humangenetik, Universities of Muenster and Hannover, Germany; 3) GenEd co-ordinating centre, Department of medicine, Manchester University, Manchester, UK; 4) VU Medical Centre, Amsterdam, Netherlands; 5) University Hospital, Lund, Sweden.

The extension of genetic knowledge to all fields of medicine involves progressively all primary care providers . The objective of this study was to measure how genetic educational needs were prioritised by the doctors practicing in 5 European countries. Methods : Questionnaires mailed to GPs, Gynaeco-Obstetricians and Paediatricians (France, Germany, Netherlands, Sweden, United Kingdom) in 2004 . Answer rate 41% (N=3686. Through a Component Principal Analysis, the 30 genetic educational priority items were reduced to 6 sub-dimensions. Results: The 3 first educational priorities for GPs were Genetics of Common Diseases, Risk assessment, and Psycho-social/counselling issues; whereas Basic genetics, Ethical Legal Public Health Issues (ELPHI), Techniques and innovations had lower scores. The ranking was consistent across the countries, but the scores differed ($p<0.01$) across the countries after multivariate adjustment. French GPs systematically quoted higher priorities for all 6 dimensions compared to other countries ($p<0.01$). The 3 first educational priorities for specialists were Basic Genetics/Congenital Malformations, Risk assessment, and Psycho-social/Counselling issues. ELPHI, Techniques/Innovations and Common Diseases were ranked in decreasing order afterwards. Ranking was consistent across the 5 countries but the scores differed significantly ($p<0.01$) across the countries after multivariate adjustment.The country effect was more heterogeneous than for GPs. Conclusion: Genetic educational priorities differ for GPs and specialists and across the countries. Interpretation should be done in according to the national health care systems and educational policies.

The provision of a multidisciplinary screening, follow-up and research clinic for families with cardiomyopathy in Newfoundland. *Y. Teplitsky[1], P. Parfrey,[2], L. Kernaghan,[3], S. MacKay,[3], B. Peddle,[1], P. Ryan,[1], C. Tilley,[1], L. Thierfelder[4], A. Bassett,[5], T. Young,[2], W. McKenna,[6], S. Connors,[1], K. Hodgkinson.[2].* 1) Faculty of Medicine, Memorial University , St. John's, NL, Canada; 2) Patient Research Centre, Memorial University, St. John's, NL, Canada; 3) Clinical Genetics, Health Sciences Centre, St. John's, NL, Canada; 4) Max-Delbruck Centre, Berlin, Germany; 5) Clinical Genetics Research Program, CAMH, Toronto, ON, Canada; 6) The Heart Hospital, London, UK.

103 families with cardiomyopathy, with and without sudden cardiac death, have been ascertained in Newfoundland. Thirteen families have hypertrophic cardiomyopathy, 40 are part of the arrhythmogenic right ventricular cardiomyopathy (ARVC) spectrum, 34 have dilated cardiomyopathy and sixteen large families have ARVC linked to a disease associated haplotype at 3p25 (ARVD5). All are followed clinically through a genetics/cardiology clinic where at-risk individuals are offered genetic counselling and routine cardiac testing. Blood is taken for known mutation testing, haplotype testing or linkage analysis, whichever is appropriate, following informed consent. To date, 93 families have been seen and 318 subjects have had at least one visit. In 3p25 families, subjects found to have a high-risk haplotype are screened yearly until treatment is recommended. Subjects with a low-risk haplotype are followed every 2-3 years (to allow for error in the absence of a known mutation); those with an unknown haplotype status for 3p25 are screened every 1-2 years. The remaining families have clinical screening every 1-3 years. We have begun to screen for known ARVC/DCM/HOCM mutations. For families negative for all DNA screening, linkage analysis is considered. The clinic addresses both clinical and research issues in a synergistic manner. We aim to determine the genetic epidemiology including geneotype/phenotype analysis, assessment of genetic and environmental modifiers to the phenotype, and the natural history and clinical course of each cardiomyopathy. To aid this endeavour, an extensive patient brochure has been produced for patients, detailing both research and clinical issues.

Family as Context in Clinical Genetics Project (FCCGP): an interactive, web-based curriculum, genetic information resource, and continuing education program for health care professionals (HCPs) and students. *C. Kenner[1], R. Parker[2], R. Fineman[2], S. Cummings[3], M. Michela[4], P. Bashook[2], L. Hruska[5], T. Swift-Scanlan[6], S. Olsen[6], A. Gallo[2], T. Savage[2], M. Knisley[5], S. Feetham[7], Y.T. Chang[8], A. Finkelman[9], S. Boyer[2], D. Siow[1].* 1) OU Nursing, OK City; 2) UIC Nursing; 3) U of Chicago Cancer Risk Clinic; 4) UIC Academic Affairs; 5) UIC Medicine; 6) Johns Hopkins U Nursing; 7) HRSA; 8) East Carolina U Medicine; 9) U of Cincinnati.

FCCGP is an interactive, web-based curriculum that aims to integrate new genetics information into medical, nursing and social work practice using the family as the context for care. This interdisciplinary project utilizes three case reports (including breast/ovarian cancer, cystic fibrosis and bipolar affective disorder) and offers learners an opportunity to integrate genetic, environmental, behavioral, psychosocial, ethical, legal and financial information into patient/family care. Core competencies from the National Coalition for Health Professional Education in Genetics and other sources were used to guide case report learning objectives, content development, and evaluation. The case reports, their pre- and post-test questions and answers, etc., have been reviewed and validated by practicing HCPs and can be found at : http://ce.nursing.ouhsc.edu/fccg/index.htm Integrating genetics and genetic services into the daily practice of HCPs continues to be one of the greatest challenges of professional genetics education. The FCCGP provides HCPs with a step-by-step process needed to deliver basic genetic services and/or referral of patients and families to genetic health care professionals. This how-to approach, coupled with downloadable tools and continuing education credits for physicians and nurses, provides practical information to HCPs, and encourages them to integrate genetics into their every-day practice. Lastly, barriers to implementing a successful, web-based curriculum, such as the FCCGP, will be described in order to help others who are interested in creating a similar online genetics education program. Supported by NIH Grant 1 R25 HG02259-01A1.

Estimation of absolute risks of morbidity and mortality of disease given a family history. *A.S. Butterworth[1], P. Pharoah[1,2].* 1) Cambridge Genetics Knowledge Park, Cambridge, United Kingdom; 2) Department of Oncology, University of Cambridge, United Kingdom.

The counselling and management of individuals with a family history of disease is dependent on reliable estimates of absolute risk. Such estimates may also be useful for appropriate weighting by insurance underwriters. However most epidemiological studies present relative rather than absolute risks.

The aim of this study was to estimate absolute risks of morbidity and mortality for several common chronic diseases based on the available epidemiological data. Relative risks for different patterns of family history of colorectal cancer, prostate cancer, stroke and multiple sclerosis were obtained by pooling the results from all available studies using random effects meta-analysis. Relative risk estimates for breast and ovarian cancer were obtained from previously published meta-analyses. These relative risks were converted into absolute risks using actuarial life-tables, which use population incidence and mortality data and take into account competing risks of mortality.

For common cancers, the relative risk is approximately doubled for an individual with a first-degree relative (i.e. parent, sib or offspring) affected by the same cancer. The risk increases further with more affected relatives or a relative diagnosed at a younger age. However absolute risks vary substantially for different cancer sites. For example, a relative risk of 2.24 (95%CI 2.06-2.43) for having a first-degree relative affected with colorectal cancer is equivalent to a lifetime risk of 3.6% (~1 in 30) for a 30 year old compared to 2.0% (1 in 50) in the general population. Having a second affected first-degree relative increases the absolute risk to 7.4% (~1 in 14). The risks of dying from colorectal cancer by age 70 are 0.75% (~1 in 130), 1.4% (~1 in 70) and 4.1% (~1 in 24) for the general population, one affected relative and two affected relatives respectively. Similar results were found for the other diseases studied. These estimates should be useful for clinical risk assessment and may also inform insurance underwriting policies.

Using family history of hemochromatosis or iron overload to aid targeted screening in a multiethnic, primary-care population: The Hemochromatosis and Iron Overload Screening (HEIRS) Study. *E.L. Harris[1], R.T. Acton[2], B.M. Snively[3], J.C. Barton[2], C. Leiendecker-Foster[4], C.E. McLaren[5], P.C. Adams[6], M. Speechley[6], T.C. Bent[5].* 1) Kaiser Permanente Center for Health Research, Portland, OR; 2) University of Alabama at Birmingham, AL; 3) Wake Forest University, Winston-Salem, NC; 4) University of Minnesota, Minneapolis, MN; 5) University of California, Irvine, CA; 6) London Health Sciences Centre, London, Ontario.

Screening family members of individuals with hereditary hemochromatosis (HH) is an approach to identify individuals at increased risk of developing clinical complications of iron overload (IO) who may benefit from preventive interventions. However, detailed family information is not always available to inform such an approach. Family history may be available. In the HEIRS Study, a multi-site, ethnically diverse, primary-care-based screening study for HH and IO, we enrolled 98,529 participants who did not report having been diagnosed with HH or IO and who were not recruited into the study by other family members. Here, we assess how strongly self-reported family history of HH or IO is associated with screening results that indicate increased risk of developing/having IO: *HFE* C282Y/C282Y (YY); or evidence of elevated body iron stores [men: transferrin saturation (TS) >50% and serum ferritin (SF) >300 g/L; women: TS>45% and SF>200 g/L].

Among 43,453 Caucasians, 1.18% of those having a family history of HH/IO were YY compared with 0.46% of those without an HH/IO family history [relative risk (RR)=2.55; 95% confidence interval (CI)=1.61-4.03]. Among 55,076 non-Caucasians, 0.17% with an HH/IO family history were YY compared with 0.022% of those without an HH/IO family history (RR=7.51; CI=1.68-33.5). Among Caucasians, 2.12% with an HH/IO family history had elevated TS and SF compared with 1.66% of those without an HH/IO family history (RR=1.27; CI=0.91-1.77). Among non-Caucasians, 1.42% with an HH/IO family history had elevated values compared with 2.25% of those without an HH/IO family history (RR=0.63; CI=0.39-1.02). These results indicate that self-reported family history of HH or IO may aid in identifying a high-risk group for *HFE* C282Y testing.

BRCA1/2 Variants of Uncertain Significance: Assessment of Hypothetical Risk Management Recommendations.

A. Tansky[1], S. Ruddle[1], S. O'Neill[1,2], W. Rubinstein[1,2], L. Shulman[1], K. Ormond[1]. 1) Northwestern University, Chicago, IL; 2) Evanston Northwestern Healthcare Center for Medical Genetics, Evanston, IL.

The main objective of presymptomatic genetic testing for hereditary cancer syndromes is to provide patients with specific risk information and tailored management recommendations. However, approximately 13% of Hereditary Breast and Ovarian Cancer testing reveals a variant of uncertain significance (VUS), an ambiguous result without established guidelines for clinical recommendations. Current VUS management is often based solely on the prior education and clinical experience of the health care provider, about which little is known. We surveyed 38 medical oncologists to assess their risk management recommendations for one hypothetical patient under 3 scenarios: 1)no genetic testing, 2)a *BRCA* mutation positive result, and 3)a VUS result. When asked a basic VUS definition question, 26.3% reported they were unsure of the meaning of a VUS. General screening, breast MRI, and surgical recommendations were significantly different between scenarios. With a VUS result, general American Cancer Society screening guidelines were less likely to be recommended than without genetic testing and more likely than with a positive HBOC result (18.9% v. 33.3% v. 5.5%; p=0.008). Breast MRI (32.4% v. 19.4%; p=0.001), breast ultrasound (16.2% v. 13.9%), ovarian cancer screening (48.6% v. 36.1%), tamoxifen (8.1% v. 2.8%) were all recommended at increased levels with a VUS result versus no genetic testing; all were most frequently recommended for patients with positive *BRCA* mutations. Respondents recommended oral contraceptives least frequently with a VUS and most frequently with positive status (5.4% v. 13.2%). Prophylactic breast and ovarian surgeries were only recommended in the positive genetic testing scenario (44.4% and 67.6% respectively). The reasoning behind all management recommendations also changed depending on the genetic testing status. A risk-based methodology was used least frequently with the VUS scenario. This study provides evidence that increased education regarding genetic testing, specifically variants of uncertain significance, is needed in the general oncology field.

No gender differences observed in stability of fragile X CGG repeats in common and intermediate alleles. *S.L. Nolin, J. Silverman, A. Glicksman, S.Y. Li, T. Sukontasup, W.T. Brown.* NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

The CGG repeat within the FMR1 gene exhibits remarkable instability in families with fragile X. Sullivan et al. (AJHG 70:1532, 2002) examined 1452 parent-child transmissions of common (10-39 repeats) or intermediate (40-59 repeats) alleles and reported that unstable transmissions were seen more often in paternal than maternal transmissions. Furthermore, they observed a low level of unstable transmissions in common repeats sizes and higher rates in the intermediate alleles. We have examined 1216 parent-child transmissions of common and intermediate alleles and observed no unstable transmissions of alleles between 10 and 39 repeats. For alleles with 40-49 repeats, 9% (4/45) of maternally transmitted alleles were unstable as compared to 8% (2/26) of paternally transmitted alleles. For alleles with 50-59 repeats, 22% (13/59) of maternally transmitted alleles were unstable and 18% (2/11) paternally transmitted alleles were unstable. These studies indicated that in our sample there was no apparent gender bias in unstable transmissions of intermediate alleles and no unstable transmissions among common alleles. AGG analysis of the intermediate alleles in males revealed that nearly all unstable transmissions occurred in alleles with pure 40 CGG repeats. Specifically, 9/19 alleles with 40-49 pure repeats and 2/2 with 50 pure repeats exhibited unstable transmissions. In addition to these, one allele with 20 pure repeats increased by 1 repeat on transmission. Thus, AGG analysis suggested that ~50 pure repeats may be the threshold for consistent instability of FMR1 alleles.

Validation of PCR Amplification and Capillary Electrophoresis for Accurate Sizing of Fragile X CGG Repeats.
S.L. Betz, J.K. Booker, K.E. Weck, R.A. Farber. Dept Pathology, Univ North Carolina , Chapel Hill, NC.

INTRODUCTON: Fragile X (FraX) premutation carriers are clinically unaffected with FraX Syndrome but females are at risk for passing expanded alleles to offspring. There is a linear correlation between the size of the premutation allele and risk for expansion; therefore, it is important to accurately determine the number of CGG repeats for individuals with alleles in the premutation range. MATERIALS AND METHODS: We employed a fluorescent PCR-based assay for detecting the number of CGG repeats in the FMR1 gene. The FraX CGG repeat region is PCR amplified using fluorescently labeled primers and products are separated by capillary electrophoresis (CE). Accuracy of sizing was determined by comparison to commercially available FraX controls. RESULTS: The FraX PCR assay was used to determine the number of CGG repeats in normal, intermediate, and premutation alleles. Ten commercially available samples were tested, three of which had repeat number verified by the GTQC Materials Program. Each sample was analyzed an average of 9 times with highly precise measurements in each replicate. The largest allele tested had 107 repeats and was consistently detected by the assay. Smaller repeats were sized accurately based on the length of known controls, whereas longer repeats gave results that varied more widely from the expected size. With the use of multiple controls of variable repeat length, we were able to accurately estimate the number of repeats to within 5 percent of the reported size. However, only 3 of the 10 samples we analyzed had repeat length verified and it is possible that the reported size of the remaining samples is inaccurate. CONCLUSIONS: We have validated a protocol for sizing of FraX CGG repeats for use in a clinical molecular laboratory. CE facilitates screening and sizing of patients with suspected FraX premutations. The PCR/CE-based FraX test is highly precise in the measurement of CGG repeats in the FMR1 gene. We found accurate sizing of alleles to vary depending on the size of the repeat. Additional control materials with repeat size verified by sequencing would greatly aid validation and quality assurance in laboratories performing this assay.

MECP2 gene rearrangements in female and male patients with features of Rett syndrome. *P. Fang[1], P.A. Ward[1], S.A. Berry[3], M. Irons[4], B. Chong[1], I.B. Van den Veyver[1], J. Neul[2], A.K. Percy[5], D.G. Glaze[2], H.Y. Zoghbi[1,2], B.B. Roa[1].*
1) Dept Molec Human Genetics; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Dept Pediatrics, Univ. of Minnesota; 4) Childrens Hospital, Boston, MA; 5) Dept of Pediatrics, Univ. of Alabama, Birmingham, AL.

About 86% female patients with Rett syndrome (RTT) have point mutations or small deletions/insertions in the MECP2 gene, which can be identified by DNA sequencing. In addition, large gene rearrangements have also been documented. We report data from our past 10 months of clinical testing for MECP2 mutations. We studied a subset of 256 female patients with well documented clinical diagnoses, including 216 classic and 40 atypical RTT cases. MECP2 sequencing identified mutations in 185 (86%) classic, and 25 (63%) atypical RTT patients. Southern analysis identified MECP2 gene rearrangements in 21 (~10%) classic and 1 (2.5%) atypical RTT patients. We also performed Southern analysis on 268 female and 65 male patients referred from various sources with limited clinical information. We found 8 female patients (3%) with partial gene deletions in this group. It is intriguing that we found a similar percentage of males with gene rearrangements - two males (3%) were identified to have duplications of the entire MECP2 gene. These cases involve a 9-year old boy and an unrelated 11.5-year old who presented with clinical features suggestive of Angelman syndrome (AS) and RTT. AS testing by either methylation or FISH analysis, and UBE3A gene sequencing were normal for both patients. MECP2 sequencing was normal, but Southern analysis showed duplication of MECP2 exons 1 through 4 in both cases. MECP2 gene duplication was verified by MLPA analysis in both patients. DNA from the 9-year old patient was further confirmed by chromosomal microarray analysis. The duplications appear to span common regions that include the L1CAM gene located ~200kb centromeric to MECP2. DNA sequencing followed by analysis for rearrangements in the MECP2 gene significantly increased the mutation detection rates for RTT, and further demonstrates the clinical value of MECP2 testing for female and male patients with a spectrum of related clinical phenotypes.

Consumer Attitudes toward Genetic Testing and Newborn Screening for Hearing Loss. *A. Pandya[1], S. Burton[2], K. Withrow[1], A. Kalfoglou[3], S.H. Blanton[1], K.S. Arnos[2].* 1) Human Genetics, Virginia Commonwealth University Medical Campus, Richmond, VA; 2) Department of Biology, Gallaudet University, Washington DC; 3) NHGRI, NIH, Bethesda, MD.

The introduction of early hearing detection and intervention programs (EHDI) and the recent progress in identification of genes for deafness has lead to greater utilization of genetic services by parents of children identified with hearing loss (HL). However, efforts to assess consumer attitudes toward genetic testing for HL have lagged behind. We held five focus groups with 44 participants to explore their attitudes towards genetic technologies, motivation for seeking genetic testing, views about newborn hearing screening and reactions to the idea of adding molecular screening for HL at birth. Focus group participants included hearing parents of deaf children, Deaf parents and young Deaf adults of diverse ethnic backgrounds. Trained moderators presented a series of questions and the discussions were recorded and transcribed. A team of co-investigators reviewed the transcripts to identify major themes and developed a qualitative coding structure. The data were coded using the qualitative data analysis software NVivo 4.0. Perceived benefits of newborn screening and genetic testing for HL included helping parents 1)accept the diagnosis 2)share results with family members 3)anticipate the need for medical care, and 4)assess chance of having additional children with HL. Attitudes about the timing for providing genetic evaluation and testing were mixed; participants placed emphasis on respecting variations in the readiness of the family. Several parents expressed an interest in being offered molecular screening for common deafness genes early, potentially as an adjunct to audiologic newborn hearing screening. However, a recurring concern was the cost effectiveness & the need for parental consent. The results of these studies highlight the effectiveness of small focus group sessions to address complex and sensitive issues. The results from this analysis will guide the development of a comprehensive and sensitive survey instrument to be used on a national level.

Population genetic research: Autonomy, human dignity and the evolution of informed consent norms in Canada in the post World War II era. *L. Sheremeta, T. Caulfield.* Health Law Institute, University of Alberta, Edmonton, Alberta, Canada.

Modern bioethical principles enunciated in the Nuremberg Code and the World Medical Association Declaration of Helsinki have served the research community and research subjects well for over fifty years. Founded on respect for human dignity, autonomy of the individual, a requirement for free and informed consent of research subjects and review of all human subject research by a research ethics board, these principles are intended to ensure that only ethically defensible and scientifically justified research is undertaken. Increasingly, the application of these principles to genomic research, which depends on the collection, storage and use of human biologic samples, is challenged. Small and large-scale biobanking projects throughout the world are struggling to deal with how consent principles impact the feasibility of population genetic research. UK Biobank, the Icelandic Health Sector Database, the Estonian Genome Project and the proposed Canadian Lifelong Health Initiative are examples of large-scale projects in which these issues have arisen. In Canada, strict interpretation of ethical guidelines and consent law preclude the use of human biologic samples without informed consent in studies where the samples are persistently linked to health information about the research subject. In the context of research involving previously stored human biologic materials this limitation is vexing to researchers. In the context of prospective research involving human biological materials the concept of informed consent demands that consent be voluntary and specifically referable to a defined research project. Given that researchers cannot predict all future research uses to which HBMs may be put, it is legally uncertain whether consent to such research can ever be informed. It has been suggested that ethical norms and the law should be weakened to facilitate research of this kind. This paper will enunciate the arguments for and against such normative evolution and will discuss the feasibility of various consent options that have emerged.

Community-based medical home for patients with complex genetic disorders- a model to follow? *H. Wang[1], L. Nye[1], J. Renner[1], J. Tumbush[1], H. Morton[2].* 1) DDC Clinic for Special Needs Children, Middlefield, OH; 2) The Clinic for Special Children, Strasburg, PA.

DDC Clinic for Special Needs Children in Middlefield, OH is a community-based, primary care facility initiated 3 years ago for children with complex genetic and metabolic disorders, and is based on The Clinic for Special Children in Strasburg, PA. The philosophy of DDC Clinic embodies the concept of the medical home for children with special needs advocated by the American Academy of Pediatrics. The medical home is characterized as accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective. DDC Clinic provides comprehensive care for over 200 patients, of whom 70% are Amish, and 30% are non-Amish. Many of the over 40 genetic and metabolic disorders seen at DDC Clinic are associated with founder genes, resulting in rare disease clusters in the community, such as prolidase deficiency, Cohen syndrome and ganglioside GM3 synthase deficiency. Patient diagnosis rate has increased from 22% to 67% over 3 years, which has dramatically enhanced disease management and family satisfaction. Although medical management for these patients remains challenging, effective care for some diseases, such as proprionic acidemia, can lead to nearly normal life. Only a small group of diseases are lethal, such as infantile cardiomyopathy and Amish nemaline myopathy, but palliative care for these patients is appreciated by the affected families. Patients also benefit from comprehensive medical care and care coordination. Through continuity of care, our increasing knowledge of each patient, and partnerships established with families, we have seen a significant shift from sick visits to preventive visits, and from high complexity visits to moderate complexity visits, from inpatient care to outpatient care, from emergent care to regular office visits, resulting in significantly decreased healthcare costs in this population. A recent anonymous survey revealed family satisfaction approaching 100%. We conclude that community-based medical home for patients with complex genetic disorders is not only medically care-effective but also cost-effective.

Family history in rural primary care. *W. Feero, D. Meyer.* Dept Community/Family Med, Maine-Dartmouth Family Practice, Augusta, ME.

Purpose: To provide information on the state of family history data in the rural outpatient primary care setting. Methods: Survey completion by attendees to the 2005 annual state family practice academy meeting in a small rural state. The survey elucidated: 1)demographics, 2)attitudes towards the importance of family history, 3)the frequency with which family history data is obtained, and 4)preferences for the format of family history tools. Results: The 34 respondents included 23 primary care physicians, and 5 NP/PAs. Most were in full time practice, 80% saw greater than 50 patients per week. 70% had been in practice greater than 5 years; only 9% practiced in communities of 50,000 or more. 54% of providers had electronic medical records (EMR) in their practices; 96% had internet access in their practices with 37% reporting internet access in patient rooms. 79% reported that family history was frequently or almost always important to out-patient care. 100% frequently or almost always obtained some family history at patient visits. Only 18% reported creating a 3 generation pedigree frequently or almost always; 57% had never generated a pedigree. 89% reported never or very rarely using a formal family history tool; a single respondent used an internet-based family history tool. When asked to predict probability of their use of a family history tool developed using a paper, internet, or EMR format 64%, 7%, and 57% reported that they would be likely or very likely to use such a tool, respectively. Conclusions: In this sample, rural primary care providers recognized the importance family history and reported obtaining family history data at a high rate. However, adherence to formal guidelines for obtaining a family history was poor, about 60% had never generated a pedigree on a patient. The prevalence of internet and EMR technologies in these practices was high; however reported use and interest in using internet based tools for family history was very low. This data suggests that there may be significant barriers to the use of internet-based family history tools in primary care, and that paper-based family history tools or those integrated into an EMR environment might be more readily accepted.

Copper Replacement Treatment for Symptomatic Menkes disease: Ethical Considerations. *P. Liu[1], S.R. Sheela[2], S.G. Kaler[1].* 1) Unit on Pediatric Genetics, Laboratory of Clinical Genomics, NICHD, NIH, Bethesda, MD; 2) Dept. of Pediatrics, Indira Gandhi Cooperative Hospital, Cochin, India.

Menkes disease is an often fatal X-linked recessive infantile neurological disorder caused by mutations in a copper-transporting ATPase (ATP7A). Subcutaneous injections of copper in Menkes disease restores circulating copper levels to normal. However, while early initiation of this treatment can lead to normal neurological development in affected infants, clinical outcomes in older, symptomatic Menkes patients have generally been disheartening. We address the ethical concerns surrounding whether copper treatment should be offered for Menkes disease infants diagnosed after neurological symptoms become manifest. These include: 1) the prospect for any benefits, 2) the potential risks and discomforts, 3) the parents wishes with respect to treatment, 4) the familys understanding of the treatments potential futility, 5) the familys understanding of the investigational nature of the treatment, 6) the potential for treatment to have an adverse impact on unaffected family members, 7) whether the ultimate decision regarding treatment should rest with health care providers or with the patients parents, and 8) the duration of treatment. An individual family report illustrates the problems and decision points encountered. We conclude that the ultimate decision on instituting a treatment with the possibility of small clinical benefits and improved patient comfort is best made by a patients parents. Clinical geneticists involved in the care of such families should provide full details on the limited benefits and potential risks of treatment, and offer adequate time for the parents to absorb and act on this information. The ethical issues encountered in providing investigative and possibly futile treatment for this difficult disorder seem relevant to other pediatric genetic conditions as well.

The Formation of Advocates' Concerns about Policy Issues Related to Genetics and Genomics. *E. Alfano, J. O'Leary, J. Martin, R. Caligiuri, E. Terry, K. Christensen, R. van der Riet, N. Robinson, L. Wise, S.F. Terry.* Genetic Alliance, Washington, DC.

Purpose: To ascertain which policy issues disease advocates consider critical to the integration of genetic and genomic discoveries into medicine, and to determine what constitutes effective engagement of the advocacy community in these issues.

Methods: We surveyed 200 advocacy organizations, to determine which policy issues they considered critical to their organizational missions. We also analyzed the methods they used to make these determinations, particularly with regard to priority setting and resource allocation. We convened the advocacy community in a number of forums - meetings, listservs and teleconferences to discuss these issues and potential methods of impacting the policy debate.

Results: In general, the advocacy community measures the importance of policy issues in a pragmatic way, by determining the impact of the issue on translation of research to medicine. Resources are allocated by determining impact of the issue on the organization. Common policy topics included genetic nondiscrimination, reimbursement, access and disparities.

Conclusions: The voice of advocates and consumers is critical to the policy debate and may advance the integration of genomics into medicine. In addition, larger and more complex organizations integrate political considerations into health outcome concerns leading to a more complex policy priority setting scheme.

Genetics websites: Quality, cultural content, and readability. *K.M. Kelly[1], R.B. Patrick[2], R. Shedlosky-Shoemaker[2], M. Katz[3].* 1) Human Cancer Genetics; 2) Dept of Psychology; 3) College of Public Health, Ohio State Univ, Columbus, OH.

The internet offers unprecedented opportunities for the communication of genetics information. However, the extent to which the internet will be useful to the general public will depend on the readability and quality of information conveyed. Studies of health-related websites have found that many have readability levels too advanced for the general population, which reads at or below the 8th grade level. The current study analyzed 55 genetics websites, identified through a National Institute of Health, Medline Plus internet search. Quality was analyzed consistent with guidelines from Health on the Net. Analysis of cultural content was guided by the Childrens Health Partnership. Readability Calculations software was used to compute 9 readability algorithms. In general, quality scores were high in ownership (98%), authoritativeness (98%), currency (96%), and interactivity (67%). Scores were lower in attributions (38%) and purpose (2%). Overall, little cultural content was included. Photos were uncommon (35%), but graphics were noted in most sites (82%). Although none of the sites were multi-lingual, some sites included links to multi-lingual (31%) and cultural (16%) sites. The average number of words per site was near 1,500. Reading levels were computed with the Flesch Reading Ease (M=38.9, SD=15.5), FOG Index (M=15.3, SD=3.1), Flesch-Kincaid Grade Level (M=12.5, SD=2.8), SMOG Tool (M=14.0, SD=2.1). Both the Flesch Reading Ease and FOG Index were more difficult than their target scores of 60 ($p<.001$) and 8 ($p<.001$). Both the Flesch-Kincaid Grade Level ($p<.001$) and SMOG Tool ($p<.001$) showed websites were written above the average grade level of the general population. Additional data regarding quality of genetics websites will be available at the time of presentation. In sum, the quality of websites identified through Medline Plus was high. However, most sites lacked cultural content and were written at a grade level too high for the general public. Efforts are needed to increase the accessibility of genetics websites to increase knowledge and awareness in the general public.

Non genetics health professionals' confidence in caring for individuals and families with genetic conditions: Preliminary data from the European GenEd study. *I. Nippert[1], C. Julian-Reynier[2], H.J. Harris[3], L.P. Ten Kate[4], U. Kristoffersson[5], J. Schmidtke[6], C. Benjamin[7], K. Challen[7], R. Harris[7].* 1) Women's Health Research, UKM, Muenster, Germany; 2) INSERM, Marseille, France; 3) Brooklands Beacon Medical Practice, Manchester, UK; 4) University Hospital, Amsterdam, The Netherlands; 5) University Hospital, Lund, Sweden; 6) MHH, Hannover, Germany; 7) St Mary's Hospital, Manchester, UK.

Introduction: Non-genetics health professionals will increasingly be faced with individuals and families who have a need for genetics information and services. It is of increasing importance that non-genetic health professionals are ready to understand the role of genetics in health care and to provide adequate information and services. **Methodology:** In order to assess the preparedness to care for individuals and families with a need for genetic services, 12 genetic service items were listed in the GenEd questionnaire. The questionnaire was distributed in 5 European countries and more than 4.700 health professionals responded. Service items ranged from taking a family history to obtaining informed consent before taking blood for DNA-tests. Respondents were asked to report their confidence in their ability to carry out these services. **Results:** The majority of the respondents was confident or highly confident in identifying specialist genetic services in their area of practice (59%) or in taking a family history (55.9%), however, less than a third of the respondents were confident or highly confident in providing 8 out of 12 services. The lowest confidence rates were reported for counselling a woman for a predictive testing for Huntington's disease (9.5%), for recognising when malformations may be genetic in origin (12.7%) and for identifying patient support groups for rare genetic disorders (19.7%). Professionals with education in genetics were significantly more confident in providing 10 out of 12 services than professionals with no education in genetics. **Conclusion:** A coordinated international effort is needed among genetic professional associations and non-genetic professional associations to raise the level competence and confidence.

Unpacking the Justifications for the Canadian Ban on Therapeutic Cloning. *C. Kurata, T. Bubela, T. Caulfield.* Health Law Inst, Univ Alberta, Edmonton, AB, Canada.

Introduction: In 2004, the Canadian Parliament enacted the *Assisted Human Reproduction Act*, using criminal law to ban all forms of human cloning, including somatic cell nuclear transfer (therapeutic cloning). The official justifications for this sweeping ban are stated in the Report of the Standing Committee on Health, *Assisted Human Reproduction: Building Families*, and in Health Canada media releases that accompanied a proposed version of the Act in 2001. These justifications are threefold: 1) concerns about the commodification of human reproductive capabilities and commitment to the ideal of human dignity, 2) concerns about public health and safety, and 3) claims of a social consensus respecting the impropriety of human cloning. Since it is Parliament - and not the bureaucratic machinery of Health Canada - which enacts Canadian law, discrepancies between the official justifications and those proffered in Parliamentary debate are both significant and worth documenting. This study examines whether such discrepancies exist.

Methods: First, we perform a qualitative, thematic analysis of the concerns about therapeutic cloning voiced in submissions to the Standing Committee on Health. Next, we see which of these submitted concerns resurface in the Committees Report. Finally, we analyze Parliamentary debates about the *Act* to see which justifications held sway at the moment of the legislations enactment.

Results: As the debate about the *Act* progressed from submissions to the Standing Committee to the final stages of Parliamentary debate, the tenor of the discussion shifted. From the plurality of arguments voiced in submissions, the three aforementioned official justifications emerged in the Standing Committees Report. Finally, Parliamentary debates - the final stage of political scrutiny - were marked by concerns about the moral status of the embryo.

Conclusion: The official justifications for the ban on therapeutic cloning do not reflect the concerns of the legislators who enacted it.

Peter Severinus (1540-1602) and the Transplantation of Hereditary Disease. *M.T. Walton[1], R.M. Fineman[2].* 1) Independent Scholar, 16th Cent Studies Group, Salt Lake City; 2) Independent Scholar, Seattle.

The re-discovery of the works of Mendel and others has added greatly to our understanding of genetics. Such is now the case of Peter Severinus, with the recent re-discovery of his seminal work, Idea Medicinae Philosophicae (1571). Severinus concurred with Paracelsuss (1493-1541) concept of seeds (little chemical factories) that worked on matter to form living things; but he was also aware of transplantation (grafting and cross-pollination) that changed phenotypes and genotypes in plants. He applied this understanding to hereditary diseases in humans and extended Paracelsian theory. He believed that certain diseases in ones offspring were caused by a parents infected (abnormal) seed. Severinus also observed that some hereditary diseases skip generations, and some eventually lost their force and died out. Severinuss understanding of hereditary diseases also gave hope for their treatment, i.e., the chemical imbalance associated with a hereditary disease could be altered with the proper chemical remedy. Severinuss theory of hereditary disease was discussed and respected for almost a century but, eventually, it was forgotten as medicine moved towards a mechanical view of biological processes, and focused on the matter theory, measurement, and eventually Lavoisiers oxygen chemistry. Severinuss transplantation of hereditary disease was forgotten before the 19th century, although 19th century ideas of seed and germ plasm descend from Paracelsianism. His ideas were probably unknown to Mendel, who understood his own experiments in terms of the then current theory of germ plasm. Still, Severinuss budding understanding of hereditary disease shows that Paracelsian biochemical theory could yield a reasonable conceptualization of unseen processes, just as the theory of germ plasm did later. Severinuss coupling of keen observation with theory deserves to be re-discovered (a search of the U.S. National Library of Medicine web site finds little or no information about Severinus or his work) and acknowledged in much the same manner as Mendels work. Indeed, we can learn a great deal from how past thinkers conceptualized their theories and made observations.

Comparison of Healthcare Professionals Responses to Ethical, Legal, and Social Issues in Cancer Genetics. *K. Banks, K.R. Blazer, J. Culver, K. Lowstuter, D.J. MacDonald, J.N. Weitzel.* City of Hope, Duarte, CA.

The evolving practice of genetic cancer risk assessment raises complex ethical, legal, and social implications (ELSI) concerning the appropriate treatment of genetic information. We surveyed health care professionals attending a one-day clinical cancer genetics education conference regarding their attitudes and knowledge about specific ELSI issues in clinical cancer genetics using hypothetical case scenarios. The 116 participants recorded their profession and responses (yes, no, or unsure plus explanation) to ten ELSI scenarios on an anonymous answer sheet which was collected prior to discussion of the scenarios. Reported professions included 32 doctors (MD), 23 nurses/student nurses (RN), 21 Genetic Counselors/genetic counseling students (GC), and 15 others. Most respondents recognized scenarios of potential genetic discrimination in health insurance (75%) and employment (91%), with no significant differences in knowledge between MDs, RNs, and GCs. For scenarios in which patient autonomy conflicted with duty to warn the patient, there were significant differences between professions, in that GCs favored patient autonomy, while RNs and MDs favored duty to warn ($P < 0.05$). Similar results were found in scenarios where patient confidentiality conflicted with duty to warn at-risk family members. Regarding the use of genetic testing to determine predispostion to an adult-onset hereditary cancer syndrome in a minor or for prenatal diagnosis, there were significant differences between professions with GCs being the least likely to facilitate testing in either scenario ($P < 0.001$). Differences in responses between professions likely reflect differences in their disciplines predominant approach to healthcare. Given the ethical challenges inherent in cancer genetic testing, involvement of a multidisciplinary team with complementary training backgrounds may be beneficial for the patient. Our findings suggest that while health care providers have basic knowledge about bioethical principles, the unique and dynamic nature of genetic information poses ethical challenges in practice which may be better understood through case-based training in ELSI issues.

Is carrier screening for Gaucher disease type 1 justified? Lessons from the Israeli program. *S. Zuckerman[1,2], E. Levy-Lahad[1,2], A. Zimran[2,3], A. Shmueli[2], A. Lahad[2], M. Sagi[2,4].* 1) Medical Genetics, Shaare Zedek Medical Center (SZMC); 2) Hebrew University-Hadassah Medical School; 3) Gaucher Clinic, SZMC; 4) Medical Genetics, Hadassah University Hospital, Jerusalem, Israel.

Gaucher disease type 1(GD-1) is an autosomal recessive storage disorder. Presentation is variable, and includes hepatosplenomegaly, bone disease, and lack of neurological disease. One in 17 Ashkenazi Jews is a GD carrier. The most common mutation, N370S (75%), is mild, ~70% of homozygotes are virtually asymptomatic, and there is effective enzyme replacement therapy (ERT). Carrier screening for a low penetrant, treatable disease is controversial, but GD is part of the Ashkenazi panel and is widely offered in Israel since 1995. We conducted a nationwide study evaluating screening outcomes and experiences of at-risk couples identified. Between 1995-2003, ~35,000 persons had GD testing. 83 GD-1 carrier couples were identified, 65 (78%) of which were interviewed about decisions, knowledge, and attitudes towards GD/screening. 78% had prenatal diagnosis. Of 16 GD-1 fetuses diagnosed, pregnancies were terminated in 2/13(15%) N370S homozygotes and in 2/3(66%) N370S compound heterozygotes. Two of 4 couples who terminated pregnancies regret doing so. None of the GD-1 children (including older sibs) have required ERT (mean follow-up 5.6 yr). Attitudes toward pregnancy termination correlated with perceptions of GD as severe, of a high risk for severe disease in homozygotes, and with the expected genotype (with or without one severe GD allele). Most subjects recall getting minimal information pre-testing and only 55% felt post-testing counseling was sufficiently informative, though knowledge of GD was found to be very good. About 50% also met with a GD expert. 76% did not regret testing and 68% support program continuation. Despite high ERT costs, screening is not cost-effective since most couples do not terminate GD-1 fetuses. Though most couples perceived no harm, we conclude that GD-1 screening is unjustified: its benefits are unclear, it is not cost effective, and can result in questionable pregnancy terminations. If screening is performed, thorough genetic counseling is imperative to avoid harm.

Recruitment to a familial cancer study: Balancing privacy protection and research quality. *J. Slutsman, B. Graubard, A. Garceau, G. Willis, L. Wideroff.* National Cancer Institute, Bethesda, MD.

Family-based research involving participation of index subjects and relatives is critical to cancer research. Little empirical data are available about factors associated with relatives participation in research, although this information is important for conducting studies. This research evaluates an investigator driven recruitment strategy enabling index subjects to first discuss the study with relatives. We assessed whether the index subjects willingness to give investigators permission to contact relatives was associated with their own demographic characteristics and other relative characteristics. In 2001, a random digit dial phone survey was conducted to determine the accuracy of family cancer history reported by 1,380 index subjects(response rate=70%). After obtaining a family roster and cancer history for 1st and 2nd degree relatives, a random sample of relatives was identified for validation of their cancer histories. Index subjects were given calling cards to facilitate discussion with relatives and were then asked to allow investigators to contact relatives. Determinants of contact permission were assessed using weighted multivariate logistic regression. Sixty-five percent of index subjects contacted at least one relative to discuss the study, although non-whites were less likely to do so than whites (OR=0.52 [0.32-0.84]). Furthermore, 67% gave investigators permission to contact some or all sampled relatives for an interview. After adjustment for educational level, index subjects were more likely to give permission to contact relatives with a history of cancer (OR=1.19 [1.08-3.37]), and those with whom they had a supportive relationship (OR=5.13 [2.66-9.92]). Overall, 90% of the 717 relatives whom the investigators were given permission to contact agreed to participate. With two-thirds of index subjects granting contact permission, this recruitment strategy was relatively successful, particularly among whites or for relatives with a supportive relationship or cancer history. This approach may enhance feasibility of population-based family studies and provide an effective balance between scientific objectives and ethical responsibility.

Gender specific differences in the psychosocial adjustment of parents of a child with Duchenne Muscular Dystrophy (DMD): Two points of view for a shared experience. *A.A. Samson[1], S.A. Miles[2], M.C. Choquette[2], P.J. Jacob[1,2], P.K. Chakraborty[1,2], E.M. Tomiak[1,2].* 1) University of Ottawa, Ottawa, Ontario, Canada; 2) Children's Hospital of Eastern Ontario, Ottawa.

We have conducted a qualitative analysis of couples having a child living with DMD. Each member of the couple was interviewed separately. The focus of the semi-structured, open-questioned interview was on the key psychosocial aspects of the process of adjustment to the illness of their child (family and spousal relationships, daily life, emotions, career, spirituality, coping strategies). There was evidence of gender specific differences in constructing the different aspects of the shared experience. This finding has implications for the design and implementation of intervention strategies aimed at spouses caring for a child with DMD, or with other severe, chronic and uniformly fatal illnesses. Preliminary data of the in-depth interviews will be presented.

Physicians' beliefs about the role of genetics in health differences and the importance of race/ethnicity and gender in clinical decision making. *E. Warshauer-Baker[1], V.L. Bonham[1], J. Jenkins[1], N. Stevens[2], Z. Page[1], A. Odunlami[1], C. McBride[1].* 1) Social and Behavioral Research Branch, National Human Genome Research Institute, Bethesda, MD; 2) University of Washington School of Medicine, Seattle, WA.

Recent research in genomics, pharmacology, and public health has sparked controversy over the use of race/ethnicity and gender in medicine. In particular, scholars argue whether the genetic contributions to group differences in health are overemphasized. There are little data on physicians' beliefs about these issues. We conducted a web-based survey of 1035 members of the American Academy of Family Physicians in January 2005, and we asked them the extent to which they thought racial/ethnic and gender differences in health were due to genetics and the environment. We also asked physicians to rate the importance of race/ethnicity, gender, age, family history, and insurance status in their clinical decision making. Overall, physicians surveyed reported that gender differences in health outcomes were due slightly more to genetics than to the environment (3.6 on a 7 point scale, where 1 = genetics, 4 = equally attributable, and 7 = environment; SD 1.3), and that racial/ethnic differences in health outcomes were due slightly more to the environment than genetics (4.6 on same scale; SD 1.2). In reference to their clinical decision-making, physicians rated age to be most important (5.9 on a 7 point scale, where 1 = not at all and 7 = essential; SD 1.1). Race/ethnicity (4.4; SD 1.4), gender (4.6; SD 1.5), family history (4.4; 1.5), and insurance status (4.3; SD 1.7) were rated similarly, and of less importance than age. Physicians' beliefs about racial/ethnic and gender health differences were not predictive of their ratings of the importance of race/ethnicity and gender in clinical decision making. To our knowledge, these data serve as a first, albeit modest, step toward understanding physicians' conceptualizations and conscious considerations of race/ethnicity and gender in their clinical decisions. Future research is needed to further elucidate these beliefs and better understand how they influence patient care.

COST-BENEFIT ANALYSIS OF THE NEWBORN SCREENING PROGRAM OF THE PHILIPPINES. *C.D. Padilla[1,2], L.F. Dans[2,3], S.C. Estrada[1,2], M.R. Tamondong[1], R.M.S. Bernal[1].* 1) Institute of Human Genetics, National Institutes of Health Philippines, University of the Philippines College of Medicine, Manila, Philippines; 2) Department of Pediatrics, University of the Philippines-Philippine General Hospital; 3) Department of Clinical Epidemiology, University of the Philippines College of Medicine.

Objective: 1) To establish the incidence rate of CH, CAH, Gal, PKU and G6PD deficiency; 2) To determine whether the PNSP is cost-beneficial for each disorder individually or in combination from a societal perspective. Methods: The study was conducted through a screening survey of the 24 Metro Manila hospitals. Newborns were screened for CH, CAH, GAL, PKU and G6PD after the 24th hour of life. Newborns who screened positive underwent confirmatory testing. Using incidence rates from the survey, a population of 1.5 million and different screening combinations, the costs for the detection and treatment of the five disorders were compared to the benefits projected from preventing the corresponding complications and consequent productivity losses. Sensitivity analyses for varying incidence and discount rates were conducted to test the strength of the conclusions. Results: Of the 5 disorders, the most commonly detected is G6PD deficiency, followed by CH. Among the 5 disorders, only CH ($5.29 M) and G6PD deficiency ($15.44 M) had net benefits when screened individually. Pairing the disorders with CH showed benefit:cost ratios above 1, except for CH+PKU. Combinations of disorders also resulted in mostly cost-beneficial results, except when PKU was added. The total costs of screening of the 5 disorders amounted to $28.94 M, while the total benefits amounted to $40.36 M, yielding net benefits of $11.42 M. Conclusion: This study demonstrates that the benefits of a newborn screening program of the Philippines vs. a do-nothing alternative far outweighs the costs.

Ethical Dilemmas in the Prenatal Diagnosis of Huntington Disease. *W. Hogge, M. Kolthoff.* Center for Medical Genetics, Magee Womens Hosp, Pittsburgh, PA.

Prenatal diagnosis is a well established reproductive technology. The principle goal of this technology is to diagnose fetuses with chromosomal abnormalities. Amniocentesis and chorionic villus sampling also may be used to diagnose classic genetic disorders of the fetus such as Tay-Sachs disease. Prenatal diagnosis for serious or fatal childhood diseases is generally well accepted. Current technologies also allow for the prenatal diagnosis of adult-onset genetic disorders such as Huntington disease (HD). It has been argued that prenatal diagnosis for HD followed by selective abortion is morally problematic because an affected fetus will likely experience decades of asymptomatic life. Furthermore, it is conceivable that some couples will decide to continue their pregnancy despite a prenatal diagnosis of HD. This scenario is worrisome because the future child may be harmed by their HD diagnosis while gaining little or no medical benefit from it. Finally, similar to the genetic testing of children, the prenatal diagnosis of HD in a continuing pregnancy raises concerns regarding future autonomy. The future child would not have a choice as to when or if to find out their true HD-status. Yet, in contrast, the PND of HD plays a vital role in the reproductive decision-making. Many at-risk couples feel strongly that they are responsible for preventing HD and its associated suffering in their children. Alternatives such as preimplantation genetic diagnosis with embryo selection or gamete donation are often prohibitively expensive, medically invasive, or do not allow for the preservation of genetic relationships between parent and child. Without PND, at-risk couples may be left to choose from natural conception, adoption, or to forgo child-bearing entirely. Limitation of reproductive autonomy to this degree requires demonstration of clear harm in order to be ethically reasonable. However, the proposed harms to future children have yet to be established or substantiated. Furthermore, the majority of pregnancies diagnosed with HD end in termination. In conclusion, the prenatal diagnosis of HD should be regarded as morally sound and should be available to at-risk couples in order to respect their reproductive autonomy.

Navigating the ethical minefield between genetic research and clinical genetic services. *K. Hodgkinson[1], T. Young[1], S. Connors[1], A. Bassett[2], P. Parfrey[1], D. Pullman[1].* 1) Patient Research Ctr, Memorial University, St John's, NL, Canada; 2) Clinical Genetics Research Program, CAMH, Toronto, ON, Canada.

What responsibilities does a research team incur following the determination of clinically relevant genetic data for a serious disease with high recurrence risk and ameliorative interventions? Is the research team responsible for testing until clinical services can provide the results? Should research ethics boards (REB) require that provisions be made for clinical follow-up of subjects prior to project approval? Is it ethical to do genetic studies outside the locale of the primary research team unless there is local clinical follow-up of families? Should DNA results be seen as any other clinical test, and should a subject have the right to learn about a DNA result with health implications in the absence of permission from an affected relative? These questions have arisen in a Newfoundland research project on 16 families with autosomal dominant arrhythmogenic right ventricular cardiomyopathy (ARVC) that share a disease-associated haplotype at 3p25. This disease causes sudden cardiac death that can be treated effectively with implantable cardioverter defibrillators. DNA haplotyping within the context of a research project is part of the clinical work up. The lethality of ARVC has forced us to re-evaluate our procedures. Our consent form now requires that DNA results be given when available and we are considering a genetic Miranda statement to allow genetic information to be passed to family members if subjects cannot. Our molecular geneticists are covered for clinical liability by the University and Hospital. Our REB now considers the ability of local services to continue to follow and treat families after project completion as a criterion for project approval. Newfoundland has been the site of external research projects where no provision was made for clinical follow-up. These issues are doubly important in such circumstances as local clinical services must be able to respond effectively to increased demand. In recognition of such issues, draft legislation is in progress requiring that all Newfoundland research projects on human subjects be assessed by a provincial REB.

The Use of Nude and Identifiable Photographs in Medical Genetics Textbooks: Ethical Considerations. *M.E. Burchett, A.L. Gustafson, C.A. Francomano, N.B. McDonnell.* Laboratory of Genetics, National Institute on Aging, Baltimore, MD.

Patient photographs are often used in medical genetics textbooks to illustrate phenotypes. Although such photographs are a valuable educational tool, utmost respect should be maintained for patient privacy and autonomy. Measures to protect the patients identity should be employed without compromising the educational value of the photographs. We encountered patients who have recognized their own nude photographs, taken during childhood, in medical textbooks and report that this is a distressing experience. We have reviewed sixteen major textbooks of medical genetics published in the last ten years for the presence of photographs of identifiable children and adults. Fourteen textbooks had at least one photograph of a completely identifiable nude patient. The range of such photographs was one to 217, and the mean number was 28. We located over one thousand photographs in which the patients full and identifiable face was depicted. The majority of nude and identifiable photographs represented minors. A statement on protection of patients rights to privacy, agreed upon by the International Committee of Medical Journal Editors in 1995, proposes that every measure should be employed to protect patient anonymity. The American College of Medical Genetics issued guidelines on informed consent for medical photography in 2000, stating that patients should be able to withdraw consent for the use of their photographs at a future date. The publication of an identifiable full face and/or nude photograph in a publicly accessible medical textbook makes the withdrawal of consent difficult to implement. We believe that the use of such photographs is not compatible with the spirit of protection of patient privacy, and should not have a role in medical textbooks. In the rare cases where a nude photograph is necessary to illustrate the genetic condition, the facial image should not be associated with the representation of the body. Efforts should be made to assure that the patient continues to give consent to the use of their images in subsequent editions of medical textbooks.

Successful partners for community cancer genetic services: oncology practitioners and a nonprofit organization supporting individuals genetically predisposed to developing cancer. *A.S. Tranin[1], C. Nichols[2], S. Seidler[2], C. Boyne-Schuh[2], S. Ethirajan[1], A. Jew[3].* 1) Kansas City Cancer Centers, Overland Park, KS; 2) STAR (Supporting Those At Risk) Foundation, Overland Park, KS; 3) Breast Specialty, Menorah Medical Center, Overland Park, KS.

Cancer genetics is a rapidly evolving field, such that practitioners who do not specialize in the field are often not able to stay current with genetic discoveries and studies, or their psychosocial and ethical implications. The STAR (Supporting Those At Risk) Foundation is a unique nonprofit organization dedicated to the support of those who are genetically predisposed to developing any type of cancer. An oncology nurse specializing in genetics, a medical oncologist, a breast surgeon, three high-risk clients, and community leaders founded a successful high-risk support group in 1999 that evolved into the IRS designated non-profit organization, the STAR Foundation, in 2002. The founders recognized that many high-risk individuals were not appropriately identified, and their needs - emotional and medical - were often overlooked. In partnership with cancer genetic and oncology professionals, STAR promotes awareness of high-risk issues by presenting educational programs to healthcare providers and the public. STAR also provides access to cancer genetic counseling and testing for individuals who cannot otherwise afford these services. In addition, STAR directs a peer support group for those at risk for breast and ovarian cancer, assists in the placement of clients into suitable national clinical cancer genetics studies, and advocates for issues pertinent to high-risk individuals. STARs work assists a variety of community clinical practices in caring for individuals at risk. STAR has reached hundreds of diverse clients; helping to identify high-risk individuals and empowering them to manage their health proactively. The STAR Foundation is a successful example of an organization partnering with healthcare professionals to promote quality care, education, and advocacy designed for high-risk individuals.

Report of an international survey of molecular genetic testing laboratories. *M.M. McGovern[1], R. Elles[2], E. Ronchi[3].* 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) National Genetics Reference Laboratory, Manchester, UK; 3) Organization of Economic Cooperation and Development, Paris, FR.

A detailed survey of molecular genetic testing (MGT) laboratories developed a group of international experts was conducted in 18 countries on 3 continents between June and October 2003(response rate 63%; n=827). QA and reporting indices were calculated for each responding laboratory to allow comparison of practices with other variables. Most (99.9%) directors had a doctoral degree, were certified to practice laboratory medicine (74%), and had training in molecular genetics (67%) although qualifications varied by country since some have specific legal and training requirements. Notably, the QA and reporting indices were significantly higher in laboratories that had directors with formal training in molecular genetics. Similarly, participation in proficiency testing (PT) was associated with a higher QA index which is important as it is known that PT programs are not currently available for many genetic tests, or are limited in their dissemination to certain countries or regions. Of interest, there was no statistically significant difference in the mean QA index between laboratories in different settings, or across the different countries, indicating that the QA standards included in the survey have penetrated widely. In contrast, there was a significant difference in the mean reporting index between research labs compared to all other settings ($p<0.05$). Since the majority of responding laboratories both receive (64%) and refer (60%) specimens across national boundaries, many of which are for rare disease testing carried out in research laboratories, this finding suggests that improvement in reporting practices is needed. The high rate of transborder flow of specimens also suggests the need to delineate best practices for informed consent, storage of specimens and confidentiality in order to promote confidence in genetic testing. The results of this survey which will be presented in detail document that MGT is provided under widely varying conditions and regulatory frameworks and may be a useful guide for policy action at both governmental and professional levels.

A prospective study of reported genetic discrimination after screening for hemochromatosis and iron overload.

M. Hall[1], B. Snively[1], J. Barton[2], O. Castro[3], A. Ruggiero[1], J. Reiss[4], C. McLaren[5], R. Acton[6], P. Adams[7]. 1) Wake Forest Univ, Winston-Salem NC; 2) Southern Iron Disorders Center, Birmingham AL; 3) Howard University, Washington DC; 4) Kaiser-Permanente; 5) University of California, Irvine; 6) University of Alabama at Birmingham; 7) London Health Sciences Center, Ontario.

Methods As part of the Hemochromatosis and Iron Overload (HH/IO) Screening (HEIRS) Study, 2037 participants from 6 states and Canada received genotype and phenotype screening for HH/IO and a subset received clinical examination. One year later, they reported whether they had any problems with insurance, employment, or blood donation that they attributed to HH/IO. 876 of respondents had HFE C282Y/C282Y or had elevated transferrin saturation and serum ferritin (TS/SF); 631 had lower indications of possible health risk such as H63D or other C282Y genotypes, or less serious TS/SF elevations; and 530 were control subjects with normal HFE genotypes and TS/SF levels.

Results 28 of 2037 HEIRS participants (1.4%) reported problems with employment or insurance they believed were related to HH/IO, and 56 (2.7%) reported being turned down as a blood donor due to HH/IO. 30% of problems were reported by participants who were diagnosed before the HEIRS Study. Among those not previously diagnosed who receive a clinical exam (n=792), 0.51% (4) reported a problem with employment, 0.76% (6) with health insurance, 0.76% (6) with disability insurance, 0.88% (7) with life insurance, and 3.79% (30) with blood donation. Among participants who were screened by not examined, the rate of reported problems was no greater in those with some indication of possible health risk than in controls.

Conclusions The incidence of reported genetic discrimination one year after screening for HH/IO is low, but is greater for those who underwent clinical examination, and is much greater for those who were previously diagnosed. This study was unable to determine whether problems increase over time or whether reports of discrimination were accurate.

Organization, administration, and funding of state genetic services programs. *G. Wang[1], A. Roche[2], C. Watts[3], R. Carlson[3], D. Lochner-Doyle[2], Genetic Services Policy Project.* 1) Public Health Genetics, Univ. of Washington, Seattle, WA; 2) Genetic Services Section, WA State Dept of Health, Kent, WA; 3) Health Services Dept, Univ. of WA, Seattle, WA.

Purpose: The Genetic Services Policy Project describes the delivery of genetic services via state genetics programs. This review identifies policies and practices that may affect utilization of and access to genetic services. Given the dynamism of the health care system and subsequent effects on state budgets, evaluating state genetics programs gains importance as states critically examine their services. Methods: We systematically reviewed literature identified through PubMed and the GEMdatabase for information about the delivery of genetic services via state programs. Results: Analysis of the 18 states with genetics plans or needs assessments showed five categories of state genetics activities: 1) newborn screening; 2) testing and counseling services ranging from prenatal to adult diagnostic testing; 3) programs providing treatments to individuals with genetic disorders; 4) educational activities; and 5) birth defects surveillance programs. States vary in how they organize and fund care, education, and surveillance activities. Responsibility for these activities generally falls to either state genetics units or children with special health care needs units. Funding to support state genetics activities comes from service-related fees, state and federal governments, and private sources. Conclusion: States play an important role in delivering health services, including genetic services. Examining state systems and their effect on utilization of genetic services may reveal models for making access to services more equitable and administration more efficient. Changes in state-sponsored and publicly administered genetic service programs could substantially affect providers, payers, and consumers if public services are eliminated or transferred to the private sector. To continue its work in describing genetic services delivery models, the Genetic Services Policy Project plans to collect information from key stakeholders in order to translate genetics research into practice.

Birth defects in Brazil: proposals for structuring and integrating care in the public health system. *D. Horovitz[1,2], J. Llerena Jr[1], R. Mattos[2].* 1) Instituto Fernandes Figueira, Rio de Janeiro, Brazil; 2) Universidade do Estado do Rio de Janeiro, Brazil.

The impact of birth defects (BD) in Brazil is increasing, shifting from fifth to second cause of infant mortality between 1980-2000, pointing to the need of specific health policy strategies. Actions related to BD in Brazil comprise teratogenic and metabolic disease information services, folic acid flour fortification, BD monitoring, newborn screening and treatment programs for some genetic diseases. Despite the importance of such initiatives, the organization of the genetic services as a functional network in the Brazilian public heath system (SUS) has not been contemplated. Aiming to map genetic services in Brazil, a questionnaire was sent all over the country, with data obtained from 60 services: 33 with clinical and laboratory services, 15 clinical, 8 laboratories and 4 medical teaching institutions. When estimating the need for clinical consultations related to BD, combining the research data and figures from the SUS database, there is clearly a consultation deficit. Regarding laboratorial support, an informal network operates among genetic services in the country, lacking official billing mechanisms. Propositions to improve care regarding BD are formulated, such as turning clinical genetics into an official medical specialty in the SUS, formalization of a national laboratory network with creation of billing mechanisms and the establishment of reference clinical and laboratorial centers integrated to the SUS. Also, a national BD registry based on birth certificates and educational programs for medical and general population are advised. It is presently unlikely in the SUS, where most decisions regarding health care are based on county administrations, that BD can be viewed from an integrated standpoint. A specific national policy regarding BD must be formulated, contemplating general care and alternative funding and billing options. Only with the active participation of the Ministry of Health, using the existing genetic services as a dorsal spine, will it be possible to structure a regionalized, hierarchical and functional network for the care of BD in Brazil.

Licensure of genetic counselors: lessons learned in Oklahoma. *A.E. Weedn, S.J. Hassed, J.J. Mulvihill.* Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Licensure for genetic counselors is imperative to provide accountability and quality assurance to patients receiving genetic counseling. One state, Utah, has implemented licensing, California and Illinois have achieved legislation, and several others are at various points in the legislative process. The Policy Committee of the Oklahoma Genetics Advisory Council (*Am J Hum Genet* 2000;69:A62) initiated efforts to create legislation to license the states genetic counselors. The Genetic Counseling Licensure Act, modeled after the Utah and California bills, was drafted and circulated to the leaders at NSGC, ACMG, and ASHG to solicit feedback. The bill defined the profession and scope of genetic counseling, described licensure and continuing education requirements, prohibited other healthcare professionals from representing themselves as genetic counselors, and directed the State Board of Health to promulgate rules and licensure requirements. The bill unanimously passed the Health Committee in the Senate, but was challenged on the Senate Floor due to concern regarding the potential for abortion counseling. An amendment modifying the scope of practice was adopted, and the bill passed the Senate Floor. In the House Health Committee, the bill met opposition from the Chair of Oklahomans for Life, sparking a debate regarding the bills presumed potential for increasing abortions in the state. Ultimately, the bill (available at www.lsb.state.ok.us/) failed to pass out of committee by a narrow vote despite support voiced by a majority of non-committee Representatives. The bill will be reintroduced next year with plans to focus on quality assurance and access to care. Lessons learned from this experience include: the need for effective lobbying at every step of the legislative process with early formation of a lobbying coalition, simplifying language, partnering with national and local organizations to gain support, distributing compelling documentation on the importance of licensure, and educating the public and legislature on the practice of genetic counseling and the need for setting a professional standard of quality care.

Releasing Results of Genetic Testing to Research Participants: A Multidisciplinary Consensus Statement. *M. Cho, S. Tobin, H. Greely, D. Magnus, J. Illes, CIRGE Genetics Research Policy Working Group.* Ctr Biomedical Ethics, Stanford Univ, Palo Alto, CA.

With recent advances in molecular technologies, a wide variety of genetic research projects now involve large-scale genotyping of individual participants. For example, such studies may seek to define the genetic contribution to disease, or may look for correlations between sequence variations and pharmaceutical safety or effectiveness, or may assess large populations to detect interactions between environmental exposures and heritable susceptibilities. All investigators engaged in the design and conduct of such projects are faced with the dilemma of whether, how, and when to report findings from genotyping to those who participate in their research studies. These findings may be genetic testing results specifically collected as part of the study, or DNA sequence of clinical significance but incidental to the purpose of the study. A dizzying array of medical, social, legal, and ethical factors can be considered, each of which may influence study design, conduct of informed consent, dissemination, composition of research teams, and availability of resources. Most principal investigators, proposal reviewers, and research administrators are not prepared to address these complex issues and their implementation.

In the summer of 2005, the Center for Integration of Research on Genetics and Ethics (CIRGE) at Stanford University invited a group of nationally known genetics researchers and ethicists to attend a workshop to address these issues. A consensus among these experts was sought through interactive case-based exercises, targeted presentations, small group discussions, and deliberations involving all attendees, with a charge to craft detailed recommendations useful for researchers, policymakers, research administrators, and funding agencies. The goal of this group effort is to create a flexible tool that will assist with creation and evaluation of projects that advance knowledge in genetics and acknowledge the complexity of handling genetic information about individuals appropriately.

Bringing Science and the Law Together. *M.W. Sharp[1], J.P. Evans[2], T. Caulfield[1].* 1) Health Law Inst, Univ Alberta, Edmonton, AB, Canada; 2) Departments of Genetics and Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Introduction: Science and the law have traditionally been perceived as distinct cultures. The knowledge, training, and philosophies of scientists are divergent from those of lawyers and judges. In modern practice, the increased interaction between science and law is demonstrated, for example, by the use of genetic information as forensic evidence and by government regulation of genetic research. Science and law can no longer act as completely separate pursuits, and an understanding of their differences is necessary to achieve a synthesis to confront important emerging societal issues. This study will examine how science and the law interact and will highlight the differences between the two cultures. **Methods:** An analysis of pertinent case law, legislation, and professional organization policy statements was performed to examine the roles of science and the law and how the two disciplines interact. **Results:** The scientific and legal cultures serve different roles in society. While the ultimate goal of uncovering the truth is arguably common to both positions, there are different tools available and limits upon each to pursue this goal. While science can generally be described as an active pursuit of answering questions, the law has a passive role, addressing conflicts as they arise. In modern North American society, science is subservient to the law, allowing scientific pursuits to be restricted and regulated by legislation and court decisions. **Conclusion:** This examination of science and the law demonstrates that the fundamental differences between scientists and members of the legal profession are a potential source of confusion and conflict between the two cultures. Further analysis of these differences can lead to a better understanding of scientific-legal interactions, the development of an interaction model, and an enhanced method of confronting important societal issues.

Public Consultation About Reproductive Genetic Testing: An Evaluation of Two Methods. *J. Scott, K. Hudson.* Genetics & Public Policy Ctr., Johns Hopkins University, Washington, DC.

Public consultation is used to understand the publics attitudes about a specific issue and the values that shape those attitudes. A public consultation process known as deliberative democracy brings together experts, policymakers and fellow citizens to learn from each other and deliberate about the issue. It requires broad and representative participation, balanced and accurate information, and an opportunity to deliberate with fellow participants. Unlike other countries, there have been few public consultation activities in the U.S., especially on the topic of human genetics. We evaluated two deliberative democracy models on reproductive genetic testing. METHODS: *The Genetic Town Hall: Making Every Voice Count* was held in six cities using a modified town hall format and separately conducted online with 15 discussion groups. Informational videos were used to ensure uniform content in each setting. The town hall participants were recruited using community outreach. The 3-hour, scripted sessions provided a balance of pre-session polling, education, facilitated discussions, and post-session polling. Online participants, recruited from a representative web-enabled panel, took an 80 item online survey, met online for one-hour moderated discussions weekly for three weeks, then took a 76 item post-discussion survey. A randomly selected control group completed identical pre- and post-surveys. RESULTS: 536 participated in the town halls; 133 online. Significant shifts in attitudes occurred in both groups, most notably about appropriate uses of reproductive genetic testing and the need for oversight. The town halls attracted more knowledgeable stakeholders; online participants were more representative of the general public. Town halls generated media coverage and the involvement of community leaders; online groups had more detailed discussion but had limited wider impact. CONCLUSION: As genetic discoveries move from research into practice, public consultations such as these can provide a mechanism for public education and dialogue with experts and policymakers. Depending on the goals of the public consultation, however, each method has benefits and drawbacks.

Community Engagement and Genetic Variation. *S.F. Terry[1], P. Johnson-Moore[2], K.P. Deignan[2], H. Martinez[3], S. Metosky[4], T. Citron[4], Public Engagement in Genetic Variation and Haplotype Mapping Community Advisory Committee.* 1) President and CEO, Genetic Alliance, Washington, DC; 2) Iona College, New Rochelle, NY; 3) Westchester County Department of Health, Westchester, NY; 4) University of Michigan, Ann Arbor, MI.

This project assessed public reaction to the complex concepts of genetic variation, haplotype mapping and disease susceptibility in distinct populations. Using the suburb of a major city as the engagement and educational research site, this project invited community organizations, their members and the general public to participate in focus groups, public dialogue activities and a conference designed to explain, explore and examine these new scientific concepts.

The research team acquired background knowledge, established community oversight and advisory boards, convened diverse focus groups to develop an initial list of genetics issues, developed educational and issue-oriented materials relating to the issues list, convened community-based dialogue groups to select issues of concern and carry out a series of dialogue sessions, held a one-day Community Conference and disseminated the results back to the community and to other interested parties.

The communities concluded that these issues needed to be communicated to scientists working on genetic variation: disparities and access, privacy, control/decision making, identity, nonmedical uses, anthropological issues and definitions of health and disease.

This project was funded by the Ethical, Legal and Social Implications of National Human Genome Research Institute (NHGRI) through the Communities of Color and Genetics Policy Project at the University of Michigan. [NIH-ELSI GRANT: # 2 RO1 HG01005-01].

Islamic Ethical Guidelines in Genomics and Genetics: A public Health Initiative. *A. Al-Aqeel*[1,2]. 1) Dept Pediatrics, Riyadh Military Hosp, Riyadh, Riyadh, Saudi Arabia; 2) Dep of Genetics, King Faisal Specialist Hospital and Research centre.

We are at a time of unprecedented increase in knowledge of rapidly changing technology. Such biotechnology especially when it involves human subjects raises complex ethical, legal, social and religious issues. A WHO expert consultation concluded that genetics advances will only be acceptable if their application is carried out ethically, with due regard to autonomy, justice, education and the beliefs and resources of each nation and community. Public health has a poor positioning in the health system, with lack of importance and support, poor dialogue with the publics and under skilled public forces, with lack of importance and support to, and long gap between intervention and outcome. Public health authorities are increasingly concerned by the high rate of births with genetic disorders especially in developing countries where Muslims are a majority. Therefore it is imperative to scrutinize the available methods of prevention and management of genetic disorders. A minimum level of cultural awareness is a necessary prerequisite for the delivery of care that is culturally sensitive, especially in Islamic countries. Islam presents a complete moral, ethical, and medical framework, it is a religion which encompasses the secular with the spiritual, the mundane with the celestial and hence forms the basis of the ethical, moral and even juridical attitudes and laws towards any problem or situation. Islamic teachings carry a great deal of instructions for health promotion and disease prevention including hereditary and genetic disorders, therefore we will discuss how these teachings play an important role in the diagnostic, management and preventive measures including: genomic research; population genetic screening (premarital screening, pre-implantation genetic diagnosis; assisted reproduction technology); stem cell therapy; genetic counselling and others.

Beyond technomedicine: the human aspects of Preimplantation Genetic Diagnosis. *C. Bouffard.* Pediatrics, Université de Sherbrooke, CHUS, Sherbrooke, Québec, Canada.

A recent multisite ethnographic research project in medical anthropology, conducted in France at PGD-accredited centres in Strasbourg, Paris and Montpellier, on the representations that researchers, physicians and patients entertain with respect to Preimplantation Genetic Diagnosis, showed that couples who opt for the technique entertain substantially different representations than those put forth by the bioethics milieux. This is particularly so of concepts regarding eugenism, the perfect child, the embryo, biological filiation, and the selfishness and narcicism that are associated to such concepts, as well as the abuse/misuse of reproductive biotechnology and its relatively limited therapeutic use, and patient vulnerability.

Such representations go beyond the technomedical approach. As such, PGD is perceived not only as an act of love toward ones partner and unborn child, but also as an expiatory rite, a means of assuming responsibility and compensating for the biological incapacity to avoid that child the affliction of serious disease. The ritual of PGD affords such couples the opportunity to demonstrate courage, love, a desire to conform, and a spirit of sacrifice, each of which also empowers both partners.

Our data suggest that PGD patients have developed novel representations with respect to reproduction and ethical concepts which coherently integrate the individual, familial, cultural, social, moral, technological and medical levels, and enable the perception of PGD as a human practise that offers informed couples the means to protect their offspring from an invalidating genetic combination. This makes it all the more difficult to elaborate guidelines and bioethical rules, with respect to reproductive genetics, without knowing or taking into account the points of view and experiences of patients, despite the fact that their representations, of what may be ethical or not, differ from those of the experts that preside the elaboration of such norms.

Taking a Family History from a Cultural Perspective. *C. Fernandez[1], F. McKain[1], I. Harlow[2], N. Robinson[3], S.F. Terry[3], P. Kyler[4], M. Puryear[4], J. Boughman[5].* 1) Institue for Cultural Partnerships, Harrisburg, PA; 2) American FolklifeCenter, Library of Congress, Washington, DC; 3) Genetic Alliance, Washington, DC; 4) Genetic Services Branch,MCHB,HRSA, Rockville, MD; 5) ASHG, Bethesda, MD.

Healthy Choices through Family History Awareness is a project developed by the Institute for Cultural Partnerships in collaboration with the American Folklife Center, the American Society of Human Genetics and the Genetic Alliance through a cooperative agreement with the Genetic Services Branch of Maternal and Child Health Bureau. Using an approach designed to tap into a familys own oral history and traditions, the folklorists and colleagues have developed a consumer-based family history tool that encourages and provides a format for individuals and families to organize and preserve family history and health related records. The Allison Hill area of Harrisburg, Pennsylvania, with a high density of low income African American and Latino populations, is marked by significantly poor health outcomes including diabetes, heart disease and stroke, cancer, and infant mortality, all conditions in which genetic factors play a critical role. Methods in tool development have included focus group feedback, field testing, and training of community advocates to encourage and assist families. By using this tool, we seek to increase genetic literacy among African American and Latino individuals and families residing in the area. The project has identified family practices regarding genetic health information management. Coupled with consumer education, the project will enable family members to better communicate about potential genetic risk factors among themselves and with their health care and social service providers. The project will serve as a model for increasing awareness of family history and its relevance to health for both consumers and providers.

Towards a New Paradigm: Redefining Race, Ethnicity & Underserved Communities in Light of Genetic Advances. *L. Wise[1], N.T. Robinson[1], R. van der Riet[1], G.C. Christopher[2], P. Kyler[3], M. Lloyd-Puryear[3].* 1) The Genetic Alliance, Washington, DC 20008; 2) Health Policy Institute, The Joint Center for Political & Economic Studies, Washington, DC 20005; 3) Genetic Service Branch, Maternal & Child Health Bureau, HRSA, HHS.

Purpose: In the light of recent advances sequencing & interpreting the human genome, some posit that human race does not meaningfully exist at the genetic level, while others think it does. The impact & validity of this debate is being studied by many organizations, including the National Commission on Health, Genomics & Human Variation.

Methods: A report is being prepared on how the field should interpret & respond to this debate. Through substantive research, including focus groups, the Genetic Alliance has developed a new paradigm on the roles that race, ethnicity & underserved communities should play in field of health care that considers current genetic resources & the future of health in America. The Genetic Alliance has developed a broad dissemination plan, including training sessions & workshops, to encourage the consideration and use of this new paradigm in health care.

Results: The production of a teachable framework & workshop for a new philosophy & practice of considering race, ethnicity & underserved communities in health care will be delivered to the field.

Conclusions: In order to reduce health disparities & absorb genetic resources, new ways of thought & practice in health care regarding race, ethnicity & underserved communities are required.
Project funded by the Genetics Services Branch of the Maternal & Child Heath Bureau, HRSA, HHS - cooperative agreement #U33MC00214-04-00.

Gene expression profiling distinguishes subsets of patients with Sjogrens syndrome and sicca symptoms. *E.S. Emamian, L. Tobon, J. Leon, A.N. Leiran, C.M. Meyer, E.C. Baechler, T.W. Behrens, A. Huang, B. Segal, N.L. Rhodus, K.L. Moser.* University of Minnesota, Minneapolis, MN.

Sjogrens syndrome (SS) is a complex autoimmune disease defined primarily by clinical manifestations related to dry eyes and dry mouth (sicca symptoms). Initial studies in our lab using microarray technology revealed over expression of Interferon (IFN) inducible genes in peripheral blood of 34 SS patients when compared with 22 normal subjects. All 34 patients fulfilled the 2002 revised European criteria for SS and 91% were seropositive for anti-Ro/SSA and/or anti-La/SSB autoantibodies. Overexpression of the IFN inducible gene cluster was also positively correlated to titers of anti-Ro and anti-La. In the present study, we have evaluated 14 additional sicca patients who were clinically diagnosed with SS based on subjective symptoms of both dry eyes and dry mouth, but were seronegative and failed to meet the 2002 criteria due to either unavailable or inconclusive labial gland histopathology. Comparing gene expression in peripheral blood of Sicca vs. normal subjects identified 1,043 differentially expressed transcripts ($p<0.001$ and average fold change of >1.5). Comparison of SS patients vs. normals identified 246 transcripts, 30 of which overlapped with genes identified in the Sicca group. Hierarchical clustering was used to visualize patterns of differentially expressed genes across all patients (n=56) vs. controls. The majority of SS patients clustered together. However, 13/14 of the Sicca patients clustered together and displayed a gene expression pattern that was clearly distinct from the SS patients with a prominent IFN signature. Genes that best distinguish SS patients include IFI17, IFI15, IFIT3, OASL, TNFAIP6 and IRF7. In the Sicca group, unique genes include EEF1D, RAPGEF6, MAP3K3, TNFSF14, and transportin 1. Genes that are differentially expressed across all patients include HLA-G, STAT1, IFNAR2, TNFSF10/TRAIL and IgG heavy chain. These results indicate that subsets of patients with sicca manifestations can be identified using microarrays and that different pathways may be involved in the pathophysiology of patients with sicca symptoms.

Identification of some common pathways among autism spectrum disorders. *N. Kaya, M.S. Inan, M. Asyali, N. Sakati, M. Nester, P. Ozand.* Genetics, KFSH&RC, Riyadh, Saudi Arabia.

Autism is a neuropsychiatric, neurobehavioral disorder with a wide spectrum of diseases. In most situations, autism is the result of abnormal function of multiple genes or a few genes with pleiotropic effects, and in many cases the inheritance is affected by imprinting. We hypothesize that the individual disorders existing with the autism spectrum disorders might share common disturbed physiological and molecular pathways. For this purpose we have selected three disorders with different autistic phenotypes but all of which manifest autism; Rett syndrome, FragileX with autism, and Early and severe infantile autism. We performed microarray analysis of gene expression using Affymetrix HG-U133 Plus 2.0 in order to determine the gene signatures by detecting the altered molecular pathways. We will present several altered pathways that share common denominators.

Analysis of Mouse Inner Ear MPSS Libraries to Select for Rare and Novel Expressed Genes. *L.M. Peters, I.A. Belyantseva, J.F. Battey, T.B. Friedman, R.J. Morell.* National Institute on Deafness and Other Communication Disorders, National Institutes of Health (NIDCD/NIH), Rockville, MD 20850, USA.

Massively Parallel Signature Sequencing (MPSS) is a powerful technique that allows in-depth gene expression profiling by generating millions of 20-base signatures from the 3 end of mRNA samples. We have developed MPSS libraries of mRNA isolated from dissections of postnatal day seven (P7) mouse organ of Corti, stria vascularis and vestibular sensory epithelium tissues (libraries named MoCR, MoSV and MoVB, respectively). There are a combined total of 29,672 signatures in the three libraries, after removing non-reliable or non-significant signatures. Of these, 7,848 are unique to the inner ear, by comparison with other available MPSS libraries from a variety of mouse tissues. The most abundant of these signatures identify the 3 ends of genes already well known to be prevalent in the inner ear. For example, signatures for Otogelin are the most abundant unique signatures in the MoVB library, while signatures for Otospiralin are the most abundant unique signatures in the MoCR library. The low abundance signatures are especially interesting, since they should derive from rare transcripts present at 10 to 15 copies per cell. This should equate to approximately 40 times per million (tpm) for a signature from a low abundance message in a homogeneous tissue. Since the abundance levels can be estimated to as low as 4 times per million (tpm), these libraries should reveal signatures even for rare mRNAs expressed in specific cell types in the complex tissues of the inner ear. We have identified signatures to rare genes unique to the inner ear and have confirmed the expression and structure of these genes by RT-PCR and in situ hybridization.

Downstream molecular analysis of gDNA eluted from Formalin-Fixed, Paraffin Embedded Tissue (FFPET) using a modified GenSolve Method, stored on GenVault GenPlates, and recovered using GenSolve. *J.A. McEvoy, G. Veber, J.R. Tierney, D.T. Wong, M.E. Hogan, J.C. Davis.* BioScience, GenVault Corporation, Carlsbad, CA.

The aim of this study is to evaluate the quality and purity of genomic DNA isolated and stored from formalin-fixed, paraffin embedded tissue (FFPET) using a new method compared to a organic solvent based method. Genomic DNA from normal and malignant FFPE breast, liver and kidney tissue was isolated using two methods: GenVault Recovery Solution plus proteinase and a organic solvent based extraction. Fifteen microliters of the recovered DNA slurry was aliquoted onto each GenPlate element and dried prior to room temperature storage. Using the GenSolve DNA Recovery Kit the gDNA was isolated from the element to test for quality and purity. PCR amplification, sequencing, genotyping, SNP analysis, and whole genome amplification was preformed on gDNA isolated using the GenVault Method and organic solvent based methods. Results indicate the quality and purity of the gDNA isolated using both methods were comparable. The GenVault protocol does not require toxic solvents or temperatures above 60 C and provides sufficient sample for long-term, room temperature storage on GenVault GenPlates. Downstream molecular analysis can be performed using GenVaults gDNA recovery method from FFPET samples stored on GenPlates. The system and product is compatible with all GenVault semi-automated and automated storage and retrieval systems.

Comparative Genomic Characterization of Neuro-Episodic Disease Candidate Genes. *J. Freudenberg, Y.-H. Fu, L.J. Ptacek.* Laboratories of Neurogenetics, UCSF - Department of Neurology, San Francisco, CA.

Neuro-episodic diseases are known to share important characteristics both on the molecular level and the phenotype level. In the present study, we systematically identified protein sequence families and functional categories, which are associated with neuro-episodic disease genes. As expected, the most significant results were obtained for proteins with synaptic localization or for proteins involved in synaptic transmission. A relatively high number of disease genes with synaptic function is also reflected by their significant enrichment among the full set of human disease genes. We therefore hypothesized that genes with synaptic function posses an increased potential to harbor more penetrant disease mutations. If true, this could be reflected in an increased evolutionary conservation of those genes. Therefore, we next analyzed phylogenetic profiles of neuro-episodic disease genes and disease candidate genes with known synaptic function. We found both groups displayed an increased number of orthologs in non-primate vertebrate genomes. When examining sequence evolution of human-rodent ortholog pairs, we observed increased overall constraint on neuro-episodic disease genes as well as on synaptic candidate genes. Thus the enrichment of genes with synaptic function among human disease genes is correlated with their retainment in the genomes of other species and with a decreased sequence evolution. The genetic complexity of neuro-episodic disease phenotypes, therefore, could at least partially result from an increased likelihood of deleterious mutations in genes playing a role in synaptic function.

The Analysis of Array-CGH Data: A Change-point Approach. *N.R. Zhang, D.O. Siegmund.* Statistics Department, Stanford University, Stanford, CA.

Array-based comparative genomic hybridization (array-CGH) measures the chromosome copy number at multiple loci simultaneously, and is useful for finding the regions of genome deletion and amplification in tumor cells. However, array-CGH data is noisy, with the signals corresponding to chromosomal aberrations hard to detect. We model array-CGH data as a Gaussian change-point process, and propose a new statistic for determining the number of chromosomal aberrations. We call our statistic the "modified BIC" because of its similarity to the Bayes Information Criterion, which is a classic statistic for model selection but not applicable to this change-point problem.

We tested our method on both the simulation data from Olshen et al. (2003) and the array-CGH data sets from Snijders et al. (2001) and Snijders et al. (2003). The results show that the modified BIC is preferable to existing methods for statistical analysis of array-CGH data. The modified BIC has the advantages of being prior independent and impartial, and also much simpler to use than most of the current procedures. The method can also be applied to other problems involving model selection of change-point like problems.

Comparative analysis of chimpanzee full-length cDNAs mapped onto human genome unveils potentially large inter-species divergence in gene loci. *R. Sakate[1,2], Y. Suto[3], T. Imanishi[2], I. Hayasaka[4], T. Gojobori[2,5], K. Hashimoto[6], M. Hirai[7].* 1) Integrated Database Group, JBIRC, JBIC, Tokyo, Japan; 2) Integrated Database Group, BIRC, AIST, Tokyo, Japan; 3) 2nd Research Division, Japanese Red Cross Central Blood Institute, Tokyo, Japan; 4) Kumamoto Research Park, Sanwa Kagaku Kenkyusho CO.,Ltd., Kumamoto, Japan; 5) Center for Information Biology and DNA Data Bank of Japan (DDBJ), National Institute of Genetics, Shizuoka, Japan; 6) Division of Genetic Resources, National Institute of Infectious Diseases, Tokyo, Japan; 7) International Center for Molecular, Cellular and Immunological Research, Tokyo Women's Medical University, Tokyo, Japan.

Chimpanzees are our closest relatives in the evolutionary lineage and their genome sequences are highly similar to ours. In spite of the genetic similarity, there exists distinctive divergence between humans and chimpanzees, particularly in cognitive abilities and morphological traits. In order to elucidate the cause of the divergence at the transcript level, we constructed chimpanzee full-length cDNA (FLcDNA) libraries. In this study, chimpanzee cDNA sequences representing 87 gene transcripts were analyzed with the mapping information onto human genome. We found that, by comparing the alignable sequence pairs, the degree of diversity, including substitution and insertion/deletion (indel) events, in 5'-untranslated region (UTR) and 3'-UTR was smaller than that of synonymous substitution in coding sequence. We also found that the transcription start site (5'-UTR end) was more variable than the transcription termination site (3'-UTR end), and that putative species-specific alternative splicing occurred more frequently in 5'-UTR while large indels occurred more frequently in 3'-UTR. These results imply that different types of functional constraint exist between 5'-UTR and 3'-UTR along the human and chimpanzee lineages. Finally, given all the small and large-scale sequence divergences considered, the chimpanzee transcripts differed from their human orthologous counterparts by 2.6% in nucleotide sequences, which was larger than the difference formerly estimated.

Highlights of Genetic and Genomic Resources at NCBI. *D. Maglott, NCBI staff.* Natl Ctr Biotechnology Info, National Library Medicine, NIH, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) continues to increase the depth and breadth of the many databases and services that are accessed by millions of users daily. Building on the foundation of publications (PubMed, PubMedCentral, Books), sequence (GenBank, RefSeq) and maps (CancerChromosomes, Map Viewer), NCBI provides resources focused on genes (dbMHC, Gene, HomoloGene, UniGene), protein sequences and structures (TaxPlot, COGs, CDD, COGs, BLink), expression (GEO, GENSAT), phenotypes (GeneTests, OMIM, OMIA, PhenoDB), small molecules (PubChem), and variation (dbSNP). Recent developments of note include several new Entrez databases (GENSAT, Genome Project, OMIA, PhenoDB, Probe), tools to align mRNAs to genomic sequence (Splign), a robust client to analyze and annotate sequences (Genome WorkBench), enhancements to BLAST, and improved coverage and interrogation of such model organisms as bee, cow, dog, chicken, opossum, sea urchin, and zebrafish. More alternate assemblies of key genomes have been made available to complement official ones. The focus of the presentation will be the use of Genome Workbench and NCBI's databases in the areas of probe identification, gene structure, comparative genomics, and correlating sequence and phenotype.

Predictions and analyses of mutable sequences flanking the repeats in Friedreich's ataxia and Fragile X syndrome. *V. Handa, B.E. Wright.* Division of Biological Sciences, University of Montana, Missoula, MT-59812.

Genetic instabilities of triplet repeat sequences including $(CTG)_n(CAG)_n$, $(CGG)_n(CCG)_n$ and $(GAA)_n(TTC)_n$ have been found to associate with at least 14 genetic neurodegenerative diseases. Evidence suggests that DNA secondary structures formed by abnormally long repeats block the progress of DNA polymerase, resulting in extended pause sites and further expansions (or contraction) of these repeats during slippage replication. We have developed a computer algorithm *mfg* that can predict the location of unpaired, mutable bases in the secondary stem-loop structures [SLS(s)] of single stranded DNA during transcription. For a chosen window size, or length of nucleotides, *mfg* folds that number of nucleotides successively, beginning with each base in the sequence analyzed. The output of the program shows the percent of all folds in which each base is unpaired and the most stable (-G) SLS(s) in which it is unpaired and therefore most likely to mutate. We have used *mfg* to examine sequences flanking the repeats in two trinucleotide repeat disorders [Friedreichs ataxia (FRDA) and Fragile X syndrome (FXS)] with *mfg*. The program predicted intrinsic mutability of the sequences flanking the repeats. In the region upstream of the GAATTC repeats in FRDA, 21 mutable bases (2 deletions and 19 base substitutions) have been identified (Bidichandani et al., 1999).Different bases mutated in normal individuals compared to symptomatic individuals. In fact, *mfg* found different populations of SLS(s) in these normal individuals compared to symptomatic individuals and it could be shown that most of the mutable bases in symptomatic individuals were rarely unpaired while in normal individuals most of the mutated bases were unpaired. Similar analyses by the *mfg* program of the sequences flanking CGGCCG repeats in FXS have predicted that about 33 nucleotides 5 and 58 nucleotides 3 of the repeats are mutable. To verify the *mfg* predictions, we are amplifying these regions in normal, premutated and mutated Fragile X cell lines by polymerase chain reaction and sequencing them.

SNPselector: a web tool for selecting SNPs in genetic association studies. *H. Xu, E.R. Hauser, M.A. Hauser, S. Züchner, S.G. Gregory, J.E. Stenger, M.A. Pericak-Vance, J.M. Vance.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Single nucleotide polymorphisms (SNPs) are the most common form of polymorphism in human genome. They are commonly used in genetic association studies of complex diseases. With the recent advance of SNP genotyping technology, researchers are able to assay thousands of SNPs in a single experiment. However, the process of manually choosing thousands of genotyping SNPs is time consuming. We have developed a web program, SNPselector, to automate this process. SNPselector is implemented in PERL language. It can be run as a UNIX command-line application, with a CGI wrapper to provide the web interface. A local MySQL database is developed as back end of SNPselector to store SNP information, including SNP location, allele and allele frequency, function, validation, and HapMap genotyping data. To increase the program performance, Ensembl gene structure and UCSC genome annotation data are downloaded and stored in the local database as well. The local database is updated whenever new public data are released. SNPselector takes a list of gene names or genome regions as input and finds all available SNPs in the genes or genome regions. SNPs with experimentally-verified genotyping or allele frequency information are considered as high quality SNPs. SNPselector finds tagging SNPs by calculating LD bins of genotyped SNPs. It then finds SNP function based on whether the SNP may affect the gene transcript structure or the protein product. It checks the regulatory potential of the SNP based on SNP location at conserved site from multi-genome comparison, conserved TFBS site, CpG island, or miRNA gene. It also checks whether the SNP is in a repeat region. Finally it prioritizes SNPs on LD tagging property, SNP quality, function, regulatory potential, and repeat status. The SNP selection result is put into Excel files. Users can do further analysis on the SNP result files to select SNPs with specific features. Output formats include selected SNPs along with flanking sequences to Illumina or other companies for SNP assay design. Its code and database files are available upon request.

easyLINKAGE - Automated linkage analyses using microsatellite or large-scale SNP data. *K. Hoffmann[1], T.H. Lindner[2].* 1) Dept Medical Gen, Humboldt Univ, Charite, Berlin, Germany; 2) Department of Nephrology, Clinical Biochemistry/Pathobiochemistry, Medical University Clinic at the University of Würzburg, Würzburg, Germany.

Most of linkage analyses software was traditionally developed for UNIX environments restricting calculations to a limited number of experienced users. The time-consuming generations of input files as well as missing or very basic graphical outputs are further limitations. Nowadays, scientists prefer to perform their own analyses right after generating the genotypes. However, an automated tool for performing linkage analyses under the same operating environment where scientists get their daily PC work done was not available so far. We have developed the program easyLINKAGE that covers all those issues. It combines automated setup and performance of linkage analyses and/or simulation studies under an easy to handle graphical user interface for Microsoft Windows 2000/XP. The current version of the program supports FastLink, SuperLink, SPLink, GeneHunter/-PLUS/-Imprinting/-TwoLocus, Allegro, Merlin, SimWalk, and FastSLink with automatic loop breaking. Further, we integrated conditional multipoint analyses. easyLINKAGE provides genome-wide and chromosomal plots of LOD scores, NPL scores, P values, and many other parameters. The program generates input files for pedigree/haplotype drawing software such as HaploPainter. The program can test for HWE deviations, NON-/Mendelian inheritance problems. Data can be analyzed for predefined chromosomal intervals and in marker sets. The latter option enables the handling of thousands of markers on a chromosome. easyLINKAGE can simulate multipoint linkage data and performs subsequent linkage analyses according to the users model. To run the program marker files containing subject IDs/genotypes, a pedigree structure file (LINKAGE format), and a marker database are required. All options for the covered linkage programs can be set interactively. easyLINKAGE boosts the use of most known linkage programs under a Windows environment and enables to perform analyses for a wide audience (http://www.uni-wuerzburg.de/nephrologie/molecular_genetics/download.htm).

Modeling of Dynamic Genetic Networks. *Y. Sun[1], L. Jin[3], M. Xiong[2].* 1) Statisitcs, Fudan University, Shanghai, Shnaghai, China; 2) Human Genetics, University of Texas Health Scince Center at Houston; 3) School of Life Scicne, Fudan University, Shanghai, China.

A complex biological system has two states: equilibrium and disequilibrium. Static models of genetic networks are unable to reveal important information on how a biological process changes from one state to another or how to respond to environmental stimuli. It is also widely recognized that the regulatory interactions between genes in the networks can be fully revealed only through perturbation of biological systems. Therefore, a systematic understanding of these processes requires the development of mathematic tools for modeling dynamic genetic networks. Although dynamic Bayesian networks are emerging as a promising tool for dynamic genetic network modeling, they do have limitations for genetic network identification and analysis. First, dynamic Bayesian networks cannot model feedback structure of networks. Second, it is very difficult to develop nonlinear dynamic Bayesian networks. In this report, we propose to use dynamic structural equations as a basic tool for modeling dynamic genetic networks, which allow to model feedback structure of the networks and can incorporate dynamic Bayesian networks as a special case of dynamic structural equations into the dynamic genetic network modeling. Three-stage least square methods will be used to estimate the parameters in the networks and genetic algorithms will be employed to identify the structure of the genetic network which best fit the data. The statistics for testing the interactions between the genes in the networks will be discovered. The proposed dynamic structure equation models will be applied to cell cycle and drug response analyses.

Design of multiplexed oligionucleotide ligation assays for high throughput insertion/deletion and single-nucleotide polymorphism genotyping. *R. Koehler, Z. Zhang, N. Peyret, J. Day, S. Short, M. Wenz, F. De La Vega.*
Dept Bioinformatics, Applied Biosystems, Foster City, CA.

Insertion and deletions are important mediators of disease and disease susceptibility. We developed a multiplexed high throughput assay based on oligonucleotide ligation to determine genotypes of insertion/deletions and SNPs. The assay platform is based on the oligonucleotide ligation assay (OLA) followed by universal PCR and utilizing capillary electrophoresis as the readout. Three oligonucleotide probes address each SNP or insertion/deletion (indel) polymorphic loci with sequences including target site-specific and universal components. Target site-specific portions are designed to meet thermodynamic and specificity requirements, ensuring that probes bind efficiently and exclusively to only the intended polymorphic target sites. Universal components must not interfere with probe binding and probe sets must function without interfering with other probes in a multiplex. Potential interferences include probe-probe interaction, probes acting as ligation templates for other probes, and probes that inadvertently ligate to probes designed for another target loci. Avoiding regions of low sequence complexity and secondary structure also improves assay robustness. These rules are implemented in an automated design pipeline. We now describe design improvements aimed at increasing conversion rate, assay performance, specificity, and multiplex level for both SNPs and indels. Heuristics are used to screen candidate probes and design steps are ordered to reduce intensive calculations. For evaluating genomic uniqueness, we developed a fast and sensitive genome screening algorithm that takes the OLA reaction explicitly into account and uses empirically-based match/mismatch weights around each polymorphic loci. Our multiplexing algorithm uses information from the above screens together with specific probe-probe checks in a swapping strategy that partitions assays into mutually compatible multiplexes. The result is a set of OLA probes that target addressable polymorphisms and are mutually compatible within a multiplex. Comparable success rates of SNP and indel genotyping are demonstrated.

An ensemble stepwise regression approach to gene mining. *D.Y. Yang[1], X. Li[1,2], S.Q. Rao[1,3], J. Li[1].* 1) Department of Bioinformatics, Harbin Medical University, Harbin 150086, China; 2) Department of Computer Science, Harbin Institute of Technology, Harbin 150001, China; 3) Departments of Cardiovascular Medicine and Molecular Cardiology, Cleveland, OH 44195, USA.

Gene mining based on genome-wide transcriptional profiling of complex diseases has been increasingly recognized for identification of disease genes. In this study, we present an ensemble-based stepwise regression-support vector machines approach (termed ensemble SR-SVM) for hunting for the feature genes for complex diseases. The ensemble SR-SVM, a significant extension of the tree-based ensemble approach proposed previously by us, was developed to exploit the relative merits of the two core computational algorithms for analysis of high dimension microarray data. We conducted a numerical experiment to explore the ensemble SR-SVM using a public dataset of colon cancer for both identification of disease relevant genes and biological classification. Compared with several established gene mining methods, the ensemble SR-SVM achieved better performance on extracting the feature genes in terms of higher disease relevancy values, and also yielded better classification accuracy for predicting colon cancer samples.

Tuning GENEHUNTER for personal computers. *S. Bolay, E. Bagnoud, D.F. Schorderet.* IRO - Institute of Research in Ophthalmology, Sion, Switzerland.

Purpose: GENEHUNTER (gh) is a linkage software developed by Kruglyak et al (1996). Based on parametric and non-parametric algorithms, it has helped identifying many loci and associations and has become, one of the most popular linkage tool freely available to the scientific community. Unfortunately, the full capabilities of gh can only be appreciated when running on fast computers. Typically, its use on personal computers may increase the computing time up to several hours in complicated families. We therefore reengineered the source code in order to accelerate the execution time.

Methods: The reengineering of the source code was performed on a Linux operating system (processor Intel PIV 3GHz, 1GB of RAM). First, the code was tested to measure the time used for typical applications. Then, it was analyzed in order to identify and quantify the time used by each discrete function. We identified the top 10 functions in time consumption and concentrated our efforts in reengineering them by moving calls to variables outside of loops (while, for,...) and avoiding calls to variables which were pointers to pointers. The reengineered gh version was compared using real pedigrees from our linkage and mapping activity.

Results: The time needed by gh to perform calculations on our machine was decreased from 3420 to 1845 by changing the compilation optimization mode from level 0 to 3. Moreover, improving the source code in the top 10 functions has decreased the calculation time down to 501.

Conclusion: A simple re-writing of the most frequently used functions improved the speed of gh by a factor of 7. In-depth reengineering should even increase the speed of the program further .

A Flexible Framework for Data Mining and Knowledge Discovery in Human Genetics. *J.H. Moore[1], J.C. Gilbert[1], C.-T. Tsai[2], F.-T. Chiang[2], W. Holden[1], N. Barney[1], B.C. White[1].* 1) Computational Genetics Laboratory, Department of Genetics, Dartmouth Medical School, Lebanon, NH; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan.

Detecting epistasis or gene-gene interactions in studies of human disease is a computational and a statistical challenge. To address this problem, we have previously developed a multifactor dimensionality reduction (MDR) method for collapsing high-dimensional genetic data into a single dimension (i.e. constructive induction) to facilitate statistical modeling of interactions. Here, we describe a comprehensive and flexible framework for detecting and interpreting epistasis that utilizes 1) advances in information theory for selecting interesting single-nucleotide polymorphisms (SNPs), 2) MDR for constructive induction, 3) machine learning methods for classification, and 4) graphical models for interpretation. We illustrate the usefulness of this strategy using artificial datasets simulated from several different two-locus and three-locus epistasis models. We show that the accuracy, sensitivity, specificity, and precision of a naïve Bayes classifier are significantly improved ($P < 0.05$) when SNPs are selected based on their information gain (i.e. class entropy removed) and reduced to a single predictor using MDR. We then apply this strategy to detecting, characterizing, and interpreting epistatic models in a genetic study (n=500) of atrial fibrillation and show that both classification and model interpretation are significantly improved ($P < 0.05$). All methods and procedures are implemented using open-source and freely-available software packages. The MDR approach is written in JAVA and is freely available from www.epistasis.org as part of the open-source Weka-CG software package. Inclusion of MDR in Weka-CG makes it possible to integrate this powerful method for modeling interactions with a wide variety of existing machine learning tools for data transformation and normalization, variable selection, classification, and visualization. Combining MDR with variable selection procedures will make it possible to detect epistasis in genome-wide association studies.

Design and validation of resequencing primer sets for 16,336 human genes for analyses of sequence variation and SNP discovery. *X. Lin[1], J. Ni[1], Z. Zhang[1], G. Merkulov[1], J. Hoover[1], M. Rydland[1], R. Sanders[1], P. Ma[2], C. Heiner[2], A. Lakdawalla[2], M. Martinyak[2], P. Li[1], E. Spier[2].* 1) Applied Biosystems, 45 West Gude Dr. Rockville, MD 20850; 2) 850 Lincoln Centre Dr. Foster City, CA 94404.

Increasing attention has been focused upon SNP discovery and genotyping in an effort to associate disease/phenotypes with gene variations and mutations, and to determine evolutionary relationships, but reliable primer design and data analysis remain two of the major challenges.

high-throughput, high quality computational pipeline has been developed to design PCR primer pairs for resequencing of human genes. Primer design is driven by the primer3 program and supplementary algorithms developed at the Applied Biosystems. All known SNP/MNP sites in the genomic sequence are avoided during primer design. The resulting primers are then QAed by two computational tools: the first one checks the primer pairs for genomic redundancy using a proprietary version of the e-PCR program with refinements for mismatch adjustment; the second tool, developed using a wet-lab validated training set of 200K amplicons, then predicts the probability of success of the primer pairs. Project Template files containing information for the gene targets are generated to allow integrated analysis workflow with the Seqscape software.

We are in the process of designing resequencing sets for all 16336 human genes with Refseq sequences. Annotation data from 20,617 RefSeqs and from 27,499 Celera transcripts have been combined to define the structure of these genes. For the 5176 genes for which design has been completed, we have achieved coverage of 92% of all bases (coding exons, UTRs and 1kb upstream) and 94% within the coding regions. On average 21 amplicons are required to sequence a whole gene and 13 to sequence just the coding region. For validation, 800 randomly selected amplicons were lab-tested, with an overall success rate of 95%.

Complete designs and associated data will be released to the research community.

SNP Selection Algorithm for Optimal Density and Information Content. *B.G. Kermani, A. Oliphant.*
Bioinformatics, Illumina, Inc, San Diego, CA.

The recent utility of multiplexed SNP genotyping arrays emphasizes the importance of the selection of a set of appropriate and informative SNPs. A selection process is required as the number of available SNPs identified by the SNP Consortium (~9 million) considerably outnumbers the number of SNPs one could place on the current high-end multiplexed genotyping arrays (~500,000). Even upon completion of the HapMap Project, SNP selection will remain crucial, as the number of expected Tag SNPs may be larger than the capacity of the state-of-the-art genotyping arrays. There are two main parameters in SNP selection: distribution in the region(s) being studied, and the informativeness of the set. Informativeness can be estimated using various quality metrics of specific SNPs, such as validation level, uniqueness, proximity to repetitive regions, and minor-allele frequency. Our algorithms utilize an iterative process that starts with an empty set or a set of user-defined mandatory SNPs. At each iteration, one SNP is added to the set, based on the relative performance metric of a SNP to the final score. A SNP is selected that contributes most to the final score. This score is composed of the static and dynamic components. The static score is fixed for each SNP throughout the iterative process, and includes several parts, e.g., MAF, validation and uniqueness scores. The dynamic score changes at each iteration, and is based on the landscape made by the set of mandatory and already selected SNPs, using a Parzen estimator model with Gaussian neurons. At each iteration and for each of the candidate SNPs, the dynamic score is computed and subsequently combined with the corresponding static score via a Sugeno fuzzy inference system. The algorithm can be adapted to use the haplotype block boundary information. In the simplest form, the spread of each neuron could be set to the corresponding length of the haplotype block for a certain Tag SNP. This algorithm has been successfully used to select SNPs for HapMap, linkage and fine map panel applications.

Exploring structural roles of evolutionarily conserved residues in two-dimensional contact map space. *Z. Li*[1,2], *U.K. Muppirala*[2]. 1) Department of Chemistry & Biochemistry, University of the Sciences in Philadelphia, Philadelphia, PA; 2) Bioinformatics Program, University of the Sciences in Philadelphia, Philadelphia, PA.

Protein structure prediction remains a fundamental challenge in the post-genomics era and understanding protein sequence-structure relationships is essential to the development of computational tools for structure prediction. Evolutionarily conserved amino acid residues are generally assumed to play a structural or functional role in proteins. Understanding how they contribute to the integrity of a proteins three-dimensional structure individually is valuable to protein structure prediction. We propose to study the contributions of conserved residues via contact maps derived from their structures and then examining the pattern of connectivity. We systematically applied this method to diverse fold-type sets of proteins. Several distinguishing features of conserved and conserved hydrophobic residues were identified: (i) Within a native fold, the average degree of connectivity increased in the order of all residues < conserved residues < conserved hydrophobic residues; (ii) The percentage of residues occupying the high end of the distribution of degree dimension followed the same order of all residues < conserved residues < conserved hydrophobic residues; (iii) The range of the maximum degree of connectivity of any residue in a native fold was between three and eight; (iv) The majority of residues with the maximum degree of connectivity are either completely or highly conserved hydrophobic amino acids. We give a test case in which we applied these rules to help differentiate native from non-native structure.

A Web-Based Java Application for Genotype and Phenotype Database Management. *J.-L. Li[1,2], M.-X. Li[2], H. Deng[3], H.-W. Deng[2,3,4].* 1) Seattle Biomedical Research Institue, Seattle, WA; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China; 3) Osteoporosis Research Center, Creighton University Medical Center, Omaha, NE; 4) The Key Laboratory of Biomedical Information Engineering of Ministry of Education, and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P.R.China.

In genetics and genomics studies for complex human diseases, it is not unusual that large numbers of genotype and phenotype data points are acquired. Efficient and effective management of a vast amount of genotype and phenotype data is then necessary. Previous software developed in MS ACCESS for large-scale management of genotype data has its limitations, i.e., Operating System (OS) dependency, limited database capacity and lacks of functions for management of phenotype data. To overcome these limitations, we developed a web-based Java application for genotype and phenotype database management (GPDB). GPDB has been developed based on Java 2 Platform, Enterprise Edition (J2EE). One advantage of Java programming is OS independency. As a result, GPDB can virtually run on any major Operating Systems including Windows, Linux, and UNIX. In addition, instead of MS ACCESS, MySQL has been employed as the backend database server. Comparing to MS ACCESS, MySQL can handle larger amount of data sets gracefully; therefore, the database capability has been increased dramatically. Moreover, new functions to manage phenotype data have been developed and incorporated into GPDB. Entity-Attribute-Value (EAV) model has been applied to develop the phenotype data management system. By applying the EAV model, this application allows users to manage arbitrary phenotypes and customize data entry forms; therefore it is suitable for different and multi-center projects. Last, phenotype data, pedigree data and genotype data can be compiled together in GPDB for further data analysis or directly feeding linkage analysis software such as QTDT and GENEHUNTER. The test version of GPDB is publicly accessible at http://apps.sbri.org/gpdb.

Now you see it, now you dont. *T.P. Sneddon[1,2], E.A. Bruford[1,2], T.A. Eyre[1,2], V.K. Khodiyar[1,2], R.C. Lovering[1,2], M.J. Lush[1,2], K.M.B. Sneddon[1,2], C.C. Talbot Jr[1,3], M.W. Wright[1,2], S. Povey[1,2].* 1) HUGO Gene Nomenclature Committee (HGNC); 2) Department of Biology, University College London, Wolfson House, 4 Stephenson Way, London, NW1 2HE, UK; 3) The Johns Hopkins School of Medicine, Institute of Genetic Medicine, The Johns Hopkins University, Baltimore, MD, 21205-2196, USA.

The HGNC has to date approved over 21,000 unique symbols and names, the majority of which are for genes, i.e. genomic segments that are transcribed and translated into functional proteins.

What happens when these genes, initially thought to be single copy in the human genome, turn out to be variable in copy number between individuals? This is the case for an increasing number of genes with already approved symbols, including members of the well-established amylase, defensin, protocadherin and blood group antigen gene families.

It has yet to be determined to what extent these additional gene copies are functional, what effect they have on genome stability and disease susceptibility, and how they contribute to individual phenotypic differences. Whatever their impact they will inevitably need to be discussed in the literature, preferably using a meaningful and systematic nomenclature that is globally accepted.

So it falls to the HGNC to meet the needs of the scientific community by addressing this issue. Examples of variable copy number genes and the potential problems they pose to the current nomenclature system will be presented alongside proposals for additional/alternative nomenclature schemes. We would welcome your suggestions and comments so please visit us at our booth in the Exhibit Area, email us at nome@galton.ucl.ac.uk, or go to http://www.gene.ucl.ac.uk/nomenclature for further information.

The work of the HGNC is supported by NHGRI grant P41 HG003345, the UK Medical Research Council and the Wellcome Trust.

A new portal as an aid for mutation collection. *C. Talbot Jr[1], R.G.H. Cotton[2, 3].* 1) Inst Genetic Medicine, Johns Hopkins Sch Medicine, Baltimore, MD; 2) Genomic Disorders Research Centre Fitzroy, VIC 3065, Australia; 3) The University of Melbourne Parkville, VIC 3010, Australia.

Single gene disorders affect around 1% of all births and mutations have been estimated to affect 60% of all humans in their lifetime. Despite this there has been no systematic attempt to collect all mutations. Some collection has occurred in general databases but it has been limited due to funding or commercial restraints. This collection has, by necessity, been centralised without the involvement of experts in genes.

In 1994, an initiative began to attempt to form a federation of curators of lists of mutations in genes (locus specific databases or LSDBs) to attempt to collect and curate all mutations in all genes in an expert manner. Since that time, problems to be faced have been solved and procedures have been put in place to such an extent that in 2000 all that was required was funding. Funding has been elusive but considerable progress has been made (see this and earlier progress on www.hgvs.org).

The ultimate aim is for the clinician/diagnostician to have instantly at their finger tips, all reports of mutations and their effects in a complete and accurate manner in a standard format. Progress towards this end includes: 1. Availability of new software from those wishing; to curate mutations in their gene of interest (http://www.dmd.nl/LOVD/1.1.0/); a portal, 2. A plan for a dedicated central database, 3. Numerous recommendations and publications which will be detailed in the presentation and 4. The Waystation, through which mutations can be channelled to a journal for publication and a Pub Med ID, currently undergoing beta testing (http://www.centralmutations.org/).

A group of 20 scientists have been identified so far testing submissions and a sample submission will be presented. This submission is based on a submission form developed by 38 members of the Human Genome Variation Society.

Expansion of GAA trinucleotide repeats in mammals. *R. Clark, S. Bhaskar, M. Miyahara, G. Dalgliesh, S. Bidichandani.* Dept Biochem & Molec Biol, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK.

We have previously shown that GAA trinucleotide repeats have undergone significant expansion in the human genome. Here we present the analysis of the length distribution of all ten non-redundant trinucleotide repeat motifs in 20 complete eukaryotic genomes (six mammalian, two non-mammalian vertebrates, four arthropods, four fungi and one each of nematode, amoebozoa, alveolate and plant), which showed that the relative expandability of GAA trinucleotide repeats is specific to mammals. Analysis of human-chimpanzee-gorilla homologs revealed that loci with large expansions are species-specific and have occurred after divergence from the common ancestor. PCR analysis of human controls revealed large expansions at multiple human (GAA)30+ loci; nine loci showed expanded alleles containing >65 triplets, analogous to disease-causing expansions in Friedreich ataxia, including two that are in introns of genes of unknown function. The abundance of long GAA trinucleotide repeat tracts in mammalian genomes represents a significant mutation potential and source of inter-individual variability.

Customizations To GeneMapper For Use In a High Throughput Genotyping Environment. *B. Craig[1], B. James[2], S. Newman[2], M. Barnhart[1], C. Boyce[1], K. Hetrick[1], J. Romm[1], C. Bark[1], Y. Tsai[1], E. Pugh[1], C. Boehm[1], K. Doheny[1].* 1) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Applied Biosystems Informatics North American Professional Services, Foster City, CA.

The Applied Biosystems (AB) GeneMapper software was designed to replace and add to the functionality of previous Genescan and Genotyper fragment analysis programs. GeneMapper software allows for simultaneous sizing and genotyping of capillary electrophoresis data from Applied Biosystems 3730 and 3700 genetic analyzer platforms. GeneMapper software did perform sizing and genotyping of data with minimal user review in addition to creating or modifying binned allelic data; however many limitations to the program made it difficult for use in a high throughput genotyping environment. CIDR contracted with Applied Biosystems NA Professional Services to modify the released GeneMapper software in order to accommodate interaction with CIDRs new LIMS and increase its functionality for use in a high throughput genotyping lab. Enhancements to the GeneMapper software graphic user interface involved modifications to the size match editor, adding defined review comments to an individual or group of genotypes from a list of user-defined values, an analysis option for re-analyzing samples by marker(s), a modified panel manager plot viewer to quickly check outlier data points and ability to view all florescent dyes in the allele size range of a selected genotype. In addition to program modifications new features were developed to allow for integration of the GeneMapper database schema and aspects of the 3730 Unified Data Collection software into CIDRs new master database structure. Additions include real time inter-run size adjustments, a server to local database project Check-out application, autonomous serialization and migration of the 3730 run data into CIDRs central database and data integrity checks based on CIDR QA/QC standards. Overall, we expect the customized GeneMapper software product will allow CIDR to increase throughput per technician, reduce the need for manual review and increase the speed of data analysis.

1,000 KAO-NASHI (Face-less) genes and their functional annotation. *A. Shimizu[1], S. Asakawa[1], T. Sasaki[1], M. Furutani-Seiki[2], H. Kondoh[2], N. Shimizu[1].* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Kondoh Research Group, SORST, JST, Japan.

The Human Genome Project has provided the DNA sequences of 3 billion base pairs and identified over 23,000 protein-coding genes in the human genome. However, many of these protein-coding genes are not fully proven by experimental evidences. In general, proteins with known motifs are readily classified, but substantial numbers of protein have no obvious motifs in their sequences. We designated these genes/proteins without obvious motifs as KAO-NASHI (Face-less) and initiated a project to unveil their face (kao) by comparative genomics and knockdown analysis using Medaka (a small teleost fish) as animal model. We extracted 1,000 KAO-NASHI genes from whole human genome using motif analysis by InterPro, homology search by BLAST and document search by PubMed. In order to unveil these KAO-NASHI genes, we decided to use Medaka (Oryzias latipes) as a model animal because it is easy to obtain embryos and to observe the organs or anatomical structure. We have identified Medaka orthologs for over 60% of human KAO-NASHI genes using the Medaka EST and whole genome shotgun sequence databases. A series of cDNA extracted from Medaka embryo was used for the first annotation of KAO-NASHI genes. Developing stage of Medaka embryo was divided into 39 stages based on the diagnostic features of the developing embryos. We extracted mRNA separately from each stage and used for expression analysis of KAO-NASHI genes. Many of the initial 100 genes showed ubiquitous expression during development. However, several genes showed gastrula, neurula or organs forming stage-specific expression. These expression profiles are useful for initial functional annotation. The gene knockdown strategy provides information on gene function by showing the effects of a drastic reduction in expression of the target gene. Morpholino oligonucleotides (MOs) injection has been successfully used to knockdown gene expression in Medaka embryo. We will present some morphological changes during Medaka development due to knockdown of several KAO-NASHI genes.

PrimerTile: designing overlapping PCR primers for resequencing. *P. Chines, A. Swift, L.L. Bonnycastle, M.R. Erdos, J. Mullikin, F.S. Collins, NIH Intramural Sequencing Center.* NHGRI, NIH, Bethesda, MD.

PCR-based resequencing is currently the optimum method to exhaustively identify all of the variants that exist in a given genomic region among a set of DNA samples. Existing software can adequately design PCR primers in coding regions and other non-repetitive DNA. However, a comprehensive search for functional variants should also include as much as possible of the large fraction of genomic sequence that shows homology to known repeats. Successful amplification of these regions is more difficult.

We have created software, called PrimerTile, to optimize primer selection in resequencing projects. PrimerTile uses several techniques to avoid non-specific amplification, including several different repeat masking strategies and low-stringency electronic PCR, taking advantage of the strengths of each. In order to achieve the greatest accuracy, most SNP-discovery programs require complete reads from both strands. High quality double-stranded reads cannot be achieved when long homopolymer (or certain microsatellite) repeats are included in PCR products, since slippage of the polymerase leads to varying numbers of bases in the repeats, resulting in out-of-phase traces and poor sequence quality downstream of these regions. PrimerTile avoids including homopolymers in products, instead anchoring primers in or near such repeats, minimizing the size of the regions that cannot be analyzed.

PrimerTile efficiently covers the target region with PCR fragments of the specified size, and with as few gaps as possible. The program also avoids placing primers on top of known variants, in order to maximize the success of PCR amplification and sequencing. We report our experience with using this program, including the proportion of sequence captured by the designed PCR amplicons, the rate of successful amplification, and the proportion of amplified bases resulting in high quality bi-directional sequence.

Automation of the Affymetrix GeneChip Mapping 100K Set. *H. Hobbs[1], C. Bark[1], M. Barnhart[1], R. King[1], E. Kwasnik[1], J. Strand[1], R. Mei[2], M. McKown[3], J. Cahlik[4], K. Doheny[1].* 1) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore MD; 2) Affymetrix, Santa Clara, CA; 3) PerkinElmer (PE), Boston, MA; 4) Acme Automation, Spring City, TN.

Standard protocols for Affymetrix GeneChip Mapping 100K Set involve manual processing of small sample sets. CIDR requires laboratory and informatics automation for high throughput environments in order to reduce human error. Many labs running the 100K set, or other Affymetrix platforms are processing samples in a single tube format. CIDR is leveraging its knowledge base and resources to process samples in a 96 well plate format. CIDR collaborated with Affymetrix to incorporate unique positive controls that validate correct sample position for each experiment and detect cross contamination. Robotic automation programs were developed using the Beckman Biomek 2000 and FX for the Digestion and PCR steps. PEs Multiprobe II was utilized for PCR plate consolidation, sample addition to the hybridization master mix, and chip injection which is informatically validated to ensure correct sample/chip association. Access to the chips was made possible via collaboration with PerkinElmer and Acme Automation. On the informatics side, the Affymetrix sample experiment importer was extended to allow for batch uploads of sample experiment combinations, including chip barcode, into the GCOS software, a time consuming process that could lead to incorrect data being entered manually. The end result is a process that utilizes robotics for the majority of the sample handling steps involved, incorporating various methods of QA/QC to ensure the data does not become compromised.

Repetitive sequence environment distinguishes housekeeping genes. *C. Eller[1], M. Regelson[1], B. Merriman[1], S. Nelson[1], S. Horvath[1,2], Y. Marahrens[1].* 1) UCLA Department of Human Genetics David Geffen School of Medicine, Gonda Center, 695 E. Young Drive South, Los Angeles, California 90095-7088, USA; 2) UCLA Department of Biostatistics, School of Public Health, Gonda Center, 695 E. Young Drive South, Los Angeles, California 90095-7088, USA.

Housekeeping genes are expressed at high levels and across a wide variety of tissues. In view of reports of repetitive sequences influencing gene expression, we investigated whether an association exists between the breadth and magnitude of housekeeping gene expression and their repetitive sequence context. We show that Alu elements are concentrated around housekeeping genes while several other repetitive sequences, including LINE-1 elements, are excluded from these regions. These properties, in combination with other previously published sequence properties of housekeeping genes, were used to develop a method of predicting housekeeping genes on the basis of DNA sequence alone. Using expression across tissue types as a measure of success, we demonstrate that repetitive sequence environment is by far the most important sequence feature identified to date for distinguishing housekeeping genes. We also examined whether relationships exist between repetitive sequence environment and the breadth and magnitude of expression throughout the entire genome. We find that Alu abundance correlates with breadth of gene expression. Alu elements were also progressively more abundant as one considered more and more highly expressed genes while the densities of LINE-1 elements and several other repeats were negatively correlated with magnitude of gene expression. We propose that Alu elements constitute a cellular defense that protects genes against the repressive effects of other types of repeats.

Recent Advancement of H-Invitational Database, An Integrated Database of the Human Transcriptome. *T. Imanishi[1], C. Yamasaki[1], Y. Fujii[1,2], Y. Yamaguchi-Kabata[1], T. Itoh[1,3], T. Gojobori[1,2,4], H-Invitational Consortium.* 1) Biological Information Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan; 2) Japan Biological Information Research Center, Japan Biological Informatics Consortium, Tokyo, Japan; 3) National Institute of Agrobiological Sciences, Ibaraki, Japan; 4) Center for Information Biology and DNA Data Bank of Japan, National Institute of Genetics, Shizuoka, Japan.

On behalf of the H-Invitational Consortium, we present recent advances of H-Invitational Database (H-InvDB; <A HREF="http://www.h-invitational.jp">http://www.h-invitational.jp/), an integrated database of human transcriptome based on extensive annotation of human full-length cDNA (FLcDNA) clones. The latest release of H-InvDB (release 2.0, in preparation) drastically increased the number of FLcDNA clones registered by 37%, and contains annotation of 56,419 FLcDNAs. The number of loci predicted by mapping these FLcDNA sequences onto the human genome also increased by 21% to 25,585 loci. The database consists of descriptions of their gene structures, alternative splicing isoforms, functional non-protein-coding RNAs, functional domains of proteins, predicted subcellular localizations, metabolic pathways, predictions of protein 3D structure, mapping of SNPs and microsatellite repeat motifs, co-localization with orphan diseases, gene expression profiles, and comparisons with mouse full-length cDNAs in the context of molecular evolution. All the data in H-InvDB are shown in two main views, the cDNA view and the Locus view, and five auxiliary databases with web-based viewers; DiseaseInfo Viewer, H-ANGEL, Clustering Viewer, G-integra and TOPO Viewer, and provided as flat files and XML files. H-InvDB is a product of the H-Invitational project, an international collaboration to systematically validate human genes by analysis of a unique set of high quality FLcDNA clones using automatic annotation and human curation under unified criteria. This unique integrative knowledge-based platform for conducting *in silico* data mining represents a substantial contribution to resources required for the exploration of human biology and pathology.

Gene mining: gene relevancy networking for complex human diseases. *X. Li[1,2], W. Jiang[1], L.H. Wang[3], Q.K. Wang[4], S.Q. Rao[1,4].* 1) Department of Bioinformatics, Harbin Medical University, Harbin 150086, China; 2) Department of Computer Science, Harbin Institue of Technology, Harbin 150001, China; 3) Department of Immunology, Harbin Medical University, Harbin 150086, China; 4) Departments of Cardiovascular Medicine and Molecular Cardiology, Cleveland Clinic Foundation, OH 44195, USA.

We have witnessed tremendous progress in elucidating the functional relationships between thousands of genes using high-dimension genomic data (e.g. microarrays), but less in mining the specific genetic networks relevant to the molecular pathogenic pathways for complex human diseases. In this study, we attempted to develop a robust data-mining-oriented alternative to unravel disease relevancy networks to complement the current model-based epistasis analysis utilized in human genetics. We designed a frequency measure (called adjusted frequency vote) to evaluate the strength of the relationships between the disease-relevant genes and to characterize their behaviors and topology within the disease-relevant gene forest. The empirical significances of the identified genetic relationships were determined by permutation tests. We have validated the proposed approach by building the colon-cancer relevancy networks using a publicly available microarray dataset. The results demonstrated that the disease-relevancy networks are the intricate interplays of the genes that are involved in the biological processes of cell proliferation, cell apoptosis, cell differentiation, mitogenesis and immunity. This study represents a pioneering and systematic endeavor to probe the underlying genetic complexities for complex human diseases.

Lamin A/C and emerin mutations in Emery-Dreifuss muscular dystrophy disrupt Rb-MyoD pathways.

M. Bakay[1], G. Melcon[1], Z. Wang[1,2], J. Xuan[2], P. Zhao[1], Y. Dong[2], Y. Chen[1], E. Pegoraro[3], Y. Nevo[5], S. Winokur[4], Y. Wang[2], E. Hoffman[1]. 1) Center Genetic Medicine, Children's National Medical Center, Aashington, DC; 2) Electrical Engineering and Computer Science, Catholic University of America, Washington DC; 3) Neurology, University of padova, Padova, Italy; 4) Department of Biological Chemistry, University of California, Irvine, CA; 5) Pediatric Neourology, Hadassah Medical Center, Jerusalem, Israel.

Mutations of the Lamin A/C gene cause a large variety of human genetic disorders. We tested the transcriptional perturbation model using 125 human muscle biopsy mRNA profiling dataset containing 13 diagnostic groups. We show that two muscular dystrophies involving the nuclear envelope are highly related to each other (autosomal dominant EDMD [Lamin A/C], and X-linked recessive EDMD [emerin]). This data was consistent with Lamin A/C mutations causing similar downstream transcriptional perturbations as the Lamin A/C-interacting protein, emerin, and with the identical clinical symptoms in these two forms of EDMD. We used a multi-group bio-informatic method to define specific transcriptional pathways perturbed in Lamin A/C patients and emerin patients. We identified highly specific disturbances of a transcriptional regulatory pathway involving Rb, MyoD, Lamin A/C, and CREBBP/p300. Our data was consistent with a block in the transfer of Rb/MyoD-associated acetylation-deacetylation complexes during the differentiation of myoblasts to myotubes, and relative failure of appropriate timing and activation of downstream MyoD targets needed for differentiation. Consistent with this model, we found a coordinately regulated change in nuclear envelope components during muscle regeneration in vivo, with LaminB1-LAP1-LBR-emerin expressed during myoblast proliferation, and LaminB2-LAP2-LaminA-emerin coordinately induced during myoblast differentiation. We present a molecular model for transcriptional perturbations caused by Lamin A/C and emerin mutations, where lack of appropriate Lamin A/C - emerin - Rb - MyoD interaction and coordinated acetylation states leads to incorrect timing of exit from cell cycle and terminal differentiation of myogenic cells.

A Novel Method Combining Linkage Disequilibrium Information and Imputed Functional Knowledge for tagSNP Selection. *R. Rochat[1, 2], L. de las Fuentes[2], V.G. Dávila-Román[2], G.D. Stormo[3], C.C. Gu[1].* 1) Division of Biostatistics, Washington University, St. Louis, MO; 2) Cardiovascular Division, Washington University, St. Louis, MO; 3) Department of Genetics, Washington University, St. Louis, MO.

The application of high density SNP maps in genetic studies has introduced problems of prohibitive genotyping costs and inflated false discovery rates. To attenuate this effect, selection strategies have been developed to choose subsets of representative SNPs (tagSNPs) for genotyping and analysis. Existing methods take two distinctive approaches to reducing dimensionality in SNP data for tagSNP selection. One approach is to focus on the biological property inherent to each SNP (Zhao et al. Human Mutation 2004, 23:534-9) and select those that are more likely to bear relevant functionality. The other approach utilizes the underlying linkage disequilibrium (LD) data structure among SNPs and selects by factor analysis (FA) those that are informationally representative (Nyholt et al. American Journal of Human Genetics 2004, 74:765-769). Methods assessing only functional information ignore LD data structure in the SNPs, whereas the FA approach neglects the biological significance of the SNPs. We propose a method using a weighted factor analysis (WFA) model that combines the strengths of both the functional and the informational approaches. We applied this method to highly dense SNPs found in cardiovascular candidate genes via re-sequencing by the SeattleSNPs program (NHLBI PGA), and compared our results with those derived by other popular tagSNPs selection strategies. The findings have been encouraging. For example, in the candidate gene PPAR-, from 78 SNPs in the European sample, tagSNPs selected by the WFA method seems to be more robust against varying minor allele frequencies (MAF), and consistently picked SNPs that were missed by focusing on function or LD structures alone. We will present a complete report of the analyses of SNPs by WFA in selected candidate genes re-sequenced by the SeattleSNPs PGA.

Screening of mRNA sequences for alternative ORFs: potential effects on the complexity of the proteome and gene regulation. *C. Schoenbach[1], I.V. Kurochkin[1], A. Konagaya[2], M.S. Ali[3].* 1) Immunoinformatics Research Team, RIKEN Genomic Sciences Center, Yokohama 230-0045, Japan; 2) Advanced Genome Information Technology Research Group, RIKEN Genomic Sciences Center, Yokohama 230-0045, Japan; 3) Indian Institute of Technology, New Delhi 110016, India.

In general translation is initiated at the first AUG codon that is flanked by a favorable context sequence called Kozak consenus. However mechanisms such as leaky scanning and re-initiation through an internal ribosome entry site can initiate translation at a secondary AUG codon. We systematically examined translation initiation under the aspect of alternative translation using mouse cDNAs with complete coding sequence information extracted from GenBank. Predicted alternative open-reading frames (2,444 ORFs) candidates that shared at least 400 nucleotides with the GenBank-derived ORF (known ORF) were computationally categorized and annotated according to the type of ORF-overlap, Kozak context, AUG distance, cross-species conservation, protein motifs and solubility and potential similarity to known disease genes. The rule-based procedure yielded 1,597 alternative ORFs of which 288 were assigned a high probability of being translated. Among those, candidates with homology to human proteins and changes in protein properties are of particular interest. For example, one candidate transcript encodes in the known ORF a zinc finger motif-containing protein and a hypothetical protein in the alternative ORF, starting 184 nucleotides downstream of the known ORF. The protein encoded by the alternative ORF is tissue-specific and has been experimentally confirmed using antibodies. Translation of alternative ORFs not only increases the complexity of the proteome but implies new control mechanisms (i.e. transcriptional activation/repression) with implications for inducible processes such as immune response activation.

Gene expression profiles of fragile X cells: comparison with normal controls and effect of 5-aza-2-deoxycytidine treatment. *P. Chiurazzi[1], C. Bernardini[2], A. Terracciano[1], C. D'Ambrosio[3], B.A. Oostra[4], P.J. van der Spek[5], G. Neri[1].*
1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Institute of Anatomy, Catholic University, Rome, Italy; 3) Genomics Labs, IRCCS San Raffaele, Rome, Italy; 4) Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands; 5) Department of Bioinformatics, Erasmus University Medical Center, Rotterdam, The Netherlands.

Fragile X syndrome is caused by transcriptional inactivation of the FMR1 gene and absence of the FMRP protein in affected patients. We investigated the expression profile of 18400 transcripts, including 14500 well-characterized human genes, in lymphoblastoid cell lines established from fragile X patients and normal male controls. We used the Affymetrix GeneChip Human Genome U133A 2.0 array and analyzed the transcriptional activity of two unrelated male patients with fragile X syndrome and a full mutation with 250-350 CGG repeats. The arrays were read with the Scanner 3000 and data were analyzed with the GCOS software and then with GeneSpring 7.2. Fragile X and control cell lines have consistently different expression profiles, which may prove useful in the identification of proteins interacting with and genes regulated by FMRP. Furthermore, we treated all cell lines (3 fragile X and 2 control) with 1 M 5-aza-2-deoxycytidine (5-azadC) for 7 days, extracted total RNA and prepared cDNA. We first tested the reactivation of the FMR1 gene in the fragile X lines by real-time RT-PCR, which reached 12%, 37% and 70% of normal controls, respectively. Then we prepared the cRNA probes and hybridized more arrays. We thus identified a set of genes up- or downregulated by the 5-azadC treatment in both fragile X and control cells, and also characterized the reactivation effect of 5-azadC on those genes that were differentially expressed between fragile X and normal males. Finally we checked the gene expression profile of the lymphoblastoid cell line (5106) with an unmethylated full mutation derived from a rare individual with an active FMR1 gene and normal intelligence. This work was supported by grant GGP030202 from Fondazione Telethon to G.N.

Annotation of Genetic Polymorphisms in Drug-Metabolizing Enzymes. *C. Chiang[1], Z. Gu[1], S. Cai[1], R. Charlab[1], K.D. Lazaruk[2], A. Levitsky[1], C. Wan[1], T. Harkins[2], D. Ingber[1].* 1) Celera Genomics, 45 West Gude Drive, Rockville, MD 20850; 2) Applied Biosystems, 850 Lincoln Centre Drive, Foster City, CA 94404.

Many polymorphisms within the genes of drug-metabolizing enzymes (DME) have been shown to alter drug responses in individuals. A DME genotyping platform would allow researchers to screen for these polymorphisms and may serve as an aid to determine individualizing treatment choice. However, a comprehensive catalog of DME polymorphisms is lacking, presumably due to the challenges in facing inconsistent nomenclatures and the high-degree homology of DME-coding genes. Here we report a bioinformatics process to annotate DME polymorphisms based on the data collected from both public and proprietary databases. Our process involves mapping the flanking sequences of polymorphic sites to genome assemblies, clustering DME polymorphisms, and assigning functional classification to the polymorphisms based on their relative positions to DME proteins. Ambiguous results were inspected and resolved manually by experts. Each unique cluster was assigned to a Celera accession number (CV), which represents one non-redundant polymorphic site. Several locus-specific allele nomenclature committees (e.g., Human Cytochrome P450 Allele Nomenclature Committee, http://www.imm.ki.se/CYPalleles) have been maintaining standard allelic designations, which are often haplotypes consisting of a set of polymorphic sites. To help researchers identify the polymorphisms reported by these committees, we assigned standard allele nomenclature to CVs by a pipeline that extracts and calculates the coordinates of DME polymorphisms on the reference sequences designated by the committees. DME alleles were assigned to CVs if their locations and bases both match. We have so far annotated more than 3,000 protein-coding SNPs for 218 DME-related genes.

Custom Chip Definition Files For Affymetrix GeneChip Expression Microarrays. *R.J. Clifford, J. Zhang, R.P. Finney, K.H. Buetow.* National Cancer Inst, Bethesda, MD.

Affymetrix GeneChips are widely used for the analysis of gene expression, and many experiments performed with the HG-U95 and HG-U133 chip sets are now in the public domain. Probes on these arrays were designed against clusters from UniGene builds 95 and 133, respectively. In the time since array design human genome annotation has greatly improved and the UniGenes used for probe design have been refined. mRNA and EST sequences have been added to or removed from some clusters; other clusters have been split or merged. As a result, roughly 10% of probes on these microarrays hybridize to transcripts from multiple loci while another 10% do not match their target genes. Correct annotation of the HG-U95 and HG-U133 microarrays is critical for the analysis of gene expression experiments using these "legacy" platforms.

To address this need we have created custom Chip Description Files (CDFs) for the Affymetrix HG-U95A and HG-U133 microarrays. In our CDFs non-specific probes and mis-targeted probes are excluded from downstream analysis. To take advantage of the latest genome annotation, probes are grouped into sets based on NCBI Entrez Gene loci rather than the original UniGene clusters. If probes from more than one Affymetrix GeneChip probe set recognize the same gene, they are combined into a single probe set in the custom CDF. To examine gene expression in novel ways we have created three additional types of Chip Description Files: 1) CDFs containing probes sets that assay alternative splicing events, 2) CDFs that contain only probe sets located at the 3' ends of transcripts, and 3) CDFs containing probe sets that assay the expression of families of related genes.

Our custom CDFs are designed for use with the BioConductor statistical software package, which allows gene expression to be analyzed using a variety of algorithms such as MAS5 and RMA. We will demonstrate the advantage of using custom CDFs for gene expression by comparing results obtained from custom CDFs with those from traditional Affymetrix CDFs.

Transcriptome analysis of a transgenic murine model of anxiety overexpressing the neurotrophin-3 receptor (NTRK3). *M. Guidi, I. Sahún, A. Amador-Arjona, M. Gratacòs, M. Dierssen, Y. Espinosa-Parrilla, X. Estivill.* Genes & Disease Program, Center for Genomic Regulation, Barcelona, Catalonia, Spain.

Neurotrophins and their receptors are essential for the development of the vertebrate nervous system by promoting neuroblasts survival, whereas in the adult brain they modulate neurite patterning and synaptic plasticity. Neurothrophic tyrosine kinase receptor 3 (*NTRK3*) is highly expressed in the *locus coeruleus* (LC) and its ligand neurothrophin-3 has trophic effects on noradrenergic LC-neurons. Changes in *NTRK3* expression might be implicated in the aetiology of anxiety disorders by inducing an overactivity of the noradrenergic system. A transgenic mouse overexpressing *NTRK3* (TgNTRK3) was generated. TgNTRK3 mice show an anxiety-related behaviour and an increase in the number of noradrenergic cells in the LC. The aim of this work is to study the consequences of *NTRK3* overexpression at the transcriptome level. Two transgenic murine lines were analysed. Total RNA was extracted with Trizol Reagent and DNase-treated RNA was used for microarray analysis (Agilent Mouse 22k-Oligo-Array) and RT-PCR expression studies. Developmental and postnatal stages were examined for TgNTRK3 expression, which was detected from embryonic stage E13 on. Microarray analysis was performed in cortex and hippocampus from 6 wild-type and 6 transgenic adult mice. We observed alterations in the expression of several cell signalling molecules and phosphatydilserine decarboxylases as well as a slight deregulation of some neuropeptides. Interestingly, a 3-fold downregulation of the thyroxine-binding protein (transthyretin) and a 1.3-fold downregulation of the thyroid hormone receptor interactor 10 (*Trip10*) were detected in the hippocampus, indicating a possible alteration of the thyroid hormone regulation in the transgenic mice. Some of the deregulated genes have been implicated in the modulation of fear and anxiety responses, in the regulation of the noradrenergic system or in panic and other psychiatric disorders. These results are consistent with the behavioural-histological phenotype previously observed in TgNTRK3, supporting the hypothesis of *NTRK3* being involved in anxiety disorders.

Transcriptional profiling for detection of a gene signature in Rett Syndrome. *M.S. INAN[1], N. Kaya[1], M. Asyali[1], N. Sakati[2], M. Nester[2], P. Ozand[1,2].* 1) KING FAISAL SPECIALIST HOSPITAL AND RESEARCH CENTER DEPARTMENT OF GENETICS, RIYADH; 2) KING FAISAL SPECIALIST HOSPITAL AND RESEARCH CENTER DEPARTMENT OF MEDICINE, RIYADH.

Discoveries of a characteristic gene signature in various human disorders may help to reveal molecular mechanisms that responsible for the aggressive behavior of some of the diseases with possible translational implementation. Transcriptional profiling in various human disorders is an important tool to understand molecular mechanisms underlying a disease or syndrome. Herein, we performed whole gene expression analysis to identify a characteristic signature in on two families of multiple Rett patients using HU133 plus 2.0 Affymetrix GeneChips containing more than 47000 transcripts. Consistently over- and underexpressed genes in Rett patients as compared to normal individuals were found in various biological pathways. Several genes of interest that are differentially expressed between Rett patients and normal individuals were identified and confirmed with Real Time PCR. These genes will be presented with their biological functional groups such as signal transduction, metabolism, development, neurogenesis, cell growth, and regulation of transcription. These observations could help understanding the mechanisms of Rett syndroom and finding the pathways possibly involved in manifastation of Rett syndroome.

***LRRK2* mutation screening in 100 families with autosomal dominant Parkinsons disease.** *J.M. Kachergus[1], I.F. Mata[1], J.P. Taylor[1], S. Lincoln[1], J. Aalsy[2], T. Lynch[3], M.M. Hulihan[1], R.A. Hauser[4], R.M. Wu[5], C. Lahoz[6], Z.K. Wszolek[1], M.J. Farrer[1].* 1) Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Department of Neurology, St. Olav's Hospital, Trondheim, Norway; 3) Department of Neurology, Mater Misericordiae University Hospital and Conway Institute of Biomolecular and Biomedical Research, Dublin, Ireland; 4) Departments of Neurology, Pharmacology and Experimental Therapeutics University of South Florida and Tampa General Healthcare Parkinson's Disease and Movement Disorder Center ,Tampa, FL; 5) Departments of Neurology, Pediatrics and Medical Genetics, College of Medicine, National Taiwan University, and National Taiwan University Hospital, Taipei, Taiwan; 6) Servicio de Neurología, Hospital Universitario Central de Asturias, Oviedo, Spain.

In the last seven years mutations in six genes (*SNCA, PRKN, PINK1, DJ1, MAPT* and *UCHL-1*) have been linked to familial parkinsonism. We have identified mutations in a seventh gene, *LRRK2*(Leucine-rich repeat kinase 2; PARK8:OMIM609007), as responsible for autosomal dominant Parkinsons disease (PD). *LRRK2* maps to chromosome 12q12 (GenBank: AY792511) and encodes a large, multifunctional ROCO protein. Objective: To determine the contribution of *LRRK2* mutations in affected probands of kindreds with a family history of parkinsonism . Methods: All 51 exons were sequenced in 100 probands in which PD segregates as an autosomal dominant trait and in which DNA from at least two affected family members was availiable. The mutations identified were verified by ABI assay-on-demand probes in ethinicity-matched control samples and mutation segregation analysis was also performed. Semi-quantitative multiplex PCR was also used in order to rule out possible whole gene multiplications or deletions. Results: A total of 26 coding variants were identified, seven apparent pathogenic mutations, three of which are novel. The other 19 variants may be relevant to disease susceptibility or severity. The position of mutations within the gene, and the protein domains affected suggest aberrant kinase activity may underlie disease pathogenesis.

Expression Changes Associated with the Tumor Suppressor Protein, Menin. *Y. Ji, E. Novotny, N. Prasad, J. Crabtree, A. Elkahloun, S. Chandrasekharappa.* Genome Technology Branch, NIH/NHGRI, Bethesda, MD.

Loss or inactivation of the MEN1 gene leads to multiple endocrine neoplasia type 1 (MEN1), an autosomal dominant disorder characterized by multiple tumors of the parathyroid, anterior pituitary and entero-pancreatic endocrine tissues. The amino acid sequence of MEN1 encoded protein, menin, provides little clues as to its function. In mouse models, homozygous loss of Men1 alleles results in embryonic lethality (E11.5-E12.5) suggesting importance of menin in early development. However, upon loss of the remaining Men1 allele as they age, heterozygous mice develop endocrine tumors resembling the human MEN1 condition. Menin, a nuclear protein, has been shown to interact with several proteins including transcription factors, JunD, SMAD1, 3 and 5, NFkb and MLL. To gain insight into the basic biological function of menin, we sought to identify target genes whose expression is altered in the absence of menin. For this we generated four wildtype (WT) and four null mouse embryonic fibroblast (MEF) cell lines from E9.5 embryos. Loss of menin does not appear to alter growth in these MEFs. RNA samples from WT MEFs were compared with RNA from null MEFs using high-density (20K cDNA) arrays to explore global expression changes. In addition, we looked at the menin-associated expression changes by expressing menin in Null MEFs lacking menin. We found that Fibulin-2 (Fbn2) and heat shock protein 25 (Hsp25) were abundantly expressed in the presence and absence of menin, respectively. Among several genes that showed significant changes were genes encoding adhesion/signaling/extra-cellular matrix proteins. Expression of several of these transcripts was verified by quantitative-PCR. Menin-mediated transcriptional regulation was evaluated using promoter for Cd24a in Luciferase reporter assays. The Cd24a promoter activity in Null MEF cell lines was suppressed by expressing wild type menin but not by mutant menin. The importance of expression changes in Cd24a and other genes in understanding the role of menin in development and tumorigenesis, if any, needs to be explored.

Proteomic Analysis of gastric carcinomas. *H. Kurosaki[1], R. Nishigaki[2,3], M. Osaki[1,4], M. Hiratsuka[3], T. Toda[2], H. Ito[4], T. Inoue[3], M. Oshimura[1,3].* 1) Dept. Biomed. Sci., Tottori Univ. Grad. Sch. Med. Sci., Yonago, Japan; 2) Proteomics Collabo. Res. Group, Tokyo Metro. Inst. Geront., Itabashiku, JAPAN; 3) Dept. Hum. Genome. Sci., Tottori Univ. Grad. Sch. Med. Sci., Yonago, JAPAN; 4) Div. Organ Pathol., Dept. Microbiol. Pathol., Tottori Univ. Fac. Med., Yonago, JAPAN.

Although genetic alterations in proto-oncogenes, tumor-suppressor genes, cell cycle regulators, and cell growth factors have been implicated in the process of human gastric carcinogenesis, the principle carcinogenic mechanisms are not fully clarified. In this study, we used a proteomic approach to search for genes that may be involved in gastric carcinogenesis and that might serve as diagnostic markers. We identified 9 proteins with increased expression and 13 proteins with decreased expression in gastric carcinomas. The two most notable groups included proteins involved in mitotic checkpoint (MAD1L1 and EB1) and mitochondrial functions (COX5A, ECH1, and CLPP). This suggested that there are links between dysfunctions in these processes and gastric carcinogenesis. We also observed the differential expression of CYR61 and HSP27 proteins in gastric carcinoma, whose expression is known to be altered in other types of tumors. Furthermore, the study identified proteins whose function in gastric carcinomas was previously unsuspected and that may serve as new molecular markers for gastric carcinomas. Importantly, immunohistochemical analyses confirmed that the levels of expression of MAD1L1, CYR61, and HSP27 were altered in gastric carcinoma tissues. Therefore, our study suggested not only that the proteins identified in this study can be useful diagnostic markers but also that a proteomics-based approach is useful for developing a more complete picture of the pathogenesis and function of gastric carcinomas.

Genomic Copy Number Detection with Microsphere-Based Suspension Hybridization. *H.L. Newkirk[1, 2], M. Miralles[1, 2], P.K. Rogan[1, 2], J.H. Knoll[1, 2].* 1) Childrens Mercy Hospitals and Clinics School of Medicine Childrens Mercy Hospitals and Clinics; 2) School of Medicine University of Missouri-Kansas City.

A microsphere-based suspension hybridization assay has been developed for high throughput detection of changes in genomic copy number. This assay allows for the direct analysis of whole genomic DNA extracted from residual fixed cell pellets and nick translated with biotin-dUTP. Single copy (sc) probes ranging in length from 60 to 2300 bp (100 bp average; Rogan et al Genome Res 11:1086, 2001) from ABL1 (chromosome 9q34), TEKT3 (17p12) and HOXB1 (7p15) were conjugated to spectrally-distinct polystyrene microspheres (Molecular Probes). Reactions were hybridized and detected using streptavidin-phycoerythrin conjugate and analyzed by flow cytometry. Using multiplex hybridization assays, 5 ABL1 deletions in patients with chronic myelogenous leukemia were confirmed by comparison of mean fluorescence intensities of chromosome 9q34 probes with the HOXB1 control (2 copies per diploid genome). The intensities of the chromosome 9 probes were significantly reduced in 5 deletion patients relative to the control probe. Similar experiments were performed with three trisomic 9 cell lines and in four duplication positive patients with Charcot-Marie-Tooth Type 1a disease (CMT1a). Using HOXB1 as an internal control, the assay distinguished 3 vs 2 alleles of chromosome 9 and 17 probes in the abnormal cell lines, where the mean fluorescence intensity of the chromosome 9 and 17 probes was about one third higher than for the control probe. Reproducibility studies for all patient samples yielded mean fluorescence intensity ratios that consistently distinguished copy number differences between the control probe and ABL1 or CMT1a probes. Unlike oligonucleotide bead hybridization assays, prior amplification of locus-specific target DNA was not required because the increased length and single copy composition of the hybridization probes increase the specificity required for direct detection of homologous genomic target sequences.

Expression profiling of osteochondrodysplasia causative genes across the human growth plate. *E. Mougey, K. Mann, B. Maguire, J. Sylvester, R. Olney.* Nemours Biomedical Research, Nemours Children's Clinic, Jacksonville, FL.

The growth plates of long bones are located near each end of the bone and are responsible for the majority of linear growth. The growth plate can be divided into four functional regions or zones based on the characteristics of the chondrocytes that compose them. The recognized zones are (beginning from the articular end and progressing in the direction of differentiation): reserve, proliferative, pre-hypertrophic, and hypertrophic. A fifth zone, the perichondrium is located in apposition to the growth plate at its circumferential surface. The progression of growth plate chondrocytes through these different regions, and hence growth, is regulated by an exquisite interplay of signaling pathways. Defects in these signaling pathways that affect growth are manifested as osteochondrodysplasias. Currently, there are more than 200 known osteochondrodysplasias that have been divided into 33 clinically distinct groups, and seven distinct molecular-pathogenic groups. As of 2003, the molecular defect was known for slightly less than half of all osteochondrodysplasias. Acquisition of the expression profile of the long bone growth plate would be an important first step towards understanding its intricacies. Through a combination of laser microdissection, linear mRNA amplification, and Affymetrix U133 plus 2.0 GeneChip analyses, our laboratory has examined the expression profile of the five long bone growth plate fractions from two normal patients. Out of a possible 54,000 probe sets, the average number called positive by MAS 5.0 for all five arrays is 12,193 for patient 1 and 18,454 for patient 2. The average of the homologous inter-array correlations for the $\log_2$ expression levels is 0.910.01. Here we present the long bone growth plate expression profiles of expressed genes known to cause osteochondrodysplasias.

Loci of shared segmental aneuploidy in the genomes of healthy and mentally retarded subjects detected by Array-CGH. *J.K. Ploos van Amstel, M.J. Eleveld, P.F.R. Hochstenbach, M. Poot.* Dept Medical Genetics, Univ Medical Ctr, Utrecht, Netherlands.

Using a 3,700 BAC array we performed Array-CGH on 131 children suspected of chromosomal disorders and 21 of their unaffected parents. Per individual we found on average statistically significant aberrant signals with 35 BACs. In 6% of our patients some of these signals represented pathogenetically relevant aberrations. In the remainder of our subjects these aberrant signals appeared independent of clinical symptoms and occurred with a frequency of 2% to 49%. In the patient and in the parent subset of our study population the same BACs occurred with similar frequencies as loci of shared segmental aneuploidy (SSA). In total more than 657 BACs indicated loci of SSA, which covered in total 2.8% of the euchromatin. Approximately 22% of loci of SSA occurred as duplications only, 35% as deletions only, and 44% as both deletions and duplications. The genomic distribution of loci of SSA varied widely among autosomes, with equal frequencies among Giemsa-light and Giemsa-dark bands. Approximately 34% of loci of SSA contained no genes at all, 8% contained only enzymes, and the remainder mixtures of genes from different classes, including numerous transcription factors. We conclude that loci of SSA occur frequently in the general population. The segregation of SSA from healthy parents to affected children, suggests that they have no apparent major clinical consequences.

Whole genome microarray analysis of gene expression in Prader-Willi syndrome. *D.C. Bittel[1], N. Kibiryeva[1], S. Sell[2], T. Strong[2], M.G. Butler[1].* 1) Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Alabama, Birmingham, AL.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, hypogonadism, mental deficiency and hyperphagia leading to early childhood obesity caused by loss of paternally expressed genes located in the 15q11-q13 region. A paternal 15q11-q13 deletion (Del) is found in about 70% of PWS subjects, uniparental maternal disomy (UPD) 15 in 25% and an imprinting defect in 3%. We used whole genome microarrays (Affymetrix U133A Plus 2.0 Array) to compare gene expression from actively growing lymphoblastoid cells from nine young PWS adult males (6 with Del, 3 with UPD) and four obese comparison males. As expected, there was no evidence of expression of paternally expressed genes (e.g., *SNRPN*) in the PWS cells. Of more than 47,000 genes examined, 22,151 met the inclusion criteria and 64 were overexpressed ($\geq$ 2X) and 386 were underexpressed ($\leq$ 2X) in the PWS cells relative to comparison cells. Of more highly expressed genes in PWS, four (*BCL2L11, CD47, CREM, UCHL1*) were assigned to neurological development/function, two (*CREM, DHRS9*) to endocrine function and two (*CD47, DHRS9*) to lipid metabolism. Of genes in PWS with reduced expression, 19 were related to neurological development/function, five to endocrine function, seven to lipid metabolism and 11 to respiratory function. GABA receptor genes (A5, B3) in 15q11-q13 had expression reduced by 1.7X in PWS relative to controls consistent with previous paternal bias observations. *HTR2B* a serotonin receptor and genes involved with controlling eating behavior (*POMC, CART*) along with an oxytocin receptor, all outside of 15q11-q13, had reduced expression while an 8X increase in expression of the orexin gene which stimulates eating were found in PWS compared to controls. The number of candidate genes with detectable altered expression is relatively small consistent with a recent report of microarrays in a PWS mouse model (Stefan et al., 2005). In addition, 61 genes were more highly expressed ($\geq$ 2X) in the PWS-UPD group relative to the PWS-Del group and 65 genes were more highly expressed in the PWS-Del group compared to PWS-UPD.

The diverse impacts of mobile elements on the human genome. *P. Deininger[1], S. Gasior[1], V. Perepelitsa-Belancio[1], T. Wakeman[2], B. Xu[2].* 1) Tulane Cancer Center and Dept of Epidemiology, New Orleans, LA; 2) Dept. of Genetics, LSUHSC, New Orleans, LA.

Long INterspersed Element-1 (L1) is probably the only active human autonomous retroelement, and it also drives the retroposition of the non-autonomous elements, Alu and SVA. The proposed mechanism of insertion for L1 suggests that cleavage of both strands of genomic DNA is required in a process termed target-primed reverse transcription (TPRT). In an effort to look at the double-strand breaks (DSBs) made by the L1 and how the cell is responding to them, we found that L1 expression leads to a high level of DSBs in DNA relative to the level of retrotransposition insertions. This level is several orders of magnitude higher than needed for the number of retrotransposition events needed. This was demonstrated using immunolocalization of -H2AX foci, phospho-ATM foci and direct measurements of DNA breaks with the COMET assay. Similar to its role in mediating DSB repair in response to radiation, ATM kinase appears to be required for L1 retrotransposition. DSBs produced by endogenously expressed L1 likely contribute to chromosomal rearrangements in the human germ line and somatic tissues independent of insertional mutagenesis and represent a major new endogenous source of DSBs. This is likely to include increased levels of recombination, particularly Alu/Alu recombination. The cell responds to these DSBs with induction of DNA repair responses, but they may overwhelm the cell and become toxic. These impacts are likely to vary depending on cell type in which L1 is expressed and to be greatly enhanced in many tumors where L1 expression is deregulated. It is also likely to be influenced by environmental influences and the genetic background of different individuals.

Submicroscopic genomic aberrations: RPGR and OTC contiguous gene deletion revealed by array CGH. *K.A. Rauen[1], R.C. Gallagher[2], P.D. Cotter[1], A.L. Estep[1], G.M. Enns[2], M.F. Marmor[2].* 1) University of California, San Francisco, CA; 2) Stanford University, Palo Alto, CA.

Retinitis pigmentosa (RP) is a progressive retinal dystrophy that is genetically heterogeneous. X-linked RP (XLRP) accounts for approximately 10% of affected individuals. Of three XLRP loci on Xp, one of these (RPGR) is in close proximity to the gene for ornithine transcarbamylase (OTC). OTC deficiency is the most common urea cycle defect. Each of these disorders presents with severe clinical symptoms in affected males and a spectrum of symptoms in carrier females, from asymptomatic to severely affected. We present a family with both XLRP and OTC deficiency and examine the clinical utility of a genome scanning microarray to detect a possible aberration affecting the X chromosome. The propositus is a 45-year-old woman noted to have a 30 year history of reduced vision and retinal "scars", with recent complaints of night blindness and field loss. Ophthalmologic evaluation demonstrated decreased visual acuity. The fundi showed vascular narrowing and mild waxiness of the discs. There was diffuse thinning of the retinal pigment epithelium in both eyes. Full-field electroretinograms were abnormal and cone b-waves were markedly delayed. Her 23 year-old daughter had a similar ophthalmic history and findings, and the propositus had a son who died of a hyperammonemic episode as an infant. Testing of the propositus revealed OTC deficiency by protein challenge. The family history was highly suggestive of a contiguous gene deletion involving chromosome Xp, but a high resolution karyotype was found to be normal. Further evaluation by array CGH demonstrated 4 BACs with single copy loss indicating a 3.8 Mb submicroscopic deletion of chromosome Xp11.4-p21.1, encompassing the RPGR and OTC genes. The same deletion was also found in her daughter. This study demonstrates that families with XLRP need to be thoroughly evaluated including a detailed family history to look for possible signs and symptoms of OTC deficiency and that array CGH is a powerful tool for the identification and characterization of chromosome abnormalities not readily identified by conventional cytogenetic analysis.

2D proteomicmap of amniotic fluid supernatant sample. *A. Mavrou[1], A. Kolialexi[1], P. Karamessinis[2], A. Antsaklis[3], M. Fountoulakis[2], G. Tsangaris[2].* 1) Med Gen, Aghia Sophia C H, Athens Univ Medical Sch, Athens, Greece; 2) Division of Biotechnology, Center of Basic Research, Foundation of Biomedical Research of the Academy of Athens, Athens, Greece; 3) 1st Department of Obstetrics & Gynecology, Athens University School of Medicine, Athens, Greece.

Proteomic analysis, combining two-dimensional electrophoresis and mass spectrometry has the potential for a wide range of applications in biological and medical sciences, as protein screening in tissues obtained from healthy and diseased conditions can be performed for the detection of drug targets and diagnostic markers. Conventionally, amniotic fluid samples (AF) are routinely used for prenatal diagnosis of a wide range of fetal abnormalities. Proteomics have already been applied in the analysis of tissues from fetuses with Down syndrome, in order to detect differences in their protein profile as compared to the normal ones and to determine possible diagnostic tools. A detailed two-dimensional protein database for the normal human AF cells has not as yet been reported. In the present study we constructed the two-dimensional protein database of the normal human AF supernatant. Fifteen AF samples from women carrying normal fetuses were analysed by two dimensional gel electrophoresis. A mean of 412 spots per gel were analysed and protein identification was carried out by MALDI MS and MS/MS. We constructed a two-dimensional protein map comprising of 152 different gene products. The majority of the identified proteins are enzymes, secreted proteins, carriers and immunoglobulins. Twelve hypothetical proteins are also icluded. The normal AF supernatant proteome map is a valuable tool for the study of aberrant protein expression and the search for proteins as possible markers for the prediction of abnormal fetuses.

Use of whole genome amplification and comparative genomic hybridization to detect chromosomal copy number alterations in small amounts of tumor tissue. *V. Rusakova, L. Nosek, E. Mueller, T. Favello, T. Rull, R. Valdes-Camin.* R&D, Sigma-Aldrich, Saint Louis, MO.

Cancers often induce structural genetic alterations creating either gene loss or gene amplifications. These changes are difficult to measure due to the limited amount of biopsied clinical material. We have established that DNA array comparative genomic hybridization (CGH) can be accurately used to identify genome-wide copy number abnormalities of nanogram DNA samples after amplification with Sigmas GenomePlex Whole Genome Amplification Kit (WGA). We present data for both control and cancer samples that demonstrate the fidelity and reproducibility of WGA for the determination of genome-wide ploidy differences. This example demonstrates the WGA kit generates sufficient DNA for CGH analysis without introduction of sequence representation bias. The combination of whole genome amplification and CGH using gDNA extracted from cancer patient material has the potential for permitting the studying of DNA from small cancerous loci, and may help to identify genomic markers for early diagnosis.

Screening to find genes causing cleft lip and palate. *K. Osoegawa[1], R. Pfundt[2], J. Staaf[3], E. Lammer[1], J. Murray[4], A. Borg[3], E. Schoenmakers[2], P. De Jong[1].* 1) Childrens Hosp Oakland Research Inst, Oakland, CA; 2) Dept. Human Genetics, University Medical Centre Nijmegen, The Netherlands; 3) Dept. Oncology, Lund University, Sweden; 4) Pediatrics and Biological Sciences University of Iowa, IA.

Human bacterial artificial chromosome (BAC) libraries have played a critical role for construction of physical maps and genome sequencing. We have developed a high-resolution overlapping-BAC collection of >32,000 well-characterized clones, spanning the entire human genome. We have used PCR-amplified DNAs from these BACs to create the array comparative genomic hybridization (CGH) slides with a detection resolution for copy number variation of about 70 kbp. Cleft lip with or without cleft palate (CL/P) are common structural birth defects. We have begun to survey the genome for candidate gene regions by searching for deletions/duplications using DNA sample derived from CL/P patients. In our first control experiment, approximately 8% of the clones (2,500) generated ratios outside the arbitrary low and high cut-off points (0.3) of log2 (T/R) values. We consider these data points to indicate the false positive rate. The second control experiment used male DNA with a known deletion (11.3 Mb) on chromosome 9 and female DNA with a known deletion (21.9 Mb) on chromosome 7, labeled with Cy5 and Cy3, respectively, and co-hybridized on a single 32k array slide. As expected, we were able to detect the sex mismatch as copy-number variation for chromosomes X and Y, and revealed the chromosome -9 and -7 deletions. Our control experiments gave us the confidence that we will be able to identify genomic changes as small as 300 kb. We have identified large numbers of deletions and duplications using DNA from 11 CL/P patients as test sample against reference DNA. We have identified novel large duplication on chromosome 8p21.3-8p12 (8.8 Mb) and deletion on chromosome 8q23.1-8q24.12 (11.2 Mb) from one of the samples. Some copy number changes were identified from multiple samples. We are in the process of analyzing lager number of samples, creating catalog of duplicated and deleted regions and list of genes located in the regions.

Sequencing the chimpanzee Y chromosome to understand its evolutional and biological characteristics. *Y. Kuroki[1], A. Toyoda[1], H. Noguchi[1,2], T.D. Taylor[1], H.S. Park[3], S.H. Choi[3], Y.S. Lee[3], D.W. Kim[3], D.S. Kim[3], T. Itoh[4], T. Yamada[2], S. Morishita[2], M. Hattori[1,5], S. Sakaki[1], A. Fujiyama[1,6].* 1) RIKEN Genomic Sciences center, Yokohama Kanagawa, Japan; 2) School of Frontier Sciences, Kashiwa, Chiba, Japan; 3) Genome Research Center KRIBB, Daejeon, Korea; 4) Mitsubishi Research Institute Inc., Chiyoda-ku, Tokyo, Japan; 5) Kitasato University, Sagamihara, Kanagawa, Japan; 6) National Institute of Informatics, Chiyoda-ku, Tokyo, Japan.

Human chromosome Y is known to have male-specific characteristics and a peculiar genomic structure including abundant chromosomal-specific repeats, large-scale duplications, and complicated chromosomal rearrangements. To understand the evolutional and biological characteristics of the Y chromosome, we have started a comparative sequence analysis between the human and chimpanzee Y chromosomes. We first constructed a physical map of chimpanzee Y chromosome, and then started sequencing clone by clone. To date, we have completely finished the sequencing of 100 BAC and fosmid clones; the total non-redundant length of the sequenced region is about 11 Mb. This region contains 27 genes which are derived from human Yp and Yq. Many structural differences such as rearrangements, insertion-deletions, and duplications have been found so far in this study. In addition, we have also identified chimpanzee-specific regions or the regions which are very low in conservation between human and chimpanzee by end sequence analysis of chimpanzee Y-specific fosmid clones. By comparing the genomic sequence and the clone mapping patterns from FISH analysis, we can identify the conserved or diverged regions along the chromosome. We will perform a population analysis for these differences to distinguish the polymorphisms from the species-specific differences. The diversity between species or individuals will become clearer with this study. These results will be helpful to understand the human-specific characteristics and the evolutional aspects of the peculiar Y chromosome.

Definition of genomic structural variation and mutation by segregation analysis: the 8p23.1 beta-defensin region as a model system. *E.J. Hollox[1], A. Doria[2], J.A.L. Armour[1].* 1) Inst Genetics, Univ Nottingham, Nottingham, United Kingdom; 2) Joslin Diabetes Center, Harvard Medical School, Boston, MA.

Several recent studies have emphasised the widespread nature of large-scale genomic polymorphism, such as inversions and copy number variation. Analysis of such regions is limited both by their intrinsic variability and the standard technology, which is most suitable for invariant single copy genomic sequences. Here we show that analysis of recombination and segregation in well-characterised families can yield important information on the organisation and behaviour of such complex regions. As a model system we analysed the 8p23.1 region, which shows common copy number polymorphism, common inversion polymorphism, frequent pathological chromosomal rearrangements, and has been implicated by linkage in several diseases such as type 2 diabetes, deafness and schizophrenia. With additional marker information, we analysed several families from the CEPH cohort, as well as five families with comprehensive genetic marker information, cytogenetic information on inversion status, and dosage information using multiplex amplifiable probe hybridisation (MAPH). We identified recombinations within 8p23.1 that caused alteration of beta-defensin copy number, confirming this as the mutational mechanism for loss or gain of beta-defensin repeats and allowing estimate of the mutation rate can also be made from this data. We also show that inversion carriers can be identified from segregation patterns, and that recombination within the inverted region shows that the beta-defensin repeats are polymorphic in chromosomal location, with repeats consistently present at one site but variably present/absent at the other site.

Gene-Expression profiles in human nasal polyp tissues from aspirin intolerant asthma patients. *T. Sekigawa[1], Y. Sakamoto[1], A. Tajima[1], S. Matsune[2], I. Inoue[1].* 1) Div Genetic Diagnosis, Inst Medical Sciences, Tokyo, Japan; 2) Department of Otolarynology, Faculty of Medicine, Kagoshima University.

In a subset of asthmatic patients, aspirin and several other non-steroidal anti-inflammatory drugs (NSAID) that inhibit cyclooxygenase (COX) enzymes induce severe asthmatic attack generally termed aspirin intolerant asthma (AIA). In 198 unrelated AIA patients, we identified prostaglandin E2 receptor subtype 2 gene is a susceptibility to AIA (Hum Mol Genetics 2004), however, the etiology of AIA can not be approached simply by genetic factor. Symptoms of AIA are characterized by aspirin sensitivity, asthma, and nasal polyposis known as Sameters triad. It is known that rhinosinusitis or nasal polyp is frequently observed before the onset of asthmatic attack. Therefore, hyperplastic rhinosinusitis associated with aspirin intolerance should play important roles in the development of AIA. In the current study, we determined the gene-expression profiles of nasal polyp tissues from 13patients including six aspirin intolerant asthma and five eosinophilic sinusitis and two chronic sinusitis using Agilent Human Oligo 1A ver2 comprising approximately 18,000 unique DNA oligonucleotides for gene-expression detection. We identify 52 genes whose expression were significantly different (2 fold up-regulated 45 genes or 0.5 fold down-regulated 7 genes were defined as differential expression, T-test P-values ware less than 0.05) between AIA and eosinophilic sinusitis. For clustering purpose, nonnegative matrix factorization (NMF) was applied and the expression profile was classified into three groups. One group was particularly rich in genes participating arachidonic acid metabolic cascade and inflammatory response. These groups would help to identify susceptibility and pathophysiolosical pathway underlying AIA. The study will now being proceeded to disclose expression profiles and individual genes related to AIA that would illustrate the bio-pathway and genetic abnormality of AIA.

The Identification and Functional Analysis of Conserved Noncoding Sequences of *SCN1A*, *SCN2A*, and *SCN3A*.

M. Martin, A. Escayg. Department of Human Genetics, Emory University, Atlanta, GA.

Two voltage-gated sodium channel alpha subunits, *SCN1A* and *SCN2A*, have been implicated in different epilepsy subtypes. Mutations in both genes lead to Generalized Epilepsy with Febrile Seizures Plus (GEFS+). *SCN2A* mutations also lead to Benign Familial Neonatal-Infantile Seizures (BFNIS), while *SCN1A* dysfunction frequently leads to Severe Myoclonic Epilepsy of Infancy (SMEI). Many *SCN1A* mutations are predicted to abolish channel function, suggesting that reduced channel expression leads to altered neuronal excitability. To determine if mutations in transcriptional regulatory regions of *SCN1A* or *SCN2A* contribute to disease, we conducted comparative sequence analysis to locate potential regulatory regions. Comparative genomics was conducted across a 1.1Mb region on human chromosome 2q24.2 containing a cluster of neuronal voltage-gated sodium channels, *SCN1A*, *SCN2A*, and *SCN3A*. The genomic organization of the locus was conserved across the human, mouse, dog, and chicken genomes. Twenty-two conserved noncoding sequence blocks greater than 100bp in length and 75% sequence identity were discovered from orthologous regions of the human, mouse, and dog genomes. Six noncoding regions were conserved across the human paralogs, *SCN1A*, *SCN2A*, and *SCN3A*. Nineteen of these conserved noncoding sequences (CNSs) were also present in the chicken genome. The CNSs at the *SCN1A* locus were examined by luciferase reporter gene assays for their ability to alter transcription. One CNS (CNS3) significantly increased the transcription of the SV40 promoter. The possible RNA secondary structures of each CNS were determined by *in silico* analysis. CNS7 formed a stable hair-pin-loop structure characteristic of miRNAs, illustrating that a subset of CNSs potentially represent noncoding RNAs.

Standardization of RNA Quality Assessment for better reproducibility and reliability of gene expression experiments using the RNA Integrity Number (RIN). *M. Valer[1], S. Lightfoot[2], R. Salowsky[1].* 1) Agilent Technologies, Waldbronn, Germany; 2) Agilent Technologies, Palo Alto, Germany.

Good RNA quality assessment is considered one of the most critical elements to obtain meaningful gene expression data via microarray or real-time PCR experiments. Advances in microfluidic technology have improved RNA quality measurements by allowing a more detailed look at patterns of RNA degradation via the use of electrophoretic traces. However, the interpretation of such electropherograms still requires a certain level of experience and can vary from one researcher to the next. The RNA integrity number(RIN) algorithm is introduced to assign a user-independent integrity number to each RNA sample. The RIN has been developed using neural networks by teaching this algorithm with a large number of RNA integrity data. The RIN score, based on a quality numbering system from 1-10 (in ascending quality), facilitates the classification of RNA samples to be used in the context of the gene expression workflow. In order to correlate microarray results with RIN and other alternative RNA quality measures, samples degraded for different times, where hybridized on microarray chips together or in parallel experiments. The results clearly show an important influence of the RNA sample integrity state as determined by the RIN towards the accuracy and noise levels in the array experiments..

Identification of an additional 5% of protein-coding genes in the human genome. *T.D. Taylor[1], Y. Totoki[1], T. Yada[2], Y. Sakaki[1], T. Takeda[1].* 1) Comp Exper Sys Biol Grp, RIKEN Gen Sci Ctr, Yokohama, Japan; 2) Dept Intell Sci & Tech, Kyoto Univ, Kyoto, Japan.

Ab initio gene-finders have essential potentialities for exhaustive rare gene predictions. The remarkable feature of ab initio gene-finders is their high sensitivity, especially at the DNA level. We introduce a method for identifying novel genes expressed at an extremely low level by using our DIGIT gene-finding program. DIGIT finds genes exhaustively and effectively by combining gene predictions from multiple ab initio gene-finders such as FGENESH, GENSCAN and HMMgene. DIGIT discards many false positive exons predicted by the other gene-finders and yields remarkable improvements in specificity without lowering sensitivity.

We applied DIGIT to human chromosome 11 and predicted 68 novel gene loci whose genomic regions do not overlap with Ensembl genes or human mRNAs in GenBank. To verify these candidate genes, RT-PCR was performed using primers prepared based on the predicted exon sequences with a single-strand cDNA library prepared from various human tissues. In the first round of RT-PCR, we could scarcely identify the PCR products for most of the predicted gene candidates, suggestive of extremely low expression in the tested tissues or uncertainty of the gene prediction. We then conducted a second round of PCR using nested-PCR primer sets with the diluted RT-PCR products.

We finally identified 39 novel gene loci which transcribe 74 distinct mRNAs. The success rate of our experimental verification was 57%. The identified genes were expressed at an extremely low level, and were likely absent from the cDNA libraries were used in various high-throughput full-length cDNA and EST sequencing projects. 73% of the novel transcripts were specifically expressed, suggesting that these gene products physiologically are operating in a tissue-specific manner.

Based on our analysis of the entire genome, we predict that the number of human protein-coding genes may be as much as 5-10% higher than current estimates.

Selecting SNPs for genetic association studies based on the genome-wide patterns of linkage disequilibrium inferred from the HapMap Project data. *C.R. Scafe, H. Isaac, F.M. De La Vega.* Applied Biosystems, Foster City, CA, USA.

The design of genetic association studies using single-nucleotide polymorphisms (SNPs) requires the selection of subsets of the variants providing high statistical power at a reasonable cost. SNPs must be selected to maximize the probability that a causative mutation is in linkage disequilibrium (LD) with at least one marker genotyped in the study. Reports have shown significant variation of LD across regions and populations, implying that efficient marker selection should consider the empirical patterns of LD. The HapMap project performed a high-density, genome-wide survey of genetic variation with about a million SNPs typed in four populations, providing a rich resource to inform the design of association studies. A number of strategies have been proposed for the selection of SNPs based on observed LD. These include the metric LD maps, which provide a means to place markers according to the local LD context, and the selection of haplotype tagging SNPs. Statistical power calculations are important, as irreproducible associations are partially due to under-powered studies. Integrating all these methods and annotations can be challenging: the algorithms required to develop LD maps, select tagging SNPs, estimate power, etc, are complex to deploy, and all the necessary data and annotations are deposited in disparate databases. To simplify this process, we developed the SNPbrowser Software, a freely available tool to assist in the LD-based selection of markers for association studies. In its current version, this stand-alone application provides fast query capabilities and swift visualization of SNPs, gene annotations, power, haplotype blocks, and LD map coordinates derived from the HapMap project data. Wizards implement several common SNPs selection workflows and SNP tagging algorithms. Optimal sets of tagging SNPs provide reduction in genotyping burden by 55-75%, depending on the metric/threshold used. These sets have been screened for their conversion potential to either TaqMan SNP Genotyping Assays or the SNPlex Genotyping System, expediting the set-up of genetic studies with an increased probability of success.

Transport conditions impact DNA yield from buccal cell specimens collected in epidemiologic studies. *M. Gallagher, C. Sturchio, M. Honein.* CDC, Atlanta.

The National Birth Defects Prevention Study (NBDPS) is one of the largest case control studies of birth defects ever conducted in the United States. The goal of this ongoing multi-center study is to identify environmental and genetic risk factors for birth defects. Information on environmental risk factors is collected through a maternal interview, and DNA is collected from the infant and both parents for evaluation of genetic risk factors. Cheek cell (buccal) specimens are obtained because of their low cost and ease of use for sampling infants without the direct involvement of health-care workers. However, unlike whole blood, buccal specimens yield lower amounts of DNA that is often of poorer quality. Initially, NBDPS study participants received buccal cell collection kits containing sterile cytology brushes in sealed plastic tubes. After collecting the specimens, participants were instructed to place the brushes back into the plastic tube and mail them to the NBDPS Center. Although the plastic tubes provided a convenient storage container, laboratory data from several NBDPS Centers suggested that buccal specimens that are kept in a moist environment have lower DNA yields which is worsened at elevated temperatures such as those occurring in summer months. Beginning in August 2003, the packaging for the cytology brushes was changed to non-resealable peel pouches. Use of this type of packaging allows the brushes to air dry during return transport through the mail. To evaluate the impact of the change in the buccal collection protocol, DNA yields from a subset of specimens obtained from one Center were determined using real time PCR. Mean yields of human DNA from buccal brushes stored in plastic tubes compared to brushes stored in peel pouches were 1.09 g (range 0-8.2) vs. 2.17 g (range 0.73-9.99) for specimens obtained from mothers, 1.15 g (range 0-5.85) vs. 2.01 g (range 0.07-17.6) for fathers, and 0.76 g (range 0-6.22) vs. 2.06 g (range 0.12-10.5) for infants. The use of peel pouches for temporary storage of buccal brushes significantly increased yield of human DNA obtained from specimens from all family members; the largest increase in DNA yield was observed in specimens obtained from infants.

ABRF/DSRG DNA Sequencing Troubleshooting Guide. *H. Escobar[1], D. Adam[2], M. Detwiler[9], S. Hardin[8], J. Kieleczawa[7], D. Needleman[3], R. Pershad[4], P. Schweitzer[5], G. Wiebe[6].* 1) University of Utah, Salt Lake City, UT; 2) University of British Columbia, Vancouver, BC; 3) USDA/ARS Eastern Regional Research Center, Wyndmoor, PA; 4) University of Texas M.D. Anderson Cancer Center, Houston, TX; 5) Cornell University, Ithaca, NY; 6) Max Planck Institute of Molecular Cell Biology & Genetics, Dresden, Germany; 7) Wyeth Research, Cambridge, MA; 8) University of Houston, Houston, TX; 9) Roswell Park Cancer Institute, Buffalo, NY.

The importance of automated DNA sequencing as a genetic tool is evidenced by the considerable expansion of facilities performing such analyses. Coupling this with the rapid growth of the technology itself creates a vast network of operators presenting varying experiences with instrument platforms and chemistries. Yet despite recent advances in the automated DNA sequencing process, periodic problems associated with instrumentation and reaction processes continue to exist. The establishment of a public database would allow for a continually evolving resource, which grows and expands with the technology, utilizes the experiences of a wide variety of contributors, and offers the unique advantage of always being current. The aim of the ABRF/DSRGs (Association of Biomolecular Resource Facilities/DNA Sequencing Research Group) web-based DNA Sequencing Troubleshooting Resource is to provide a forum for users to share information, through the creation of a searchable, comprehensive troubleshooting guide for the DNA sequencing community. With the launch of the live web-site scheduled for the end of 2005, we will present a snapshot of the resource as it exists presently.

Whole genome quantitative association studies implicate SNPs in Oxysterol-Binding Protein 2 (OSBP2) in the regulation of cholesterol metabolism. *J.C. Engert[1], L. Oksanan[2], B. Ge[2], M. Lemire[2], S. Gurd[2], K. DesBiens[3], D. Shah[3], S. Bailey[1], J. Faith[2], T.J. Hudson[1,2], T. Pastinen[2].* 1) Department of Human Genetics, McGill University, Montréal; 2) McGill University and Genome Quebec Innovation Centre, Montreal; 3) McGill University Health Centre, Montréal.

We, and others, have previously demonstrated heritability of mRNA levels in the pedigrees of CEPH families. We have now performed a large-scale survey of quantitative variation associated with specific SNPs that were included in the HapMap project. If we examine quantitative traits in the unrelated parents of these trios (the cell lines from which was derived the HapMap data), these experiments are the equivalent of performing a whole genome quantitative association scan in 60 individuals. Specifically, an association analysis was conducted between the SNPs from the Caucasian (Utah) samples of the HapMap project and the mRNA level of the low-density lipoprotein receptor (LDLR). The LDLR mRNA was measured in the lymphoblast cell lines of 30 CEPH trios under cholesterol deprivation conditions. Previous work has shown that these cells can be an appropriate cell model for the regulation of certain lipid metabolic pathways. In addition, one of the key responses to cholesterol deprivation is an increase in LDLR and this response is preserved in lymphocytes. Approximately 600,000 SNPs from the HapMap project were available, and we tested the approximately 400,000 that had an allelic frequency of at least 0.025. We have 80% power to detect an SNP that contributes to 20% of the variance. This approach allowed us to identify the Oxysterol-Binding Protein 2 (OSBP2) as a candidate gene for the control of cholesterol metabolism. The OSBP2 gene contains 14 exons, and spans 200 kb of chromosome 22q12. We observed two SNPs that that seem to contribute to the variation in the level of LDLR mRNA after cholesterol deprivation. Combining the detailed genetic information provided by the HapMap from cell lines with biomedically relevant quantitative phenotypes collected from these same cell lines should demonstrate great utility. Thus, we believe this technique will be applicable to complex traits and associated biochemical pathways.

Pathway analysis reveals mitochondrial OXPHOS defects and increased apoptosis in T-cells from individuals at-risk for Type 1 Diabetes. *P.A. Jailwala[1], J. Waukau[1], G. Duinkerken[2], B.O. Roep[2], D. Eckels[1], L. Meyer[1], M. Hessner[1], J. Rovensky[1], H. Khoo[1], S. Milosavljevic[1], S. Jana[1], S.W. Guo[1], S. Ghosh[1].* 1) Max McGee National Research Center for Juvenile Diabetes, Medical College of Wisconsin, Milwaukee, WI; 2) Dept. of Immunohaematology & Blood Transfusion, Leiden University Medical Center, Leiden, The Netherlands.

Type 1 diabetes mellitus (T1DM) is a T-cell mediated disease in which the insulin-producing pancreatic beta cells are destroyed. In this study, we examined gene expression in response to anti-CD3 stimulation, in two types of CD4 T cell clones: a GAD65-specific clone from a pre-diabetic and a Hepatitis C-specific clone. Microarray analysis was carried out with human gene chips containing 9,128 genes. Co-hybridization (6 replicates) for the three time points (1, 2 and 4 hours) was carried out, comparing *anti-CD3 stimulation* to *no stimulation*. After data filtering and normalization, we performed mixed-model ANOVA and bootstrapping (99% CI), to identify truly differentially expressed (DE) genes. The results show that there are no DE genes in common between GAD and HepC across 3 time-points. To test for gene-sets that might by systematically altered in each clone, we then used pathway over-representation analysis, which determines whether there is an over-represented pathway in the DE category compared to the proportion of genes in the same pathway on the whole microarray chip. Results show that the GAD clone undergoes perturbation of genes involved in oxidative stress/OXPHOS at the 1hr time-point. At 2hrs, this previous mitochondrial activity is usurped by apoptosis genes in the DE list. We identified 13 down-regulated anti-apoptotic genes and 20 up-regulated pro-apoptotic genes in GAD. Furthermore, CASP3 up-regulation indicates triggering of the caspase cascade in response to cytochrome-c release from the mitochondria. We are currently confirming expression of these apoptosis/OXPHOS genes by RT-PCR in the GAD clone. Finally, we confirmed increased apoptosis in at-risk individuals in a larger sample size through an apoptosis assay on a heterogeneous population of anti-CD3 stimulated CD4+CD25- T-cells.

Genome-wide Analysis of Hereditary Prostate Cancer Families Using High Density Microarray-based SNP Genotyping. *W. Liu[1], B.L. Chang[1], S.L. Zheng1[1], T. Li[1], J. Sun[1], A. Tolin[1], W.B. Isaacs[2], J. Xu[1].* 1) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

The existence of more than 10 million DNA variations, primarily single nucleotide polymorphisms (SNPs), allows for fine dissection of the associations between genetic variants and complex diseases. A number of commercially available microarray based systems, with different resolutions, are currently available for whole-genome genotyping (Syvanen, 2005) using diploid genomic DNA from different sources. In an effort to screen for DNA sequence variants associated with prostate cancer, we utilized the GeneChip Human Mapping 100K microarray which contains 116,204 SNP probes on two chips (Hind 240 and Xba240) to assay genomic DNA isolated from blood and corresponding lymphoblastoid cell lines. Four large hereditary prostate cancer (HPC) families with a total of 25 subjects have been analyzed thus far. The average successful SNP call rates using genomic DNA from blood for Hind 240 and Xba 240 were 99.15% and 99.25%, respectively, while the average SNP call rates using genomic DNA from cell lines were 98.65% and 98.71%, respectively, for these two chips. The average concordance of genotyping between blood and cell lines was 98.57% with a standard deviation of 0.4%. The majority of the non-concordant genotypes between blood and cell lines were due to non calls instead of different calls. In summary, the data from our study reveals that excellent SNP call rates can be achieved using Affymetrix GeneChip Human Mapping 100K microarrays. Secondly, the data provide evidence that we can accurately genotype SNPs to facilitate genome-wide association studies. Finally, cell line DNA can be reliably used as a substitute for blood DNA for genome-wide genotyping analysis.

Evol-genomic: a software tool for translational genomics. *M.A. Zapala[1], G. Hsiao[2], K.N. Chang[3], N.J. Schork[1].* 1) Biomedical Sciences, UCSD School of Medicine, La Jolla, CA; 2) Department of Bioengineering, UCSD, La Jolla, CA; 3) Division of Biological Sciences, UCSD, La Jolla, CA.

The inference that genes influencing phenotypes in model organisms also influence similar phenotypes in humans is complicated by a number of evolutionary phenomena. We interrogated factors that may mediate gene expression differences between humans and mice using DNA sequence data, synteny maps, gene/protein structural information, and expression data, in an effort to facilitate understanding of factors that may complicate translatability of genetic analysis findings in mice to humans. The Homologene database was downloaded from NCBI, syntenic data was downloaded from Ensembl and breakpoint data was downloaded from TIGR. Multiple regression was used to combine scores of sequence similarity, synteny, genetic distance and the ratio of non-synonymous to synonymous SNPs. A comparison of mouse to human kidney gene expression data was used as a training set to obtain a regression model. Only orthologous genes that were scored as Present in both mouse and human samples were included. The regression model attempted to predict the absolute difference in gene expression between human and mouse. The model produced an R value of 0.564 indicating a relationship with a third of the variation predicted by the model. An ANOVA was performed (F Statistic 0.05) showing that the variation explained by the model was significant. Using gene expression data from human and mouse heart tissue, a cross-validation of the model was performed with 0.11 shrinkage indicating moderate universality of the model. There has yet to be an inclusive assessment of multiple evolutionary factors which might lead to insights into the reliability of translating gene expression across mice and into human populations. Evol-genomic fills this vacuum and provides bench scientists with a user-friendly intuitive tool that empowers them to gain knowledge into how evolutionary factors may have impacted their candidate genes. Evol-genomic is designed for users to input a set of candidate genes from their expression studies in mice and output a ranked list of genes whose expression is most likely to be preserved in humans.

Genome-wide survey of gene copy number change spanning over 20 million years of human and primate evolution. *J. Sikela[1], L. Dumas[1], Y. Kim[2], A. Fortna[1], A. Karimpour-Fard[1], J. Hopkins[1], J. Pollack[2].* 1) Human Medical Genetics, Univ Colorado Health Sci Ctr, Aurora, CO; 2) Department of Pathology, Stanford University, Stanford CA.

We have previously applied cDNA array-based comparative genomic hybridization (aCGH) genome-wide across human and four great ape genomes and identified over 1,000 genes showing lineage-specific increases or decreases in copy number. We have now extended the breadth of this technology to compare genomes that are more closely related (i.e. within the human population) and those that are more distantly related (estimated divergence >20 MYA, e.g. between human and macaque/baboon).

Within-species comparisons used DNAs from 15 diverse human sub-populations covering three major continents. Among copy number polymorphisms (CNPs) identified and independently confirmed were two for adjacent genes (MTX-1 and GBA) in two African samples. A previous study of these genes found them to be CNPs particularly in African-Americans, consistent with our data. These CNPs were not found by three published genome-wide studies of human CNPs, suggesting that in certain cases, cDNA aCGH may identify CNPs not detected by other platforms.

Extension of cDNA aCGH to the macaque and baboon identified over 1400 genes that gave aCGH signatures indicative of lineage-specific copy number changes. These were specific to either macaque or baboon or shared by both, with similar numbers of increases and decreases. A number of genes gave strong positive aCGH signals indicative of pronounced lineage-specific copy number expansions.

Finally, because human is used as the reference in all comparisons, cDNA aCGH datasets from a wide range of species can be related to one another and gene copy number expansions that have occurred across large evolutionary time frames (>20 MY) directly identified.

Highly efficient recombination-based methods for bacterial artificial chromosome fusion and mutagenesis. *B.L. Sopher, A.R. La Spada.* Lab Medicine and Center for Neurogenetics & Neurotherapeutics, Univ Washington, Seattle, WA.

To extend the utility of bacterial artificial chromosomes (BACs) for the study of gene function and disease modeling, we have developed: i) a simple bacteriophage-based methodology for recombining overlapping BACs into a single larger BAC, and ii) a new methodology for targeting "seamless" mutations into BACs. In the first method, overlapping sequence from the terminus of one BAC is cloned alongside a selectable marker and placed between unique sequence arms from the terminus of the other BAC to create a targeting construct. Two successive rounds of recombination-based cloning are then performed to fuse the two BACs into one contiguous BAC that encompasses both of their insert sequences. The robustness of this methodology is demonstrated herein by using it to obtain a 254 kb BAC containing the entire human androgen receptor (hAR) gene from two smaller BACs. In the second method, transient expression of three bacteriophage genes (exo, bet, and gam) to pop-in a targeting cassette is followed by RecA expression from the targeting vector itself to pop-out the vector backbone. This new "hybrid recombineering" method thus combines the strengths of bacteriophage and RecA based bacterial recombination systems, while avoiding their major weaknesses. Successful application of this method for introduction of a properly targeted 162 CAG repeat expansion into the hAR 254 kb BAC is shown. With "hybrid recombineering", we believe that the power and utility of the classical pop-in / pop-out approach - so commonly and efficiently employed in yeast for decades - can now be achieved with BACs.

Insertion pattern analysis of transgenes in a transgenic mouse line by genomic walking. *O. Suzuki, M. Koura, K. Takano, Y. Noguchi, K. Uchio-Yamada, J. Matsuda.* Experimental Animal Models, Natl Inst Biomed Innovation, Ibaragi-Shi, Osaka, Japan.

Simple and accurate genotyping methods, especially zygosity check systems, are necessary for efficient use and management of transgenic animals as laboratory animals. For this purpose, we previously reported a simple and efficient method for genetic mapping and zygosity check of transgenes (Noguchi et al., Exp. Anim. 53:103-111, 2004). Here we report that our transgene mapping technique using genomic walking can be used for analysis of transgene integration patterns in transgenic mice. The technique revealed that a transgenic mouse line (GM1-sy#116) harbored inverted and direct tandem repeats of both intact and partial pCAGGS-based transgenes in the G2 region of the chromosome one. It is widely accepted that concatemers, mostly direct tandem repeats, are formed from vector constructs before integration into chromosomes. According to Bishops model (Reprod. Nutr. Dev. 36:607-618, 1996), the reason why direct-tandem repeats is more common than inversed tandem repeats is that concatemers are created by homologous recombination of circularly permuted linear molecules. In our case, however, the complicated chromosomal integration of transgenes might be caused by a simple end-joining of DNA constructs which might have been fragmented by exposure to a UV transilluminator during gel-purification as well as by nuclease digestion inside zygote pronuclei. Our results indicate the usefulness of genomic walking technique, and also suggest that care should be taken at preparation of vector constructs to avoid unexpected fragmentation prior to microinjections to zygotes.

A genome-wide definitive haplotype structure determined using a collection of complete hydatidiform moles. *Y. Kukita[1], K. Miyatake[1], R. Stokowski[2], D. Hinds[2], K. Higasa[1], N. Wake[3], T. Hirakawa[3], H. Kato[3], T. Matsuda[3], K. Pant[2], D. Cox[2], T. Tahira[1], K. Hayashi[1].* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Perlegen Sciences Inc., Mountain View, CA; 3) Division of Molecular and Cell Therapeutics, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan.

We present a genome-wide definitive haplotype structure determined using a collection of 74 complete hydatidiform moles, each of which carrying the genome derived from a single sperm. The haplotypes consist of 280,000 common SNPs, genotyped by a high throughput array-based oligonucleotide hybridization technique. Comparison of haplotypes inferred from pseudo-individuals (constructed by randomized mole pairs) with those of moles showed minor errors in resolution of phases by the computational method. The effects of those errors on local haplotype structure and selection of tag SNPs are discussed. We also show that the definitive haplotypes of moles may be useful for elucidation of long-range haplotype structures, and should be effective ways to detect extended haplotype homozygosities that are indicative of positive selections.

Detection of extremely rare mutations by multiple oligonucleotide mismatch PAP-A (MOM-PAP-A). *Z. Chen, J. Feng, S.S. Sommer.* Molecular Genetics, City of Hope National Medical Center, Duarte, CA.

Pyrophosphorolysis-activated polymerization (PAP) was developed to detect extremely rare mutations in a DNA pool with primers modified by adding a 3-terminal dideoxynucleotide. The theoretical selectivity of blocked primers is 1 part in 3.3×1011. However the practical selectivity of PAP is 1:104 to 1:105 because of misincoporation within the extension product from the opposing primer. Bi-directional PAP allele specific amplification (Bi-PAP-A) eliminates the bypass reaction using two opposing blocked primers with one nucleotide overlap at their 3 termini, and can selectively detect one copy of a single base substitution in 109 copies. However, the selectivity for detection of deletions, insertions, and indels is about one part in 104. Herein, we present multiple oligonucleotide mismatch PAP-A (MOM-PAP-A), an ultra-sensitive form of PAP for detection of mutations other than single base substitutions, including deletions, insertions, or indels. For MOM-PAP-A, both downstream and upstream primers are blocked and separated, resulting in an amplified segment of 100~300bp. One primer is mutant-specific and the 3 terminus is a few nucleotides away from the site of the deletion. The result is that the mutant-specific primer mismatches the wild type sequence at 2~7 nucleotides. The selectivity of MOM-PAP-A was examined using the epidermal growth factor receptor (EGFR1) gene as a model and the EGFR2 and F9 genes as controls. One molecule of the deletion or complex mutation can be detected per 50 microliter amplification reaction and there is no signal in the presence of >108 or >109 wild type molecules. In conclusion, MOM-PAP-A is the most sensitive way to detect rare mutations including deletions, insertions and indels. MOM-PAP-A can be applied to detect mutations in single cells because of its high sensitivity. MOM-PAP-A also can detect somatic mutations from surgically removed tumors in blood, allowing detection of minimal residual disease at orders of magnitude greater sensitivity than by conventional methods.

Genetic Interaction between ionotropic and metabotropic serotonin receptors in antipsychotic response. *V. De Luca, R. Hwang, D.J. Mueller, C. Zai, J. Volavka, S.G. Potkin, H.Y. Meltzer, J.A. Lieberman, J.L. Kennedy.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

Serotonin receptor genes have for many years been considered excellent candidate genes in the etiology of neuropsychiatric diseases. Defects in the in promoter regions could be cause of inherited disease, affecting the efficiency of RNA transcription. Clozapine is a potent antagonist of 5-HT2 and 5-HT3 receptors. Reynolds and colleagues (2002), demonstrate an association between antipsychotic drug induced weight gain and a promotor region polymorphism (C-759T) of the 5-HT2C receptor gene. In the only clozapine response study of the 5-HT3A gene, Gutierrez et al. (2002) found negative results with the C178T marker. We prospectively assessed a sample of 101 patients with DSM-IIIR diagnoses of schizophrenia using the Brief Psychiatric Rating Scale (BPRS) at baseline and following six weeks of clozapine treatment. The patients were categorized as responder and non-responder defined as 20% reduction of BPRS score. Single gene analysis produced a positive result for the 178T allele of 5HT2A predicting response (chi-square=6.52, 2df, p=0.03) and negative results for -759T (chi-square=2.58, 2df, p=0.27). A logistic regression analysis was used to examine the combined effect the variant alleles (-759T) and (178T). No statistically significant differences were found between the presence of two alleles combined (chi-square=2.918; 2df p=0.232) and clozapine response. Our failure to find positive results with gene-gene interaction may be attributed to sample ethnicity differences (African American and Caucasian). It is possible that the alleles at each polymorphism are in different linkage disequilibrium conditions among the ethnic groups. Further investigation is required to assess whether these polymorphisms may have a predictive role for clozapine response.

Single molecule sequencing by synthesis. *S.N. Lapidus, P.R. Buzby, T.D. Harris, J.W. Efcavitch.* Helicos BioSciences Corp, Cambridge, MA.

We will present a technology which sequences true, non-amplified, single molecules of DNA, and will highlight its utility in complex disease association studies and heterogeneous tumor analysis. The platform is based on sequencing by synthesis, which provides sequence information from individual strands of DNA attached to a glass substrate and processed in parallel. Using DNA polymerase and fluorescently labeled nucleotides, single base incorporations are monitored simultaneously on multiple template strands by fluorescence microscopy. Our optical setup consists of a total internal reflection microscope and a cooled CCD camera, which is capable of imaging an entire substrate (30,000 fields) in 50 minutes. For disease association studies, high throughput targeted gene resequencing with this technology allows the discovery of rare genetic aberrations including point-mutations, insertions/deletions and amplifications. In tumor samples, the high coverage afforded by parallel sequencing reveals mutations as rare as 1%. Eventually, this technology promises to enable whole human genome resequencing directly from genomic DNA purified from 100 cell equivalents without amplification. 10X genome coverage will be achieved in days, reducing resequencing costs 1000X vs. conventional Sanger sequencing.

Evaluating data in a high throughput SNP genotyping facility to maximize quality, cost, and efficiency. *C. Bark, E. Pugh, H. Hobbs, Y. Tsai, B. Craig, K. Hetrick, I. McMullen, J. Romm, M. Zilka, M. Barnhart, J. Goldstein, R. King, C. Boehm, M. Brehm, J. Gearhart, K. Doheny.* IGM, Johns Hopkins Univ, Baltimore, MD.

In recent years, SNP genotyping has risen in prevalence due to increases in scalability and information content, in conjunction with decreases in cost, laboratory resources and manual data review. However, the advances made in these areas have produced their own complications. The Johns Hopkins University has provided high quality microsatellite data to the scientific community over the last eight years and is dedicated to providing the same level of quality for its SNP genotyping services. Compared to microsatellite genotyping, per experiment, SNP genotyping methods have increased both the number of samples and loci processed. Because one experiment may include hundreds of samples for thousands or even hundreds of thousands of SNPs, a user or system error can have a large impact on overall data quality and cost. This has required that quality control methods be revised to focus on real time evaluation of data. Some of the methods used include; 1) Creating unique plate signatures through sample placement that allows incorrect sample transformations informatically or in the laboratory to be easily distinguished during the initial quality assurance stage. For standard marker panels, known CEPH controls are used. For custom marker panels, known genotypes for CEPH controls are compiled from public databases. 2) Safeguarding against sample plating and manifest errors by genotyping all DNA samples with two multiplexed microsatellite test panels containing 21 markers. 3) Using Spotfire DecisionSite and in house tools to visualize data trends in both standard and flexible formats. Problems can be identified and addressed closer to real-time. 4) Creating validated reagents and procedures for troubleshooting experiments to identify questionable operations, reagents and consumables in an expedited manner. These tools enable lab personnel to explore the data and to troubleshoot problems quickly and independently.

Genotyping 500K SNPs on a pair of arrays. *R. Mei, H. Matsuzaki, H. Loi, M. Lu, K. Travers, J. Law, T. Berntsen, M. Chadha, X. Di, G. Liu, E. Hubbell, G. Yang, T. Webster, S. Cawley, G. Marcus, M. Shapero, S. Walsh, K. Jones.*
Affymetrix, Santa Clara, CA.

Genome-wide association analysis provides a powerful means of identifying the common variants that contribute to complex disease predisposition and drug response. However, this type of studies requires a dense set of SNPs across the genome and a tool to score the SNPs accurately and cost-effectively. We present a high throughput platform that enables the parallel genotyping of over 500,000 SNPs on a pair of arrays. Achieving this goal required a number of advancements in array technology and assay development, most notably shrinking feature sizes down to 5 ^{2}, reducing the feature numbers to 24 features per SNP and increasing target complexity to ~660 Mbases. Call rates across the 500,000 SNPs are > 98%, reproducibility is > 99.9%, and accuracy, as measured by inheritance in trios and concordance with the HapMap Project, is > 99.5%. The average inter-marker distance is 3.3 kb, and 80% of the genome is within 10 kb of a SNP. To assess the utility of the 500,000 SNPs for genome-wide association studies in various populations, we determined heterozygosity and allele frequencies and, more importantly, analyzed the extent of linkage disequilibrium (LD) in four populations, namely Yoruba in Ibadan (Nigeria), Japanese in Tokyo (Japan), Han Chinese in Beijing (China), and CEPH (Utah residents with European ancestry).

GENOMIZER - An Integrated Analysis System for Genome-Wide Association Data. *A. Franke[1], A. Wollstein[1], M. Teuber[1], M. Wittig[1], T. Lu[3], P. Nürnberg[2], M. Krawczak[3], J. Hampe[1], S. Schreiber[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts University Kiel, Germany; 2) Cologne Center for Genomics, University of Cologne, Germany; 3) Institute for Medical Informatics and Statistics, Christian-Albrechts University Kiel, Germany.

Genome-wide association analysis appears to be a promising way to identify heritable susceptibility factors for complex human disorders. However, the feasibility of large-scale genotyping experiments is currently limited by an incomplete marker coverage of the genome, a restricted understanding of the functional role of given genomic regions, and the small sample sizes used. Thus, genome-wide association analysis will be a screening tool to facilitate subsequent gene discovery rather then a means to completely resolve individual genetic risk profiles. The validation of association findings will continue to rely upon the replication of "leads" in independent samples from either the same or different populations. Even under such pragmatic conditions, the timely analysis of the large data sets in question poses serious technical challenges. We have therefore developed public-domain software, GENOMIZER, that implements the workflow of an association experiment, including data management, single-point and haplotype analysis, "lead" definition and data visualisation. We suggest that the use of this software will facilitate the handling and interpretation of the currently emerging genome-wide association data. The software is available for academic use at http://www.ikmb.uni-kiel.de/genomizer/.

This implementation was performed as a pilot project in the German GRID computing initiative MEDIGRID.

STRP Genotyping Methods: Implementation of Cost Reduction and Quality Control Processes in a High Throughput Environment. *M. Zilka[1], J. Romm[1], C. Bark[1], C. Boyce[1], B. Craig[1], K. Hetrick[1], H. Hobbs[1], M. Brehm[1], C. Ongaco[1], A. Robinson[1], C. Boehm[1], J. Cahlik[2], K. Doheny[1].* 1) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Acme-Automation, Spring City, TN.

High throughput genotyping facilities require implementation of cost and time saving methods as well as strict quality controls. CIDR recently reduced its standard PCR volume from 5uL to 3uL using a script from Acme Automation for the Biomek 2000, which allows for a 3ul dispense into dry plates. This change alone resulted in a savings of 2.5 cents per genotype or over $275,000 per year. Savings are also accomplished by bulk PCR master mix reagent creation. The advent of improved spectral resolution over a wider dynamic range on ABs 3730 allowed for the optimization of large multiplexes of PCR primers. The multiplex primer pools and bulk mastermix are tested before use to ensure adequate performance. Before production begins on a project, CIDR runs a set of test markers to ensure the DNA is not contaminated, is amplifying well and to identify sample misidentification. Performance of each of our 404 markers is tracked automatically and checked periodically to quickly identify problems. 3730 runs are automatically monitored for failure and immediately requeued. Data analysis incorporates automatic flags at the genotype level for unexpected positive control values, more than 2 alleles, discrepant allele size and bin name values, and failure to review a poor quality genotype. CIDR also has automated systems for requeuing PCR marker failures and validating that all expected data is present as a project is finalized.

Molecular response to acute shortening and lengthening exercise in human. *M.C. Kostek[1], D.J.R. Cuthbertson[2], M. Fedele[3], K. Esser[3], M. Rennie[2], YW. Chen[1].* 1) Genetic Medicine, Children's National Med Center, Washington, DC; 2) Department of Medicine, Ninewells Hospital and Medical School, University of Dundee, Dundee, Scotland;; 3) School of Biomedical Sciences, Graduate Entry Medical School, University of Nottingham, Derby City Hospital; 5School of Kinesiology, University of Illinois, Chicago, USA.

Phenotypic changes in size and maximal force production have been well characterized in skeletal muscle in response to stimuli. Furthermore, it is known that eccentric muscle contractions (EC) lead to greater increases in muscle hypertrophy and maximal force production than concentric contractions (CC). However, little is known about the molecular basis of these differences. In this study, we examined the changes in skeletal muscle gene expression in response to a single bout of EC and CC using expression profiling. Three healthy male volunteers, 25 5 y, underwent an acute bout of training of the quadriceps. Each subject performed CC to fatigue with one leg while the contralateral leg underwent the same number of EC. Muscle biopsies were taken before exercise and 3, 6, and 24 hours post exercise from each leg. RNA isolated from these samples was expression profiled using a custom Affymetrix MuscleChip microarray containing ~4,000 muscle specific transcripts. Differences in gene expression between the two types of contractions were compared at each time point using Welch t-test. We identified 57, 57 and 148 genes differentially regulated at 3, 6 and 24 h time point respectively. At the 3 and 6 h time point, half of the known genes differentially regulated between the EC and CC were involved in stress responses and gene regulation, while at 24 hours, mybfibrial and cell growth related genes in addition to stress response genes were dominant. One of the genes, cardiac ankyrin repeat protein, which was up-regulated at 24 hours was verified by Western blot (~30%) at the protein level. This study in conjunction with our previous studies demonstrated specific patterns of gene expression in response to a hypertrophy inducing stimulus. The data suggests that CC and EC can produce similar yet distinct patterns of gene expression.

LINKAGE AND MUTATION ANALYSIS OF THE ZFHX4 GENE IN PATIENTS WITH CONGENITAL PTOSIS. *W. Chan[1], C. Andrews[1,3], E.C. Engle[1,2,3].* 1) Department of Pediatrics (Genomics), Children's Hospital Boston, Boston, MA; 2) Department of Neurology, Children's Hospital Boston, Boston, MA; 3) Harvard Medical School, Boston, MA.

Congenital isolated ptosis (CIP) is the most common eyelid anomaly and manifests as abnormal drooping of the upper eyelid with narrowing of the palpebral fissure. CIP is unilateral in ~75% of sporadic cases, and is more frequently bilateral when inherited. We previously mapped a CIP gene, PTOS1, to chromosome 1p32-p34.1. In 2000, McMullan et al identified a de novo balanced translocation 46, XY,t(1:8) (p34.3;q21.12) in a patient with bilateral CIP. The chromosome 1p breakpoint is 13 Mb outside the PTOS1 region, while the chromosome 8 breakpoint disrupts intron 4 of ZFHX4, a 10-exon zinc finger homeodomain transcription factor whose mouse homolog is expressed in embryonic midbrain and muscle. To determine if any of our CIP probands harbored mutations in ZFHX4, DNA was extracted using standard techniques from peripheral blood of 17 familial and 15 sporadic CIP study probands. Linkage analysis was performed by fluorescent PCR amplification of 6 polymorphic markers flanking the ZFHX4 region. ZFHX4 exons and flanking intronic sequences were PCR amplified and analyzed by DHPLC (Transgenomic WAVE). Variant amplicons were sequenced bidirectionally (ABI 3730 DNA Analyzer, Applied Biosystems). The structure of 12 of the familial cases permitted meaningful linkage analysis, and 9 of these pedigrees were consistent with linkage to ZFHX4. Therefore, ZFHX4 was sequenced in 14 familial and 15 sporadic probands. None of the 29 probands harbored ZFHX4 mutations. Eleven polymorphisms were identified. The absence of ZFHX4 mutations suggests that the reported balanced translocation may result in ptosis by a position effect of the chromosome 1 breakpoint on the unidentified PTOS1 gene.

Molecular characterization of the canine factor VIII gene and duplicated sequences related to a common gene inversion mutation. *N. Tayebi, L. Wood, J.N. Lozier.* Laboratory of Hemostasis, Division of Hematology, CBER/FDA Rockville MD.

Hemophilia A (HA), the deficiency of the coagulation factor VIII (FVIII), is the most common sex-linked inherited bleeding disorder. It is cause by mutations in the large (186 kb and 26 exons) and complex FVIII gene on chromosome Xq28. The major identified mutation hot spots are in intron1 and intron 22 with 40 to 50% of severe HA cases arising from intron 22 inversions. The best characterized animal model of HA is the Chapel Hill HA dog, which has an inversion similar to the common human intron 22 FVIII gene inversion. To understand the mechanism of HA in the Chapel Hill hemophilia A dogs Better, we set out to determine the complete sequence of the normal dog FVIII gene. The RPC1-81 BAC library is derived from normal male Doberman Pinscher genomic DNA. BAC clones 291 M9, and 292 C4 from this library were shown to contain FVIII gene sequences by hybridization with dog FVIII exon probes. BAC clone 292 C4 contains exon 1-22 and BAC clone 314 O16 contains intron 21-exon 26. A third BAC clone, 291 M9 contains non FVIII sequence that is found in HA dog FVIII transcripts in the place of exons 23-26. All three BACs carry a factor 8 associated (F8A) sequence, which is the site of recombination in the common inversion mutation. High throughput sequencing established 14 contiguous fragments of sequence for BAC clone 292 C4. We have established overlaps between 10 of these fragments by PCR, subcloning and sequencing of overlap fragments from the 292 C4 BAC and dog genomic DNA. We have identified overlapping FVIII sequence in BAC clone 314 O16 beginning at intron 21. Comparison of our existing Doberman FVIII genomic DNA sequence with that FVIII genomic DNA sequence derived from the canine genome project (http://ensembl.bii.a-star.edu.sg/Canis_familiaris/) that used Boxer genomic DNA showed 99% homology between exonic DNA sequence but numerous intronic polymorphisms. Complete FVIII genomic sequencing will permit development of a rapid PCR diagnostic test for the common FVIII inversion in dogs.

Vega: a bright new star in the genome browser firmament. *L.G. Wilming, J.L. Harrow, C. Amid, A. Frankish, R.C. Gibson, J.G.R. Gilbert, E.A. Hart, G.K. Laird, J.E. Loveland, J. Mudge, J. Rajan, H.K. Sehra, C.A. Steward, M.-M. Suner, D. Swarbreck, S. Trevanion, T. Hubbard.* Wellcome Trust Sanger Institute, Genome Campus, Hinxton, Cambridgeshire CB10 1HH, United Kingdom.

The Vega (VErtebrate Genome Annotation) web browser is an Ensembl derived system dedicated to browsing manually annotated genomic sequence, currently mostly human, mouse and zebrafish. Vega displays manual annotation performed by the Havana group at the Sanger Institute, as well as that produced by other genomic annotation groups (WashU GSC, Genoscope, JGI, Broad, IMB Jena). Manual annotation is better suited to accurate determination of tandem duplicated gene clusters and classes of genes like pseudogenes and (potentially) non-coding genes than automatic systems such as Ensembl. Additionally, polyA features, splice variation and nomenclature benefit from manual annotation.

Apart from the emphasis on manual annotation, Vega also differs from Ensembl in that the underlying genomic sequence assembly is more up-to-date as it is not bound to a fixed update cycle. Vega also shows unique data not found elsewhere, for example human chromosome 6 MHC haplotypes and the dog chromosome 12 MHC.

Here we present data on comparisons between Vega annotation of syntenic human and mouse regions. For example the significant re-arrangements that have taken place between human chromosome 9 (hs9) and a deletion region on mouse chromosome 4 (mm4) and between a disease related part of hs17 and mm11. In both cases groups of genes consecutive in one species are found in a significant different order on the other species owing to micro and macro rearrangements. We also observe gene duplications or genes unique to one species and gene clusters such as Krt, Krtap and Mup expanded in one species relative to the other. Other comparisons being explored are hs20 versus mm2, which contains the entire syntenic region of hs20, and mm4 versus hs1 and hs6. Vega will be able to display the annotation of any of these regions simultaneously in human and mouse through the MultiContigView interface.

TaqMan siRNA assays by stem-loop RT-PCR. *R. Tan, C. Chen, K.J. Guegler.* Advanced Research and Technology, Applied Biosystems, Foster City, CA.

RNA interference (RNAi) induced by short interference RNA (siRNA) is a powerful tool for gene silencing. The short life of synthetic siRNA has limited its applications. Short hairpin RNAs (shRNAs) driven by polymerase III promoters have been investigated as an alternative strategy to stably suppress gene expression. Since the position at which Dicer RNase III cleaves a hairpin of shRNA is not well defined, a single shRNA molecule may generate several putative siRNA products at both sense and antisense orientations. We have recently developed a new real-time quantitation method termed stem-loop RT followed by real-time PCR for accurate and sensitive detection of microRNAs. We report here the use of this method to specifically quantify shRNA-derived siRNAs. Concordance between siRNA copy number and the level of target gene expression was observed in the shRNA vector-transfected cells. Our results have further demonstrated the accuracy and sensitivity of the looped-primer RT-PCR method in the quantitation of shRNA-derived siRNA products, and have also demonstrated that the profiles of shRNA-derived siRNA products depend on the structure and sequence of shRNA. The TaqMan siRNA assay is a valuable tool in optimizing the shRNA construct, monitoring the level of siRNAs, understanding the shRNA-based RNA interference (RNAi) pathway, and evaluating the stability and efficacy of shRNAs as a therapeutic agent.

Allele-Specific PCR (ASPCR) Pre-screening for High-throughput Genomics. *A. Scott, J. Bodnar, J. Goldstein, G. Spangler.* Institute of Genetic Medicine, Johns Hopkins School of Medicine 600 N. Wolfe Street, Baltimore, MD 21287.

Background: Genotyping centers process hundreds of samples per day. Quality control measures for reagents, instrumentation, and procedures generally insure reliable results. However, sample mislabeling, or cross-contamination may occur before processing. It is essential that mistakes be discovered before analysis. We wished to develop an economical method to identify sample mislabeling associated with gender. The assay should be facile and add little time or expense to the overall genotyping process. Methods: Design of three primers using allele-specific parameters allowed amplification of the amelogenin gene to produce a single band for females (279bp) and two bands for males (279 and 159bp.) These were resolved by standard agarose gel electrophoresis. PCR product size determination and subsequent gender calls were performed automatically. Experimentation involved two phases 1) Condition testing to optimize the method, and 2) concordance testing to validate the assay. Demonstration of the amplification as a predictor of amplification success was demonstrated using a heparin titration, and exposure to DNaseI. Results: Optimization experiments produced an inexpensive and robust assay that could be performed in less than two hours with complete automation. A mock run reproduced and identified a pipetting error similar to that for which the assay was designed. Analysis of samples previously processed in a high-throughput facility identified an incorrectly labeled sample. Furthermore, performance of our assay gave an indication of sample performance on amplification-based SNP platforms. Conclusions: Confirmation of sample identity and DNA quality using our method is possible with little expense, negligible sample consumption, and little time added to the high-throughput genotyping process.

Resequencing Process for the Discovery of Variants in Human Mitochondrial DNA. *Y. Lei, P. Ma, X. Chen, L. Leong, X. Lin, M. Rydland, P. Baybayan, C. Heiner.* Applied Biosystems, Foster City, CA.

Human mitochondrial DNA is present in large numbers in every cell in the body, and exhibits characteristics that make this molecule ideal for evolutionary studies, forensic analysis, and clinical genetic diagnosis. This DNA is a circular molecule that has 16,569 bp, encoding 37 genes for oxidative phosphorylation, two rRNAs genes and 22 tRNA genes. We have developed a complete resequencing workflow for mitochondrial DNA, and designed primers to cover the entire genome. Our primer design resulted in 46 amplicons, including 9 for the control region. Our workflow includes protocols for PCR amplification and cycle sequencing, and uses SeqScape software v2.5 for mutation detection and report generation. We tested our primer sequences and workflow by completely sequencing the mitochondrial DNA from 23 Coriell DNAs, obtaining high quality data in both orientations for at least 97% of the mitochondrial genome in all cases. We also discovered novel variants from samples when the sequences were compared to Mitomap Reference sequence. We will describe the details of our workflow and our results.

High-throughput Alternative Splicing Quantification by Primer Extension and Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. *C. Ding[1], R.M. McCullough[2], C.R. Cantor[3].* 1) Centre for Emerging Infectious Diseases, Faculty of Medicine, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong Special Administrative Region; 2) Program of Molecular and Cellular Biology, Boston University; 3) Center for Advanced Biotechnology, Boston University.

Alternative splicing is a significant contributor to transcriptome diversity, and a high-throughput experimental method to assess quantitatively predictions from EST and microarray analyses may help to answer questions about the extent and functional significance of these variants. Here we describe a method for high-throughput analysis of known or suspected alternative splicing variants (ASVs) using PCR, primer extension and MALDI-TOF mass spectrometry. Reverse transcribed mRNA is PCR amplified with primers surrounding the site of alternative splicing, followed by a primer extension reaction designed to target sequence disparities between two or more variants. These primer extension products are assayed on a MALDI-TOF mass spectrometer and analyzed automatically. This method is high-throughput, highly accurate and reproducible allowing for verification of the existence of splicing variants in a variety of samples. An example given also demonstrates how this method can eliminate potential pitfalls from ordinary gel electrophoretic analysis of splicing variants where heteroduplexes formed from different variants can produce erroneous results. The new method can be used to create alternative variant profiles for cancer markers, to study complex splicing regulation, or to screen potential splicing therapies.

Comprehensive Assessment of Metabolic Enzyme and Transporter Polymorphisms. *D. Fu[1], T. Daly[1], P. Hardenbol[2], X. Miao[2], N. Bauer[1], S. Kirkwood[1], R. Hockett[1].* 1) Genomic Medicine Group, Diagnostic and Experimental Medicine, Eli Lilly & Co, Indianapolis, IN; 2) ParAllele Biosciences, South San Francisco, CA.

Understanding drug metabolism and transport are increasingly important to the concept of personalized medicine, accounting for a significant fraction of therapeutic unresponsiveness and/or adverse events. Currently available assay systems for genotyping patients measure only a fraction of the known drug metabolic enzymes and transporters (DMETs). We developed a genotyping platform to comprehensively measure ~2,000 polymorphisms in the 184 known DMETs. The system uses ParAlleles Molecular Inversion Probes and Affymetrix Tag arrays. A subset of 29 genes (171 variants), with documented effects on drug disposition, have been validated for clinical use according to regulatory guidelines. Since the field is rapidly changing, with the discovery of new genes and new variants, the sytem was designed to be flexible, robust, and cost effective. The utility of a comprehensive assessment of DMETs for drug development revolves around building a patient database of know genotypes that could be recruited into new clinical trials. A thorough understanding of DMETs will also aid the investigation of drug related adverse events and the exploration of proper drug dosing. A review of 750 patients, on all 2,000 variants, will be presented, with particular emphasis on the frequency of rare alleles.

Detailed Genotype Comparison of ABI Taqman, SNPlex and Illumina Platforms. *J. Rose, J. Bunch, C. Haynes, E.R. Hauser, M. Pericak-Vance, J.M. Vance, S.G. Gregory.* Department of Medicine, Duke Center for Human Genetics, Durham, NC.

The increasing application of SNP-based linkage and association analyses to the study of disease research has been driven by the development of genotyping platforms that are capable of multiplexing assays. Our aim was to compare the pass and call rates of the Illumina Bead Array and ABI SNPlex platforms with ABI Taqman using 460 samples derived from an on going coronary artery disease study. A total of 19 SNPs were genotyped on all three platforms across 460 DNAs, with a further 1119 DNAs being in common between SNPlex and Taqman. Our controls consisted of two in-plate QC samples and two standard across-plate CEPH samples for Illumina and SNPlex, and 12 in-plate/across-plate QC samples and two standard across-plate CEPH samples for Taqman. The quality of 41 samples that had been whole-genome amplified by Molecular Staging Inc., as reported by the manufacturer, showed no effects on Taqman pass rates. In both Illumina and SNPlex platforms, a similar trend was observed with a decreasing pass rate associated with 3 useable amplified samples (75% average pass rate) and 2 not useable amplified samples (average 52% pass rate). Of the 384 SNPs included in the custom Illumina Oligo Pooled Assay, 22 were excluded due to poor performance. The in-plate controls for Illumina showed only 6 mismatches when compared to Taqman results out of a possible 3840 matches, which dropped to zero after the exclusion of 22 poor markers. The sample match rate to Taqman was also perfect after exclusion of these 22 samples. The remaining 362 Illumina markers had an average call rate of 99.3% (high=100%, low=92.5%). Of the 47 SNPs used in the SNPlex assay, 4 were excluded due to poor performance (<55% call rate). The remaining 43 SNPlex markers had an average call rate of 88.15% (high=98.49%, low=55.94%), with an average mismatch rate compared to Taqman of 1.12% (high=5.08%, low=0.21%). Together, these data suggest that Taqman and Illumina results are very reliable after stringent exclusion of poorly performing markers, however, SNPlex genotyping resulted in genotyping discrepancies and lower efficiencies.

Academic three-color microarrays passing prehybridization QC generate data quality equivalent to that of commercial array systems. *M. Hessner[1,2], B. Xiang[1], R. Geoffrey[2], S. Holmes[1], S. Jia[1], L. Meyer[2], X. Wang[1,2].* 1) Dept Pediatrics, Medical College of WI, Milwaukee, WI; 2) The Human and Molecular Genetics Center, Medical College of WI, Milwaukee, WI.

Despite their lower cost and high content flexibility, a substantial limitation of academically fabricated arrays is their susceptibility to quality control (QC) issues. To solve this we developed a novel three-color system where arrays are directly visualized prior to hybridization, allowing for QC of slide fabrication independent of hybridization. We benchmarked our rat cDNA array against two common commercial systems, the Affymetrix U34A and Agilent G4130A arrays, utilizing liver RNA of Wistar and BioBreeding rats. 2,824 Unigenes represented on all three arrays served as the comparison basis. First, we identified probes that yielded significant t-test results ($p<0.05$) and passed their respective quality control criteria using the 50% cutoff established by the default Affymetrix MAS 5.0 thresholds. Probes for 79 UniGenes met these criteria and Pearsons correlation coefficients of 0.95, 0.92, and 0.91 were determined for the overall $\log_2$ ratios between the Affymetrix U34A versus the Agilent G4130A, the Affymetrix U34A versus the MCW cDNA array, and the Agilent G4130A versus the MCW cDNA array, respectively. To date, we have conducted real-time qRT-PCR for 42/79 of the common loci that were significantly detected on all three platforms. All platforms showed good agreement with qRT-PCR, possessing Pearsons correlation coefficients of 0.90, 0.90, and 0.96 for the Affymetrix, Agilent, and MCW cDNA arrays, respectively, however each platform underestimated $\log_2$ ratios relative to qRT-PCR, possessing respective slopes of 0.86 (R^2=0.81), 0.65 (R^2=0.81), and 0.70 (R^2=0.92). We find differentially expressed genes among the highest quality data derived from each platform are highly correlative. Our combined novel three-color array and unique QC/analytical approaches provide a robust platform for functional genomics that rivals commercially available systems at approximately 1/10th the cost, allowing for experimental designs less constrained by cost considerations.

Computer simulations of the Genomic State Reconstruction dynamical systems algorithm for within-individual predictive systems biology. *I.P. Kovac, A.J.M. Sorant, A.F. Wilson.* Genometrics, NHGRI, Baltimore, MD.

The Genomic State Reconstruction (GSR) is a dynamical systems algorithm for bottom-up within-individual prediction and delineation of genomic basis in complex biological systems, such as common human systems-level disorders (Kovac, unpublished manuscript, etc; McGill University). Briefly, the state (phenotype) of the dynamical system (individual organism) is predicted using the high-dimensional reconstructing vector of one-to-one genomic or genomic-subset similarity measurements (by the proportion of identical allelic states) between the specific within-individual polygenic allelic combination and a plurality of affected individuals, based on the prevailing assumption of positive correlation between genomic and phenotypic similarity. Comprehensive exposition of the GSR algorithm is presented elsewhere. The subsequent simulation study now includes up to 20 SNP loci, population of 5000 individuals, and phenotype prevalences of .01 and .02. Polygenic phenotypes included within-individual loci-additive, loci-multiplicative, and emergent systems-level phenotypes where units of phenotypic information are developmental systems combinations of different loci. The GSR successfully predicted all phenotypes, without specification of the underlying polygenic model. Using the complete set of etiological loci, individuals ranged from those well below population risk to those at elevated risk, up to several ten-folds or more over population risk. The truncation of etiological loci and/or addition of non-etiological loci typically decreased predictive accuracy, the more so with the number of truncated or added loci. For emergent phenotypes the amount of decrease due to truncation depended on systems relations. These predictive differences were used to delineate maximally predictive within-individual genomic subset. As mathematically expected, the GSR performed well only when the noted prevailing assumption was built into the models. The results apply to other population and data sizes. Computer simulations provide additional support for experimental research to empirically evaluate the GSR algorithm.

SNP Genotyping: DNA quantification with the PicoGreen assay and clustering of SNP genotypes utilizing the Illumina GoldenGate assay and BeadArray technology for varying DNA concentrations. *K. Hetrick, C. Bark, Y. Tsai, C. Boehm, E. Pugh, K. Doheny.* Center for Inherited Disease Research, Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Illumina utilizes a single read of the PicoGreen assay (pico) to evaluate input genomic DNA concentration for the SNP GoldenGate assay (50 ng/ul minimum). Investigators often only have OD 260 readings available and limited sample DNA. We examined single-point pico readings and clustering of genotypes for a range of concentrations in order to establish a practical cut-off for rejecting a sample for processing. A single CEPH DNA sample (356 ng/ul by OD as provided by the Coriell Cell Repository) was serially diluted into 11 aliquots of different concentrations. Pico readings were performed via the Illumina BeadLab Make QDNA protocol (dynamic range 0-100ng/ul for input DNA) on two different robots. These samples were genotyped and clustered by the Illumina BeadLab GenCall (Version 6.0.7) software after processing the samples through the GoldenGate assay. For concentrations between 10-100 ng/ul, the mean pico readings were slightly lower than expected by OD with standard deviations (s.d.) of ~10% of the pico means. The mean for water was 0.39 with a s.d. of 0.48. Pico reading for samples beyond the dynamic range of assay increased only slightly with concentration. Genotypes for water samples did not cluster with the other genotypes. Genotypes for samples at 10, 25 and 356 ng/ul were more likely to be greater than 1 s.d. from the cluster mean of a locus. Because all genotypes came from one individual and only the best 874 loci of an 1152 SNP panel were used for analysis, these results may be atypical. Based on our results, we are currently rejecting samples with a pico reading of less than 25ng/ul. We are currently comparing clustering for investigator provided samples of varying DNA concentration.

An Automatic Sequencing-based Method of Genotyping for Tri-nucleotide Polymorphisms as a Replacement / Complementary Approach to Fragment Analysis. *S. Xu, E. Wang.* Department of Biochemistry and Molecular Biology and Gheens Center on Aging University of Louisville School of Medicine 580 South Preston Street Delia Baxter Building, Room 109 Louisville, Kentucky 40292.

Trinucleotide repeats are among the most polymorphic markers utilized in linkage and association studies. Up till now, genotyping of these repeats has been done either by agarose or polyarylamide gel electrophoresis, or by capillary electrophoresis coupled with the automatic DNA sequencing analysis. In either cases quantitation of the triplets is obtained by inference of electrophoretic mobility by comparing them with a standard, thus an indirect method in calculation of the repeats. Here, we report a new method to obtain the direct measurements of the triplet repeats, thus allowing accurate genotyping for three triplet repeat loci: androgen receptor (AR), myotonic dystrophy (DM, and Huntingtons disease (HD). This direct measurements is done by designing the primers flanking the triplet repeat regions in the way that the outcome genotype in sequencing format be analysed by counting the number of A or T peaks alone, contained in whole triplet tracts. Specific starting and ending motifs defined by properly designed primers, as well as graphics visualization by means of a single sequencing reaction, make it possible to read out homozygous as well as heterozygous genotypes, not only with ease but also without ambiguity. In addition, this method avoids the need of loading DNA ladders and thus is cost- and time-effective; suitable for both small and large-scale genotyping. Moreover, the genotyping data generated by our method can be analyzed by any commercially available image processing softwares and provide value-added high-throughput power for the final datamining tasks. With this approach we did genotyping and obtained allele frequencies of AR, DM and HD in Taiwanese population accurately.

Performance Analysis and Improved Base-Calling for Large Scale Resequencing Arrays. *B. Merriman[1], M. Ogdie[1], M. Kane[2], J. Jen[2], Z. Chen[1], S. Nelson[1].* 1) Dept. of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Dept. of Neurology, University of California, Los Angeles, Los Angeles, CA.

Hybridization-based resequencing on high density DNA oligo arrays provides a potentially attractive approach to large scale resequencing projects, such as screening large numbers of samples and genes for rare variants related to a disease. Here we present a detailed analysis of the performance of an 30kb resequencing array (from Affymetrix) designed to resequence the coding portions of 4 human genes, comprising 28800 bases of sequence from chromosome 3. We find a very high proportion of the probes (~98%) give signals consistent with the consensus sequence, and that probes also exhibit several consistent indicators for detection of non-consensus sequence. We also show that there are a variety of hybridization artifacts that systematically affect the probe performance, and in particular impact accurate base detection, and that these artifacts can be reliably identified largely from the local sequence context. Based on these fundamental performance observations, we present a new base calling algorithm which substantially improves upon the call rate and heterozygous detection capabilities of the standard software (Affymetrix GDAS 3.0), as validated by capillary sequencing and mendelian inheritance analysis in familial sample sets. Thus array-based resequencing can be a reliable means of resequencing for disease variant detection. The sequence-based artifacts identified also suggest directions for future development of improved array designs or protocols, relevant to general array formats. Finally, as a novel application of the technology, we show that the human *re*-sequencing arrays can be used for the *de-novo* sequencing of primate species. We test a variety of primate samples, show they have very similar hybridization properties to the human samples, and, using our enhanced base-calling algorithms, we clearly identify numerous instances of non-conservative human-primate sequence differences.

Novel High-throughput Assays using Shape Encoded Particles. *Z. Chen[1], B. Merriman[1], J. Tsai[2], M. Xie[1], J. Chen[1], C.J. Kim[2], S. Nelson[1].* 1) Dept. of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Micromanufacturing Laboratory, Dept. of Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, CA.

We have developed a novel system for highly multiplexed biological assays using shape encoded micro-particles as probe-carriers. Millions of distinct Shape Encoded Particles (SEPs) can be created by etching unique patterns of notches on the edge of flat silicon particles using standard microfabrication techniques. The system has been demonstrated as probe carriers for oligonucleotide and protein binding assays, where it provides an attractive alternative to microarray-based techniques due to the potential for efficient mass production, high through-put, scalability and flexibility. Here we extend this basic technology to allow multiplexing of much more general types of biochemical assays. First, we have extended this approach to cellular assays, using the SEPs as encoded cell carriers. As a demonstration, different cancer cell lines were grown on distinct shapes, mixed, and induced for programmed cell death. Cell-line specific apoptosis was clearly detectable on SEPs, illustrating the possibility of multiplex cell-based drug or functional screening. Second, we extended the SEP approach to multiplex complex reactions that normally require individual tubes or wells, by making Shape Encoded Micro-Reactors (SEMRs), consisting of particles with a micro-well (1 picoliter1 nanoliter volume) etched into the center. Using novel techniques for parallel loading and sealing, a standard assay for proteinase activity was successfully multiplexed into the SEMR system, to create the equivalent of an enzyme array capable of screening activities of many enzymes in one macro-scale reaction. This has potential application to large-scale enzyme inhibitor screening, and also illustrates the utility of SEMRs for multiplexing arbitrary biochemical reactions.

Increased Efficiency of SNP Genotyping on Sequenom MassArray. *L. Ziaugra[1], N. Burtt[1], I. Musil[1], M. Goyette[1], T. Considine[1], M. Beaullieu[2], D. Lough[2], E. Munk[2], D. Altshuler[3], S.B. Gabriel[1].* 1) Broad Inst, Cambridge, MA; 2) Sequenom INC., San Diego; 3) Harvard Medical School and Massachusetts General Hospital.

Several high throughput genotyping platforms now offer multiplexing of SNPs at the level of thousands of SNPs at once. While these technologies are enabling for whole genome scans, multiplexing at a more modest level will be required to quickly and efficiently follow up results of these large scale association studies. The iPLEX technology is a newly developed SNP genotyping assay for use on Sequenom MassArray platform. The most significant difference of the iPLEX compared to the existing Sequenom MassArray assay(hME) is that all reactions are terminated after a single base extension (SBE). The other important feature is that iPLEX assay incorporates mass-modified di-deoxyterminators thus allowing better mass resolution (15Da) and a four fold increase in multiplexing capacity (20-30 plex for iPLEX compared to 5-7 plex with hME). We performed a pilot study of 97 SNPs which were designed into five multiplex pools (4-23 plex and 1-5plex). The pools were genotyped on the HapMap CEU plate. Results obtained with the iPLEX assay were compared to genotype calls made using the previously well-validated Sequenom hME assays for the same SNPs. Of the 97 SNPs, 80 passed genotype quality metrics yielding 99.7% concordance with consensus genotypes and averaged 97% call rates. The SNP pools will be applied to a large case control study.

Selecting tag SNPs of 328 candidate genes responsible for adverse effects of cancer chemotherapeutics. *M. Isomura[1], H. Fujisawa[2], M. Ushijima[1], S. Miyata[1], M. Matuura[1], Y. Miki[1].* 1) Genome Center, Cancer Institute, Tokyo, Japan; 2) Institute of Statistical Mathematics, Tokyo, Japan.

Appearance of adverse effects of cancer chemotherapeutics depend on polymorphisms of recipient'fs genome. As demonstrated on certain chemotherapeutics, deleterious mutation on genes related with drug metabolism increase risk of adverse effects. However, frequencies of those mutations are relatively low. Thus, those are insufficient to predict most of severe adverse effects that may cause interruption of treatment, although those polymorphisms are useful to prevent lethal event on a small number of patient. A number of low risk polymorphisms have to be identified to construct prediction system of adverse effects on chemotherapeutics. To screen polymorphisms associated with adverse effects of chemotherapeutics more efficiently, we attempted to estimate haplotype block structure of candidate genes to select tag SNPs. To elucidate genes responsible for adverse effects of chemotherapeutics, we selected 507 candidate genes. These included genes related to drug metabolism, DNA repair, apoptosis, cell cycle regulation, angiogenesis, and inflammation. SNPs located in or around those genes were obtained from JSNP databases, and 3,246 SNPs were selected for genotyping. Genotypes of those genes were determined on 1,421 cancer patients by Invader assay. SNPs with low minor allele frequency (0.1), and those departed from Hardy-Weinberg equilibrium were eliminated from further analysis. In addition, genes covered by only one SNP were eliminated. By those selections, 2,249 SNPs covering 328 genes were used for haplotype block analysis. After estimating haplotype frequencies of genomic loci of those genes, haplotype block structures were estimated by ADBlock software, which is based on ancestor derived model and MDL principle. Those analyses revealed that genomic loci of 328 genes were subdivided into 547 haplotype blocks. The average length of haplotype block was 18.7kb and the average number of major haplotypes in each haplotype block was 3,7. Based on haplotype block structure, 1,432 tag SNPs, representing more than 90 % of haplotypes observed in 547 haplotype blocks, were selected.

Gene Entrapment Libraries For mouse Functional Genomics. *Q. Lin, S.L. Donahue, T. Moore-Jarrett, S. Cao, A. Nashabi, A. Osipovich, H.E. Ruley.* Microbiology & Immunology, Vanderbilt University, Nashville, TN.

Mutations induced by gene entrapment in murine embryonic stem (ES) cells have been widely used to characterize gene functions in mice. However, entrapment mutations are typically recessive and can be studied only after they have been introduced into the mouse germline and bred to a homozygous state. The present study describes novel poly(A) gene trap vectors capable of targeting both alleles of mammalian genes with a single gene entrapment event. The vectors, which contain features to facilitate the identification of disrupted genes and for post-entrapment genome engineering, were used to characterize a library of 980 mutant stem cells. All 10 mutations tested were easily transmitted into the germline and 4 of them generated obvious phenotypes, establishing the library as a resource for constructing mutant mice. For example, Hesx1 -/- mice have an ¡eyeless¡ phenotype, pfdn1 (Prefoldin) -/- mice die before 5 weeks of age, have CNS abnormalities consistent axon extension defects and deficiencies in B-cell development. A neomycin resistance gene (Neo) inserted by the vector was used to select for homozygous mutant cells in 36 of 37 entrapment clones following selection for higher levels of drug resistance. The frequency of apparent LOH increased with increasing distance from the centromere, suggesting that mitotic recombination plays a significant role in generating losses of heterozygosity. The ease and efficiency of obtaining homozygous entrapment mutations will enhance the utility of mutant stem cell libraries by eliminating the need to pass mutations through the germline in cases where functional studies would be best performed in cell lines rather than in mice. Moreover, the vectors will enable new strategies to identify genes responsible for recessive phenotypes in mammalian cells.

Array-CGH deletion mapping excludes the involvement of VCXA in mental retardation. *E. Scala[1], C. Pescucci[1], R. Caselli[1], I. Meloni[1], D. Lugtenberg[2], F. Mari[1], H. van Bokhoven[2], A. Renieri[1].* 1) Molecular Biology, University of Siena,Italy; 2) Dept of Human Genetics, University Medical Center of Nijmegen, The Netherlands.

VCXA has been recently proposed as a candidate mental retardation (MR) gene. To better define the involvement of this gene in MR we have performed array-CGH deletion mapping using a 200 kb resolution X chromosome specific BAC arrays. We have compared the deletion present in a familial case with X-linked ichthyosis (XLI) and MR to that present in a sporadic case with XLI and Kallmann syndrome (KAL). In the case with XLI and KAL, array-CGH analysis showed the presence of a large deletion of approximately 3 Mb. The deletion includes the STS gene, the KAL1 gene (responsible for KAL) and also VCXA, VCXB, VCXB1 and VCXC genes. In the case with XLI and MR the analysis revealed the presence of a smaller deletion, approximately 0.6 Mb, spanning from clone RP11-483M24 to clone RP11-645P06. The deletion does not include the VCXA gene, which has been previously suggested to be involved in mental retardation. The deletion involves the STS gene responsible for XLI (OMIM#308100) and only a second gene, named HDHD1A. This gene, also known as GS1 (OMIM#306480), has been reported deleted in patients with isolated XLI. The deletion map in these two cases exclude the involvement of the VCX genes in mental retardation. A possible involvement of GS1 as a low penetrance MR gene is discussed.

NCBI Entrez Phenotype Resources. *M.D. Mailman, S.T. Sherry, D.R. Maglott.* National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, 45 Center Dr., Bethesda, MD, 20892, USA.

NCBI recently launched a new Entrez database, PhenoDB, to represent phenotypes, possible causative factors, and the defining assays. In the data model, potential contributing factors include genotype (ie: haplotypes, SNPs, alleles), epigenetic status, gene expression, exposure to drugs or atmospheric conditions, diet, previous occurrence, and ancestry. A phenotype is linked to a controlled vocabulary or ontology term when possible, such as the Mouse Genome Informatics (MGI) Mammalian Phenotype Ontology or Gene Ontology, and has an associated species (NCBI Taxonomy), gender, relevant anatomical site (Foundational Model of Anatomy and species-specific vocabularies), species-specific developmental stage, inheritance pattern, and penetrance. Phenotypes can be associated with one or more diseases from the MeSH vocabulary, the NCI Metathesaursus, the Online Mendelian Inheritance in Man (OMIM), or the Online Mendelian Inheritance in Animals (OMIA). We have linked over 1000 SNPs from dbSNP to allelic variants described by OMIM and have linked diseases in OMIM to phenotypes by mapping OMIM Clinical Synopses to the Mammalian Phenotype Ontology. A similar mapping has been made between phenes in OMIA and the Mammalian Phenotype Ontology. In addition, PhenoDB models the raw data and the assays that are used to generate them. This is important because phenotypic data is relevant only in the context in which it was measured. PhenoDB will store phenotype and phenotype-related data from any species. Cross-species comparisons will be facilitated by linkage to common phenotype ontology terms. We expect that this resource will be useful in the generation of hypotheses about factors that could be associated with a phenotype using the power of our knowledge of factors in multiple species. Integration of PhenoDB with the NCBI Entrez system allows for convenient linkage to relevant records in other databases at NCBI such as dbSNP, Gene, GEO, Taxonomy, OMIM, OMIA, Probe, MapViewer, and PubMed. Links will also be provided, directly or indirectly, to data contributors or ontology providers such as MGI, Rat Genome Database, PhysGen, NCI, MeSH, and Gene Ontology.

Clinically relevant VKORC1 haplotype and CYP2C9 genotype frequencies in multiple world populations. *S. Marsh, C.R. King, R.M. Porche-Sorbet, T.J. Scott-Horton, C.S. Eby, B.F. Gage, H.L. McLeod.* Washington University School of Medicine, St Louis, MO.

Warfarin, a commonly used treatment for preventing blood clotting, has a narrow therapeutic index, and over or under-dosing can be life-threatening. Warfarin is metabolized by CYP2C9 and the vitamin K epoxide reductase complex (VKORC1) is the drug target. Recent studies have identified haplotype-dependent predictions for warfarin dosing. In addition, CYP2C9 genotype has also been described as a predictor for warfarin dose. VKORC1 haplotype predicted 21-25% of the required warfarin dose, and CYP2C9 genotypes reduced the required warfarin dose up to 31% in Caucasians. Screening of VKORC1 and CYP2C9 prior to initiating therapy will provide essential information for improving dose selection. Population differences of VKORC1 haplotype and CYP2C9 genotype frequencies have also been observed. In order to identify the high risk genotype combination frequency across world populations we assessed four haplotype tag SNPs for VKORC1 (685, 861, 5808 and 9041) and CYP2C9 (*2 and *3) using PCR and Pyrosequencing in 556 unrelated healthy individuals from European American (95), African (95), African American (95), Hispanic (Mexican (95) and Peruvian (81)) and Asian (95) populations. VKORC1 haplotypes were classified into Haplotype A (low warfarin dose) and Haplotype B (high warfarin dose) groups. Haplotype A group frequencies ranged from 27% in Peruvians to 85% in Asians. Caucasians had a Haplotype A group frequency of 42%. CYP2C9 polymorphisms were more frequent in Caucasians (14% CYP2C9*2, 6% CYP2C9*3) and were least common in Peruvians (1% for both variants).Caucasian populations had the highest frequency of combined VKORC1 and CYP2C9 polymorphisms (18% of individuals had at least one VKORC1 haplotype A and at least 1 CYP2C9 variant allele). Based on VKORC1 haplotype frequencies and CYP2C9 polymorphisms, these data suggest that Caucasian and Asian patients have higher risks of warfarin overdose whilst African and Peruvian populations are likely to have greater warfarin-dose requirements.

NIEHS Environmental Genome Project: Functional Significance of Environmentally-Responsive Genotypes for Human Disease. *K. McAllister, F. Tyson, L. Maull, K. Gray, S. Srinivasan, L. Reinlib, G. Collman.* DERT, NIEHS, Res Triangle Park, NC.

The National Institute of Environmental Health Sciences initiated the Environmental Genome Project (EGP) to identify and characterize genetic variants that influence human susceptibility to environmental agents. The EGP is a multi-component project comprised of research in the following four areas: (1) The resequencing effort initially focused on a panel of 90 human samples to identify single nucleotide polymorphisms (SNPs) in ERGs and a new panel of ethnic identifiers has recently been added. This effort now includes 466 ERGs related to DNA repair, cell cycle control, cell signaling, cell division, homeostasis, and metabolism. The GeneSNPs database, http://www.genome.utah.edu/genesnps/, integrates this gene, sequence, and polymorphism data into individually annotated gene models. (2) The Comparative Mouse Genomics Centers Consortium has approximately 60 SNP and tool mice strains developed from DNA repair and cell cycle genes that display aging, diabetes, and cancer phenotypes. Validated mouse models and resources developed by the CMGCC are available to the scientific community and can be accessed at the CMGCC website, http://www.niehs.nih.gov/cmgcc. (3) The molecular epidemiology planning grants have provided insights into the environmental susceptibility of several neurodegenerative diseases, childhood leukemia, birth defects, and asthma. (4) Finally, the ELSI grants have focused on developing policies to effectively deal with the concerns of the community relating to environmental health research. Insights into the functional relevance of the identified human DNA polymorphisms from these projects will contribute to a greater understanding of the complex relationships between genetic susceptibility, environmental exposures, and human disease.

Mutation Screening of WDR36 and Two of Its Binding Partners, MAX and E2F6, in Families with Adult-Onset Primary Open Angle Glaucoma (POAG). *S. Monemi[1], G. Spaeth[2], E. Ilitchev[3], J. Liebmann[3], R. Ritch[3], E. Heon[4], R.P. Crick[5], A. Child[6], M. Sarfarazi[1].* 1) Dept Surgery, Univ Connecticut Health Ctr, Farmington, CT; 2) Wills Eye Hospital, Philadelphia, PA; 3) Glaucoma Service, New York Eye and Ear Infirmary, NY; 4) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Canada; 5) International Glaucoma Association, London, UK; 6) St. Georges Hospital Medical School, London, UK.

Recently, we mapped a new locus *(GLC1G)* for Adult-Onset POAG to 5q22.1 and subsequently identified *WDR36* as a novel causative gene at this locus. Screening of this gene in 130 unrelated POAG families revealed 4 disease-causing mutations (N355S, A449T, R529Q and D658G) and 20 other DNA variations. These evolutionary conserved mutations observed in a total of 17 unrelated subjects, 11 with high- and 6 with low-pressure glaucoma. By Northern blotting and RT-PCR, expression of this gene and its homologue, *Wdr36*, were established in human and in mouse, respectively. The mRNA expression profiling of *WDR36* in different human ocular tissues was consistent with its role in the etiology of glaucoma. WDR36 is a 951 a.a. multi-tasking protein with different motifs (i.e., G-protein beta WD40 repeats). As this protein may function in a number of biological processes and/or participate in different biochemical pathways, identification of WDR36-interacting proteins and their encoding genes may provide new insights for delineation and underlying molecular mechanisms of glaucoma. Recently, transcription factor E2F6 and MAX proteins were reported as WDR36-binding partners. Therefore, we aimed to screen their encoding genes in a group of unrelated glaucoma families. Haplotype analyses of a group of 139 POAG families recently scanned for the entire genome revealed potential genetic linkages to 2p25.1 and 14q23 regions, encompassing *E2F6* and *MAX* genes, respectively. Direct DNA sequencing of *MAX* in a group of 10 POAG families revealed only 7 intronic variations, including 3 novel SNPs. DNA sequencing of *E2F6* in another group of families is currently in progress. Supported by EY-009947 and M01RR-06192.

Exceptionally low LD and high recombination in human immune genes. *X. Ke[1], J. Kelley[2], G. Abecasis[3], J. Marchini[4], R. Copley[1], J. Trowsdale[2], L.R. Cardon[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Pathology, University of Cambridge, UK; 3) Center for Statistical Genetics, Dept. of Biostatistics,University of Michigan, USA; 4) Department of Statistics, University of Oxford, UK.

The human genome is estimated to contain 20,000-25,000 protein coding genes, including about 20,000 known genes. Of these known genes, at least 7% are estimated to be involved in the human immune system. Many immune genes, particularly those in the major histocompatibility complex (MHC), have been studied intensively. The profile of linkage disequilibrium (LD) and historical recombination events of the immune genome, however, is still not well understood. In the present study, we have carried out a genome-wide survey of the level of LD, LD decay, and recombination rates on immune genes in CEPH, Chinese, Japanese, and Yoruban populations using genotype data from the International HapMap Project. LD of immune genes is significantly lower than LD of genes in the rest of the human genome. Immune genes are also associated with quicker LD decay and higher recombination rate. Among the immune genes, those interacting directly with pathogens usually have less LD and higher recombination rate, whereas those processing antigens have the highest LD and least recombination. The antigen-processing genes, such as are commonly found in the MHC, are also found to have marginally stronger LD than the genome average. These observations reflect the complexity of the human immune system as well as the evolution and conservation of the individual immune genes.

Microarray gene expression profiling of skin melanocytes from patients with vitiligo. *C.M. Mailloux[1], G.D. Shipley[2], R.A. Spritz[1].* 1) Human Medical Genetics Program, University of Colorado Health Sciences Center-Fitzsimons, Aurora, CO; 2) Cascade Biologics, Inc., Portland, OR.

Generalized vitiligo is a common polygenic, multifactorial disorder in which white patches of skin and hair result from autoimmune loss of pigment-producing melanocytes in these areas. Vitiligo is highly associated with other autoimmune diseases, and appears to involve a non-inflammatory T-cell immune response directed against pigment cells. Nevertheless, relatively little attention has been paid to cell-autonomous properties of the cellular target, the melanocyte. To address this, we have carried out genomewide expression profiling analysis of vitiligo melanocytes. Although it is extremely difficult to grow primary skin melanocytes from adults, we cultured melanocytes from uninvolved skin of two affected sisters from a large family in which vitiligo has been linked to chromosome 1p, their unaffected mother, and a number of unrelated female controls. We extracted RNA from the cultured melanocytes and carried out genomewide RNA expression profiling using Affymetrix HG-U133 plus 2.0 microarrays, which interrogate 47,000 transcripts. Data from replicate samples showed very high correlation, and cluster analysis grouped the affected patients separately from the controls. Gene expression profiles of the affected patients were compared to profiles of the controls, and genelists of significant expression changes, ranked by fold-differences and by *p*-values of the differences, were compiled. The data were subjected to pathway analysis to organize genes into functional groups, and genes were sorted by chromosomal location for comparison with genetic linkage data for vitiligo. These analyses identified a limited set of genes whose expression was significantly up- or down-regulated, most notably including an HLA gene and a number of genes involved in regulating melanocyte cell-cycle and cell division. Our studies thus suggest there may be primary dysregulation of melanocyte growth in at least some patients with vitiligo, and identify potentially important candidate genes that may contribute to the pathophysiology of vitiligo and other associated autoimmune diseases.

Serum biomarker discovery for MPS disease: Utility of the murine MPS I model. *D.R. Randall[1], G.B. Sinclair[2], K.E. Colobong[1], L.A. Clarke[1].* 1) BC Research Institute for Childrens and Womens Health, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Biochemical Genetics Laboratory, Department of Pathology and Laboratory Medicine, Childrens and Womens Health Centre of BC, Vancouver, BC, Canada.

Objective: Mucopolysaccharidosis I (MPS I) results from an inherited deficiency of the lysosomal enzyme -L-iduronidase (IDUA), causing an altered ability of cells to metabolise heparan and dermatan sulphate containing glycosaminoglycans (GAGs). These GAGs accumulate in the lysosomes of virtually all cells and subsequently lead to cellular, tissue, and multi-system organ dysfunction. Currently, there are few objective criteria available to evaluate the burden of disease in MPS I nor responsiveness to therapeutics. The serum proteome presents a potential source of protein biomarkers for MPS I management but is technically challenging due to the presence of high-abundance proteins that mask detection of useful proteins. **Methods:** Two independent pools of serum from six 20-week-old IDUA knock-out mice and matching control samples were depleted of albumin, transferrin, and IgG. Aliquots were analysed by isotope tagged (iTRAQ) differential proteomics and by 2-D gel electrophoresis (2DGE) with and without prior solution-phase isoelectric focusing (IEF). **Results:** 2DGE revealed multiple proteins with altered expression levels representing possible biomarkers for MPS disease. IEF prefractionation will be used to increase sample loading for protein identification and relative quantitation of low abundance species. iTRAQ was used to quantify and compare the expression of more than 200 proteins and indicated a homeostatic compensation mechanism of factors involved in coagulation to resist the burden of disease imposed by GAG accumulation. Such factors may be ideal biomarkers to enhance clinical management of MPS patients and MPS research. **Conclusion:** Prefractionation methods are effective tools in probing the serum proteome for candidate biomarkers of disease. We have identified several potential biomarkers for MPS I disease utilizing the mouse model; further validation of these markers in humans is now underway.

Assessment of schizophrenia genomes for DNA copy number alterations. *S.E. Holmes[1], N.A. Sachs[1], J.K. Cowell[2], J. Conroy[2], N.J. Nowak[2], D. McQuaid[2], M.R. Rossi[2], D.P. Gaile[2], S.L. Christian[3], M. Wigler[4], J. Sebat[4], C.A. Ross[1], L.E. DeLisi[5], R.L. Margolis[1].* 1) Department of Psychiatry, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) Roswell Park Cancer Institute, Department of Cancer Genetics, Buffalo, NY; 3) Department of Psychiatry, The University of Chicago, IL; 4) Cold Spring Harbor Laboratory of Biology, Cold Spring, NY; 5) Department of Psychiatry, New York University, New York, NY.

Introduction: Comparative genome hybridization array (aCGH) and Representational Oligonucleotide Microarray Analysis (ROMA) were used to determine whether genomes of individuals with schizophrenia contain deletions and/or duplications. Methods: Polymerase chain reaction representations of 6,116 bacterial artificial chromosomes (BACs) spanning the human genome at 0.5-1 mb intervals were arrayed in triplicate for aCGH, while approximately 85,000 70-mer oligos with an approximate 100 kb resolution were used for ROMA. Subject genomic DNA was derived from lymphoblastoid cell lines of 27 individuals with schizophrenia and 6 individuals with schizoaffective disorder, all from families with multiple members affected with schizophrenia or other major mental illness originally ascertained as part of a genetic study of sibpairs. In each array, uniquely labeled subject and control DNA is hybridized and alterations in hybridization may correspond to DNA copy number changes. Additionally, aCGH analysis of genomic DNA isolated from control lymphoblastoid cell lines was hybridized against stock control DNA to determine the baseline rate of abnormal hybridization signals. Altered hybridization signals from subject DNA at an equivalent BAC to that observed in control DNA were generally disregarded in future analyses. Results: Real-time qPCR assays were designed to test the 27 most significant regions of DNA copy number changes detected by aCGH or ROMA. Thus far, a deletion detected by aCGH at 5p15.1 in a subject with schizophrenia has been substantiated by qPCR. Conclusions: Two previous linkage findings are close to 5p15.1, supporting the notion that deletion of this region may contribute to the genetic risk of schizophrenia.

Identification of disease causing mutations using high-density whole-genome SNP genotyping microarrays. *D.W. Craig[1], M.J. Huentelman[1], D. Hu-Lince[1], K.D. Coon[1], K.M. Ramsey[1], J.P. Parod[1], M.C. Kruer[1], J.M. Pearson[1], E.G. Stephan[2], D.A. Stephan[1].* 1) Neurogenomics Division, TGen, The Translational Genomics Division, Phoenix, AZ; 2) Clinic for Special Children, Lancaster, PA.

The technology to simultaneously genotype hundreds of thousands of single nucleotide polymorphisms (SNPs) in a single assay has only recently been developed. These technological SNP genotyping advances have the potential to revolutionize our ability to identify disease-associated genes, both in complex and in Mendelian inherited diseases. We describe application of this technology for discovery of novel mutations using several different experimental approaches. First, for familial linkage studies we describe using the Affymetrix GeneChip 10K SNP Mapping Arrays to discover disease-causing mutations for four separate disorders. Second, we describe using copy number analysis of SNP genotyping microarrays as an approach to discover a novel amplification and a novel deletion in two separate disorders. Third, we describe approaches for pooling genomic DNA on the 100K and 500K SNP Mapping Array platforms as a pre-screening approach in association studies of complex disorders. Finally, we describe our progress towards genotyping 7,000 individuals for 10,205 SNPs as part of the Autism Genome Project and our progress towards completion of a 2000 case-control whole-genome association study in Alzheimers disease.

Using DNA pooling to screen large samples for candidate gene associations with general cognitive ability. *J.K.J. Kennedy, C.J.C. Curtis, L.M. Butcher, E. Meaburn, R. Plomin.* SGDP, Institute of Psychiatry, London, United Kingdom.

Candidate gene association studies are frequently reported for complex traits and common disorders but frequently fail to replicate in subsequent research. Such studies are often underpowered to detect and to replicate the small effect sizes expected for quantitative trait loci (QTLs) for complex traits and common disorders. DNA pooling of cases versus controls or low versus high groups greatly expedites screening large samples for QTL associations. We used DNA pooling to screen nine genes that have been recently reported to be associated with general cognitive ability (g, often referred to as intelligence), which includes mild mental impairment at its low extreme. From a sample of more than 6000 7-year-old children assessed on four cognitive measures, we conducted two DNA pooling studies in order to replicate our results: (1) a case versus control study in which cases were selected for very low g scores and controls were unselected (n=515 and n=1028, respectively), and (2) a low versus high study (n=503 and 505, respectively). For each of these four groups, five independent subpools were created in order to assess sampling variation. None of the nine candidate genes yielded significant differences in the expected direction in either study. In order to confirm these pooled DNA results, we individually genotyped our entire sample of 6000 children for the most frequently reported association with g, a functional SNP (Val108/158Met) in catechol-O-methyltransferase (COMT). We again found no evidence for association: g scores for the three COMT genotypes were nearly identical and the correlation between g scores and additive genotypic values was .000. We conclude that, although candidate gene association studies are valuable, larger samples and replication designs are needed. In addition, systematic whole-genome approaches using SNP microarrays will provide an important complement to candidate gene studies.

Molecular Detection of Bacterial DNA in Human Peritoneal Fluid Samples by Broad-Range PCR Amplification.

S.L. Woon[1], Y.F. Ngeow[1], J.A. Tan[2]. 1) Dpt Medical Microbiology, University Malaya, Malaysia; 2) Dpt Molecular Medicine, University Malaya.

Identification of infectious diseases can be difficult when the organisms are problematic to culture. An alternative to culture identification is the use of molecular techniques such as DNA amplification to rapidly amplify specific regions of bacterial genomes followed by direct sequencing of the amplicon. Bacterial DNA can be amplified from human samples using primers specific to bacterial DNA consensus sequences. This study presents preliminary work on development of a broad-range PCR amplification of the 16S rRNA gene sequences for bacteria detection in peritoneal fluid samples. PCR results were compared with results from known standard laboratory culture techniques. DNA was extracted from the 62 peritoneal fluid samples using an alkaline-heat-wash method.

DNA amplification was carried out using primers that targeted the conserved bacterial 16S rRNA gene sequences and which also allowed Gram-typing. Amplified DNA was then directly sequenced and the results submitted for BLAST analysis.

Seventeen peritoneal fluid samples were culture-positive while the remaining 45 showed negative culture results. Concordance between culture-positive and PCR techniques was obtained in only 10 samples. Using PCR and direct sequencing, all 10 bacteria were identified to the species level. Seven culture positive samples were found to be PCR negative. One culture-negative sample obtained from a patient treated with antibiotics was found to be PCR-positive. Overall, the sensitivity of the broad-range PCR assay for amplification of the 16S rRNA gene sequences was 58.82 % in this study.

Further work needs to be carried out to evaluate and optimize the broad range PCR assay for improve sensitivity with peritoneal fluid samples. In addition, more effective rapid DNA extraction and purification techniques should be developed as the insensitive DNA amplification in this study may be due to inefficient DNA extraction and low DNA purity.

Comparison of Whole-Genome Amplification Methods Using a 10K Microarray Platform. *C.J.C. Curtis, E.L. Meaburn, I.W Craig, R. Plomin.* SGDP research centre, Institute of Psychiatry, London, United Kingdom.

Although immortalization of cell lines yields unlimited amounts of DNA, many large-sample population studies need to rely on DNA extracted from buccal smears for which DNA quantities are much more limited, and re-sampling of DNA stocks is costly and time consuming. Whole-genome amplification (WGA) can extend DNA stocks and provide high yields of unbiased amplification products of the entire DNA template from very small amounts of DNA. In this study we compare four available WGA methods for quantity, quality and accuracy of DNA product produced: (1) primer-extension-preamplification PCR (PEP) which uses random femtomers in a PCR-based reaction; (2) GenomiPhi() and (3) REPLI-g() multiple-displacement amplification, which uses a proofreading enzyme, ()29 DNA polymeraseand (4) GenomePlex(), which converts randomly fragmented genomic DNA into PCR-amplifiable library molecules flanked by universal priming sites. DNA samples for five individuals were amplified using the four WGA methods and genotyped for 10,000 SNPs using Affymetrix GeneChip() Human Mapping 10K Array. Microarray results using amplified DNA were compared to microarray results for the five individuals using original non-amplified DNA. Although the four WGA methods differ in relation to performance, cost and ease of use, the main message is that WGA is a viable technique to amplify DNA.

High-resolution amplicon melting analysis, a time- and cost-effective method for rapid mutation scanning and frequency studies in the VLCAD gene. *R.K.J. Olsen[1], S. Dobrowolski[2], M. Kjeldsen[1], D.M. Hougaard[3], H. Simonsen[3], C.K. Boesgaard[3], N. Gregersen[1], B.S. Andresen[1, 4].* 1) The Research Unit for Molecular Medicine, University of Aarhus, Denmark; 2) Idaho Technology, Salt Lake City, Utah, US; 3) Department of Clinical Biochemistry, Statens Seum Institut, Copenhagen, Denmark; 4) Department of Human Genetics, University of Aarhus, Denmark.

Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency is an autosomal recessive inborn error of fatty acid oxidation. More than 150 mutations have been identified in the VLCAD gene. Three mutations (779C>T, 830_832del and 848T>C) are frequent in clinically affected patients with VLCAD deficiency and may account for up to approximately 40% of mutant VLCAD alleles in newborns identified by tandem MS based newborn screening. Because newborn screening by acylcarnitine profiling for fatty acid oxidation defects, including VLCAD deficiency, is becoming standard of care in many countries world-wide, there is a need for more time- and cost-effective gene analysis methods for confirmation of screening positive samples. Moreover, knowledge of the carrier frequencies of the most common VLCAD mutations in the general population would allow evaluation of the diagnostic specificity of newborn screening for the disease.

High-resolution melting of PCR amplicons amplified in the presence of the DNA dye LCGreen^{TM} was recently introduced as a homogeneous, closed-tube method for genotyping using the single-sample HR-1^{TM} instrument from Idaho Technology. With the newly developed LightScanner^{TM} from Idaho Technology this method can now been adapted to a 96 well plate format system. Here we validate the LightScanner^{TM} as a mutation scanning instrument by blinded genotyping of >50 sequence variants that we have identified in patients with VLCAD deficiency. We also demonstrate that this method is a very time- and cost-effective method for population carrier testing allowing simultaneous genotyping of three mutations (779C>T, 830_832del and 848T>C) in 2000 Danish blood spots using only one set of primers and the DNA dye LCGreen^{TM}.

Sequencing the entire mtDNA coding region in LHON patients without Primary LHON Mutations: Biochemical and Molecular Characterization. *K.K Abu-Amero[1], T.M Bosley[2].* 1) Dept Medical Genetics, King Faisal Specialist Hosp, Riyadh, Central, Saudi Arabia; 2) King Khaled Eye Specilaist Hospital.

We investigated the biochemical and molecular characteristics of mitochondria in patients with the Leber hereditary optic neuropathy (LHON) phenotype with and without primary LHON mutations. Patients were selected from neuro-ophthalmology clinic that reported subacute loss of vision in both eyes with optic neuropathies compatible with the LHON phenotype. We reviewed history, clinical examination, and neuroimaging; sequenced the entire mitochondrial DNA (mtDNA) coding region; assessed mtDNA content; and measured mitochondrial respiratory function in some patients and family members. Thirty-five patients (average age at onset 19.0 years; 21 male and 14 female) met diagnostic criteria with median visual acuity 20/200. Six patients (17%) had primary LHON mutations. These patients were all male, and they had increased mtDNA content. The remaining 29 patients did not have primary LHON mutations or increase in their mtDNA content despite a similar clinical presentation, but they had potentially pathologic non-synonymous mtDNA changes (resulting in amino acid changes) significantly more frequently than controls. Seventeen of 19 studied patients had mitochondrial respiratory dysfunction, including two patients with no mtDNA abnormality. In conclusion, the prevalence of primary LHON mutations may be less than generally recognized when patients are selected from a clinical setting rather than from multigenerational families. Nevertheless, patients with the LHON phenotype without primary LHON mutations have evidence of abnormalities involving mitochondrial DNA and respiration, implying that mitochondrial dysfunction plays a role whether or not the primary LHON mutations are present. Complete diagnostic evaluation of these patients could include sequencing the entire mitochondrial coding region and measuring mitochondrial respiratory function.

A Polymorphism Resource for Genetic Mapping in Zebrafish. *K. Bradley, B. Elmore, J. Breyer, B. Yaspan, J.R. Smith.* Vanderbilt University Medical Center, Departments of Medicine and Cancer Biology, 529 Light Hall, Nashville, TN.

Zebrafish (*Danio rerio*) is a powerful model organism for genetic investigation, enabling rapid mapping of traits in mutagenesis screens. We sought to improve genetic polymorphism maps in Zebrafish by large-scale investigation of sequence data in Sanger databases. Nearly all sequence is sampled from a German laboratory isolate that is not an inbred strain (Tuebingen). Those polymorphisms located within unique genomic sequence are potentially useful for genetic mapping. Roughly one third of the zebrafish assembly harbors non-unique sequence and was used to create a repeat database to enable masking of non-unique clone and shotgun sequence. We employed high-throughput BLAST to compare finished clone sequence to other clones and to shotgun reads to identify all mismatch positions in unique sequence as potential SNPs. We also identified polymorphic STRs on all finished clones. An algorithm assessing the number of instances of each allele allowed us to assign a confidence score for each candidate polymorphism. Empiric sampling of a separate Tuebingen laboratory population and inbred strains (SJA, SJB, and SJC) suggests that over 400K of 600K high confidence SNPs are polymorphic in zebrafish populations publicly distributed by ZIRC for use in the genetic mapping community.

Fast and reliable mutation screening using Conformation-Sensitive Capillary Electrophoresis. *E. Sistermans, K. van der Donk, E. Bosgoed, M. Ligtenberg, L. Hoefsloot, F. Hol, H. Scheffer.* Dept of Human Genetics, Radboud University Nijmegen Medical Centre, The Netherlands.

Day to day practice in Molecular Genetics Laboratories has seen many drastic changes over the last decade, one of them being the almost complete shift from linkage analysis to mutation analysis. This rapid evolution was made possible by radical improvements of the methods to find mutations either directly by sequencing or by a scanning method. Although large-scale mutation analysis by sequencing is now possible and very accurate, it still is relatively laborious and expensive. Current indirect scanning methods such as DGGE and dHPLC are reliable, but the throughput is limited. We have studied whether Conformation-Sensitive Capillary Electrophoresis (CSCE) using the new POP^{TM} Conformational Analysis Polymer (CAP, Applied Biosystems) might be a fast and reliable alternative for these methods. Using this polymer under semi-denaturing conditions on an automated sequencer (Applied Biosystems 3730) we validated 165 different mutations in 14 genes, including 74 mutations in *BRCA1*, 43 mutations in *CHD7* (CHARGE syndrome) and 9 mutations in the mitochondrial DNA. All mutations were correctly identified due to a shift in the peak pattern. For mitochondrial DNA, mutations present at 10% heteroplasmy could easily be identified. Several parameters were tested to further optimise the method, such as the withdrawal of Urea from the CAP polymer, the running temperature, the addition of GC-clamps, the influence of the length of the fragment and the use of common primers for labelling of the fragments. As CSCE allows the possibility of multiplexing, at least 4 fragments can be simultaneously analysed in each capillary in one sequencer run (2 hours, 50 cm capillary). For a 48 capillary sequencer this results in a throughput of approximately 2300 fragments within a twenty-four hours period. Since the data-analysis is also relatively straightforward, CSCE proves to be a fast and reliable method for routine mutation detection. Furthermore, as no optimization is needed, this technique can also be used for the rapid analysis of candidate genes.

Analysis of 1,924 disease genes for evaluating utility of functional sequence annotation for mutation screening. *T. Braun[1,2,5], B. O'Leary[5], S. Davis[5], M. Smith[5], H. Almabrazi[5], B. Brown[5], J. Ritchison[5], S. Shankar[2], T. Scheetz[1,2,4], V. Sheffield[3], E. Stone[2], T. Casavant[1,4,5].* 1) Dept Biomedical Engineering, Univ of Iowa, Iowa City, IA; 2) Dept Ophthalmology and Visual Sciences, Univ of Iowa, Iowa City, IA; 3) Dept of Pediatrics, Univ of Iowa, Iowa City, IA; 4) Center for Bioinformatics and Computational Biology, Univ of Iowa, Iowa City, IA; 5) Coordinated Laboratory for Computational Genomics, Univ of Iowa, Iowa City, IA.

The availability of the complete sequence of the human genome has dramatically impacted mutation screening and the search for phenotypically associated sequence variations. In fact, the actual screening of human populations and the subsequent interpretation of observed variations present a larger barrier than the discovery and characterization of candidate genes. We test the hypothesis that some segments of candidate genes are more likely than others to contain disease-causing variations and that these segments can be predicted bioinformatically. A bioinformatic technique (PAR - Prioritization of Annotated Regions) was developed to guide mutation screening based upon functional sequence annotation. In addition, the PAR technique has been optimized using a genetic algorithm and easily scales to additional sequence annotation. This technique was evaluated by using it to analyze 1,924 genes that collectively harbor 27,750 previously published mutations. Nearly 50% of the genes were recognized as disease-associated after screening less than 10% of the complete coding sequence of these genes. The PAR technique identified 90% of the genes as containing at least one mutation with less than 40% of the screening resources that traditional approaches would require. These results suggest that prioritization strategies such as PAR may accelerate disease gene identification through more efficient use of screening resources.

A newly developed multiplex SNP typing method, DigiTag assay. *N. Nishida[1,2], T. Tanabe[3], M. Takasu[1], Y. Kaneko[2], K. Tokunaga[1].* 1) Department of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Biomedical Business Incubation Division, Olympus Corporation, Tokyo, Japan; 3) R&D Division, NovusGene Inc., Tokyo, Japan.

Numerous single nucleotide polymorphisms (SNPs) are considered to be candidate susceptibility or resistance genetic factors for multifactorial diseases. Genome-wide search for disease susceptibility regions followed by high-resolution mapping of primary genes require high-throughput, cost-effective and highly reliable technology. At present, there are a variety of SNP genotyping applications, however, many applications need to select relevant SNPs for their assay by in silico assay design, and then a part of candidate SNPs will be excluded from investigation. To accomplish successful typing for all candidate SNPs at a low cost, new technologies must be developed. We developed a new multiplex SNP typing method, named DigiTag assay, and performed typing for 28 SNPs using 40 genomic DNA samples. One of 28 SNPs was revealed to be monomorphic in 40 samples and was therefore excluded from further analysis. This assay was found to be successful in SNP genotyping, giving a high success rate (24 of 27 SNPs) for randomly chosen SNPs. Three SNPs out of 27 SNPs showed indistinct clusters, presumably resulting from miss-ligation in the encoding step (SNP#6 and SNP#9) and insufficient amplification in the multiplex PCR (SNP#19). We demonstrated that mismatch induced 5'f-query probes, which had an artificial mismatch at the fourth position from the SNP base, can sufficiently suppress the false positive signals observed from SNP#6 and SNP#9 without decreasing the positive signals. This newly developed DigiTag assay has the potential to analyze almost all kind of the SNPs with high accuracy and reproducibility by applying mismatch induced 5'-query probes and re-designed primer pairs.

High frequency of WDR36 missense mutations in a group 301 glaucoma patients from Germany. *F. Pasutto[1], C.Y. Mardin[2], H. Sticht[3], K. Michels-Rautenstrauss[1], B. Rautenstrauss[1], F. Kruse[2], A. Reis[1].* 1) Inst. of Human Genetics, University of Erlangen-Nuremberg, Germany; 2) Dept. of Ophthalmology, University of Erlangen-Nuremberg; 3) Dept. of Bioinformatics, University of Erlangen-Nuremberg.

Mutations in WDR36, a novel gene involved in T-cell activation, on chromosome 5q22.1 (GLC1G) have recently been identified in adult-onset primary-open angle glaucoma (POAG) patients (Monemi, et al. 2005). In our ongoing study on the genetics of glaucoma we now investigated a cohort of 301 unrelated glaucoma patients of German origin for WDR36 mutations. 191 patients presented with POAG, 68 had normal tension glaucoma (NTG) and 42 juvenile-onset primary open-angle glaucoma (JOAG). We screened the entire coding sequence through direct sequencing in all 301 patients and identified a total of 37 different DNA variations. We verified all variants in a group of 96 healthy individuals of comparable age, who had repeated normal ophthalmologic examinations. We classified 10 variants, of which 6 are novel (P31T, D33E, Y97C, H212P, T403A, H411L), as disease causing based on evolutionary conservation of the respective residues in all orthologues and absence from healthy controls. Moreover protein structural analysis based on homology modelling showed that at least some of these WDR36 variations critically affect the stability of the three dimensional structure. These variations were found in 31 patients (10% of total) (23 POAG, 5 NTG, 3 JOAG). Two conserved variants that were previously reported as disease-causing (A449T, D658G) were also found in controls at a comparable frequency (around 1%) and thus most probably represent polymorphisms. Two further variants, previously reported as conferring disease susceptibility (L25P, A163V), were each found in 5 patients but not in controls, further substantiating that they confer risk. In summary, our findings provide further evidence that WDR36 plays an important role in the aetiology of glaucoma. WDR36 gene mutations are associated with adult onset of glaucoma both with high and low intraocular pressure and also with juvenile open angle glaucoma. Supported by DFG Collaborative Research Centre SFB539.

Molecular changes induced by chronic exposure to the antidepressant paroxetine in a neuronal cell culture system. *M.A. Kennedy[1], P.C. McHugh[1], D.M. Glubb[1], G.R. Rogers[1], P.R. Joyce[2].* 1) Dept Pathology, Christchurch School of Medicine & Health Sciences, University of Otago, Christchurch, New Zealand; 2) Dept of Psychological Medicine, Christchurch School of Medicine & Health Sciences, University of Otago, Christchurch, New Zealand.

Genetic variation may affect individual responses to antidepressant drug treatment. As a means of identifying genes that may be important in antidepressant response, we are exploring the molecular effects of antidepressants in the brain. For this purpose we established a mouse embryonic stem (ES) cell-derived neuronal culture model, and exposed it to the selective serotonin reuptake inhibitor paroxetine. Microarray and proteomic methods were applied to identify genes and proteins undergoing differential expression as a result of chronic (12 day) exposure to paroxetine. Several proteins and genes with synaptic or brain-specific functions were identified in this screen, and the observed expression changes are currently being validated by real-time quantitative PCR and immunoblotting analysis. Expression changes identified in this screening approach may be relevant to antidepressant function and individual drug responses or they may be unrelated bystander effects, and it is necessary to further evaluate the specificity and relevance of the observed expression changes. However, it is possible that a subset of the novel candidate genes and proteins identified here may contribute to the therapeutic effects of paroxetine or provide pharmacogenetic insights into treatment of depression and related illnesses.

Automation of microarray sample processing using magnetic bead-based SPRI technology. *B. Packard, H. Ebling, E. Gustafson, K. McKernan.* Research & Development, Agencourt Bioscience, Beverly, MA.

Microarray technology is a highly effective and versatile tool for the studying of gene expression, with a wide variety of applications in the pharmaceutical, academic, and clinical research fields. The current trend of microarray technology use is toward multi-sample processing using high, medium, and low-feature density microarray chips arranged in 96 well formats. Sample preparation and processing involves several steps: RNA isolation from various sources, cDNA synthesis, *in vitro* transcription, and generation of labeled probes. Reliable and efficient automation of these steps is required to take full advantage of high throughput array systems. Several column plate-based sample preparation systems are currently available, but are not easily integrated into automated platforms for multiple parallel sample processing. Agencourt Bioscience has developed a group of highly automation friendly magnetic bead reagents using patented SPRI (Solid Phase Reversible Immobilization) technology for the efficient isolation of RNA from cells and tissues, and, a single reagent for the clean up of both cDNA synthesis and in vitro transcription reactions. Agencourts SPRI process allows multiple samples to be easily processed in parallel and offers overall efficiency gains that result in lower total RNA input requirements as well as lower total sample processing costs. In addition, Agencourts magnetic bead sample preparation and processing reagents can be readily integrated into multiple automation platforms. We will present data illustrating an optimized, automated, microarray sample preparation workflow, which demonstrates the capacity of our SPRI magnetic reagents systems to produce high quality, highly reproducible microarray data.

Identification of NR1I2 genetic variation using resequencing. *C. King[1], M. Minton[1], J. Yu[1], M. Xiao[2], N. Addleman[2], D. Van Booven[1], P. Kwok[2], S. Marsh[1], H. McLeod[1].* 1) Department of Medicine, Washington University School of Medicine, Saint Louis, MO 63110; 2) Cardiovascular Research Institute, Department of Dermatology, University of California, San Francisco, CA, 94143.

Direct activation of NR1I2 occurs in response to a range of xenobiotics, which causes the formation of a heterodimer with RXR. This heterodimer binds to the nuclear receptor response elements and induces expression of genes involved in drug metabolism and transport, including CYP3A4 and ABCB1. This study determined the extent of NR1I2 variation through pooled resequencing in 3 world populations (African, Asian, and European). Of 36 polymorphisms identified, 24 were in the untranslated region, 8 were intronic, and 4 exonic. 36% were unique to the African population and 6% unique to the Asian population. None were specific to the European population. In comparison with previously published data and public database resources, we identified 17 novel polymorphisms. SNPs (NR1I2 -2098, -566, -205, IVS2+55, IVS2+78, IVS6-17, and +1792) were validated in an independent group of 95 African and 95 European subjects. Genotyping was performed using PCR and Pyrosequencing. There was a clear difference in variant allele frequencies between populations. Variant allele frequencies ranged from 0.16 to 0.40 in the European population, and 0.32 to 0.98 in the African population. Of 30 haplotypes, the most common was found at 39% in Europeans, while at 0.68% in Africans. The most common haplotype for Africans (23%) was absent in Europeans. In 52 colorectal caner patients, the NR1I2 genotypes were identical between colon tumor and adjacent normal tissue. Using the Kruskall-Wallis test the 5FR SNP, -566, was associated with CYP3A4 and ABCB1 RNA expression in colorectal tumor samples (p=0.04 in both cases). Polymorphisms in NR1I2 may, in part, explain the considerable inter-individual heterogeneity in ABCB1 and CYP3A4 expression. However, consideration of population differences in allele frequencies should be taken into account when incorporating NR1I2 into pharmacogenetic studies.

Organization of satellite I and satellite III sequences on human chromosome 21. *R. Hettinger[1], J. Bavarian[1], P. Patel[1], T. George[1], M. Puckelwartz[1], S. McCutcheon[2], M. Cummings[2], J. Doering[1].* 1) Loyola Univ Chicago; 2) Univ Illinois, Chicago.

The human genome sequence does not include the heterochromatic regions, although these sequences comprise 10-15% of the genome. We are constructing a detailed physical map of the HC21 centromere and short arm as a model for the organization of these regions. Our work previously identified two subfamilies of satellite I (sat I) on HC21 which share 80% sequence identity. The N6 subfamily is located solely on the p arm distal to the rDNA cluster, while pTRI-6 sequences are present both in the p arm proximal to the rDNA and in the centromere. The HC21 centromeric sat I cluster has been physically mapped, and portions of it have been sequenced. It is 0.3 Mb long and located within 0.1Mb of the p arm end of the major alphoid cluster, D21Z1. Internally, the sat I cluster consists of tandemly repeated pTRI-6 sequences frequently interrupted by other sat I sequences that have only 80% identity to pTRI-6. These newly-identified sat I sequences are quite distinct from the N6 subfamily or any other sat I sequences in the database, indicating they represent a new subfamily. This centromeric sat I cluster is not found on other chromosomes, and its size and internal organization are polymorphic in the population. It is thus a strong candidate for an HC21-specific centromeric marker. Satellite III (sat III) sequences are found on the p arm of HC21 both proximal and distal to the rDNA. We have isolated three new sat III sequences (2.5-4.4 kb in length) from a HC21 specific library, and through the use of an HC21 hybrid cell mapping panel, find them to be located proximal to the rDNA. Sequencing reveals that all three are members of sat III subfamily I, which is characterized by high percentages of the typical GGAAT monomer repeat and very low levels of the GGAGT variant repeat. The sequences have highly heterogeneous organizations with no obvious higher order repeats. BLAST comparisons showed that the three new sat III sequences have less than 80% identity to each other or with any other currently known sat III sequence in the human genome. Thus, they are candidates for HC21p-specific probes.

Characterization of the chAB4 duplicon on proximal 21p. *E. Miller[1], N. Alvi[1], K. Arendes[1], L. Chen[1], R. Ganith[1], M. Cummings[2], J. Doering[1].* 1) Loyola Univ Chicago; 2) Univ Illinois, Chicago.

While 10-15% of the human genome is composed of heterochromatic DNAs, these regions are not included in the completed sequence. We are creating a detailed physical map of the centromere and p arm of HC21 as a model for the organization of such regions. Our previous work identified a number of low copy number (LCNR) sequences in the centromere of HCY and on the proximal short arm of HC21p. These sequences have a very similar linear order on both HC21 and HCY, except that the order on HC21 is inverted relative to that on HCY. We have now sequenced 9 of these LCNRs ranging in size from 663bp to 4,856bp. BLAST analysis indicates that at least 5 of these LCNRs are part of the larger chAB4 duplicon. The chAB4 duplicon is ~86kb in length and is composed of a chAB4 DNA segment adjacent to a 48bp satellite array of variable length, followed by an NF1-related pseudogene. While others work suggested that chAB4 has a palindromic organization, sequence analysis of a number of loci containing the chAB4 duplicon and adjacent LCNRs shows no evidence that it is part of a palindrome on HC21 or HCY. This data clarifies the organization in a previously uncharacterized region of the centromere on HCY. On HC21 a full copy of the chAB4 duplicon and adjacent LCNRs is found on the proximal p arm in the 21-II region. The 21-II region is composed of monomeric alphoid, LINEs, and other satellite DNAs. Using BLAST, we identified BACs containing chAB4 duplicon sequences that had not been placed in the genome map. By comparing these BAC sequences, copies of chAB4 on HC21, Y, 17, and 22 showed at least 90% similarity. This work indicates that chAB4 may actually be part of a larger duplicon ~200kb in size. Heterogeneity in the duplicon structure is indicated by a ~25kb insertion into the sequence on HCY and HC17. BACs containing chAB4 and adjacent LCNRs located in the proximal p arm of HC21, as well as BACs found at the distal end of the D21Z1 region containing monomeric alphoid DNA and satellite III, will allow closing the gap between the two regions. This will create a contiguous map of ~5Mb that links the 21-II and D21Z1 regions, joining the p arm to the q arm.

Detecting Polymorphisms in Drug Metabolism Genes Uncovers More than Genotypes. *W. Tom, S. Liew, T. Harkins, D. Ingber, C. Chiang, Z. Gu, S. Cai, R. Charlab, Y. Wang, K. Lazaruk.* ART, Applied Biosystems, Inc, Foster City, CA.

Polymorphisms within the drug metabolism pathways have been difficult to study due to the complexity of genetic information associated with these genes. Many of the genes within these pathways are part of large gene families that include several pseudogenes, thus generating large homology barriers that are difficult for most technologies to overcome. Additionally, many of the polymorphisms are identified in public SNP databases that do not use common genomic identifiers that allow researchers to readily understand which polymorphisms they are dealing with. To overcome these barriers, Applied Biosystems has developed an extensive collection of TaqMan Genotyping Assays to detect SNPs, multiple nucleotide polymorphisms (MNPs), and insertion/deletions (in/dels) within 220 drug metabolism genes. The polymorphisms identified for this collection are within regulatory elements, coding regions, or splice junctions. Each assay was wet-lab tested on 180 DNA samples from 4 human populations, (Caucasian, African American, Chinese and Japanese) to estimate the minor allele frequency in each of these populations and all assays were checked for Hardy-Weinberg Equilibrium. During the performance testing of the assays, many of the genes in this collection were identified as having unique characteristics, for example, gene deletions or amplifications (GSTM1 and CYP2D6) that can affect the interpretation of results from SNP genotyping assays. It is important to understand the underlying biology of particular genes when interpreting results from genotyping experiments, and when evaluating how well a particular genotyping technology performs.

Sequence context analysis of single nucleotide polymorphisms (SNPs) in human CpG islands. *Z. Zhao*[1, 2]. 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, VA.

A detailed examination of the non-random sequence context where the genetic polymorphism occurs is important for understanding the mechanism of mutation, protein-DNA interaction and genome sequence evolution. CpG islands are commonly found in the promoter regions of the genes in vertebrate genomes and involve in the regulation of gene expression and cell differentiation by methylation mechanism. In this study, we first searched for CpG islands in the human genome using the CpG island searcher program (CpGi130) and then categorized SNPs (dbSNP build 123) in the CpG islands by matching the position of a SNP with the location of a CpG island in a contig sequence. We identified 34,928 putative CpG islands in the human genome and located 133,591 SNPs within these islands. The proportion of nucleotides, CpG dinucleotides and CpG SNPs in the CpG islands on each chromosome correlated with the GC content of the chromosome. In the CpG islands, the frequency of CpG dinucleotides at the polymorphic sites was nearly the same as that in the CpG island sequences, although this was 6.09 times that in the human genome sequences. Moreover, CpG SNPs were 3.92-fold less prevalent relative to the presence of CpG dinucleotides in the CpG islands. Finally, an analysis of SNPs in the mouse CpG islands revealed the similar patterns, though the degree was somewhat different between the two species. These results provide strong evidence for the suppression of the nucleotide changes at CpG dinucleotides in the CpG islands and the hypermutability of methylated CpG dinucleotides in the non-CpG island sequences in the human and mouse genomes.

Identification of SNPs with metabolic impact. *N.J. Marini[1], J.S. Ziegle[2], K.L. Hunkapiller[2], D.G. Ginzinger[2], P.D. Thomas[2], D.A. Gilbert[2], J. Rine[1].* 1) Molecular and Cellular Biology, Univ. of California, Berkeley, CA; 2) Applied Biosystems, Inc., Foster City, CA.

Compelling data from human and bacterial genetics show that the phenotype of some mutations in vitamin-dependent enzymes can be suppressed by vitamin supplementation. Such vitamin-remedial mutations can affect the binding site for the vitamin cofactor, or can destabilize the protein in a way that higher vitamin concentration can remedy. The few known cases from human genetics are rare and typically result in severe disease that is vitamin remedial. To test the hypothesis that there may be polymorphisms that more subtly affect enzyme activity, yet are vitamin-augmentable by the same principles, we have begun a re-sequencing study on 4 prototypical genes in a large (564 individual), ethnically diverse population. All missense variations from Ornithine Aminotransferase (OAT), Thymidylate Synthase (TYMS), Methylenetetrahydrofolate Reductase (MTHFR) and Glycinamide Ribonucleotide Transformylase (GART) are being evaluated in functional assays based on complementation in the yeast, Saccharomyces cerevisiae. Thus far, we have completed sequence analysis for 14 of 33 total coding exons (comprising parts of each of the four genes). We have identified 12 novel low frequency coding variants (allelic frequencies <.003) with at least one variant seen in each of the four genes. The sum total of such alleles potentially indicates a significant contribution to functional variation in the population. The current status of variants identified and functional assessment will be presented as well as the implications for the broader genomic set of vitamin-dependent enzymes.

TaqMan based SNP genotyping using whole genome amplified products from FTA blood samples. *G. Sun, R. Kaushal, P. Pal, H. Cheng, Y. Shen, J. Mallik, R. Deka.* Center for Genome Information, Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

FTA cards provide a convenient medium for collection, storage and shipment of blood samples for DNA analysis. However, the amount of extractable genomic DNA is limited for use in large-scale typing of genetic markers. Whole genome amplification (WGA) has emerged as a fundamental method for reproducing abundant quantities of DNA. Two of the widely used WGA methods include improved-primer extension preamplification (I-PEP) and multiple displacement amplification (MDA). We have evaluated the relative efficiencies of these two methods in amplifying DNA obtained from blood spots collected on FTA cards for high-throughput single nucleotide polymorphism (SNP) analysis. We used the TaqMan assay to type 27 SNPs using genomic DNA extracted from 30 FTA cards and their corresponding I-PEP and MDA products. Using the I-PEP protocol, we obtained high fidelity of amplification and allelic discrimination in 23 of the 27 markers (85%), whereas only 8 of the 27 markers (30%) could be comparably scored using MDA products. Compared to FTA genomic DNA, MDA products showed 7 mismatches out of 240 genotypes (2.9%) while I-PEP showed only 1 mismatch in a total of 690 genotypes (0.14%). We computed the sensitivity and specificity rates for both protocols by fixing the Quality-value at 90% in the SDS software of the 7900HT machine. The sensitivity rate for I-PEP was 82.7% compared with 28.8% for MDA. The specificity rates for I-PEP and MDA were 96.4% and 79.4%, respectively. Our results demonstrate relative advantage of the I-PEP protocol in the analysis of SNP markers from FTA blood spots. WGA products obtained from a single punch of the FTA card (1.2 mm, approximately 0.5~1 ml of blood) could be sufficient for ~750 PCR reactions.

Automated Preparation and Analysis of Multiplex Mutation and SNP panels. *N. Udar, J. Mariana, J. Parker, D. Clark, L. Pajak, T. Reyes, S. Boyer.* Beckman Coulter Inc., Fullerton, CA.

Genotyping using Single Nucleotide Polymorphisms (SNPs) has become common in areas such as linkage/association studies, pharmacogenetics, forensics, etc. Single Base Extension (SBE), the gold standard technology for SNP genotyping, provides a robust solution in a multiplexed format. Although high throughput SNP detection platforms are available, there is significant demand for medium throughput capabilities, especially on a time tested mainstream capillary electrophoresis platform. We have used SBE technology to extend an unlabeled primer with a labeled terminator to detect base changes in the DNA. Single nucleotide changes, deletions and insertions can be scored by this technique using a single primer extension reagent mixture. An important consideration is that there are no additional secondary steps like ligation or enzymatic cleavage after the extension step. The products are treated with SAP and loaded on a capillary electrophoresis system for detection. We demonstrate multiplex capability using SNP panels of at least 10 SNPs. A multiplex cystic fibrosis (CF) mutation panel was also tested using patient samples. The CF panel of mutations among others includes deltaF508, G85E, N1303K, R117H, 3659delC. Signal balance between the two heterozygous alleles is crucial for accurate detection. We measured this signal balance for each of the two alleles of the 6 possible heterozygote combinations and found an average signal ratio of 1:1.6. The allele calling accuracy for a 10-plex reaction is 99%. An automated DNA extraction step on a robotic platform was then integrated to increase process performance, reduce possible sampling errors and hands on time per sample. Tests were also carried out to determine capillary array life and our results demonstrate that the capillary life can significantly be extended due to the reduced time in the run method. Comparisons were done using different sources of DNA including DNA extracted from cell lines and those prepared from whole genome amplification. Our results demonstrate an efficient process of producing more than 960 SNP/mutation screens per plate on a 8-capillary electrophoresis platform.

Identification of transcription factor bindings sites at base pair resolution by chromatin immunoprecipitation and genomic microarrays. *C. Wadelius[1], A. Rada-Iglesias[1], O. Wallerman[1], C. Koch[2], A. Ameur[3], S. Enroth[3], G. Cleland[2], S. Wilcox[2], O. Dovey[2], P. Ellis[2], V. Wraight[2], K. James[2], R. Andrews[2], C. Langford[2], P. Dhami[2], N. Carter[2], D. Vetrie[2], J. Komorowski[3], I. Dunham[2].* 1) Dept Gen/Pathology/Rudbeck Lab, Uppsala Univ, Uppsala, Sweden; 2) Sanger Institute, Cambridge, UK; 3) Linnaeus Centre for Bioinformatics, Uppsala, Sweden.

Introduction: In a genomic perspective very little is known of how gene activity is regulated. One objective for the ENCODE project is to evaluate methods to characterise gene regulatory networks in 1% or 30 Mb of the human genome. Methods: Antisera against HNF3b, HNF4a, USF1 and acetylated histone H3 were used in chromatin immunoprecipitation to enrich DNA interacting with each protein in the liver cell line HepG2. Precipitated DNA and reference DNA were differentially labelled and hybridised to a high resolution tiling path genomic array of ~19500 PCR fragments covering 75% of the ENCODE region and positive spots were identified. Results: HNF3b and HNF4a are frequent regulators of gene activity in HepG2 cells, with 154 and 194 binding sites respectively. USF1 is more specialised with 31 binding sites. Many sites are in 5 ends of genes but presumed regulatory sequences are frequently also found in intronic and intergenic regions. Acetylated histones are mostly found at 5 ends of genes. Bioinformatic analysis of the sequences bound by each TF shows an overrepresentation of motifs highly similar to the in vitro established consensus sequences. Based on these data we have identified tentative binding sites at bp resolution. Some of these sites have previously been found by in vitro analysis and others were verified in vitro in this study. It is likely that positive signals are generated in every ChIP-chip study as a consequence of indirect DNA-protein interaction but by this strategy it is possible to identify some of them. Conclusion: It is possible to identify at least some TF binding sites at bp resolution in a genomic ChIP-chip analysis and to distinguish between direct and indirect DNA-protein interaction. This strategy can be used for many other transcription factors and may be scaled up to still larger parts of the genome.

Comparative genomic analysis identifies endothelial cell-specific gene conserved noncoding sequences (EC-CNSs) that are DNase hypersensitive. *J.A. Bernat[1], A.S. Kondrashov[2], G.E. Crawford[3], F.S. Collins[3], D. Ginsburg[1,4,5].* 1) Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI; 2) NCBI, NIH, Bethesda, MD; 3) NHGRI, NIH, Bethesda, MD; 4) Dept. of Internal Medicine, Univ. of Michigan, Ann Arbor, MI; 5) HHMI, Univ. of Michigan, Ann Arbor, MI.

Von Willebrand factor (VWF), a key blood clotting protein, is a standard histologic marker for endothelial cells. Previous studies examining the proximal promoter region have failed to fully recapitulate the endogenous pan-endothelial VWF expression pattern. To identify potential novel *VWF* distal regulatory elements, as well as a more general endothelial-specific expression program, we aligned human and mouse orthologous genomic sequences from *VWF* and 27 other endothelial-specific genes, extending from the neighboring 5-upstream gene to the end of intron 1 (excluding the core promoter and exon 1). We analyzed the resulting 262 EC-CNSs by quantitative PCR for hypersensitivity to DNase I digestion. 33% of the EC-CNSs (including 6 of 9 upstream of *VWF*) were hypersensitive (HS) in human umbilical vein endothelial cells (HUVECs), while only 16% were HS in control human fibroblast cells. 20% of the EC-CNSs were HS in HUVECs only, suggesting that they may identify novel endothelial-specific transcriptional elements. When the 262 EC-CNSs were compared to CNSs from non-endothelial genes, a single motif, AGGAAR, was identified as overrepresented in EC-CNSs. This association was replicated in an independent set of 28 additional genes with high HUVEC expression. The motif was also overrepresented in the subset of DNase HS EC-CNSs. The AGGAAR motif includes the core binding sequence (GGAW) of the Ets family of transcription factors, which contains several members implicated in tissue-specific gene expression. These results suggest that the AGGAAR motif may represent the target sequence for a specific Ets family member critical for determining the endothelial-specific gene expression program. We are currently testing this hypothesis by analyzing this motif in *Vwf* BAC transgenic mice containing 177kb of upstream sequence, including all nine identified EC-CNSs.

Quantitative gene expression profiling of multiple toxicity mechanisms in chemically-treated, liver-derived rat cells using a toxicity panel of 25 genes. *J. Luo[1], H. Chi[1], G. Jackson[1], S. Joo[1], K. Oades[2], P. Pezzoli[2], G. Vansant[2], S. Boyer[1].* 1) Beckman Coulter Inc; 2) Althea Technologies Inc.

Gene expression profiling analysis is becoming one of the most frequently used tools for functional genomics. Here, we describe an optimized gene expression profiling system that utilizes a patented amplification strategy with both gene-specific and universal primers designed by a proprietary multiplex primer design algorithm. After multiplex reverse transcription and a few initial PCR cycles, the universal primers, one of which is labeled with a fluorescent dye, amplify multiple target fragments simultaneously and uniformly. Therefore, gene transcript ratios in RNA samples are maintained during the multiplexed RT-PCR amplification process. The multiplex primers are optimized to generate amplified, dye-labeled fragments that are well separated eletrophoretically in a size range of 100-400 nucleotides for unambiguous gene identification. The amplification products are well balanced within a linear detection range of the CE system for precise signal quantification. Reference genes are included to allow peak signal normalization for relative quantitative analysis. With this design interface, a rat toxicity panel, called Rat MultitoxPlex, was developed targeting 25 genes, most of which are involved in different toxicity pathway elements. The quantitative assay compares variation in cellular transcription profiles, as end-points of different toxicity mechanisms or pathways. RNA samples of 20-25 nanograms from compound-treated and un-treated rat hepatocytes were amplified using MultitoxPlex reagents. Amplified, dye-labeled fragments were separated by CE. Gene-specific peaks were identified, quantitated, normalized, and gene expression profiles created and visualized using our proprietary software. The results illustrate the ability of the MultitoxPlex to accurately capture the gene expression changes caused by compound treatment, lending insight to their impact on specific mechanistic toxicities in cells. We find this approach to be a cost-effective, automated alternative for acquiring sensitive and accurate information of quantitative gene expression profiles.

Automated verification of predicted tissue and tumor specific splice isoforms by Microfluidic separations of RT-PCR products. *M. Greiner[1], R. Salowsky[1], D. Zink[2], S. Haas[2], B. Korn[2].* 1) Agilent Technologies, Waldbronn, Germany; 2) RZPD Ressourcenzentrum für Genomforschung, Heidelberg, Germany.

Alternative splicing of transcripts may lead to different mRNA species and therefore to potentially different proteins. Any failure or error in the splicing control mechanism can be involved in a number of pathological processes, such as cancer. Therefore, splice isoforms that are disease specific could serve as excellent diagnostic markers, which are easily identifiable by PCR. Computational prediction of alternative splice variants has been highly facilitating the identification of novel splice isoforms. Our prediction strategy is based on the genomic mapping (SpliceNest) of EST consensus sequences and library annotation provided in the GeneNest database. This revealed 427 genes with at least one tissue specific transcript as well as 1120 genes showing tumor specific isoforms. Out of these genes, a subset of predicted isoforms were experimentally verified by an RT-PCR screening approach. We have set up an experimental strategy that allows us to screen expression of genes in up to 112 different human tissues of multiple developmental stages and cell lines. To circumvent the bottleneck of DNA separation using slab gel analysis, an automated on-chip electrophoresis system that allows unattended high throughput analysis of DNA fragments was implemented in the workflow. In our experimental set-up, we analyzed RT-PCR samples on 4 x 96 well plates within a defined sequence of consecutive one-on-one measurements. The high throughput experimental verification of computationally predicted tissue specific isoforms revealed a high success rate in confirming their expression in the respective tissue.The combination of computational prediction of alternative splicing events with high throughput microfluidic verification facilitates the efficient detection of tissue and tumor specific transcripts.

HOXA13 In Vivo Regulatory Binding Sites. *C.D. McCabe[1], J.W. Innis[1,2].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Pediatrics, University of Michigan, Ann Arbor, MI.

Few authentic, regulatory binding sequences in mammalian genomic DNA are known for the 39 mammalian HOX transcription factors. To further our understanding of gene regulation by HOX proteins we sought to identify HOXA13 DNA binding sites in vivo using chromatin immunoprecipitation (ChIP) in a 3T3-derived cell line that stably expresses nuclearly-localized, FLAG-tagged HOXA13. We have published that numerous endogenous genes are reproducibly up- or down-regulated in these cells. Using anti-FLAG ChIP we isolated and sequenced 85 randomly chosen genomic ChIP clones and prioritized 21 for reproducibility testing in five subsequent independent ChIP experiments. 33% of the tested fragments were enriched in 5 experimental replicates. One of these fragments is located within intron 2 of Enpp2. ENPP2, also known as autotaxin, is known to modulate tumor and normal cell motility and expression is highly upregulated by HOXA13 in these cells. Reporter gene expression constructs were minimally enhanced in cotransfections with HOXA13 by including this fragment, suggesting that alone this HOXA13-ChIP fragment is insufficient to promote the high level of Enpp2 expression induced in these cells. Taking a candidate approach, three out of four additional candidate HOX binding sites within the Enpp2 promoter region were highly enriched in ChIP. A deletion/point mutation set of Enpp2 promoter fragments is being tested for response to HOXA13 co-transfection. Our studies have discovered novel, genomic binding sites for HOXA13 through a non-candidate approach and for one target gene show a direct correlation between induced expression of Enpp2 and association with the promoter and gene chromatin by HOXA13.

L1 Integration in a Transgenic Mouse Model. *D.V. Babushok[1], E.M. Ostertag[1,2], C.E. Courtney[1], H.H. Kazazian, Jr[1].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA.

In the race against mutational inactivation, choosing an integration site that permits transcription, yet is dispensable for the hosts survival, is key to a retrotransposons evolutionary success. To study integration preferences of the human LINE-1 retrotransposon (L1), we developed a transgenic mouse model of L1 retrotransposition that displays both germline and somatic *de novo* L1 insertions at a high frequency. We mapped 3 integration sites of 51 *de novo* L1 insertions by Thermal Asymmetric Interlaced PCR (TAIL-PCR). Analysis of integration locations with respect to genomic landmarks revealed a generally broad distribution with a modest preference for intergenic regions. We characterized the complete structures of 33 of these *de novo* retrotransposition events. Our results highlight the tremendous number of highly truncated L1s, with over 52% (27/51) of total integrants less than 1/3 the length of a full-length element. New integrants carry structural characteristics typical of natural genomic L1 elements, with a number having inversions, deletions, and 5-end microhomologies to the target DNA sequence. Notably, at least 13% (7/51) of all insertions contain a short stretch of extra nucleotides at their 5 end, including various regions of identity to sequences surrounding the insertion target site. Similar 5 extra nucleotides have been described previously for LINE-like elements. We propose that most of these unexplained nucleotide additions in the context of 5-truncated L1s can be accounted for by a combination of 1) template-jumping of the L1-encoded reverse transcriptase onto the cleaved host DNA 5 to the elements integration site, 2) very short inversions, and 3) reverse-transcriptase mediated insertion of a few untemplated nucleotides. These data represent the first characterization of a large number of *de novo* L1 integrants *in vivo*.

Rho GTPases Expression in embryonic rat cortical neurons induced by phenylalanine. *X. Gu, Y. Zhang.* Shanghai Inst Pediatric Res, Xin Hua Hosp, Shanghai, Shanghai, China.

Phenylketonuria is characterized by elevated blood phenylalanine levels and mental retardation. Rho GTPases are key signaling proteins that regulating neurite growth and synaptic connectivity. To understand the mechanisms of phenylalanine neurotoxicity, the role of Rho GTPases in neuronal injury induced by phenylalanine has been examined. After 2 days and 4 days exposure to phenylalanine (0.9mM), cultured embryonic cerebral cortical neurons were fixed and double-immunostained with a polyclonal antibody against MAP2 and a monoclonal antibody against Tau-1. The results demonstrated that phenylalanine reduced primary dendrite and its branch number and spine density in cultured neurons induced by phenylalanine. Real time PCR and Western blot analysis were used to evaluate the Rho GTPases (Rac1, Cdc42, RhoA) mRNA and protein expression. We discovered that phenylalanine downregulated Rac1, Cdc42, RhoA mRNA and protein expression. Active Rho GTPases were pulled down by GST¨CPBD or GST¨CRBD. Western blot showed that phenylalanine decreased Cdc42/Rac activity with time dependent, but increased RhoA activity. These results may provide important insights into the molecular mechanism underlying abnormality of dendrite and dendrite spine induced by phenylalanine, and probably is one of complicated mechanism of neuronal injury induced by phenylalanine.

Intraallelic variability in the R408W phenylketonuria mutant lineages in Europe. *D. Croke[1], O. Tighe[1,2], G. Bertorelle[3], C. O'Neill[2], E. Naughten[2], P. Mayne[1,2].* 1) Dept Biochemistry, Royal Col Surgeons, Dublin, Ireland; 2) Department of Pathology, The Children's University Hospital, Dublin, Ireland; 3) Dipartimento di Biologia, Universita di Ferrara, Ferrara, Italy.

The common Phenylketonuria mutation in Europe, R408W, is observed on chromosomes of two distinct haplotypes as the result of recurrent mutation: the two lineages are referred to as R408W-2.3 and R408W-1.8. Spatial autocorrelation analysis of their frequency distributions suggests that R408W-2.3 was dispersed across central and eastern Europe by human migration while R408W-1.8 arose in Ireland with limited subsequent spread [O Donnell et al., Eur. J. Hum. Genet. 2002, 10: 530-538; Tighe et al., Hum. Mutat. 2003, 21: 387-393]. This study aimed to investigate the two R408W lineages further to assess allele ages and the effect that selection may have played in their population history. Three novel dinucleotide Short Tandem Repeat (STR) markers within and flanking the human Phenylalanine Hydroxylase (PAH) locus were identified by in silico methods. These markers were typed by standard PCR-based methods in a set of anonymised patient and control DNA samples (n=182) from fifteen European populations genotyped previously for the markers used traditionally to determine PAH haplotypes [7 SNPs, 1 VNTR and 1 tetranucleotide STR]. This sample set included individuals of wild-type (n=49), R408W homozygote (n=75), compound heterozygote including R408W (n=16) and R408W heterozygote (n=8) genotypes. Haplotypes were reconstructed using the PHASE v2.02 software. Phylogenetic analysis based upon STR haplotypes produced unrooted star-like networks demonstrating comparable levels of diversity for the R408W-2.3 and R408W-1.8 lineages. Both networks were centered on a major haplotype [61% of R408W-1.8 alleles; 49% of R408W-2.3 alleles] and contained a total of 17 mutational steps. Estimates of allele age based upon intra-allelic variation generated values of 4,850 - 37,975 yBP for R408W-1.8 and 7,700 - 44,050 yBP for the R408W-2.3 mutation. Neutrality tests suggested that the two R408W lineages increased in frequency over time due to population expansion rather than heterozygote advantage.

Moyamoya syndrome in a patient with concomitant mitochondrial and fatty acid oxidation disorders. *N. Longo[1], I. Schrijver[2], H. Vogel[2], L.M. Pique[2], T.M. Cowan[2], M. Pasquali[1], G.L. Hedlund[1], S.E. Ernst[1], R.C. Gallagher[2], G.M. Enns[2].* 1) Univ Utah, Salt Lake City, UT; 2) Stanford Univ, Stanford, CA.

MELAS (mitochondrial encephalopathy with lactic acidosis and stroke-like episodes) is a maternally inherited disorder characterized by recurrent cerebral infarctions that do not conform to discreet vascular territories. Here we report a patient who presented at 7 years of age with loss of consciousness and severe metabolic acidosis following vomiting and dehydration. She developed progressive sensorineural hearing loss, myopathy, ptosis, short stature, and mild developmental delays after normal early development. Biochemical testing identified metabolites characteristic of Medium Chain Acyl CoA Dehydrogenase (MCAD) deficiency (hexanoylglycine and suberylglycine), but also severe lactic acidemia (10-25 mM) and, in urine, excess of lactic acid, intermediates of the citric cycle, and marked ketonuria, suggesting mitochondrial dysfunction. She progressed rapidly to develop temporary cortical blindness. Brain imaging indicated generalized atrophy, more marked in the left side, in addition to white matter alterations consistent with a mitochondrial disorder. Magnetic resonance angiography indicated occlusion of the left cerebral artery with development of collateral circulation (Moyamoya syndrome). This process aggravated over time to involve the other side of the brain. A muscle biopsy indicated the presence of numerous ragged red fibers. Molecular testing confirmed compound heterozygosity for the common mutation in the MCAD gene (985A>G) and a second pathogenic mutation (233T>C). mtDNA testing indicated that the muscle was almost homoplasmic for the 3243A>T mutation in $tRNA^{Leu}$, with a lower mutant load (about 50% heteroplasmy) in blood. 3243A>T $tRNA^{Leu}$ has been previously associated with MELAS and severe encephalopathy. These results indicate that mitochondrial disorders may be associated with severe vascular disease resulting in Moyamoya syndrome, and angiography may be indicated in MELAS since Moyamoya syndrome may be improved with surgery. The contribution of the concomitant MCAD deficiency to the development of the phenotype in this case is unclear.

A 32 y/o male with MMA, progressive dystonic spastic diplegia, cystic encephalomalacia of the globus pallidum and Wallerian degeneration. *D. Adams[1], J. Sloan[1], U. Sundaram[4], E. Baker[3], A. Gropman[2,5], C. Venditti[1].* 1) NHGRI, NIH, Bethesda, MD; 2) Center for Functional and Molecular Imaging, Georgetown U., Washington, D.C; 3) CC/DRD, NIH, Bethesda, MD; 4) Virginia Commonwealth U., MCV, Richmond,VA; 5) NINDS, NIH, Bethesda MD.

We present a 32 y/o male with B12-responsive methylmalonic aciduria (MMA) and progressive dystonic spastic diplegia. He was in good health and developing appropriately until 13 months of age when he suffered a catastrophic neurological crisis with encephalopathy leading to coma. He was afterward diagnosed with MMA and began oral cyanocobalamin. Due to presumed static encephalopathy and spastic diplegia, he carried a diagnosis of cerebral palsy for two decades. He was ambulatory, ran, and participated in the Special Olympics. Over the past 10 years, he experienced increasing difficulty with ambulation and worsening spasticity, necessitating use of a walker. Brain MRI performed at 3T on a GE magnet disclosed focal increased T2 signal in the globus pallidum adjacent to the posterior limb of the internal capsule, and cystic encephalomalacia of the remainder of the nucleus. There was also suggestion of Wallerian degeneration. MRS of gray, white, and CSF territories performed at long and short TE did not demonstrate lactate elevation. Initial labs showed a serum B12 level of 5507 pg/ml, a homocysteine level of 8 umol/L, and a urine MMA excretion 694.7 mg/24 hrs. Approximately 24 hours after a single intramuscular dose of hydroxycobalamin (1 mg), the urine B12 excretion dropped to 275.6 mg/24 hrs. In summary, important features in this case are functional motor decline, despite the apparent lack of metabolic crises, and metabolic stability with oral cyanocobalamin therapy alone. The MRI findings provide an illustration of the pathological evolution of a remote metabolic infarction of the globus pallidus culminating in cystic replacement. The Wallerian degeneration of the corticospinal tract suggested by neuroimaging may partially explain the progressive nature of motor symptoms seen in a subset of patients with MMA s/p metabolic stroke. Additional neuroimaging is planned to better understand this patients pathophysiology.

Intracellular galactose-1-phosphate accumulation leads to environmental stress response in yeast. *K. Lai[1], M. Tang[2], T. Slepak[1].* 1) The Dr. John T. Macdonald Foundation Center for Medical Genetics, Dept Pediatrics, University of Miami SOM, Miami, FL; 2) Dept Biochemistry and Molecular Biology, University of Miami SOM, Miami, FL.

Inherited deficit of galactose-1-phosphate uridyltransferase (GALT) can lead to the potentially lethal disorder Classic Galactosemia. Although the biochemical defects associated with GALT deficiency have been described in detail in patients and various model organisms, few attempts have been made to characterize the pathogenic mechanisms of Classic Galactosemia at the molecular level. Here we report the use of high-throughput DNA microarrays to examine how galactose affects gene expression in isogenic yeast strains that are deficient in either galactokinase (GALK) or galactose-1-phosphate uridyltransferase (GALT), two enzymes which are essential for normal galactose metabolism. We confirmed that the growth of our GALT-deficient, but not GALK-deficient yeast strain ceased 4 hours after challenge with 0.2 percent galactose. Such inhibition was not associated with a reduction of ATP content, and was reversible after removal of galactose from medium. We compared the gene expression profiles of the GALT-deficient and GALK-deficient cells in the presence/absence of galactose. We revealed that in the absence of galactose challenge, a subset of genes involved in RNA metabolism was expressed at a level 3-fold lower in the GALT-deficient cells. Upon galactose challenge, significantly more genes involved in various aspects of RNA metabolism and almost all ribosomal protein (RP) genes were down-regulated in the GALT-deficient, but not GALK-deficient cells. Remarkably, genes involved in inositol biosynthesis and turnover were exclusively induced at high level in the galactose-intoxicated, GALT-deficient cells. Our data thus suggested that RNA metabolism, ribosome biogenesis and inositol metabolism were likely targets for galactose-1-phosphate, a toxic intermediate that is uniquely accumulated under GALT-deficiency.

Classic Galactosemia: A Paradigm for Endoplasmic Reticulum Stress Response. *T. Slepak, K. Lai.* The Dr. John T. Macdonald Foundation Ctr. for Med. Genetics, Ped. Dept., U of Miami, Miami, FL.

In humans, deficiency of galactose-1-phosphate uridyltransferase (GALT) can lead to the potentially lethal disorder Classic Galactosemia. Although the biochemical abnormalities associated with this disease are well-characterized, few attempts have been made to delineate the pathogenic mechanisms of the disorder at the molecular level. Here we report the use of high-throughput DNA microarrays to examine how galactose challenge affects global gene expression in primary fibroblasts derived from 3 un-related galactosemic patients. To control for genetic variation among individuals, we compared the gene expression profiles of the 3 patient cell lines infected with a lentiviral vector expressing the GALT gene (*tests*) with the corresponding patient cell lines infected with a lentiviral vector expressing the green fluorescent protein (GFP) (*controls*). Consequently, 3 pair-wise comparisons were resulted from the 3 patient lines that had been challenged with 0.1%; galactose for 48 hours. We focused on the genes whose expression level was changed over 2-fold in a similar manner in all three comparisons. In the controls, we detected an 11-fold increase in the expression level of the BiP gene, which encodes the major ER stress sensor protein. Expression of genes that encoded numerous ER-resident molecular chaperones, foldases, proteases and lectins were also up-regulated at a level of 3-fold or higher in these cells. To confirm the effect of galactose on ER function in the galactose-challenged, GALT-deficient fibroblasts, we examined the functional expression of epidermal growth factor receptor (EGFR), a glycoprotein with 11 *N*-linked glycosylation sites, in the controls. Despite a 3-fold up-regulation of EGFR mRNA level, we saw a sharp reduction in the EGFR protein in the controls when compared to the tests. Our findings were highly significant because not only did they show, for the first time, that galactose challenge in human GALT-deficient cells led to ER stress, they also unveil novel molecular targets/signaling pathways that were affected by the *in vivo* accumulation of toxic metabolites under GALT deficiency, notably galactose-1-phosphate and galactitol.

Atypical presentation of citrin deficiency. *D. Dimmock[1], K. Kobayashi[2], M. Iijima[2], A. Tabata[2], T. Saheki[2], B. Lee[1], F. Scaglia[1].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Molecular Metabolism & Biochem Gen, Kagoshima University, Kagoshima, Japan.

Citrin deficiency is a rare inborn error of metabolism previously seen in Southeast Asian patients. It is caused by mutations in the *SLC25A13* gene that encodes an aspartate-glutamate carrier, leading to two different age-dependent clinical phenotypes, neonatal intrahepatic cholestasis (NICCD, MIM#605814) and adult-onset type II citrullinemia (CTLN2, MIM#603471). Severe intrahepatic cholestasis with fatty liver is the most common presenting feature in NICCD; however, neonatal hepatitis, positive newborn screening for galactosemia, tyrosinemia, hemolytic anemia, and bleeding tendencies have been described. Here we report the first case of a European-American infant with citrin deficiency and an atypical clinical presentation. The proband was born to non-consanguineous parents and had a normal newborn screening. There was no evidence of hyperbilirrubinemia or intrahepatic cholestasis in the neonatal period. She presented with a gastrointestinal bleed at six months of age. At nine months she had another bleeding episode, and in addition significant failure to thrive, and macrocytic anemia were noted. The evaluation for her bleeding diathesis revealed an abnormal clotting profile with no hepatocellular damage. An extensive diagnostic work-up for failure to thrive included plasma amino acids with hyperglutaminemia and no elevation of citrulline levels. Her ammonia level was normal. Repeat plasma amino acid analysis exhibited a profile with elevations in citrulline, methionine and threonine. Western blotting demonstrated citrin deficiency and the patient was found to be homozygous for a deletion of exon 3 in the *SLC25A13* gene. The patient was given a high protein, low carbohydrate formula and the failure to thrive and bleeding diathesis resolved. This is the first report of citrin deficiency in a Caucasian infant. The later age at presentation of this patient without obvious evidence of intrahepatic cholestasis expands the clinical spectrum of citrin deficiency and shows that a normal newborn screening or normal chromatogram does not exclude the diagnosis of this condition.

Homozygosity for TNSALP Mutation C1348T (Arg433Cys) Causes Infantile Hypophosphatasia Manifesting Transient Disease Correction and Variably Lethal Outcome in a Black Kindred. *M.P. Whyte[1,2], K. Essmyer[1], M. Geier[2], S. Mumm[1,2].* 1) Ctr Metab Bone Dis & Mol Res, Shriners Hospital; St Louis, MO; 2) Division of Bone and Mineral Diseases, Wash Univ Schl Medicine; St. Louis, MO.

Hypophosphatasia (HPP) features low circulating alkaline phosphatase (ALP) activity (hypophosphatasemia) from deactivating mutation of the gene encoding the tissue nonspecific isoenzyme of ALP (TNSALP) and is associated with a remarkable range of disease severity. Extracellular accumulation of inorganic pyrophosphate (PPi), one of several TNSALP substrates and an inhibitor of hydroxyapatite crystal nucleation, impairs skeletal mineralization causing rickets or osteomalacia. There is no established medical therapy. Here, we characterize HPP prevalence in blacks and determine the molecular basis for variably lethal and transiently reversible infantile HPP in a black kindred.

Our report (J Peds 108:82, 1986) details temporary correction of severe HPP in this black family where infantile HPP was fatal in two of three patients representing two sibships. At that time, the improvement in one patient followed efforts to increase TNSALP activity endogenously and suggested upregulation of the *TNSALP* gene. Here, we assessed 29 years experience to document HPPs prevalence in blacks and identified this kindreds *TNSALP* defect.

Ethnicity was known for 119 HPP families studied directly and race was ascertained for an additional 159 of 235 consultand HPP families worldwide. Only this family was black. Homozygosity for *TNSALP* missense mutation C1384T(Arg433Cys) accounted for their infantile HPP. The *TNSALP* promoter was intact. Modeling of TNSALP(433Cys) indicated compromise of the enzymes catalytic site.

We find that HPP is especially rare in blacks. Homozygous *TNSALP*(C1348T) causes variably lethal and transiently reversible HPP in this black kindred. The mutation has been reported to cause severe HPP in whites. Although not fully understood, HPP manifestations from homozygous TNSALP(433Cys) can correct, perhaps with clues for HPP's phenotypic variation and treatment.

Peptiduria in autism and related disorders: An exploratory study. *S.G. Kahler[1,2], E. Cooper[2], D. Gaylor[3].* 1) Little Rock, AR; 2) Murdoch Childrens Research Institute Parkville, VIC, Australia; 3) Gaylor and Associates Eureka Springs, AR.

Excessive amounts of small peptides, some with opioid activity, derived from gluten and casein, have been found in the urine of many autistic children. Identification has been made by co-chromatography with synthetic standards, and immunological techniques. The peaks attributed to casein and gluten disappear with dietary elimination of their sources, and there is often amelioration of autistic symptoms. We undertook to replicate work by Reichelt, Cade, Friedman, Shattock, and others, toward the goal of confirming the identity of the peptides by mass spectrometry (MS), and quantifying them. Urine samples from children ages 1-12 years old (diagnosed with autism (N=121), developmental or intellectual delay (89), speech delay (30)), and healthy children ages 3-12 (39) were eluted with TFA and acetonitrile by HPLC from a C-18 reverse-phase column, and analyzed with dual UV detectors at 215 and 280nM. Peptiduria was quantitated as the total area under the curve (AUC) of all peaks after hippurate (~30 min) till the end of the peptide region (~68min). Retention time was expressed in relation to hippurate. Twenty-six peaks were recognized. Putative identifications include cis-indolylacryloylglycine (cis-IAG), casomorphin (CM) A5, beta(b)CM, bCM 1-4 amide, trans-IAG, alpha-gliadin, bCM 1-7, bCM 1-8. The identification of bCM 1-4 was confirmed by MS. There was notable skewing of the data from the patient groups because of high values and outliers. Statistical analysis after log transformation showed autistic children had higher total AUC ($p < 0.001$, Welchs modified t-test). Comparison of the frequency distributions showed autistic children had a significantly greater proportion of samples with values above the 75th centile for tIAG and bCM1-4 amide. Increased amounts of peptides in the urine of some children with autism/developmental problems may reflect altered intestinal function, shared etiopathogenesis, or perhaps dietary differences. Further characterization of the peaks and their significance is needed. Supported by the Murdoch Childrens Research Institute.

DNA Fragmentation And Cell Death in Activated Lymphocytes in Wilson Disease is Triggered by Fas Antigen Engagement. *R. Prasad[1], S. Attri[1], N. Sharma[1], B.R. Thapa[2].* 1) Department of Biochemistry, PGIMER, Chandigarh, India; 2) Department of Gastroenterology, PGIMER, Chandigarh, India.

Wilson disease (WD) is an autosomal recessive disorder due to the defect in CuATP7B gene and characterized by accumulation of excess copper especially in liver and brain. Hepatocyte damage in acute WD involves CD95/Fas mediated apoptosis upregulated by oxidative stress due to copper overload. Disorders of hematopoietic system also occur in WD and one third of the patients present with lymphopenia. As activated lymphocytes express CD95/Fas antigen, CD95 mediated apoptosis due to excess copper as a cause for lymphopenia was investigated in the present study. Peripheral blood lymphocytes (PBLs) were isolated from WD patients (n=6) with hemolytic anemia as well as from age matched healthy controls (n=6). Analysis of apoptosis was carried out by DNA fragmentation, FACS analysis, Annexin-V FITC and CD95 immunofluoresence studies. DNA content and cytolytic activity of anti-Fas Ab were also investigated. Copper content in PBLs from WD patients was found to be significantly higher (0.53 0.11 nmol/mg protein) as compared to controls (0.030.02 nmol/mg protein). Characteristic DNA fragmentation in PBLs of WD patients was observed on 2.0% agarose. Lymphocytes from WD patients that were positively stained by annexin were considered as early apoptotic cells and those stained by annexin and PI both were considered as late apoptotic. No annexin staining was detected in PBLs from healthy controls. The cells with DNA content less than G1 cellular DNA content indicated any possible loss due to DNA fragmentation during apoptosis and were considered as sub G1 population. PBLs from healthy subjects showed 100% DNA content in G1 phase whereas subG1 DNA content was observed in 19+4% cells from WD patients. Percentage viability was considerably low in WD patients (79.4+4.1) as compared to PBLs from controls (99.4+0.5) and was further decreased drastically on stimulation with monoclonal anti Fas antibody (59.2+6.3) indicating involvement of CD95 mediated apoptosis which was further confirmed by detection of CD95 expression in lymphocytes from WD patients by immunofluoresence staining.

Screening Newborns for Galactosemia Using Breath Tests of Total Body Galactose Oxidation to CO2. *D. Barbouth, H. Travers, H. Klapper, J.D. Wilkinson, V. Carver, L.J Elsas.* The Dr. John T. MacDonald Foundation Center for Medical Genetics and the Depts of Pediatrics and Epi & Public Health, Miller School of Medicine, Univ of Miami, Miami, Florida.

Expanded newborn screening is a developing public health project for an increasing number of inherited disorders of catabolism of fatty acids, amino acids and monosaccharides. Many of these disorders are lethal within days after birth, and these public health programs would benefit by in hospital point-of-care screening. Disorders of galactose-1-P-uridyl transferase (GALT) are exemplary of this problem. In this abstract we compare total body oxidation of 13C-D-galactose to expired 13CO2 in normal newborns and changes with increasing age in galactosemic children. Following parental informed consent, newborns were tested for 13CO2 enrichment of expired air before and after oral administration of 7 mg/kg of 13C-D-galactose. The ratios of 13CO2 to 12CO2 were quantitated by a dual isotope gas mass spectrometer at 0, 30, 45, 90, 100, 110 and 120 minutes and expressed as the cumulative percent dose recovered (CUMPD) at 120 minutes. Seven normal newborns were sequentially tested from 2 hours to 2 months of age. Normal newborns at 2, 24 and 48 hours of age had mean CUMPD of 3.913.62, 5.06 2.5, and 4.62 2.47 respectively (p= NS). Their mean CUMPD values at 2 months of age had increased to 13.26 2.96 (p 0.01). Four older children aged 11 days to 36 months with galactosemia and genotypes of K285N/delta5kb; Q188R/Q188R; Q188R/Q188R and N314D-R204X/K285N had CUMPD of 0.17; 0.80; 1.07 and 0.34 percent respectively. The mean CUMPD for these infants compared to normal infants at 2 months approached significance (p=0.08) but was limited by very small sample sizes. From these data we conclude that total body galactose oxidation to CO2 in breath increases at least three fold in normal newborns between 2 and 30 days of life; that galactosemic children have significantly less oxidative capacity than normal newborns and that newborn breath testing before discharge from the neonatal nursery may be an effective tool for prediction and prevention of premature morbidity and mortality due to classic galactosemia.

Use and pitfalls of acylcarnitine analysis in diagnosis of glutaric aciduria type I. *S.E. McCandless[1], P.E. Minkler[2], M.K. Stoll[2], C.H. Hoppel[2,3].* 1) Genetics and Pediatrics/Univ Hosp Cleveland, Case Western Reserve Univ, Cleveland, OH; 2) Medical Research Service, Louis Stokes Department of Veterans Affairs Medical Center, Cleveland, OH; 3) Departments of Pharmacology and Medicine, Case Western Reserve University School of Medicine, Cleveland, OH.

Glutaric aciduria type I (GA-I)is a severe inborn error of metabolism that often presents with severe central nervous system injury associated with metabolic stress and fever. Prior to this presentation, children may appear well, but have macrocephaly and brain MRI abnormalities. Recently, the disorder has been identified by tandem mass spectrometry newborn screening. Diagnosis is complicated by the fact that some affected individuals excrete only modest amounts of glutaric acid and 3-hydroxyglutaric acid in the urine. Our laboratory uses HPLC/MS to measure glutaroylcarnitine (C5DC) in plasma, urine and tissues. Recently, we synthesized C5DC, standardized solutions of which are used to generate multiple point standard curves (with nonanoylcarnitine as the internal standard) allowing for accurate measurement of C5DC concentrations in patient samples. Plasma (N=958) and urine (N=494) samples have been evaluated in a variety of clinically submitted samples. Plasma C5DC concentrations range from 0 to 9.6 nmol/ml, with overlap between known affected individuals and individuals with end-stage renal disease (ESRD). Also, some individuals with methylmalonic (MMA) and propionic acidemia (PA) treated with L-carnitine had plasma C5DC concentrations that overlapped the range seen in GA-I affected individuals. In urine, as has been suggested by others recently, there was a much broader range seen (0 to 3517 nm/mg creatinine), but no overlap of known affected individuals with samples from patients with MMA or PA treated with L-carnitine. As expected, C5DC excretion in urine was not elevated in ESRD. These findings suggest that plasma acylcarnitine analysis alone may lead to confusion in ESRD and in children on carnitine supplementation for other reasons. The use of urinary acylcarnitine analysis appears to clarify the diagnosis of glutaric aciduria type I, and overcomes some of these potential pitfalls.

Differential Expression Profiles in Purine Nucleoside Phosphorylase (PNP) Deficient Mice. *F.F. Snyder, B. Danielson, H. Zhang.* Dept Medical Genetics, Univ Calgary, Calgary, Canada.

PNP deficiency is associated with cellular immunodeficiency and variable neurological involvement. We produced the NPG, Trp16Arg point mutation in the mouse which exhibits age dependent depletion of thymocyte numbers and arrested thymocyte differentiation. We have backcrossed this mutant allele 14 generations on the C57BL/6J (B6-NPG) and DBA/2J (D2-NPG) backgrounds respectively as a strategy for identifying genes which modify the phenotype. Labeled thymocyte mRNA from C57BL/6J (B6) and B6-NPG mice were hybridized against a 17K 70-mer oligo array obtained from the Southern Alberta Microarray Facility. Only 6 genes showed a greater than 2-fold increase in mutant thymocytes and none were decreased. Of these, 4 were immunoglobulin genes and 2 of lymphocyte antigen 6 complexes. Real time PCR quantitation gave a mean 42-fold increased expression for IgG2a in B6-NPG thymocytes compared to B6, whereas S100a9 showing variable expression in the array was 2.7-fold increased. The relative expression of IgG2a was increased 13-, 21- and 36-fold at 1, 2 and 3 months respectively in B6-NPG mice relative to control, thereby providing the earliest signal of the anticipated changes in the thymocyte profile. We have described a secondary deficiency of dGuo kinase in PNP deficient mice. Real time PCR showed no evidence for a reduction in transcripts in B6-NPG thymocytes or spleen relative to control. Additional genes showing variable expression are being examined. A single report indicated increased IL-18 expression in a PNP deficient child. We found serum IL-18 to be marginally increased in D2-NPG, 18316, versus D2, 15111 pg/ul. On the B6 background, however, there is a marked difference in serum IL-18 between B6-NPG, 790815, and B6, 27776 pg/ul. The broad range in B6-NPG mice being due to some mice having a greater than 8-fold increase compared to wild type. Real time PCR did not show evidence of increased expression of IL-18 in spleen leukocytes. These studies are forming the basis for a more complete understanding of early events associated with disruption of T cell differentiation in PNP deficiency and secondary sequelae. Consequences of missense in alanine:glyoxylate aminotransferase and the effect of added pyridoxal phosphate.

M. Coulter-Mackie, Q. Lian. Dept Pediatrics, Univ British Columbia, Vancouver, BC, Canada.

Primary hyperoxaluria type 1 (PH1) results from a deficiency of liver peroxisomal alanine:glyoxylate aminotransferase (AGT) and is characterized by progressive deposition of calcium oxalate and progressive renal failure. More than 50 PH1 mutations have been documented in the AGT gene of which about 45% are missense. A consequence of missense common to many genetic diseases is mis-folding and subsequent proteasome-mediated destruction through cellular quality control surveillance. We have utilized pET vector-mediated overexpression of human mutant AGT proteins in E. coli to determine the effects of missense on enzymatic activity in isolation from eukaryotic quality control processes. For some mutants, re-folding the overexpressed enzyme in the presence of pyridoxal phosphate (PLP), an essential co-factor for the enzyme, restores measurable enzymatic activity to the protein. We have also used in vitro transcription/translation with rabbit reticulocyte lysates to investigate the post-translational stability of mutant AGT protein in a eukaryotic milieu. Most mutants studied showed varying degrees of instability in this system but were stabilized in the presence of PLP. These mutants were predominantly the ones for which enzymatic activity could be recovered after expression in E. coli and re-folding. Our results suggest that PLP can function as a chaperone for certain mutant proteins, restoring enzymatic activity and stability, and that, under optimal conditions, mutant AGTs may have biological activity. This work was funded by a grant from the Garrod Association of Canada and the Hospital for Sick Children Foundation, Canada.

Gene expression profiling in prosaposin deficient mice: molecular alterations precede neuronal pathology. *Y. Sun[1], L. Jia[1], M.T. Williams[2], C.V. Vorhees[2], D.P. Witte[3], G.A. Grabowski[1].* 1) The Division and Program in Human Genetics; 2) Division of Neurology; 3) Division of Pediatric Pathology, Cincinnati Childrens Hospital Medical Center, Cincinnati, Ohio.

Prosaposin encodes, in tandem, four small acidic activator proteins (saposins) with specificities for glycosphingolipids (GSL) hydrolases in lysosome. The critical roles for saposins in GSL metabolism are highlighted by the extensive GSL storage in various CNS areas in the human and mouse prosaposin deficiencies. Our hypomorphic prosaposin deficient mouse model, PS-NA, exhibit 45% of wild type expression levels of saposins in the brain. PS-NA mice survived up to 220 days and showed neurological pathology that includs GSL storage in neurons and loss of Purkinje cells. The predominantly accumulated lipids are lactosylceramide (LacCer) and glucosylceramide (GC). Impairment of neuronal function was observed by 6 weeks using narrow bridge test. To explore the molecular mechanism(s) of disease progression, whole transcriptome microarray analyses of brain tissues were conducted with mRNA from PS-NA and control mice at birth, 4, 12 and 18 weeks. The expression of the proinflammatory genes were increased by age of 4 week. The genes involved in cell death pathway were differentially expressed with response early in cerebrum and delayed in cerebellum. Immunohistochemistry demonstrated activation of microglia cells and astrocytes, along with neuronal degeneration after 12 weeks. These results show that regionally specific gene expression abnormalities preceded the histological changes and neuronal pathology in the PS-NA mouse. The proinflammatory responses in microglial cells and astrocytes might propagate the disease progression. Temporal profiling of gene expression changes provides insight for defining molecular mechanism in the progression of GSL storage disease.

Correlation between Interleukin-6 promoter gene polymorphism and the Mainz Severity Score Index for Fabry disease. *D. Elstein[1], C. Wybra[2], M. Beck[2], G. Altarescu[1].* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) University of Meinz, Germany.

Objective: To determine the functional interleukin-6 (IL-6) -174 GC allelic variants in relation to disease severity markers using the Mainz Severity Score Index (MSSI) in a cohort of patients with Fabry disease. Methods: 56 patients (34 hemizygous males, 22 females) including five children (one boy) were genotyped for the IL-6 -174 GC polymorphism. Results were correlated with the MSSI that included a general, neurological, cardiac, and kidney sub-scores and a composite total score. Results: Mean age of the adults was 42 range: 26-58) years with 30 patients having received enzyme replacement therapy (ERT) for a mean of 3.1 (2.2-4.0) years. Mean total MSSI was 26.7 (14.2-39.2) points. Prevalence of allelic variants of the IL-6 polymorphism, 48%G/G (wild type), 27%G/C, and 25%C/C, is significantly different ($p<0.05$) from the distribution reported among Caucasians, but C allele frequency was similar to that reported among patients with lacunar strokes. A statistically significant correlation was found between the neurological MSSI sub-score and the C/C genotype ($p=0.001$), with MSSI sub-scores approximately two-fold higher among patients with the C/C genotype, although the majority (12/14 patients) of those with the C/C genotype had had benefit of ERT. Conclusions: The prevalence of the C/C genotype of the IL-6 promoter polymorphism among patients with Fabry disease is greater than in control Caucasian populations, and appears to carry a greater risk for developing stroke and other neurological manifestations. Since the pro-inflammatory cytokine IL-6 may be released shortly after hypoperfusion of the brain, the interesting question raised by the current study is whether the C/C genotype may be a modifier and/or marker of microvascular abnormalities in Fabry disease.

Visceral variant of Niemann-Pick disease type C1 in an adult. Report of the third case. *L. Dvorakova, M. Bouckova, J. Sikora, M. Hrebicek, L. Stolnaja, H. Hulkova, M. Elleder.* Inst Inherit Metabol Disorders, Charles Univ, 1st Sch Medicine, Prague 2, Czech Republic.

Accidental autopsy findings of hepatosplenomegaly, lymphadenopathy and histopathological signs of visceral lysosomal storage in a 53 year old female with pulmonary embolism raised the initial suspicion of Gaucher disease (GD). There was no prior significant medical history. Additional histopathological evaluation excluded GD and rather supported the diagnosis of visceral form of acid sphingomyelinase deficiency (Niemann-Pick disease type B - NPB) or much rarer disorder, variant adult visceral form of Niemann-Pick disease type C. To verify the histopathological findings, we analyzed potentially involved genes. As only formalin fixed paraffin embedded (FFPE) tissues from the proband were available, we examined probands living relatives (mother and two sons). No pathogenic sequence variation in SMPD1 gene, mutated in NPB, was identified in any of the relatives examined. Consequently we analyzed genes associated with Niemann-Pick disease type C. While no mutations were detected in NPC2 (HE1), a heterozygous substitution c.1997GA was identified in exon 13 of NPC1 gene of all three relatives. Analysis of DNA isolated from FFPE tissues (spleen and lymph node) showed no variation in NPC2, while the presence of c.1997GA in NPC1 was confirmed in both tissues. In addition, heterozygous substitution c.2882AG was found in exon 19 of NPC1 gene. Both variations c.1997GA (S666N) and c.2882AG (N961S) detected in NPC1 gene are novel. The PCR/RFLP analysis of 318 control alleles excluded the possibility that the identified variations are common polymorphism. The expected pathogenicity of both variations is supported by their location in regions important for the protein function. The results support the diagnosis of extremely rare adult visceral form of Niemann-Pick disease type C othervise dominated by neurovisceral phenotype. Despite the low number of patients reported (two), this form of NPC should be considered in differential diagnosis of isolated hepatosplenomegaly with foam cells in the adult age. *This work was supported by grants IGA-MZ CR 8351-3 and VZ MSM CR 20620806*.

Clinical and genetic characterization of central nervous system folate deficiency. *F. Scaglia[1], P. Moretti[1,2], S. Peters[3], D. Del Gaudio[1], K. Hyland[4], T. Bottiglieri[4], R. Hopkin[5], E. Peach[5], B. Roa[1], C. Bacino[1].* 1) Dept Mol & Human Genetics; 2) Neurology; 3) Pediatrics, Baylor Col Medicine, Houston, TX; 4) Institute of Metabolic Disease, Baylor University Medical Center, Dallas, TX; 5) Human Genetics, Cincinnati Childrens Hosp Med Ctr, Cincinnati, OH.

We studied the clinical and biochemical features of 5 girls and 2 boys with an isolated deficiency of folate in the central nervous system (CNS). All patients had low cerebrospinal fluid (CSF) levels of 5-methyltetrahydrofolate, the biologically active form of folate in CSF and blood. Red blood cell folate, serum folate, and total plasma homocysteine were normal. All children exhibited psychomotor retardation, developmental regression, seizures and diskinesia with variable response to folinic acid. Two females had manifestations evocative of Angelman syndrome and a third exhibited features of Rett syndrome. Angelman syndrome DNA methylation studies and *UBE3A* mutation analysis were normal. No *MECP2* mutations or deletions were found. Five of seven patients demonstrated considerable repetitive behaviors, decreased eye gaze, and communication deficits that warranted a formal evaluation for autism. Using the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview - Revised, three subjects met criteria for autism, demonstrating deficits in communication and socialization that mirror those observed in children with idiopathic autism. Formal evaluations are currently being completed with two other patients. The selective CNS folate deficit suggested the presence of defective folate transfer across the blood brain barrier. We sequenced genes encoding proteins involved in the transport of folate across mammalian cell membranes (*RFC1*, *FBP1*, *FBP2*, *FBP3*), methylenetetrahydrofolate reductase (*MTHFR*) and dihydrofolate reductase (*DHFR*). We found no mutations in the coding regions of these genes. These findings demonstrate that children with autism, developmental delay, regression, and seizures may have abnormalities of CNS folate. Future studies will determine the general relevance and frequency of these findings and elucidate the molecular and biochemical mechanisms of reduced CSF folate in these patients.

The natural history of cognitive abilities in Hurler-Scheie syndrome: Eight years longitudinal evaluation of three siblings treated with recombinant human -L-iduronidase (laronidase, Aldurazyme). *K. Bjoraker, L. Charnas, C.B. Whitley, K. Delaney, E.G. Shapiro.* Dept Pediatrics, Univ Minnesota, Minneapolis, MN.

The natural history of cognitive development and CNS function in the intermediate form of MPS I, Hurler-Scheie syndrome, is unknown. Learning disabilities have been described; no decline was presumed to occur as in Hurler syndrome. Neuropsychological testing is not routine; thus no data are available. Are the cognitive effects are secondary to health factors (e.g., limited mobility, sleep apnea, hearing loss, hydrocephalus, poor motor skills), or are they directly related to neurotoxic effects of enzyme deficiency. IV administration of recombinant enzyme (ERT) in the canine model does not increase enzyme activity across the blood-brain barrier. ERT has improved the somatic features and corrected secondary effects on the nervous system. This allows assessment of whether cognitive function is stable in enzyme treated patients or if impairments are a direct neurotoxic effect of enzyme deficiency. Method: 3 siblings with MPS IH-S received serial neuropsychological, cranial MRI and neurological assessments over 8 years. The 15 year old received ERT for 7 years; the two siblings for 4. All had increased mobility and range of motion. All had early carpal tunnel release. The 12 and 14 year old received VP shunts for hydrocephalus prior to ERT. The eldest required VP shunt 4 years after ERT initiation. Results: IQ decreased over time in all 3 children. Memory encoding showed a dramatic decline beginning at age 12 in the 14 and 15 year olds. Math ability, visual motor skills, and spatial perception have significantly declined. Attention span, executive functions and reading ability are not affected. Adaptive skills are normal. Cranial MRI is unchanged. Conclusions: Progressive slowing of cognitive development with particular impairment in memory encoding occurs in adolescents with MPS I H-S receiving ERT. The declines are likely a primary effect on the brain and not secondary effects of MPSI on the nervous system. Additional study is needed to determine if late decline is a common feature of MPS I H-S.

Autism as the major presenting feature of inborn errors of metabolism. *Y. Choy[1], L. Ngu[1], W. Keng[1], B. Chen[2], Y. Zabedah[3], A.K.D. Pertiwi[3].* 1) Genetics Unit, Kuala Lumpur Hosp/Ped Inst, Kuala Lumpur, Malaysia; 2) Metabolic Laboratory, Kuala Lumpur Hospital; 3) Metabolic Laboratory, Institute of Medical Research.

Autism is a common childhood disorder and majority of the patients have no known underlying cause. In 5 to 10% of the patients, there is an identifiable cause including Fragile-X syndrome, Rett syndrome, tuberous sclerosis and chromosomal abnormalities such as duplication 15q11q15. Inborn errors of metabolism (IEM) in which autism has been reported as the main presenting feature include untreated phenylketonuria, urea cycle defects, mitochondrial dysfunction, purine and pyrimidine defects. Over the past 5 years, there were 196 patients referred to our center for further evaluation of autism. They had no neuroregression or physical handicaps, birth defects, neurocutaneous stigmata or specific features to suggest IEM such as cyclical vomiting, recurrent episodes of confusion or lethargy. The standard evaluation protocol included high resolution karyotype, Fragile-X testing, MECP2 testing, MRI of the brain, lead level and metabolic screen including lactate/pyruvate, ammonia, uric acid, amino acid, organic acid and acylcarnitine.

We had identified 5 cases of IEM (2.5%) in this cohort of patients. One of them had mild chronic variant of maple syrup urine disease (MSUD), another patient had non-ketotic hyperglycinemia. One had glutaric acidemia type I and one had mitochondrial dysfunction with persistent lactic acidosis. One had hypouricosuria probably due to cytosolic 5'nucleotidase superactivity. They were all treated and showed variable improvement. The most remarkable improvement was observed in the 5-year-old boy with MSUD. He actually improved with a lower protein diet when his mother stopped his milk to limit intake of casein. The findings of these patients may argue for metabolic investigation in patients with autism. Indeed, the parents of the boy with MSUD questioned the delay in metabolic testing. The diagnosis in these patients could be missed by newborn screening as they were milder variant of the disorders.

Interactions between variants of the endothelial nitric oxide synthase gene and dietary intakes of vitamin C, fruit and vegetable in association with plasma markers of endothelial function and inflammation among US diabetic men. *C. Zhang, F. Hu.* Nutrition, Harvard School of Public Healt, Boston, MA.

Background: Endothelial dysfunction and vascular inflammation contribute substantially to the accelerated atherogenesis associated with type 2 diabetes. Associations have been described between two potentially functional variants of the endothelial nitric oxide synthase (ENOS) gene (T(-786)C and G894T) and makers of endothelial function in non-diabetic individuals. Dietary vitamin C can have antioxidant-mediated tempering influence on endothelial function and inflammation in vivo. Population: 641 men (97% Caucasian) had confirmed type 2 diabetes among 18,159 men in the Health Professionals Follow-up Study. Results: After adjustment for age, body mass index, duration of diabetes and other covariates, plasma levels of soluble vascular cell adhesion molecule (sVCAM-1), soluble intercellular cell adhesion molecule (sICAM-1) and tumor necrosis factor alpha (TNF-) were significantly higher in men with the 894 G/T or T/T genotype than those with the 894G/G genotype (adjusted mean 1385 vs. 1299 ng/ml, P=0.002 for VCAM; 366 vs. 348 ng/ml, P=0.02 for ICAM; 2984 vs 2847 pg/ml, P=0.01 for TNF-). (-786) G/T or T/T genotype was associated with significantly elevated levels of sVCAM and TNF- as well. In multivariate linear regression models, ICAM-1 and VCAM levels were associated with significant interactions between the G894T variant and dietary intake of vitamin C and fruit and vegetable as continuous variables (all P-values for interaction <0.01), respectively. By using 2 categories of vitamin C and fruit and vegetable (dichotomized by median), we found significantly different effects of the G894T genotypes on ICAM-1 and VCAM levels across these dietary variables; significant elevations of ICAM-1 and VCAM levels were associated with the G894T variant only in men with lower intakes of vitamin C (<154mg/day) or fruits and vegetables (<5 servings/day. Conclusions: Our study suggests that effects of the functional variant of the ENOS gene on CAM levels were modified by dietary intake of vitamin C and fruits and vegetables- the major source of dietary antioxidants.

FREQUENCY OF A1298C (MTHFR) POLYMORPHISM IN PATIENTS WITH CORONARY ARTERY DISEASE IN NORTHWEST MEXICAN POPULATION.

L. Arnaud Jr[1], *A. Ventura-Aguilar*[2], *IP. Dávalos*[3], *L. Figuera*[3], *MP. Gallegos-Arreola*[1]. 1) Medicina Molec, CIBO, MSS, Guadalajara, Jalisco, México; 2) Departamento de Cardiología, H. de Especialidades; 3) Genética, CIBO, IMSS, Guadalajara, Jalisco, México.

INTRODUCTION. The coronary artery disease (CAD) is the most important cardiovascular disorder and the principal world cause of death. It has been considered multifactorial disease because of different risk factors (genetics and environmental). Between genetics factors we can find modifications in methylenetetrahydrofolate reductase (MTHFR) levels. This enzyme plays a role in processing amino acids like homocysteine, which is cause of damaged in vascular endothelium with expresion of aterogenic factors. Some studies have described an association between A1298C (MTHFR) polymorphism and CAD, although this association is contradictory in anothers studies and its association is unknown in northwest Mexican population. METHODS. In this study, genomic DNA from 67 CAD patients (abnormal coronariography) and 58 persons without CAD and background of CAD, diabetes mellitus and arterial hypertension were genotyped. We analized the allelic and genotypic distribution in A1298C polymorphism. RESULTS. The genotypic frecuency of 1298AA was 56.72% in CAD patients and 48.27% in control group; 1298CC was 13.43% in CAD patients and 15.52% in control group, whereas 29.85% in CAD patients and 36.21% in control group were heterozygous. Statistical differences was not observed between groups ($p<0.05$). CONCLUSIONS. Association was not observed between the genotypes and CAD, showing that this polymorphism possibly not play a role as risk factor of CAD.

Differentiation of unexplained hypouricemia. *I. Sebesta[1,2], B. Stiburkova[2], J. Krijt[2], O. Martincova[2], E. Hruba[2].* 1) Institute of Clinical Biochemistry and Laboratory Diagnostics; 2) Institute of Inherited Metabolic Disorders, Charles University, First Faculty of Medicine, Prague, Czech Republic.

Decreased serum uric acid levels result from decreased production and/or renal urate wasting. Hypouricemia is defined as a serum urate levels less than 2 mg/dL(119 umol/L). Primary hypouricemia is caused by several purine metabolic disorders. Recent identification of the renal urate transporter (URAT1,encoded by SLC22A12) led to the molecular elucidation of idiopathic renal hypouricemia (MIM 220150), which is a predisposition towards exercise-induced acute renal failure. Secondary hypouricemia in different disorders is related to proximal tubular damage, use of uricosuric drugs etc. Hypouricemia is sometimes overlooked. Therefore we have set up the diagnostic guideline for differential diagnosis. Uric acid was quantified by specific enzymic method and red cell enzyme with urinary purine nucleosides were measured by methods adapted to HPLC. Results: A proposed scheme for the investigation of unexplained hypouricemia is as follows. Estimation of: 1) excretion fraction of uric acid , 2) urinary xanthine, S-sulphocysteine, thiosulfate, 3) measurement of (deoxy)guanosine,(deoxy)inosine in urine, if positive - assay of purine nucleoside phosphorylase in erythrocytes, 4) analysis of URAT 1 gene. The evaluation of clinical history with attention to renal failure, urolithiasis, seizures and immunodeficiency is indispensable. This flow chart allows to differentiate a) idiopathic renal hypouricaemia, b) hereditary xanthinuria, c) molybdenum cofactor deficiency, d) purine nucleoside phosphorylase deficiency. Moreover, primary hyperuricemia can be excluded. Using this flow chart we have detected four new families of Czech origin with hereditary xanthinuria, one case of hereditary renal hypouricaemia and one patient with molybdenum cofactor deficiency from 3,400 serum and urine samples received during last three years. In conclusion-the exclusion of primary hypouricemia allows to search for the other causes. Accessible guideline will help for early diagnosis of purine disorders associated with hypouricemia.(Supported by grants-MSM 0021620806, VZ 64165,CZ).

Molecular analysis of glycogen storage disease type Ia, Ib, and III in Korean patients. *J. Yang[1], J. Lee[2], J. Kim[1], S. Park[1], G. Kim[1,2], J. Choi[2], H. Yoo[1,2].* 1) Genome Research Ctr, Asan Medical Center, Seoul, Korea; 2) Medical Genetics Clinic & Laboratory, Asan Medical Ctr, Seoul, Korea.

Glycogen storage disease (GSD) Ia, Ib, and III are rare autosomal recessive disorders. Their clinical manifestations such as recurrent hypoglycemia, hepatomegaly, growth failure, hyperlipoidemia, and lactic academia are so mimicking that it is often difficult to differentiate each other. GSD Ib is distinguished from GSD Ia and III by the presence of persistent neutropenia. The affected genes of GSD Ia, Ib, and III are glucose 6-phosphatase, catalytic (G6PC), glucose 6-phosphate transporter (G6PT1 or SLC37A4), and amylo-1,6-glucosidase (AGL), respectively. We studied 17 unrelated Korean patients with GSD Ia, Ib, and III. The G6PC gene was initially analyzed in the patients without neutropenia. The patients with neutropenia were analyzed for the presence of mutation in the G6PT1. Subsequently, AGL was analyzed in patients without mutation in G6PC and G6PT1 genes. Out of 17 patients clinically diagnosed as GSD, we identified 12 of GSD Ia, 2 of GSD Ib, and 3 of GSD III patients. We found 10 different mutations; three mutations (p.F51S, p.G122D, and c.624 G>T) in G6PC, three mutations (p.W138R, p.P191L, and p.L328VfsX52) in G6PT1, and four mutations (pR428K, p.L1139P, c.1735+1 G>T, and p.S603PfsX6) in AGL. Among these mutations, six were novel mutations. Those were p.F51S in G6PC, p.W138R; p.L328VfsX52 in G6PT1, and p.L1139P; c.1735+1 C>T; and p.S603PfsX6 in AGL. The mutations of three genes were heterogeneous except G6PC where the mutation was homogeneous, showing a hot spot, c.648 G>T (91.7% of allele frequency). In conclusion, we demonstrated a strategy of molecular analysis for type Ia, Ib, and III glycogen storage diseases that share common clinical findings. According to this strategy, we identified ten different mutations including six novel mutations in three genes involving glycogen storage disease Ia, Ib, and III.

Direct screening of R83C mutation in Tunisia as a rapid non-invasive diagnosis tool in south Mediterranean populations. *W. Cherif[1], E. Barkaoui[2], N. Tebib[2], Ch. Charfeddine[1], S. Chakroun[1], S. Abdelhak[1], MF. Ben dridi[2].* 1) Molecular investigation of Gen, Institut Pasteur , Tunis, Tunis, Tunisia; 2) service de pédiatrie du CHU la Rabta Tunis, Tunisia.

Glycogenosis Type Ia (GSD Ia) is an inherited metabolic disorder caused by the deficient of D-glucose-6-phosphatase (G6Pase) activity. This disease is an autosomal recessive disorder and it is pan-ethnic , it occurs in 1 / 100000 to 1/300000 individuals. GSD Ia is characterized by hypoglycemia, lactic acidemia, hepatomegaly, hyperuricemia, hyperlipidemia and renal dysfunction leading to chronic renal failure as a late manifestation of the disease. The confirmation of the clinical diagnosis is usually performed by liver biopsy .The molecular investigation may provide a time and cost effective and less invasive tool for diagnosis of GSD Ia . Recently, by the study of the molecular basis of GSD Ia in Tunisian patients we have shown that R83C is relatively frequent. Mutation screening have shown that 6 out of 9 patients were homozygous for R83C. We propose here the use of direct screening of this mutation for rapid diagnosis of GSD Ia. Five patients presenting with clinical features leading to a suspicion of GSD Ia have been explored by direct sequencing of exon 2 of G6PC. Sequence analysis revealed that the 5 patients had the R83C mutation thus confirming the clinical diagnosis and circumventing liver biopsy and enzymatic investigation. We propose the use of direct screening of R83C mutation as a rapid and valuable tool for diagnosis of GSD Ia in south Mediterranean populations.

Increased brain guanidino compounds suggests disrupted creatine metabolism in the succinate semialdehyde dehydrogenase (SSADH) deficient mouse. *K.M. Gibson[1], E.E.W. Jansen[2], N.M. Verhoeven[2], A. Schulze[3], H. Senephansiri[4], M. Gupta[4], C. Jakobs[2].* 1) Med Genet/Peds/Pathol, Univ Pittsburgh Sch Med, Pittsburgh, PA; 2) Clin Chem, Vrije Univ Med Ctr, Amsterdam, Netherlands; 3) Div Metab Dis, Univ Child Hosp, Heidelberg, Germany; 4) Molec Med Genet, Oregon Hlth Sci Univ, Portland, OR.

Guanidinoacetate (GA), an endogenous intermediate in the conversion of L-arginine to creatine, is increased in GAMT deficiency, one of the inherited disorders of creatine biosynthesis. Conversely, guanidinobutyrate (GB), first isolated from mammalian brain in 1959, has been detected in humans only when GABA is pharmacologically elevated with vigabatrin. We previously demonstrated decreased L-arginine levels in cortex (Cx) and hippocampus (Hc) from SSADH-/- mice. Since these animals have increased brain GABA, we quantified guanidino species in brain extracts. Total homogenates revealed elevated GA and GB (SSADH+/+ (n=5) 24.6 +/- 1.1 (SE) and 7.9 +/- 0.3 nmol/100 mg protein; SSADH-/- (n=3) 97.2 +/- 9.9 and 168.5 +/- 7.1), respectively ($p<0.04$). These results were confirmed in regional (Ce-cerebellum) extracts: (Ce) GA and GB (SSADH+/+ (n=6) 31.3 +/- 1.9 and 12.5 +/- 0.3; SSADH-/- (n=7) 49.0 +/- 4.3 and 279.7 +/- 19.3); (Hc) (SSADH+/+ (n=6) 40.5 +/- 5.2 and 9.5 +/- 0.3; SSADH-/- (n=6) 62.7 +/- 7.7 and (n=7) 188.9 +/- 19.1); (Cx) (SSADH+/+ (n=6) 64.2 +/- 3.6 and 11.8 +/- 0.3; SSADH-/- (n=3) 218.7 +/- 50.0 and (n=4) 168.8 +/- 5.3), respectively. Guanidinopropionate was not elevated. Guanidino species have been shown to generate reactive oxygen intermediates, activate GABA(A) receptors, and disrupt creatine metabolism, implying new pathomechanisms in this disorder. Increased GA most likely derives from competitive inhibition of the GAMT reaction by GB. Our results suggest that SSADH deficiency is the first inborn error of metabolism with endogenously elevated GB, supported by the preliminary observation of elevated GB in the urine derived from an SSADH-deficient patient. Our findings raise the potential for disruption of the nitric oxide signaling system in this disorder.

Identification of interaction partners of Hermansky-Pudlak syndrome proteins. *W. Westbroek[1], A. Helip Wooley[1], H. Dorward[1], M. Ayub[1], R. Hess[1], J. Tavernier[2], M. Huizing[1], WA. Gahl[1].* 1) Medical Genetics Branch, NHGRI/MGB/NIH, Bethesda, MD; 2) Department of Medical Protein Research, Faculty of Medicine and Health Sciences, Ghent University, Ghent, Belgium.

Hermansky-Pudlak syndrome (HPS) is a rare autosomal recessive disorder, characterized by various degrees of skin, hair and eye hypomelanosis, and a bleeding diathesis. The clinical symptoms result from defective biogenesis of lysosome-related organelles (LROs), such as melanosomes in melanocytes and dense bodies in platelets. Currently, mutations in seven genes are known to cause HPS-1 through HPS-7 in humans. However, with the exception of HPS2, the biological functions of the HPS proteins in LRO biogenesis remain elusive. It is known that different HPS proteins can interact to form Biogenesis of Lysosome-Related Organelle Complexes (BLOCs). First, we studied interactions between the human BLOC2 (HPS3, HPS5, and HPS6) and BLOC3 (HPS1 and HPS4) components by yeast two-hybrid screening. We did not detect direct interactions, which could be due to detection limitations of the yeast two-hybrid method. We then employed the innovative MAPPIT (Mammalian Protein-Protein Interaction Trap) technique to study interactions between the members of BLOC2 and BLOC3. This mammalian cytokine receptor type I based system identifies direct protein-protein interactions in their physiological context without depending on nuclear translocation of the bait and prey proteins. Interaction studies between the known members of the BLOCs are ongoing. Simultaneously, we started screening HPS1 and HPS5 against the MAPPIT placenta library to find new BLOC2 or BLOC3 members. Identification of new interaction partners of HPS proteins will not only give a better insight into the cell biology of this syndrome but will also provide strong candidate genes for patients that are clinically but not genetically diagnosed with Hermansky-Pudlak syndrome.

P450 Oxidoreductase: The cause of Antley-Bixler syndrome and apparent combined 17- and 21-hydroxylase deficiency. *C. Shackleton[1], J. Marcos[1], H. Ivison[2], V. Dhir[2], B. Hauffa[3], E. Malunowicz[4], P. Stewart[2], W. Arlt[2].* 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) University of Birmingham, Division of Medical Sciences, Birmingham, UK; 3) University Children's Hospital, Essen, Germany; 4) Childrens Health Memorial Institute, Warsaw, Poland.

Introduction: For 30 years a variant of congenital adrenal hyperplasia (CAH) has been observed that appears as combined 17- and 21-hydroxylase deficiency (17-, 21-HD) clinically leading to ambiguous genitalia and cortisol deficiency. Separately, many patients with the craniofacial and skeletal deformity Antley-Bixler syndrome were found to have impaired steroidogenesis. The common cause was recently defined as P450 oxidoreductase deficiency (ORD). Addressing the importance of documenting new disorders we describe 13 new patients. Methods: GC/MS urine steroid panels were developed for specific diagnosis of ORD in childhood and prenatally. DNA analysis was performed on most patients. Results: *Children*: Diagnostic steroid metabolites were abnormal in all patients studied. Elevated excretions were found of: 1) corticosterone metabolites (distinctive of 17-HD), 2) 17-hydroxyprogesterone and 21-deoxycortisol metabolites (distinctive of 21-HD), and 3) metabolites of precursors pregnenolone and progesterone. Androgen metabolite excretion was low. *Prenatal diagnosis*: estriol (E3) levels were low in prenatal screening of mothers with ORD fetuses. One mother showed elevated excretions of epiallopregnanediol (EAP), a metabolite of fetal pregnenolone, and androsterone (A) associated with the fetal and maternal virilization. *Genetic analysis*: An A287P mutation was the most prevalent, affecting at least one allele in 10 cases. Homozygous A287P inevitably had bone malformation. Mutations included exonic, frameshift, splice site and missense leading to the change of a single amino acid in the OR protein. Conclusion: ORD can be diagnosed postnatally from urinary steroid ratios. Low E3 and elevated excretion of EAP and A are likely diagnostic for ORD prenatally. A287P is the most common mutation in Caucasian ORD patients. Considering cases reported since finding the cause of the disease, ORD may be second to 21-HD in CAH incidence.

STUDY OF NATURAL HISTORY AND GENOTYPE ANALYSIS OF JUVENILE GM2 GANGLIOSIDOSIS.

G.H.B. Maegawa[1], M. Tropak[2], D. Mahuran[2], T. Stockley[3], R. Giugliani[4], F. Kok[5], J.T.R. Clarke[1]. 1) Division of Clinical & Metabolic Genetics; 2) Metabolism Programme, Research Institute; 3) The Molecular Genetics Laboratory, The Hospital for Sick Children, Toronto, ON, Canada; 4) Medical Genetics Service, Hospital de Clinicas, Porto Alegre; 5) Neuropediatrics Service, Centro do Genoma Humano, Universidade de Sao Paulo, Brazil.

Juvenile GM2 gangliosidosis (jGM2) is a rare neurodegenerative disorder caused by lysosomal HexA deficiency.Objective:natural history and genotype-phenotype correlation study of 21 patients from 14 unrelated families:15 diagnosed with Tay-Sachs variant(TSV) and 6 with Sandhoff variant(SV).Results:The mean age of onset was 5.3 years (1.5-17years), 11 males and 10 females. The most common symptoms at onset were gait ataxia (13/21; 63%) and speech disturbances along with coordination problems (12/21; 57%).Interestingly, developmental delay were not as important being present as first symptom in only 6/21 patients(28.6%). Correlating the genotype-phenotype, three distinctive clusters were observed.In one group, patients with c.533G>A(R178H) in one of the HEXA alleles along with an infantile mutation presented with an earlier and more severe neurological presentation.In a second group, patients with c.1496G>A(R499H) along with an infantile mutation showed an intermediate phenotype.In the third group, three siblings with a combination of c.805G>A(G269S) and an infantile mutation presented the mildest phenotype.These three patients presented in the late second decade with pronounced psychiatric symptoms.A detail clinical inquiry revealed that these patients had motor and behaviour disturbances during childhood.Two new mutations were found in the HEXA gene were characterized:c.681C>G(Y227X)and c.1330+1G>A. Among those patients with SV, four non-reported mutations were identified:c.410G>A(C137Y),c.769T>G(Y266D),c.1057G.C(G353R) and 115delG with the latter being associated with a more severe phenotype.Conclusion: Recent studies have been described clinical variability among patients with this condition (Hendriksz et al2004).In the present study, we observed considerable heterogeneity in the clinical presentation as well as in the progression of jGM2.

Two successful pregnancies with maternal diagnosis of Morquio A - clinical challenges and lessons learned. *D.J. Zand[1], D.R. Stewart[1], D. Driscoll[2], P. Kaplan[1].* 1) Division of Metabolism, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept. of Obstetrics, University of Pennsylvania Medical Center, Philadelphia, PA.

A 26 year old african american woman with both clinical diagnosis and biochemical confirmation of Morquio type A (mucopolysaccharidosis IV type A; OMIM #253000) was followed through two pregnacies. Both pregnacies carried concern for IUGR, and resulted in delivery of term, healthy children via cesarian section. The patient had been intermittantly lost to follow-up as a child and in-between pregnancies. At the time of her first delivery, she was wheelchair bound and required nursing assistance for daily care. Previous interventions had included cervical spine fusion and multiple surgical procedures for neurologic bowel and bladder. Pregnancy related evaluations were remarkable for previuosly undiagnosed and severe pulmonary hypertension. While both the patient and her younger sibling carried a diagnosis of Morquio type A, her sibling had declined on-going care for her medical needs and passed due to disease complications. The daily care provided to this patient probably altered the pregnancy outcomes, despite the severe limitations on uterine growth, pulmonary capacity, and cardiac function. Similar case histories could not be found in the literature for this diagnosis. With improvements in medical care for patients with Morquio type A, management for both routine health and reproductive concerns may be more common, demanding ease of coordinated care.

Prediction of insulin phenotypes from gene expression data by using a mathematical model of the insulin signaling pathway. *G. Sriram[1,2], J.C. Liao[2], K.M. Dipple[1,3].* 1) Human Genetics, David Geffen School of Medicine at UCLA; 2) Chemical Engineering, Henry Samueli School of Engineering and Applied Science at UCLA; 3) Pediatrics, David Geffen School of Medicine at UCLA, Mattel Childrens Hospital at UCLA.

Glycerol kinase deficiency (GKD) is an inborn metabolic disorder that predisposes affected individuals to insulin resistance and diabetes mellitus. (Gaudet et al. Am J Hum Genet 66: 1558, 2000). Our previous microarray studies revealed significantly altered expression of key genes involved in the insulin signaling pathway in glycerol kinase-knockout (Gyk k/o) mice. In this study, we employed a mathematical model of the insulin signaling pathway to quantitatively understand the effects of altered gene expression on insulin sensitivity. A mathematical model of the insulin signaling pathway was developed, based on an earlier model (Sedaghat et al. Am J Physiol Endocrinol Metab 283: E1084, 2002). The model uses gene expression values as inputs, and simulates the translocation of the glucose transporter GLUT4 for a fixed dose of insulin. The extent of GLUT4 translocation is used as a measure of insulin sensitivity. The simulation results indicated that in the brown fat of Gyk k/o mice, the altered level of expression of the genes protein kinase C (PKC, overexpressed 3.0-fold relative to wild type), protein tyrosine phosphatase (PTP, overexpressed 2.8-fold), and phosphatidylinositol-3-kinase (PI3K, underexpressed 2.8-fold) contributed significantly to a reduced GLUT4 translocation. The underexpression of PKC alone contributed to a 33.7% reduction in GLUT4 translocation (for an insulin dose of 10^{-7} M for 15 min). Together, the altered expression levels of PKC, PTP and PI3K contributed to a 44.9% reduction in GLUT4 translocation (for the same insulin dose). In conclusion, mathematical modeling studies reported here quantitatively demonstrate that altered expression of genes in the insulin signaling pathway in Gyk k/o mice predict decreased insulin sensitivity in the animals. Further analysis of gene expression data in other tissues will facilitate an improved understanding of the role GKD in insulin resistance and diabetes.

Glycerol kinase deficiency alters gene expression of genes involved in fat and carbohydrate metabolism and insulin signaling. *L. Rahib[1], N.K. MacLennan[2], S. Horvath[3,4], K.M. Dipple[1,2,3].* 1) Biomedical Engineering, UCLA, Los Angeles, CA; 2) Pediatrics, UCLA, Los Angeles, CA; 3) Human Genetics, UCLA, Los Angeles, CA; 4) Biostatistics, UCLA, Los Angeles, CA.

Glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism at the interface of glucose and fat metabolism. Individuals with a glycerol kinase (GK) mutation, N288D, are at risk for insulin resistance and diabetes mellitus (Gaudet et al., Am J Hum Genet 66:1558, 2000). Thiazolidinediones treat type 2 diabetes by inducing GK expression in adipocytes (Guan et al., Nat Med 8:1122, 2002). The purpose of this study was to evaluate the levels of expression of genes involved in carbohydrate and fat metabolism as well as insulin signaling in a glycerol kinase (Gyk) knock out (ko) mouse model. Total RNA was extracted from brown fat from three day old Gyk ko and wildtype (wt) male mice. Microarray analysis determined that there were 668 genes that were differentially expressed (1.5 fold) between ko and wt mice. This included 28 genes involved in lipid metabolism and 12 genes involved in carbohydrate metabolism. Nineteen genes involved in the insulin signaling pathway were altered in the Gyk ko male. Real Time-PCR confirmed the down-regulation of genes involved in lipid and carbohydrate metabolism including Gyk, glycogen synthase 2, alpha-N-acetylglucosaminidase, and galactose-4-epimerase as well as the upregulation of sphingosine phosphate, lipin 1, sulfotransferase family 1A, phenol-preferring member 1, and flavin containing monooxygenase 1. Genes involved in insulin signaling and insulin resistance that were downregulated and confirmed were insulin-like growth factor 1, fatty acid synthase, Jun oncogene, mitogen-activated protein kinase 6, and eukaryotic translation initiation factor 4E. The upregulation of leptin, sterol regulatory element binding factor 2, mitogen-activated protein kinase kinase kinase 6, and CCAAT/enhancer binding protein delta was confirmed. Further investigations of these genes may provide insight into the role of GK in insulin signaling, insulin resistance and type 2 diabetes mellitus.

Congenital disorder of glycosylation type 1a in Malaysia. *M. Thong, S. Chow, J. Lee, O. Asma.* Dept Pediatrics, Univ Malaya Medical Ctr, 59100 Kuala Lumpur, Malaysia.

Reports of congenital disorders of glycosylation (CDG) are uncommon in Asian populations. We report a one-day-old Malay baby girl who was referred for dysmorphic features. The parents were second cousins with no significant family history of note. The antenatal period was uneventful and she was delivered at term via Caesarean section with a birth weight of 3.6 kg. She was found to have bilateral inverted nipples, abnormal fat distribution over her thighs, buttocks and suprapubic regions, a flat nasal bridge and prominent nares. The rest of the examination was unremarkable. Investigations showed cerebellar hypoplasia on the the cranial MRI. Chest radiograph showed cardiomegaly while the echocardiogram showed pericardial effusion. The serum transferrin isoform pattern analysis showed elevated levels of the disilo-transferrin isoform and trace levels of the asialo-transferrin isoform seen in congenital disorder of glycosylation type 1. These fractions were not seen in the normal control samples. Enzyme testing of peripheral leucocytes showed decreased level of phosphomannomutase 0.6 nmol/min/mg protein (normal 3.6-9.0) and normal level of phosphomannose isomerase 19 nmol/min/mg protein (normal 12 - 15) confirming the diagnosis of CDG type 1a. Further investigations showed impaired coagulation, hypothyroidism and persistent hypoalbuminemia. She presented with recurrent episodes of acute respiratory distress as a result of the severe pericardial effusion. In view of the impaired coagulopathy, she was transfused with fresh frozen plasma before pericardiocentesis could be performed. This procedure was repeated several times over the course of 3 months. She finally succumbed to her illness at the age of 7 months. To the best of our knowledge, this is the first confirmed case report of CDG type 1a in Malaysia. To achieve an early clinical diagnosis requires a high index of suspicion. Early investigations helped to detect most of the the major complications related to CDG type 1a. Despite her early demise, the diagnosis brought comfort to the couple as prenatal diagnosis will be possible for their future pregnancies.

Recombinant Glucocerebrosidase uptake by human osteoblasts. *M.C Sa Miranda[2], M. Lamghari[1], C.C Barrias[1], M.A Barbosa[1].* 1) INEB-Instituto de Engenharia Biomédica, Laboratório de Biomateriais, Rua Campo Alegre 823, 4150-180 Porto, Portugal; 2) Unidade De Biologia de Lisossoma e Peroxisoma (UNILIPE), Instituto de Biologia Molecular e Celular (IBMC), Rua Campo Alegre 823, 4150-180 Porto, Portugal.

Gaucher Disease (GD) is an inherited disease, characterized by the deficient activity of the lysosomal enzyme glucocerebrosidase (GCR). This enzyme deficiency results in defective hydrolysis of glucosylceramide, which accumulates within lysosomes from macrophages, originating the so-called Gaucher cells. Considering the non-neuronopathic form of GD (type1), skeletal manifestations are among the most debilitating consequences, and nearly all affected patients have some degree of bone involvement. Enzyme replacement therapy (ERT) has been successful in treating many symptoms of type I GD but skeletal response lags behind. The lower response of bone to ERT could be the consequence of an inaccessibility of target lipid-engorged macrophages (Gaucher Cells) in bone compartments to circulating enzyme because of the loss of enzyme activity, short enzyme half life and may be enzyme internalisation by non-targeted cells within the bone compartment namely osteoblasts. To investigate whether osteoblasts cells are able to internalize the recombinant glucocerebrosidase (rGCR, cerezyme), we have used GCR inactivated MG63 human osteoblast. rGCR uptake by these cells was examined using 125I radiolabelling, western blot analysis and measurement of GCR activity. The data show that 1.78 % of administrated rGCR was internalized by depleted GCR human osteoblasts. 67.9% of internalized enzyme was detected in cell extract and 14.2% in cell membranes. Western blot analysis showed that the amount of GCR mature form was increased following the administrations of rGCR. With regards to the restored residual activity, the measurement of GCR activity showed that rGCR treated cells present 23.9% of control cells GCR activity. In conclusion, these data suggest that osteoblasts are able to internalize rGCR. Keywords: Glucocerebrosidase, Osteoblasts, Gaucher Disease, Enzyme Replacement Therapy, Lysosomal Diseases.

Screening for Pompe Disease - A comparative study between the lymphocyte and dried blood-based assays. *Z.J. Lukacs[1], M. Deschauer[2], E. Mengel[3], R. Hartung[3], M. Beck[3], A. Keil[1].* 1) Department of Clinical Chemist, Hamburg University Medical Center, Germany; 2) University Halle-Wittenberg, Department of Neurology, Germany; 3) University Hospital Mainz, Department of Pediatrics, Germany.

Pompe Disease is an autosomal recessive disorder which results in deficiency of acid alpha-glucosidase. Early onset of the disorder is often misdiagnosed. As enzyme replacement therapy has been shown to be effective, neonatal screening for this disorder may significantly ameliorate the outcome. However, enzymatic diagnosis is hampered by the presence of several isoenzymes of which the neutrophil enzyme maltase-glucoamylase (MGA) shows a significant overlap in activity within the acidic pH range. Therefore, accurate measurement of enzymatic activity was usually done from fibroblasts and lymphocytes which are not useful for neonatal screening. Recently, Chamoles et al. described a method for the inhibition of MGA in dried blood spots (DBS). To allow an evaluation of its positive predictive value we compared results from the well-established lymphocyte assay with the DBS assay. Samples were taken from patients with confirmed Pompe disease. Lymphocytes were incubated with an methylumbelliferyl-substrate at different pH. Neglible activity was found for all patients in the acidic range while normal activity was measured at neutral pH. DBS were eluted, and aliquots were measured at pH 3.8 and pH 7.0. In addition, maltose was used as an inhibitor. More recently, acarbose, a potent mechanism-based alpha-glucosidase inhibitor, was used to inhibit non-specific enzyme activity. Direct comparison of 40 samples showed a significant increase in inhibition when acarbose was used thereby, facilitating the identification of positive samples. Furthermore, all of our Pompe patients (currently: 10) showed a significantly increased pH ratio(> 1000; normal range 200-1000) while at the same time the activity at pH 3.8 using acarbose was reduced (patients mean: 0.02 nmol/spot; normal range > 0.09 nmol/spot). In summary, we were able to demonstrate that the novel DBS assay compares well in its diagnostic value with the lymphocyte assay and therefore, may be further evaluated within a pilot study in newborn screening.

Mitochondrial translation deficiency associated with intrauterine growth retardation and neurological deterioration. *V. SERRE, I. VALNOT, D. CHRETIEN, J. CHEBATH, A. MUNNICH, A. ROTIG.* INSERM U393, Paris, France.

Multiple respiratory chain deficiency represents a frequent and often unexplained cause of mitochondrial disorders. Among them, mitochondrial translation deficiency has been seldom described. We report here a generalized mitochondrial translation defect in a patient, born to consanguineous parents, presenting with severe intrauterine and post natal growth retardation. Permanent hyperlactatemia, hyperketonemia and normal plasma growth hormone were noted. A psychomotor retardation was apparent at two years. His neurological condition progressively worsened and he died at three years of age. Respiratory chain analysis revealed a severe combined complex I and IV deficiency in muscle and liver. Cultured skin fibroblasts and leukocytes detected a partial complex IV deficiency. Prenatal diagnosis was performed during the next pregnancy and detected a complex I and IV deficiency in the two fetus-twins and pregnancies were discontinued. The following fetus displayed normal respiratory chain activities, the pregnancy was continued and a healthy baby was born. A genome wide search allowed us to identify one chromosomal region of homozygosity on chromosome 17q25.1-qter (D17S1352-ter), possibly containing the disease-causing gene. This region (6.1 Mb) encompasses 171 genes including three genes encoding mitochondrial ribosomal proteins, namely MRPS7, MRPL38 and MRPL12. Western blot analysis was performed on total protein extracts from patient and controls fibroblasts. Immunodetection using the Total OXPHOS Complexes Detection Kit from MitoSciences showed low level of ND6 and COXII (mitochondrially encoded complex I and IV subunits) as well as core 2 and F1 (nuclearly encoded complex III and V subunits) compared to controls. The amount of SDHB subunit of complex II (the only complex entirely encoded by nuclear genes) was normal. These results are highly suggestive of a generalized mitochondrial translation defect in this pedigree. MRPS7, MRPL38 and MRPL12 are now under investigation.

A spectrum of molecular variation of the FM03 gene, in a cohort of Italian families with trimethylaminuria: novel mutations, genotype-phenotype correlation and aplotype analysis. *T. Esposito[1], C. Lombardi[2], G. Scarano[2], S. Musumeci[3], F. Lonardo[2], A. Fiumara[4], F. Gianfrancesco[1].* 1) Institute of Food Science, CNR, Avellino, Italy; 2) Division of Medical Genetics, Benevento, Italy; 3) Institute of Population Genetics, CNR, Alghero, Italy; 4) Department of Pediatrics, University of Catania, Italy.

Fish-odor syndrome or trimethylaminuria (TMAU) is a rare inborn error of metabolism inherited in an autosomal recessive fashion that is caused by deficiency of the flavin-containing monooxygenase 3 (FMO3), required for oxidize malodorous trimethylamine (TMA) into odorless trimethylamine N-oxyde (TMAO). Individuals affected with TMAU display a strong, unpleasant, fish-like odour, due to the secretion of TMA in their breath, sweat and urine. This leads to a variety of psychosocial problems, including disruption of schooling, clinical depression, and attempted suicide. We have collected a cohort of Italian families with symptoms of TMAU containing a number of affected individuals with marked reduction of TMA oxidation and other individuals with a borderline decreased TMA oxidation. We have investigated the genetic basis of the disorder detecting a spectrum of molecular variation in the FM03 gene comprising three novel deleterious mutations and a number of previously reported mutations. The first novel mutation was a missense (I37T) that was not found in the parents, revealing that it was a de novo missense mutation. This is the first report of de novo missense mutation causative of TMAU. The second, was a single nucleotide deletion of G1182 at codon 394 that result in a frame shift and cause premature termination of the FMO3 gene after codon 404. The thirth novel mutation, (R238P) was identified in a 10-year-old boy who presented a strong body odor from the age of 10 months. Moreover, we investigated by aplotype analysis a family with mild TMAU identifying a putative causative aplotype. Finally, we failed to detect any variation in other families. Our findings support the hypothesis that TMAU is not a rare recessive disorder but rather a spectrum of phenotypes in which diet and environmental exposures can play a role in triggering symptoms.

Galactosemia in Ashkenazi Jewish Due to Galactose-1-Phosphate Uridyl Transferase Gene deletion. *K. Muralidharan, B.W. Coffee, A. DeLorenzo, E.M. Courtney, L.N. Hjelm, C. Yu.* Dept Human Genetics, Emory Univ Sch Medicine, Decatur, GA.

Galactosemia is a common biochemical disorder caused by Galactose-1-Phosphate Uridyl Transferase (GALT) deficiency. Over 300 pathogenic variants have been reported in GALT gene. Most of these variants are rare and limited to one or few families. Some variants such as Q188R and N314D are common and have been reported in many populations. Certain variants however, appear to be common or limited to certain ethnic groups. For example S135L is the most common G allele in African Americans and L195P and Y209C appear to be limited to Caucasians. We have previously reported a large deletion of GALT gene detectable by Southern analysis in Ashkenazi Jewish galactosemia patients. This 5 kb deletion appears to involves the entire GALT gene and results in absence of GALT mRNA and protein. Lymphoblasts from patients homozygous for this deletion showed evidence of alternate pathways for galactose metabolism. Carriers for this deletion appear as homozygotes for the genotype of the other allele present in the patient. This can result in apparent discord between GALT biochemical phenotype and molecular genotype in patients apart from inconsistencies in familial studies. Molecular characterization of the rearrangement causing the deletion is reported here. A series of PCR reactions targeting the GALT gene and the flanking regions was performed using DNA from deletion homozygotes and normal individuals. This analysis identified the regions outside the GALT deletion in the patients. Using this information, the junction fragment was amplified by PCR and sequenced. This reveals a complex rearrangement involving a two part deletion involving the entire GALT gene except a part of exon 8-intron 8 and the insertion of a novel 14 bp sequence. This finding provides simplified testing for this variant and enables further studies on the origin and frequency of this variant in Ashkenazi Jewish galactosemia patients.

High prevalence of Fabry disease in young stroke patients. *A. Rolfs[1], T. Boettcher[1], P. Bauer[3], B. Winchester[2], M. Wittstock[1], J. Pahnke[1], R. Benecke[1].* 1) Dept Neurology, Univ Rostock, Rostock MV, Germany; 2) Institute of Child Health and Great Ormond Street Hospital for Children NHS Trust, University College London, Great Britain; 3) Department of Medical Genetics, University of Tübingen, Germany.

Fabry disease (FD) is an X-linked recessive lysosomal storage disease resulting from deficient alpha-galactosidase (AGAL) and causes an endothelial vasculopathy followed cerebral ischemia. To determine the significance of FD in the young with stroke, the frequency of unrecognized patients with Fabry disease in a cohort with of acute stroke patients was determined. Between 2001 and 2004 from 27 different clinical departments in Germany 534 consecutive, unselected German young adults aged 18 to 55 years and suffering from acute stroke were screened with informed consent for Fabry disease. In males their plasma AGAL activities was measured following by sequencing the entire AGAL gene in case of low enzyme activity. In contrast, in females the entire AGAL gene was genetically screened for mutations even if the enzyme activity was normal. Complete medical information from 478 patients (89.5%) has been sent to the investigators. 15 out 319 males stroke patients and 4 out of 215 females revealed a mutation within the AGAL gene which corresponds to a prevalence of 4.7%; and 1.8%, resp. Mean age at onset of symptomatic cerebrovascular disease is 39.6 13.4 years in the group of the male stroke patients and 42.7 14.2 years in the female group. The higher frequency of infarctions in the vertebrobasilar area correlates with more pronounced changes in the vertebrobasilar vessels like dolichoectatic pathology (33.3% vs. 5.9%). Regarding the non-neurological features male Fabry patients with stroke demonstrate a significant higher frequency of acroparesthesia, hypohidrosis and proteinuria than non-Fabry stroke patients. FD accounts for up to 5% of young males aged 18 to 55 years with stroke and about 2% in females, respectively. Fabry disease must be considered in all cases of unexplained stroke in young patients, especially in cases with the combination of infarction in the vertebrobasilar artery system and proteinuria.

DNA-Bionanosensor: Applicability to Neonatal Screening of Hemoglobinopathies. *U. Bhardwaj[1], V. Gau[2], E.R.B. McCabe[1,3,4,5].* 1) Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 2) GeneFluidics, Inc., Monteray Park, CA, 91754; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 4) Mattel Children's Hospital at UCLA, Los Angeles, CA 90095; 5) Molecular Biology Institute, UCLA, Los Angeles, CA 90095.

The primary aim of neonatal screening for the hemoglobinopathies is to identify newborns with sickle cell disease (SCD) so that penicillin prophylaxis and comprehensive care can be commenced preferably before the age of two months. In the United States, most of the neonatal screening laboratories use high performance liquid chromatography (HPLC) or isoelectic focusing as the primary method for neonatal hemoglobinopathy screening. Bionanotechnology is suitable for automated, high throughput screening because it allows for movements of small amounts of fluids and therefore requires a minimal sample volume. For this purpose, we evaluated a novel bionanotechnology-based platform to identify the single base-pair mismatch that causes sickle cell disease. An amperometric system utilizing hybridization to detect PCR amplified products from wild type (AA), sickle cell disease (SS) and sickle cell carrier (AS) samples. The amperometric signal from samples with sickle cell disease and heterozygous carriers was reproducibly distinguished from wild type samples. A minimum level of baseline noise was achieved with the system. We conclude that bionanotechnology represents a sensitive method to identify patients with sickle cell disease as well as carriers using PCR amplified DNA from newborn screening dried blood specimens. We speculate that with automation, this amperometric platform provides the opportunity for high-volume, cost-effective universal screening of hemoglobinopathies. We are working to improve the sensitivity of this platform to accommodate unamplified genomic DNA from newborn screening specimens.

High-throughput and comprehensive CHIP-based resequencing of the mitochondrial DNA in patients with OXPHOS disease. *H. Smeets[1,2], M. Gerards[1], A. Hendrickx[2], R. Van Eijsden[1], I. De Coo[3], P. Lindsey[1].* 1) Genetics & Cell Biology/GROW, Maastricht University, Maastricht, Netherlands; 2) Clinical Genetics, Academic Hospital Maastricht, Maastricht, The Netherlands; 3) Neurology, Erasmus University Medical Center Rotterdam, Netherlands.

Mitochondrial disorders are often fatal multisystem disorders, associated with abnormalities of oxidative phosphorylation (OXPHOS). Because of its dual genetic control, defects in OXPHOS can be due to mutations in either the mitochondrial (mtDNA) or nuclear DNA. Although OXPHOS disorders have common characteristics as a group, there is considerable clinical variability among patients, even in those having the same genetic defect. Also, clinically indiscernible conditions can be caused by different mutations in a number of genes and it is often not possible to directly identify the genetic defect involved. Therefore, we applied a new CHIP-based platform suitable for rapid resequencing of the mtDNA. Up to now 30 chips have been processed in different experiments. CHIPs were analysed using both the Affymetrix GDAS software and the statistic analysis software R. We found a complete match with classical resequencing in 3 samples. Two samples were mixed to generate artificially heteroplasmy at 11 positions in the mtDNA sequence. Ten were detectable as such and one gave a no-call. Analysis of mixed amounts of different mtDNAs indicated that it should be possible to quantify a mutation load of 10% (n=3). Although the platform is not optimal for the detection of small deletions or insertions, we were able to identify two samples with a single nucleotide insertion as a heterozygote call. Screening of 20 patients suspected for mitochondrial disease revealed 171 different mutations: 90 SNPs, 5 known pathogenic mutations and 71 unknown variants (5 of which were heteroplasmic). Our conclusion is that the resequencing CHIPs are a very promising tool for rapid and comprehensive mtDNA-screening. Especially for genomes like the mtDNA, where it is possible to generate the template with a single PCR, and in which the vast majority of the point mutations are nucleotide substitutions, it will become the method of choice.

Functional characterization of mutant ATP7B identified in Korean patients with Wilson disease. *S. Park[1], G. Kim[1,2], J. Lee[2], H. Yoo[1,2].* 1) Genome Research Ctr, Asan Medical Ctr, Seoul, Korea; 2) Medical Genetics Clinic & Laboratory, Asan Medical Ctr, Seoul, Korea.

Wilson disease (WND), an autosomal recessive disorder of copper transport, is characterized by excessive accumulation of intracellular copper in the liver and extrahepatic tissues. The mutation screening of ATP7B was performed in Korean patients with WND and ten novel mutations were identified. In order to evaluate the functional defects of ATP7B protein caused by novel mutations, we used the yeast complementation assay system and confocal microscopic evaluation for analyzing the localization of mutants after transient expression in mammalian cell system. Five novel mutations, p.C656X, p.G891D, p.V1106I, p.T1029I, and p.T1031A were constructed into the yeast expression vector, pSY114 and the mammalian expression vector, pEGFPC1. Three novel mutant constructs, p.C656X, T.1029I, and p.T1031A, were unable to rescue the ccc2 mutant yeast due to the reduced affinity of iron uptake in the yeast complementation system, indicating their defective ATP7B protein functions. The novel mutation found in a patient with less severe symptom, p.G891D construct partially restored ccc2 mutant yeast. A p.V1106I construct completely restored as wild type, which suggested p.V1106I was not a mutation but a polymorphism. In the trafficking analysis of the mutant ATP7B with confocal microscope, mutant p.C656X was scattered throughout transfected COS7 cells. A mutant p.G891D was partially localized to the site of the trans-Golgi network. Two mutants, p.T1029I and p.T1031A were predominantly mislocalized to perinuclear regions. A mutant p.V1106I was normally targeted to the trans-Golgi network, which was concordant with the result in the yeast complementation system. In conclusion, yeast complementation assay and confocal microscopic evaluation are useful tools for functional study on mutant ATP7B protein.

Mutational Analysis of GTP cyclohydrolase I gene in the Dopa responsive dystonia. *X. Liu, J. Ye, Y. Zhang.* Dept Pediatrics, Xinhua Hosp, Shanghai, China.

Objective Dopa responsive dystonia (DRD) is a childhood onset dystonia which responds to levodopa. Mutations in the GTP cyclohydrolase I (GCH 1) gene were recently identified in number of patients with DRD. The aim of the present study was to determine the correlations between clinical expression and the mutations in the GCH-1 gene. Methods The 6 exons and exon-intron junctions of GCH-1 gene were sequenced in 9 DRD patients from 7 no kinship family by using PCR and DNA sequence analysis. The age at onset ranged from 6 years to 14 years old. Five patients were male and 4 patients were female. Results Eight of nine patients presented with dystonia and parkinsonian, which responed to levodopa. IVS5+3insT mutation was identified in 3 patients (2 female , 1 male) from one family, originated from their mother. One (male, 5 years old) of them was asymptomatic. IVS4+121(c-t) was identified in one patient. The exons and exon-intron junctions of GCH-1 gene mutations were not identified in the rest of patients. Conclusion The mutations in GCH 1 gene were only identified in 2 of 7 DRD patient's families.

DHPLC mutation analysis of Phenylketonuria in large multi-origin population. *Y. Anikster[1], A. Elimelech[2], T. YardenI[2], S. Korem[2], G. Schwartz[1], H. Gore[2], O. Vais[2], D. Bercovich[1,3].* 1) Metabolic Disease Unit, Safra Children's Hosp, Tel-Hashomer Rama, Israel; 2) Migal - Galilee Bio-Technology Center Kiryat-Shmona,Israel; 3) Tel Hai Academic College, Israel.

The object of this research was to define the epidemiology and mutations of PAH gene (and their prevalence) that cause phenylketonuria (PKU) in different ethnic groups among the Israeli population. At the PKU center in the Metabolic Disease Unit, at Safra Children's Hospital, Sheba Medical Center, there are 450 PKU patients in treatment and follow-up, which come from 200 different families with known ethnic origin. DNA samples were collected from 174 families and mutations screening were performed using the new DHPLC technique and sequencing the DNA alterations for characterization of the mutations. Until now, all the prenatal diagnosis for the PAH gene was done by RFLP and not by specific mutation. The last study on this subject had been preformed in the late 1980's and early 1990's (up to 1992) and then a common mutation was found among Jews from Yemen, which is a deletion of part of the gene around exon-3. Since then many new patients have been added, some of them of ethnic groups whose mutations have never been characterized. In screening the 13 coding Exons of the PAH gene, we found 4 new mutations and characterize the four most common mutations (IVS10 -11G/A /N -13.59%, A300S /N -12.06%, A403V /N -9.7%, R408W /N -7.76%). About 10% of the patients were homozygous for missence mutations and 40% of the patients were found to be compound heterozygous, some with more then two mutations alleles as results from intermarried and match making. In this study we report the successful use of DHPLC to analyze rapidly the complete coding sequence of the PAH gene in a total of 174 patients from different origin. This study enables us to estimate the prevalence of the disease and the design of prenatal diagnostic tests for this disease targeted specifically to different population groups.

Molecular analysis in MPS IIID: report of two novel mutations. *C. Beesley[1], D. Concolino[2], A. Piccirillo[2], M.T. Moricca[2], B. Winchester[1], P. Strisciuglio[2].* 1) Biochemistry,, Institute of Child Health, University College London, London; 2) Department of Pediatrics, University "Magna Graecia" of Catanzaro, Catanzaro, Italy.

The Mucopolysaccharidoses (MPS) are a family of lysosomal storage diseases caused by deficiencies of enzymes required for degradation of glycosaminoglycans (GAGs). The MPS III subfamily comprises four different groups, from MPS III A to MPS III D. The latter is the rarest of the four and is caused by a deficiency of N-acetylglucosamine-6-sulfatase (GNS), which is required for the degradation of heparan sulphate. The main clinical aspects are mental retardation with relatively mild somatic involvement and mild bone dysostosis. To date, only two mutations (R355X,1169delA) have been identified, both predicting premature termination of the protein. We present the clinical, biochemical, and molecular data of two families with MPS III D: the first family included two brothers, born from unrelated parents, with mental retardation, aggressive behaviour, macrocephaly, mild coarse face, corneal opacity and a mild degree of dysostosis multiplex. In the second family there is only one patient, with the same phenotype. The diagnosis of MPS III D, in both the families, was confirmed by increased excretion of heparan sulphate in urine and deficiency of GNS activity in skin fibroblasts. Two novel mutations were identified, one in each family. In the first family, molecular analysis of the GNS gene showed that both patients were homozygous for a large intragenic deletion of 8723bp. The deletion includes 3840bp of intron 1, the whole of exon 2, intron 2 and 46bp of exon 3. Both parents are heterozygous for the deletion. In the second family, the affected patient is homozygous for a nonsense mutation in exon 7 (CAA>TAA:Gln>Stop; Q272X). Both parents are heterozygous for the nonsense mutation. Our data showing molecular heterogeneity in our two families with the same phenotype confirms the genetic heterogeneity of MPS III D, as previously described for the other Sanfilippo subtypes.

Complex Glycerol Kinase Deficiency (cGKD): Inversion-Indel Mutation Described By Breakpoint Junction Sequencing. *Y.-H. Zhang[1], B.-L. Huang[1], U. Bhardwaj[1], E.R.B. McCabe[1,2,3,4].* 1) Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA, 90095; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA, 90095; 3) Mattel Children's Hospital at UCLA, Los Angeles, CA, 90095; 4) Molecular Biology Institute, UCLA, Los Angeles, CA 90095.

Complex glycerol kinase deficiency (cGKD), an Xp22-p21 contiguous gene syndrome, involves the GK locus together with the adrenal hypoplasia congenital (AHC) and/or Duchenne muscular dystrophy (DMD) loci. Clinical features of an individual patient with cGKD depend on the loci involved. Although many cGKD patients with deletions in this region have been previously reported and gross alterations in their Xp22-p21 regions have been described, little is known about the genomic mechanisms responsible for these intergenic chromosomal rearrangements. In a previous study of cGKD, we identified eight patients with large genomic deletions in Xp22-p21 and characterized their mutations in detail. The purpose of our current investigation was to sequence the breakpoint junctions of DNA from a patient with cGKD (GKD and AHC phenotype) and a complex chromosomal rearrangement in order to gain insight into potential mechanisms. We used PCR-based genomic walking to identify the locations of the DNA breakpoints. Breakpoint junctions were sequenced (ABI 3730), and analyses performed (NCBI and UCSC browsers). The complex mutational event in this patient involved insertion of 181 bp and deletion of 693.5 kb, associated with inversion of DNA flanked by the indel. The deletion involved complete loss of the *NR0B1* and *GK* genes, consistent with the patients phenotype. The precise mechanism of this mutation remains obscure. However, we speculate that it may involve complex loop formation by interaction of complementary sequences present in the regions of the mutation breakpoints. This mechanism would lead to an inversion associated with an indel.

Elevated Homocysteine and micronuclei as a risk factor for recurrent abortions. *G. Vinukonda[1], R.R Akella[2], K.R prabhakara[2].* 1) Dept Pathology, New York Medical Col, Valhalla, NY; 2) Center for DNA finger printing and Diagnostics,Hyderabad, India.

Human reproduction is a remarkably critical process. A number of possible etiologies have been proposed to explain the occurrence of recurrent pregnancy loss in-patients. Current medical literature suggests that causes are identifiable in only 50% of patients. But still 50 percent of women with recurrent miscarriages remain unexplained through the routine investigations. Recently much attention has been focused on the potential role of hyper-homocystenemia in the etiology of neural tube defect, early and late complications of pregnancy loss. Case-control studies have shown mildly elevated levels of homocysteine to be present in high proportion of women with history of recurrent miscarriages suggesting it is an independent risk factor for recurrent fetal loss. The enzymatic defects involved in homocysteine metabolism and their genotypic associations with recurrent early pregnancy loss are not well studied. In the present study we investigated 68 couples with un-explained recurrent abortions and 40 controls to evaluate the potential role of homocysteine as a risk factor for recurrent pregnancy loss. The study estimates the total homocysteine levels in the plasma using HPLC with florescence detection. Micronuclei frequencies were assessed as marker for chromosomal/DNA damage in cytokinesis-blocked lymphocyte cultures. Further prevalence of MTHFR gene mutation and its association to elevated homocysteine in these case and controls were studied. Of the total group tested in the present study showed significant levels of elevated homocysteine between controls and RA. Of 68 RA females tested for MTHFR genotype, of which 1.4% was TT, 30.8% were CT and 67.6% were wild genotype and there is no record of TT genotype and 20.0% were CT and 80.0% were wild genotype recorded in controls. The genotypic differences between two groups were not statistically significant but it is observed there is increased t-allele frequency in cases than controls. An increased level of micronuclei frequencies was observed in the study group than controls and the differences were statistically significant. In summary the plasma homocysteine levels and micronuclei data supports the potential role in the early pregnancy loss in recurrent abortion cases. Further extension of our observation on the reasons/causative factors for elevated homocysteine, the MTHFR gene mutation alone is not a responsible factor in this group of recurrent abortion cases.

MPS I Registry: Significant disease morbidity is observed in patients with the attenuated form of Mucopolysaccharidosis Type I (MPS I) or Scheie syndrome. *J. Thomas[1], G. Pastores[2].* 1) Dept Pediatrics, Univ Colorado School of Medicine, Castle Rock, CO; 2) NYU School of Medicine, New York, NY.

MPS I is a rare, inherited lysosomal storage disorder that is chronic, progressive, multisystemic, and displays extreme heterogeneity in its clinical presentation and disease progression. Despite the absence of clear clinical definitions, MPS I patients are classified into 3 syndromes: severe, early-onset Hurler (H), intermediate Hurler-Scheie (HS), and attenuated Scheie (S). As of February 2005, the MPS I Registry accrued observational clinical assessment and outcomes data from 237 MPS I patients, of whom 44% were classified as H, 25% HS, and 14% S; 16% were not classified. The median current age for H, HS, and S patients was 5.4 (1, 23.5), 12.3 (1.8, 48.8), and 23.8 (5.6, 64.5) years, respectively. Symptom onset was reported at a median age of 0.4 (0, 6.1), 2.7 (0, 8.2), and 6.6 (0.2, 33.8) years and MPS I diagnosis was established at a median age of 0.8 (0, 6.8), 3.8 (0, 36.1), and 9.9 (1.9, 54.1) years in H, HS, and S patients, respectively. The delay between symptom onset and disease diagnosis was longest and most variable in S patients, ranging from 0 to 39.5 years. Data were collected on 23 symptoms characteristic of MPS I. While the pattern of symptoms reported by S patients was distinct from H and HS patients, several symptoms were reported at similar rates among all patients, including cardiomyopathy, hepatomegaly, hernia, corneal clouding, dysostosis multiplex, scoliosis, and sleep disturbances. No S patients reported cognitive impairment, and the rates of pneumonia, kyphosis, and hearing aid use were much lower in S compared to H patients. However, cardiac valve abnormalities, joint contractures, myelopathy, and congestive heart failure occurred at higher rates in S than H patients. Cor pulmonale was only reported in S patients. We conclude that S patients experience significant morbidity related to MPS I disease and speculate that patients exhibiting S syndrome may be under-diagnosed due to the later emergence and distinct pattern of MPS I symptoms relative to H and HS.

Identification and functional characterization of 10 novel GAA alleles causing the juvenile-adult form of Glycogen Storage Disease type II. *B. Bembi[1], A.L.E. Montalvo[1], M. Filocamo[2], A. Dardis[1], C. Danesino[3], L. Merlini[4], G. Parenti[5], D. Donnarumma[2], G. Ciana[1], M.G. Pittis[1].* 1) Metabolic Diseases Unit, Pediatric Hospital B. Garofolo, Trieste; 2) Diagnosi Pre-Postnatale Malattie Metaboliche, G.Gaslini Institut, Genova; 3) Università di Pavia, Pavia; 4) Istituto Ortopedico Rizzoli, Bologna; 5) Università Federico II, Napoli, Italy.

Glycogen Storage Disease type II (GSDII) is an autosomal recessive disorder in which deficiency of acid alpha glucosidase (GAA) results in impaired glycogen degradation that acuumulates within lysosomes. Clinically, the infantile GSDII form is the most severe subtype characterized by progressive muscle weakness and severe cardiac involvement. In the juvenile form, onset occurs after early infancy and glycogen storage predominates in skeletal muscle, usually without cardiac involvement. The adult form is similar to the juvenile form but residual enzyme activity is higher and miopathy has a slower progression. The GAA is synthesized as an inactive 110 kDa precursor which is transported to the lysosomes where it is processed into the fully active forms of 76 and 70 kDa. More than 120 mutations in the GAA gene have been described up to date (http://www.eur.nl/FGG/CH1/pompe.) We analyzed the GAA gene in 35 unrelated patients affected of juvenile-adult GSDII. Overall, we identified 22 different alleles: 10 of them are due to 12 novel mutations. Three mutations are part of a new complex allele that replaces residues 612 to 616 (HWTGD) with RGI (p.H612_D616delinsRGI). As expected, the IVS1 (-13 T/G) correlated to late onset GSDII, was the most frequent mutation, present in heterozygosis in 30/35 of the patients studied. The mutation GAA profile was characterized by mutations spread all over the sequence, including point mutations, both small and large deletions, small insertions and splicing aberrations. Functional characterization of the novel missense mutations p.A445P, p.D489N and p.H612Q was performed by enzyme assay and Western blot analysis, using a human $GAA^{-/-}$ cell line. p.D489N and p.H612Q mutants remained as the 110kD precursor expressing no enzyme activity, while the p.A445P is not even expressed or rapidly degraded.

Lysosomal disorders in Brazil: results in 26,900 high-risk patients submitted to a screening protocol. *J.C. Coelho, M.G. Burin, K. Michelin, M. Viapiana, R. Guidobono, M. Tsao, J. Mari, T. Barcelos, A. Wajner, R.F. Pires, B. Cardoso, K. Lazzaroni, J. Huve, F.T.S. Souza, M.L. Pereira, S. Leistner-Segal, U. Matte, R. Giugliani.* Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil.

A reference centre for lysosomal storage disorders (LSD) was set up in 1982 in Porto Alegre, South Brazil. Initially the centre provided diagnosis for mucopolysaccharidoses (MPS), and progressively incorporated techniques for the identification of sphyngolipidoses, glycoproteinoses, mucolipidoses, lysosomal transport defects and Pompe disease. Methods for the identification of neuronal lipofuscinoses are presently being standardised. Enzyme diagnosis is provided for most of these diseases and identification of common mutations is also performed in selected cases. Besides patient identification, the centre provides prenatal diagnosis for most LSD and carrier detection for many diseases. Several diagnostic protocols were set up. Until now the biochemical investigation was performed in 26,900 patients and an inborn error of metabolism (IEM) was detected in 2,559 cases (9.5%). The group of IEM with higher incidence in our sample was LSD (63%), followed by aminoacidophathies (18.9%). The LSD most frequently diagnosed were Gaucher disease (471 cases), MPS II (165 cases), GM1 gangliosidosis (135 cases), MPS I (135 cases) and MPS VI (113 cases). The high relative frequency of LSD recommends the formation of regional reference centres to provide diagnosis, prevention and care for the affected families. The combined efforts of physicians (diagnostic suspicion, management), academic services (lab diagnosis, research, education), research agencies (support of projects), pharmaceutical & biotech companies (development of novel therapies, registries, clinical trials), parent associations (diffusion of information, pressure for availability of treatment) and government health agencies (providing access to treatment) is essential to reduce the burden of this important group of diseases (Support: GPPG/HCPA, PROPESQ/UFRGS, FAPERGS, CNPq, CAPES, PRONEX/MCT, NORD, TKT, BioMarin, Genzyme).

Measurement of galactosamine and glucosamine in hydrolyzed urine as an aid to the diagnosis of Mucopolysaccharidoses. *P.A. Levy.* Department of Pediatrics, Children's Hospital at Montefiore, AlbertEinstein College of Medicine, Bronx, NY.

Intro: Mucopolysaccharidoses (MPS) are a group of lysosomal disorders characterized by excretion of glycosaminoglycans (GAGs) in urine. Patients suspected clinically of having a MPS generally have urine sent for an MPS spot test as a first step toward diagnosis. This test qualitatively detects the presence of GAGs, but may not detect all MPS patients. Other methods (dimethylene blue and carbaozole) measure the presence of abnormal quantities of glycosaminoglycans but do not identify the elevated component(s). Most labs then do TLC or electrophoresis that is able to detect the component GAGs (Dermatan sulfate, Heparin sulfate,etc). GAGs are polymers of either galactosamine,or glucosamine and glucuronic acid. If urine precipitated with CPC was subjected to acid hydrolysis, levels of galactosamine and glucosamine which are ninhydrin positive compounds would be detectable by an amino acid analyzer. For example, a patient with MPS VI would have elevated levels of dermatan sulfate (N-acetyl-galactosamine and iduronic acid). Acid hydrolysis should yield elevations of galactosamine. Methods: Samples were obtained from 5 controls, 3 MPS VI patients, also urine from previous testing was available from 2 MPS II patients as well as 1 MPS III patient. Urine was precipitated with CPC overnight. Acid hydrolysis was done with 4N HCl for 3 hours. A Beckman 6300 amino acid analyzer was used to detect the ninhydrin positive compounds. Results: Normal controls had low levels of both galactosamine and glucosamine. MPS VI patients had marked elevation of galactosamine. MPS II patients had elevations of both galactosamine and glucosamine. The one MPS III patient had expected increased levels of glucosamine, but in the range of controls. Ratios of Galactosamine to glucosamine were less than 1 for the controls and the 1 MPS III patient. MPS II patients were intermediate with a ratio of 2 to 4 and the MPS VI patients had a ratio greater than 13. It may be possible to detect and diagnose many of the MPS disorders by measuring levels of glucosamine and galactosamine in urine.

Diagnosis of Pompe Disease by Enzyme Assay in Dried Blood Spots. *H.K.W. Kallwass, C.L. Carr, J. Keutzer.* Genzyme Corp., Framingham, MA.

INTRODUCTION. The enzymatic defect in Pompe disease is a deficiency of lysosomal acid -glucosidase (GAA) which leads to lysosomal glycogen accumulation. GAA quantitation in whole blood is problematic due to several -glucosidase isoenzymes. Maltase-glucoamylase (MGA) is of particular concern due to its low pH optimum. Current diagnostic methods circumvent this problem by using MGA-free specimens such as muscle biopsies, cultured fibroblasts or lymphocytes. These methods are invasive, slow or technically demanding. Dried blood spots on filter paper (DBS) have been used to assay many enzymes for the diagnosis of lysosomal storage diseases. Advantages of DBS are noninvasive collection, excellent enzyme stability and low laboratory costs. Here we present -glucosidase assays in DBS for rapid and highly reliable Pompe disease diagnosis. **METHODS**. MGA interference was reduced with the competing substrate maltose in an assay with 4-methylumbelliferyl--glucoside (4-MUG) (Clin. Chim. Acta 2004, v347, p97). We examined 12 infantile and 58 late-onset Pompe DBS in this assay versus a control group of 120 normal adults. Acarbose is a potent -glucosidase inhibitor with remarkable selectivity for MGA vs. GAA (Clin. Chem. 2004, v50 p1785). We developed a novel fluorescent assay protocol with 4-MUG as substrate and acarbose as inhibitor. Eighty Pompe patient DBS (58 adult and 22 infantile) were compared to 150 normal controls. The acarbose protocol was further qualified with specimens contributed by several labs worldwide. **RESULTS**. All Pompe patients were correctly identified. With the novel and superior acarbose assay we detected 4 patients who were previously misdiagnosed using conventional methods. No mutations were found in the 4 individuals by DNA sequencing of the GAA gene. **CONCLUSIONS**. With enzyme replacement therapy in the final stages of clinical development it will be crucial to diagnose infantile Pompe patients rapidly to reduce the time to start of treatment. The assays presented here will make that possible anywhere in the world. The first GAA activity study on a large cohort of late-onset patients demonstrates that this robust and cost efficient Pompe test is also well suited for diagnosing the late-onset form of the disease.

Gaucher disease: Global gene expression profiles and the progression of pro- and anti-inflammatory pathways in mouse models. *Y. Xu, L. Jia, B. Quinn, G.A. Grabowski.* Dept Pediatrics, Div Human Gen, Children's Hosp Medical Ctr, Cincinnati, OH.

Gaucher disease (GD) is caused by defective hydrolysis of glucosyl ceramide (GC), the penultimate metabolite in the glycosphingolipid degradative pathway. The resultant accumulation of GC leads to broad functional impairments in multiple organs, but the pathogenic pathway is obscure. The presence of lipid-storage macrophages (Gaucher cells) in visceral organs is a hallmark feature of GD. To understand the molecular pathogenesis of GD, developmental global gene expression was examined by microarray analyses of total mRNAs from lung, liver, and spleen of glucocerebrosidase (GCase) point-mutated V394L/V394L (4L) and D409V/null (9V/null) mice and wild-type age-matched controls. Duplicate pooled mRNAs from three mice were analyzed using the MOE430 Affymatrix chip and ~9.5 to 17.4 % of genes showed altered expression patterns. These genes represented those of macrophage activation, signal transduction, cell adhesion, extracellular matrix protein, proteinase, transcription factor, ion transport, metabolic enzymes, and membrane proteins. Macrophage pro- (17) and anti-inflammatory (14) cytokine/mediator genes were differentially altered (>1.8-fold) in the lung, liver, or spleen of GCase 9V/null or 4L mutant mice. Progressive alterations of the INF-gamma and IL-4 pathways were similar, but to different degrees, in visceral tissues from 4L and 9V/null mice. Real-time RT-PCR, RNA dot blotting, and immunohistochemistry studies verified the altered gene expression patterns. Histopathologic analyses showed correlations of the degree of tissue/GC alterations and the gene expression profiles. These analyses implicate IFN-gamma pro-inflammatory and IL-4 anti-inflammatory networks in the temporal and differential tissue progression in GD. The disease courses and the final pathophysiology may be related to the interaction and balance of the IFN-gamma and IL-4 regulated networks.

Phenotypic heterogeneity in type 1 Gaucher disease: A comparison between Brazil and the rest of the world. *R.F. Pires[1], E. Sobreira[2], G.A. Grabowski[3].* 1) Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil; 2) FCM Santa Casa de São Paulo, São Paulo, SP, Brazil; 3) FCM Santa Casa de São Paulo, São Paulo, SP, Brazil; 3) Childrens Hospital Research Foundation, Cincinnati, OH.

Gaucher disease (GD), the most common lysosomal storage disorder, results from dysfunction of glucocerebrosidase. GD type 1 is characterized by marked phenotypic variation in age of onset and degree of hepatosplenomegaly, bony disease, and lung involvement. Most data on GD comes from the USA, Europe, and Israel, where the largest proportion of affected patients are of Ashkenazi Jewish descent. However, GD type 1 is pan-ethnic and the non-Ashkenazic variants require more thorough characterization. In 2001, Brazilian physicians began participating in the International Collaborative Gaucher Group Gaucher Registry. As of October 2004, the Gaucher Registry included demographic and longitudinal data from 3045 patients with GD type 1; 196 were from Brazil. We compared selected demographic, clinical, and genetic parameters in Brazilian GD type 1 patients with those from the entire GD type 1 cohort from the rest of the world (ROW). Overall, Brazilian GD type 1 patients were younger (<18 yrs) (65% vs 52%, p = 0.0002), included more females (67% vs 53%, p=0.0001), had more baseline anemia (57% vs 30%, p <0.0001), and had more bone pain (57% vs 36%, p=0.0004) and bone crises (19% vs 8%, p = 0.003). Fewer Brazilian patients reported Ashkenazi Jewish ethnicity (0.5% vs 39%, p <0.0001). Genotype data were available for 59% of Brazilian and 72% of ROW GD type 1 patients. In Brazil, the most common genotype was N370S/L444P (50% vs 15% in ROW, p<0.0001), whereas in ROW, N370S/N370S was the most common genotype (37% vs 7% in Brazil, p<0.0001). In Brazil, 60% of patients had at least one L444P allele vs 21% in ROW (p<0.0001). These data highlight the variation in phenotypic manifestations of GD type 1 and indicate that as a group these Brazilian GD type 1 patients have more aggressive disease than ROW patients. The findings also emphasize the need to more fully delineate GD type 1 in various groups and the need for caution in making generalizations about this disease across different demographic groups.

Fabry Disease: Characterization of -Galactosidase A Signal Peptide Mutations. *M. McCarthy, M. Yasuda, R.J. Desnick.* Department of Human Genetics, Mount Sinai School of Medicine, New York, NY.

Fabry disease is an X-linked recessive inborn error of glycosphingolipid catabolism resulting from the deficient activity of the lysosomal exoglycohydrolase, -galactosidase A (-Gal A). The structure of the 31 amino acid signal peptide of the -Gal A glycopeptide is consistent with that of the general signal peptide motif, having one basic amino acid within the first five, a hydrophobic core of >9 residues, an -helix breaker positioned between -4 and -8, and small neutral residues at positions -1 and -3. To date, eight -Gal A signal peptide mutations have been reported in patients with Fabry disease. M1I, M1R, and M1T mutated the initial Methionine residue, while L14P, A15E, L19R, and A20P occurred in the hydrophobic domain. A31V disrupted the -1 residue, which is important for proper signal peptide cleavage. Of note, the A20P mutation was identified in a patient with the cardiac variant phenotype, while the remaining mutations occurred in classically affected males. To characterize these signal peptide mutations, mutant constructs were generated using site-directed mutagenesis and overexpressed in COS-7 cells. The mutant proteins of M1I, M1R, M1T, L14P, A15E, and L19R had negligible -Gal A activity, and were not detectable by western blotting or immunofluorescence staining. In contrast, A20P had ~3% of mean wild-type activity and localized to the lysosome. While A31V had ~1% residual activity, the mutant protein predominantly localized to the ER, presumably due to failure of signal peptide cleavage. To determine whether the mutant proteins of L14P, A15E, and L19R were degraded by the ubiquitin-proteasome system, transiently transfected COS-7 cells were treated with the potent proteasome inhibitors, lactocystin and epoxomicin. Both proteasome inhibitors failed to show enhancement of protein levels, thus suggesting that this may not be the major enzyme degradation mechanism. Additional studies, including docking studies using the SRP 54 M domain structure and mutagenesis studies, are underway to further delineate the molecular mechanism by which these signal peptide mutations cause the enzyme deficiency.

Molecular Analysis of the GAA gene in -glucosidase deficiency (Pompe Disease). *M.T. Geraghty[1], E. McCready[1], N. Carson[1], P. Chakraborty[1], J. Clarke[2], J. Callahan[2], R. Casey[3], A. Chan[4].* 1) Dept Genetics, Children's Hosp Eastern Ont, Ottawa,Canada; 2) Hospital for Sick Children, Toronto; 3) Alberta Childrens Hospital, Calgary; 4) University of Alberta, Edmonton.

Glycogen storage disease, type II (GSD II; Pompe disease) is an autosomal recessive disease characterized by accumulation of lysosomal glycogen within various tissues. GSDII is caused by a deficiency in the acid- glucosidase enzyme encoded by the GAA gene on chromosome 17q25.3. The enzyme is most reliably measured in cultured fibroblasts. Molecular analysis of the GAA gene would simplify the diagnosis of individuals with GSDII and permit both pre-symptomatic and prenatal testing, but there is limited availability of such testing. We developed a clinical molecular test for the detection of GAA mutations based on cycle sequencing of the complete coding region. Exons 2-20 of the GAA gene are amplified in six independent PCR using intronic primers. The resulting products were purified and sequenced. Preliminary validation studies were conducted with genomic DNA from fourteen GSDII-affected individuals from four centers across Canada. To date, 25 of 28 mutations were detected (89% detection rate). Amongst the 14 patients, there were 7 compound heterozygotes and 5 apparent homozygotes. I the remaining 2 samples, analysis has been completed for approximately 85% of the GAA gene in one patient, resulting in the detection of a single mutation. We were unable to amplify exons 2-8 from the remaining patient, while the rest of the gene was homozygous for several known polymorphisms suggesting a deletion. The mutations spanned intron 1 through exon 19 and included eight novel mutations (c.2140delC; c.1100G>C (p.Trp367Ser); c.1540G>C (p.Gly514Arg); c.2662G>T (p.Glu888X);c.2269C>T (p.Gln757X);c.1799G>T (p.Arg600Leu); c.2040G>A (splice); c.1564C>A (p.Pro522His). Consistent with previous reports, a single mutation, c.-23-13T>G (IVS1-13 T>G), was found at a high frequency in the population studied (6/14 patients). The availability of clinical molecular testing of the GAA gene will assist with diagnosis in patients, and with prenatal and carrier testing for individuals at risk of Pompe disease.

MGC4170 is the I cell disease (mucolipidosis II) gene; mutational analysis of Japanese patients. *T. Yorifuji[1], M. Kawai[1], T. Momoi[1], J. Yorifuji[1], H. Nagasaka[2], M. Takayanagi[2], T. Nakahata[1].* 1) Dept Pediatrics, Kyoto Univ Hosp, Kyoto, Japan; 2) Dept Metabolism, Chiba Children's Hospital, Chiba, Japan.

(Introduction) Leroys I-cell disease (mucolipidosis II) is characterized by progressive psychomotor deterioration accompanied by bone/joint deformities or cardiac involvements. The disease presents very early in life, and fibroblasts of the patients have diminished activity of GlcNac-1-phosphotransferase (GNPTA), which is responsible for the correct intracellular targeting of multiple lysosomal enzymes. The gene for GNPTA previously has been mapped to chromosome 4q21-q23 by other investigators. However, there have been no publications reporting the sequence of the gene or mutational analysis of the patients. In this study, to confirm the previous mapping data, we performed a genome wide linkage analyses on Japanese families with I-cell disease, followed by the mutational analysis of a candidate gene, MGC4170. (Materials and Methods) Microsatellite markers covering the whole genome at approximately 10 cM intervals were typed on three Japanese families with multiple patients with I-cell disease. Multipoint linkage analysis was performed by using the GeneHunter 2 program under an assumption of autosomal recessive inheritance. Sequencing analysis of the candidate gene was performed by exon-by-exon amplification and direct sequencing of the amplification products. (Results and Discussion) Unlike the previous reports, the results of the linkage analysis showed that the disease maps to chromosome 12q. We have identified a candidate gene, MGC4170, within that chromosomal region of interest and performed a sequencing analysis of the gene. The results revealed multiple nonsense/frameshift mutations among affected individuals. This is the first report of mutation detection for this disorder. We conclude that the MGC4170 gene is responsible for I-cell disease. Currently we are accumulating data of the mutational analysis on additional patients. We are also in the process of confirming the results by the functional analysis.

Fabry Disease: Natural History and Quality of Life Assessment. *D. Doheny, S. Farivar, M. Cahr, M. Banikazemi, R.J. Desnick.* Dept Human Genetics, Mount Sinai Medical Ctr, New York, NY.

Fabry disease, -galactosidase A (-Gal A) deficiency, is an X-linked lysosomal storage disease. Classically affected males (<1% -Gal A activity) present in childhood with acroparesthesias, hypohidrosis, angiokeratomas, corneal/lenticular opacities, and abdominal pain. With advancing age, renal failure and cerebrovascular and cardiovascular complications lead to early demise. Manifestations in heterozygotes (hets) are variable due to Lyonization. To assess the natural history and patient-perceived quality of life (QoL) a disease-specific questionnaire, including demographics, medical history, a Pain Questionnaire, the Fabry Disease Health Assessment Questionnaire, and the SF-12 Health Survey, was sent to 363 affected males and 380 DNA-confirmed hets. Questionnaires were received from 135 (37%) affected males (9-70 yr, mean 41.0) and 195 (51%) hets (6-78 yr, mean 41.3). Mean age at diagnosis was 25.0 yr for males and 30.3 for hets. Symptoms reported more frequently by males than hets included acroparesthesias (97 v 77%) with mean age of onset of 10.3 v 16.3 yr, hypohidrosis (97.5 v 42%), temperature intolerance (99 v 80%), abdominal pain (88 v 53%), and fatigue (66 v 43%). Males had greater activity interference than hets with acroparesthesias (80 v 26%), hypohidrosis (46 v 17%), temperature intolerance (44 v 27%), and fatigue (79 v 55%), but interference from abdominal pain was similar (28 v 27%). Among 84 males and 75 hets over 40 yr, males reported more TIAs/strokes (27 v 14%) and renal failure (55 v 5%) while cardiac involvement was comparable (72 v 72.6%). Overall, more males than hets rated their general health as poor (14.2 v 4.8%); however, both reported significant disease-related limitation of activities (16.7 v 17.4%), accomplishing less most of the time (43.2 v 36.1%), with a negative effect on general mood (27.7 v 27.5%). Thus, affected males and hets of similar mean age reported significant activity interference, emphasizing that Fabry disease has a major impact on QoL, and that QoL should be evaluated, especially in hets, as an indication for enzyme replacement therapy.

The Natural History of Niemann Pick Disease Type A. *M. Wasserstein[1], R.J. Desnick[1], A. Aron[2], S. Brodie[3], M.M. McGovern[1].* 1) Human Genetics & Pediatrics, Mount Sinai Sch Medicine, New York, NY; 2) Neurology and Pediatrics, Mount Sinai Sch Medicine, New York, NY; 3) Ophthalmology, Mount Sinai Sch Medicine, New York, NY.

Type A Niemann-Pick disease (NPD-A) is a lysosomal storage disease resulting from the deficiency of acid sphingomyelinase (ASM) and the accumulation of sphingomyelin in cells of the monocyte-macrophage system. It is a severe neurodegenerative disease leading to death in infancy, although studies to delineate its natural history have not been reported. We serially evaluated ten patients with NPD-A (6 male, 4 female; age at entry: 3 - 6 mo) from 10 unrelated families at the Mount Sinai General Clinical Research Center between 1993 and 2004. All affected infants had a normal neonatal course and early development was unremarkable. The first symptom detected in all patients was organomegaly (median age of 3 months). Developmental milestone data was available for all 10 patients through direct examination during GCRC visits and from evaluations performed by referring neurologists or by early intervention programs. Development did not progress beyond 9, 12, 12 and 10 months for gross motor skills, cognitive development, expressive language, and fine motor skills, respectively and detailed data related to the timing of skill acquisition and loss will be presented. Non-neurologic disease symptoms were: 1) gastrointestinal problems including vomiting, intermittent periods of diarrhea and constipation, massive hepatomegaly and ascites; 2) recurrent respiratory infections and interstitial storage on chest radiograph; 3) irritability and sleep disturbances; 4) failure to thrive for weight beginning at median age of 9 months; and 5) retinal stigmata in all patients by 12 months of age. All patients had progressive increases in SGOT and SGPT, mild and progressive decline in hemoglobin and hemotocrit, normal white blood cell counts, markedly decreased platelets, and low HDL-cholesterol. The median time from diagnosis to death was 21 months and no patient survived past the age of 3 years. The cause of death was respiratory failure in nine patients and complications from bleeding in the tenth.

Impairment of intracellular redox state in Gaucher fibroblasts: involvement of APE/Ref-1 and peroxiredoxin-1.

M.G. Pittis[1], M. Deganuto[1], S. Dominissini[1], A. Pines[2], B. Bembi[1], G. Tell[2]. 1) Metabolic Diseases Unit, Pediatric Hospital B. Garofolo, Trieste, Italy; 2) Department of Biomedical Sciences and Technologies, University of Udine, Italy.

Gaucher disease (GD) is the most frequent lysosomal storage disorder due to an autosomal recessive deficiency of acid -glucosidase that leads to glucosylceramide (GlcCer)accumulation. The mechanisms underlying pathophysiology of GD are still not fully understood. GlcCer is a central intermediate in the synthesis-degradation pathways linking ceramide with complex glycosphingolipids. An alteration in this balance might perturb the cell metabolism contributing to the pathological phenotype. Glycosphingolipids are involved is the generation of reactive oxygen species (ROS). GlcCer accumulation increases Ca^{2+} mobilization in GD. As Ca^{2+} signalling interplays with ROS production, ROS levels are likely to be increased in these experimental models. We analyzed ROS levels in cultured GD and control fibroblasts to determine if an altered redox state might contribute to GD pathogenesis. ROS levels are 2-3 folds higher in GD cells respect to controls and revert by treatment with antioxidants; reversion of GD phenotype is almost complete in the presence of a specific blocker of NADPH oxidase, suggesting a role of this complex in ROS generation in GD. Since GD cells are subjected to a chronic oxidative stress, we analyzed systems involved in the protection of the cell from oxidative damage. In particular, we investigated the expression levels of APE/Ref-1 and Prx1. APE/Ref-1, inducible by oxidative stress, is a bifunctional protein involved in the repair of damaged DNA and in the transactivation of several transcription factors, while peroxiredoxin-1 is a ROS scavenger. Cytoplasmatic APE/Ref-1 and Prx11 levels are increased in both GD cells and control cells treated with CBE, a competitive irreversible inhibitor of acid -glucosidase. Moreover, the addition of exogenous -glucosidase (Cerezyme) reverts the Ape/Ref-1 induction in GD cells. Our data indicate that oxidative stress plays a role in the pathogenesis of GD, providing useful knowledge for the development of new therapeutic approaches.

The cognitive phenotype of Niemann-Pick type C (NPC): neuropsychological characteristics of patients at baseline in a clinical trial with oral miglustat. *V.J. Hinton[1], D. Vecchio[1], H. Prady[2], E. Wraith[2], M.C. Patterson[1].* 1) Columbia University, New York, NY, USA; 2) Royal Manchester Children's Hospital, Manchester, UK.

Background: NPC is an autosomal recessive disorder whose phenotype is progressive neurodegenerative disease with highly variable expressivity. Isolated reports exist on the cognitive deficits in NPC, but no systematic series. We report neuropsychological findings in a cohort of NPC patients at entry into a therapeutic trial of miglustat. **Methods**: Fourteen participants with NPC (12-43 years) were evaluated to define their cognitive/behavioral phenotypes. Measures of language function (receptive vocabulary, naming and verbal fluency), visuospatial abilities (matrices and drawing), memory, and executive function were included. Scores were standardized relative to age-matched norms and classified as "severely impaired" (SI) when more than 2 SD from mean, and "mildly impaired" (MI) when more than 1 SD from mean. **Results**: At study entry, all participants exhibited significant cognitive deficits. Receptive vocabulary skills were relatively preserved (4/14 scored in the MI range; 10/14 were within normal limits). In contrast, expressive language was impaired (Naming: 5/14 SI, 7/14 MI; Verbal Fluency: 14/14 SI). Nonverbal skills were also defective (Matrices: 5/14 SI, 8/14 MI; Construction: 14/14 SI), as were executive skills (Trails: 14/14 SI; Digit Span: 12/14 SI, 2/14 MI). Severely impaired memory was observed in 12/14 participants, while the remaining two had intact memory. **Conclusions**: 12/14 NPC patients who met criteria for dementia at entry into a therapeutic trial of miglustat had significant memory deficits and impairments in expressive language, visuospatial skills and executive functions. All subjects had generalized cognitive impairment and exhibited lack of insight into the degree of deficit, posing significant challenges in daily activities.

Serum levels of Osteoprotegerin and Osteoprotegrin polymorphisms in Gaucher disease. *G. Altarescu[1], I. Mazel[2], E. Lebel[3], M. Itzchaki[3], B. Rudensky[4], A. Zimran[2], D. Elstein[2].* 1) Genetic Dept, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem Israel; 3) Department of Orthopedics, Shaare Zedek Medical Ctr, Jerusalem Israel; 4) Laboratory for Microbiology and Immunology, Shaare Zedek Medical Ctr, Jerusalem Israel.

Bone involvement in Gaucher disease causes considerable disability and reduced quality of life; indeed, skeletal involvement, particularly loss of function and unremitting pain, are important indications for enzyme replacement therapy. Osteoprotegerin (OPG) decreases osteoclast activity. The purpose of this study was to ascertain whether OPG may serve as a marker of incipient bone involvement by comparing OPG serum levels relative to Gaucher severity score index (SSI) and bone mineral density (BMD), and to correlate various bone and Gaucher disease markers to OPG polymorphisms. Three common polymorphisms have been characterized in the OPG gene: OPG1-2A163G, 3-4OPGT129C, and 5-6C1217T. There is a predilection for the non-neuronopathic form (type I) Gaucher disease among Ashkenazi Jews. Of a total of 554 patients in a large referral clinic, 173 Ashkenazi Jewish patients with type I Gaucher disease were enrolled in the study and a control group of 32 healthy Ashkenazi Jews was also recruited. Serum OPG levels were detected by specific ELISA analysis. BMD was obtained by Dual X-ray Absorptiometry (DEXA). OPG polymorphisms were determined in 63 patients chosen at random. There was a statistically significant decrease in OPG values in patients as a function of age, and between OPG5-6 polymorphism and SSI. A statistically significant difference was also found between allele distributions of each OPG polymorphism compared to the general population and to healthy Ashkenazi Jews. However, there was no correlation between OPG levels and BMD in patients, neither at the lumbar spine nor femoral neck, nor with genotype or other markers of severity of Gaucher disease, implying OPG may not be the mechanism which could mitigate against bone loss due to Gaucher disease and/or that bone involvement in Gaucher disease is osteoclast but non-OPG mediated.

Amino Acids in Arginase Double Knockout Mice Demonstrate Ornithine Auxotrophy. *J.L. Deignan[1], P.K. Yoo[1], J.C. Livesay[1], S.I. Goodman[2], W.E. O'Brien[3], R.K. Iyer[1], S.D. Cederbaum[1], W.W. Grody[1].* 1) Departments of Pathology and Laboratory Medicine, Psychiatry, Pediatrics and Human Genetics and The Mental Retardation Research Center, David Geffen School of Medicine at the University of California, Los Angeles, CA; 2) Department of Pediatrics, University of Colorado Health Sciences Center, Denver, CO; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Knockout mouse models have been created to study the consequences of arginases AI and AII deficiencies, both individually and combined. The AI-/- knockout animals die by 14 days of age from hyperammonemia, while the AII-/- knockout has no obvious phenotype. The double knockout (AI-/-/AII-/-) has the phenotype of the AI-deficient mice, the absence of the AII gene product apparently not exacerbating the clinical abnormality. Plasma amino acid measurements in the double knockout have shown arginine levels increased 35-fold and levels of ornithine decreased 5-fold as compared to wildtype controls. Liver ornithine levels were reduced to 3% of normal, with arginine very highly elevated. Amino acid levels in other tissues were not changed remarkably. Amino acid analysis in the double knockouts revealed that argininosuccinate levels in liver were increased, indicating that AII may play a role in mitigating AI deficiency. Thus, we have shown that fatal hyperammonemia in the mouse AI knockout model is almost certainly due to ornithine deficiency, the amino acid needed to drive the urea cycle. The high level of expression of ornithine aminotransferase (OAT) is rapidly diminishing at this time, indicating that this enzyme is critical to the maintenance of ornithine homeostasis, at least at this early stage of mouse development. Although most human AI-deficient patients have no symptomatic hyperammonemia at birth, it is possible that clinically significant, but opaque, ornithine deficiency is present in these patients' livers as well.

Congenital Hyperinsulinism: Correlation between pancreatic [18F]Fluoro-L-DOPA PET and immunohistochemistry. *P. de Lonlay[1], M. Ribeiro[2], A. Simon-Carre[1], N. Boddaert[1], I. Giurgea[1], C. Bellanné-Chantelot[4], J.J. Robert[1], J. Rahier[3], D. Seidenwurm[5], C. Nihoul-Fékété[1], F. Brunelle[1], F. Jaubert[1].* 1) Hosp Necker-Enfants Malades, Paris, France; 2) ERM 0205 INSERM-CEA, Service Hospitalier Frédéric Joliot, Orsay, France; 3) Department of Pathology, University of Louvain, B-1200 Brussels, Belgium; 4) Department of Biology, Hôpital Saint-Antoine, Paris, France; 5) Radiological Associates of Sacramento, Sutter Medical Center, Sacramento, California, USA.

Congenital hyperinsulinism (HI) is characterized by profound hypoglycaemia related to inappropriate insulin secretion. Focal and diffuse forms of hyperinsulinism share a similar clinical presentation, but their treatment is dramatically different. Until recently, preoperative differential diagnosis was based on pancreatic venous sampling (PVS), an invasive and technically demanding technique. Positron emission tomography (PET) after injection of [18F]Fluoro-L-DOPA has been evaluated for the preoperative differentiation between focal and diffuse HI, by imaging uptake of radiotracer and the conversion of [18F]Fluoro-L-DOPA into dopamine by dopa decarboxylase (AADC). Here, we show that the focal localization of dopamine in 4 focal HI and the diffuse localization in 3 diffuse HI were fully confirmed by immunohistochemical detection of AADC in all pancreatic surgical specimens, with diffuse staining of Langerhans islets in the whole pancreas in all diffuse cases, compared to dense focal staining in all focal cases. Staining of Langerhans islets outside the focal lesion were diffusely but weakly positive. We also correlated the localization of AADC and proinsulin in normal human pancreas and in tissue from both diffuse and focal HI. One child suspected of having diffuse HI by PVS was treated with an inhibitor of AADC (carbidopa). The diffuse uptake found before treatment disappeared completely after carbidopa, demonstrating in vivo that pancreatic cells can take up amine precursors and contain AADC responsible for the conversion of [18F]Fluoro-L-DOPA into dopamine. We validate PET with [18F]Fluoro-L-DOPA as a reliable test for the distinction of diffuse and focal forms of HI.

Keratan sulfate accumulation and secondary elastin binding protein defect in a GM1-gangliosidosis patient with juvenile form. *A. Caciotti[1], M.A. Donati[1], A. d'Azzo[2], E. Zammarchi[1], A. Morrone[1].* 1) Department of Pediatrics, Azienda Ospedaliero-Universitaria Meyer, Florence, Italy; 2) Department of Genetics, St. Jude Children's Research Hospital, Memphis, TN, USA.

GM1 gangliosidosis is a neurodegenerative lysosomal storage disorder caused by beta galactosidase deficiency. Beta-galactosidase gene gives rise to the lysosomal beta-galactosidase enzyme and to the elastin binding protein, whose primary deficiency is linked to impaired elastogenesis. In addition, galactosugar-bearing moieties have been demonstrated to alter elastin binding protein function and in turn to cause impaired elastogenesis. We mainly focused in this study on elastogenesis in fibroblasts from patients with the juvenile form of the disease showing a large urinary keratan sulfate excretion together with connective-tissue abnormalities. In this patient both genetic lesions identified (R201H/C230Y) affect only the lysosomal beta galactosidase. Elastic fiber assembly was evaluated by immunofluorescence studies on normal and GM1 gangliosidosis patients' fibroblasts. In the juvenile patient, a mild elastin binding protein reduction and a decreased impaired elastic fiber assembly were detected. The addition of keratan sulfate to normal fibroblasts led to decreased elastin deposition, whereas keratanase restored normal elastostogenesis in the juvenile patient's fibroblasts. These data showed that keratan sulfate accumulation leads to impaired elastogenesis with secondary elastin binding protein deficiency in the fibroblasts of the GM1 gangliosidosis patient with juvenile form. Grant: Prin2004; AMMEC and MPS Italy are gratefully acknowledged.

Life expectancy in Type 1 (non-neuronopathic) Gaucher disease. *N. Weinreb[1], P. Deegan[2], K. Kacena[3], P. Mistry[4], G.M. Pastores[5], S. vom Dahl[6].* 1) Univ Research Foundation, Hollywood, FL; 2) Addenbrooke's Hospital, Cambridge, UK; 3) Genzyme Corporation, Cambridge, MA; 4) Yale Univ School of Medicine, New Haven, CT; 5) New York Univ School of Medicine, New York, NY; 6) St. Franziskus-Hospital, Cologne, Germany.

Objective: Investigations were conducted to estimate life expectancy at birth of patients with Type 1 (non-neuronopathic) Gaucher disease (GD). **Methods**: The GD population included all patients with Type 1 GD registered in the International Collaborative Gaucher Group (ICGG) Gaucher Registry who were diagnosed after 1991. Life expectancy was calculated according to the standard life table method (Palmore and Gardner, 1996) (method 1). Life expectancy was also calculated using the assumption that risk of death prior to Gaucher diagnosis was the same as the reference population (method 2). The reference population (World Population Prospects, 2002, UN) was males and females from the U.S. population. Approximately 40% of GD patients came from the U.S. The life expectancy of the reference population was similar to that for developed nations (as defined by the UN). The distribution of males and females in GD is similar to that of the general population. **Results**: The Type 1 Gaucher population of 2,201 patients had 90 reported deaths. The average life expectancy of the Type 1 GD population was 66.6 years for method 1, and 67.3 years for method 2. The life expectancy of the reference population was 77.1 years. **Discussion and Conclusion**: The ICGG Gaucher Registry represents the single largest dataset on GD patients worldwide. The current life expectancy at birth of people with Type 1 GD is about 10 years less than the reference population, confirming that Type 1 GD is not a benign disorder. Additional analyses of life expectancy, causes of death, and effect of enzyme replacement therapy on life expectancy are underway. Reference: Palmore JA, Gardner RW. Measuring Mortality, Fertility and Natural Increase. A self-teaching guide to elementary measures. Honolulu, Hawaii: East-West Center Publisher, 1996, pages 35-61.

Ethylmalonic encephalopathy: Delayed biochemical and physical manifestations affect newborn diagnosis. *J. Bartley[1], D. Geary-Hook[1], P. Rinaldo[2], V. Tiranti[3], W. O'Brien[4], M. Zeviani[3].* 1) Dept Ped/Div Human Gen, Univ California Irvine Med Ctr, Orange, CA; 2) Dept Medical Genetics, Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Unit of Molecular Neurogenetics, Pierfranco and Luisa Mariani Center of the Study of Children's Mitochondrial Disorders, National Neurological Institute "Carlo Besta", Milan, Italy; 4) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Ethylmalonic encephalopathy (EE) is an autosomal recessive disorder caused by mutations in ETHE1, a gene encoding a mitochondrial matrix protein. EE is characterized by recurrent petechiae, orthostatic acrocyanosis, chronic diarrhea, neurodevelopmental delay and regression, prominent pyramidal and extrapyramidal signs. Death is usually in the first decade. There is persistent lactic acidemia, elevated $C_{4\text{-}5}$ plasma acylcarnitines, markedly elevated urinary excretion of ethylmalonic acid (EMA) and elevated $C_{4\text{-}6}$ acylglycines. Symmetrical necrotic lesions in the deep gray matter structures are the main neuropathological features. We report two Mexican hispanic siblings with EE born in California. The boy at two years of age had features of EE. He was placed on a low protein diet, riboflavin and a formula devoid of selected amino acids. This diet decreased hospitalizations, but he deteriorated neurologically and died at nine years of age. His sister at birth did not have any clinical manifestations of EE. Her urine organic acids (UOA) contained no EMA at two days and at two months of age. Newborn screening using tandem mass spectrometry was not done in California when she was born. Developmental delay at four months of age was noted and the UOA had a large concentration of EMA. She is a compound heterozyote for two missense mutations of ETHE1 (406 A>G, T136A and 488 G>A, R163Q). ETHE1 was present on a Western blot and she was homozygous for the 625G allele (the allele not associated with elevated EMA) of the SCAD gene. Conclusion: The delayed accumulation and excretion of EMA could be an indication of potential false negative results by newborn screening. Retrospective analysis of the original newborn screening card is underway.

Carnitine palmitoyltransferase II deficiency: molecular aspects in twenty-five unrelated families. *J.H. Ding, B.Z. Yang, D.S. Roe, L. Sweetman, C.R. Roe.* Institute of Metabolic Disease, Baylor University Medical Center, Dallas, TX.

Carnitine palmitoyltransferase II (CPT II) deficiency, an autosomal recessive disorder of fatty-acid -oxidation, has three distinct clinical forms: the adult-onset (muscular) form, milder infantile form and severe neonatal form which may result in sudden unexplained death. In this study, twenty-five unrelated patients (probands) with CPT II deficiency were investigated. In vitro probe analysis with [16-$^{2}H_{3}$] palmitic acid from the probands fibroblasts resulted in labeled acylcarnitines consistent with CPT II deficiency. CPT II activities in lymphocytes and/or fibroblasts were measured (0.02-0.12 nmol/min per mg protein) and found to be 2-13% of mean control value. To investigate the molecular basis of CPT II deficiency, all of CPT II exons from probands DNA were amplified and directed sequenced. The common mutation S113L was detected in fifteen families, including five homozygous and ten compound heterozygous. The R124X and Q413fs were detected in four CPT II families respectively. The other mutations, including novel mutation T165I and P595fs, were identified in individual patients, and increased the number of different mutations to a current total of 44. There is significant phenotypic heterogeneity in CPT II deficiency, even within the same family. Interestingly, a probands father also notes myopathy caused by heterozygosity for single mutation Q413fs. This report demonstrated the genetic heterogeneity that may underlie the clinical variation in CPT II patients.

Heme Biosynthesis and Porphyria: Demonstration of a Cytosolic Complex Involving Uroporphyrinogen Synthase and Hydroxymethylbilane Synthase. *L.F Cunha, M. Kuti, MM. Zhou, R.J. Desnick, D.F. Bishop.* Human Genetics, Mount Sinai Sch Med, New York, NY.

Uroporphyrinogen synthase (UROS) and hydroxymethylbilane synthase (HMBS) are the third and fourth enzymes in the heme biosynthetic pathway and both are required to synthesize uroporphyrinogen III (UROgen III) from porphobilinogen (PBG). HMBS deaminates and polymerizes four molecules of PBG to form the linear tetrapyrrole hydroxymethylbilane (HMB), which UROS then cyclizes with inversion of ring D to form UROgen III. HMB has a short half-life of ~4 min, and in the absence of UROS, it non-enzymatically cyclizes to the non-physiologic and toxic UROgen I isomer. UROS gene mutations that cause congenital erythropoietic porphyria result in decreased UROS activity and the accumulation of UROgen I. It has been suggested that UROS and HMBS interact in the cytoplasm to form UROgen III. Previously, we observed a marked kinetic enhancement of UROS in the presence of HMBS, suggesting an enzyme-enzyme interaction. However, we were unable to demonstrate a complex by yeast two-hybrid and co-immunoprecipitation experiments, which detect interactions in the M range, but not weaker mM interactions. Using nuclear magnetic resonance (NMR) spectroscopy, we demonstrated the direct physical association between UROS and HMBS in the synthesis of UROgen III based on chemical shift perturbation as observed in the titration of [^{15}N,^{2}H]-labeled purified recombinant UROS with the purified recombinant HMBS apoenzyme (E) and its mono- (ES_1), di- (ES_2) and tri- (ES_3) substrate-enzyme intermediates. UROS residues perturbed by HMBS were localized mostly in and around the active site. Results from multiple experiments demonstrated an enzyme interaction proportional to the length of the growing pyrrole chain (ES_3 ES_2>ES_1>E) attached to HMBS. These studies indicate that HMBS directly interacts with UROS in the synthesis of HMB, and then hands off HMB, thereby avoiding its non-enzymatic cyclization to the UROgen I isomer. Thus, an efficient enzyme-enzyme interaction evolved to normally prevent the formation of the UROgen I isomer, which causes the disease pathology in congenital erythropoietic porphyria.

Evaluation of the glycosylation status of alpha-dystroglycan in Hereditary Inclusion Body Myopathy (HIBM).

P.J. Savelkoul[1], S. Sparks[1], G. Rakocevic[2], E. Gottlieb[1], C. Ciccone[1], M-S. Sun[1], M. Dalakas[2], D. Krasnewich[1], W.A. Gahl[1], M. Huizing[1]. 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Neuromuscular Disease Section, NINDS, NIH, Bethesda, MD.

HIBM is an adult onset autosomal recessive neuromuscular disorder characterized by slowly progressive myopathic weakness and atrophy. HIBM is caused by mutations in GNE, coding for UDP-GlcNAc 2-epimerase/ManNAc kinase, the bifunctional, rate-limiting enzyme in sialic acid synthesis. Loss of activity due to GNE mutations impairs sialic acid production, which may interfere with proper sialylation of glycoconjugates. We investigated how this would lead to muscle pathology. First, we showed normal iso-electric focusing (IEF) patterns of transferrin in HIBM patients serum, suggesting normal N-linked glycosylation. Next, we performed immunohistochemistry on HIBM muscle employing antibodies against components of the dystrophin-glycoprotein complex. -dystroglycan and laminin- 2 showed normal patterns, but antibodies against O-linked glycan epitopes of alpha-dystroglycan (-DG) showed reduced staining. -DG contains both O-GalNAc and O-mannose linked glycans; the latter are rare in mammals. Next,we showed normal IEF patterns of apolipoprotein C-III, which contains only O-GalNAc linked glycans, suggesting that O-GalNAc glycosylation is unaffected in HIBM. We conclude that incomplete O-mannosylation of -DG is the underlying defect in the pathology of HIBM, as was previously shown for other muscular dystrophies. Since HIBM is an adult onset disease, and we have shown residual GNE activity in patients, the effects of sialic acid deficiency may appear gradually. When a shortage of sialic acid occurs, some glycans (e.g.,N-linked, O-GalNAc linked, glycolipids) could be preferentially sialylated over the very rare O-mannose linked glycans. O-mannosylation of -DG might only occur in skeletal muscle; other tissues are not affected in HIBM. Understanding the function and regulation of the O-linked mannose pathway is essential for developing diagnostic tests and therapies for HIBM and other muscular dystrophies with similar pathology.

Novel *IVD* mutation in kindred with chronic intermittent isovaleric acidemia. *H. Gore, O. Vais, B. Ben-zeev, T. Shalavi, Y. Anikster.* Metabolic disease unit, Safra children's hospital, Sheba medical center, Ramat-gan, Israel.

Isovaleryl-CoA dehydrogenase (IVD) is a mitochondrial enzyme involved in the catabolism pathway of leucine. Impairment of the IVD activity causes isovaleric acidemia (IVA), a rare autosomal recessive disease. IVA can present in an acute form, which starts several days after birth, or in a chronic form. Both forms are characterized by high accumulation of isovaleric acid which is toxic to the CNS and thus can cause retardation, loss of motor skills, seizures, coma and eventually death. Other clinical features are ketoacidosis, hyperglycinemia, thrombocytopenia, leukopenia and "sweaty feet odor" during episodes. The clinical management is by restricted protein diet and administration of glycine supplementation.

We studied two siblings, aged 14 and 16, sons of first-cousin healthy parents from a Moslem Arabic origin. They both attend a regular school, with specific educational aids. Both siblings presented with vomiting episodes before age 1, but the diagnosis was made only after 4 years. The diagnosis was made by organic acid profile and high isovalerylcarnitine on both brothers (10.5 nmol/ml and 7.5 nmol/ml, normal less than 0.5).

RNA and DNA were purified from whole blood of the two siblings and their mother. The RNA was reverse-transcripted to cDNA, and the cDNA was amplified by PCR with primers to the *IVD* gene. Analysis of the *IVD* cDNAs sequences showed a homozygous missense mutation in both siblings, 774 C>G. The mother has been found heterozygote to this mutation. To confirm our finding, PCR amplification of the genomic DNA was carried out on exon 7, where the mutation should be located. A restriction enzyme assay on the PCR products revealed that both the siblings are homozygote to the mutation Cys258Trp (C258W), and their mother is heterozygote. This study brings to 17 the reported mutations in the *IVD* gene. Furthermore, it offers a quick and non-invasive pre and peri-natal diagnosis of the IVA patients and carriers, thus enables early treatment.

Mutations of argininosuccinate synthetase gene in two citrullinemia patients with different phenotypes. *Z.Q. Qiu[1], C. Obie[2], A. Hamosh[2], T. Wang[2], D. Valle[2].* 1) Peking Union Medical College Hospital; 2) Johns Hopkins School of Medicine.

Citrullinemia is caused either by deficiency of arginonosuccinate synthetase (*ASS*) (type I) or of citrin, an aspartate/glutamate transporter in the inner mitochondrial membrane encoded by *SLC25A13* (type II). Classical type I citrullinemia presents in the neonatal period with hyperammonemia and markedly elevated plasma citrulline while type II usually presents in young adults with similar but less severe biochemical abnormalities. The advent of tandem mass spectrometry (MS/MS) has resulted in recognition of citrullinemic infants with phenotypes that vary from these classical presentations. We investigated the molecular basis of 2 such infants.Patient 1 was identified by newborn screening at age 4 d and had an $_{NH_4}$ of 200 M. He responded to standard therapy and has done well clinically despite maintaining citrulline levels up to 6000M (control 10-34M). Patient 2 was asymptomatic with mild hypercitrullinemia (200-300 M) and normal ammonia, which have persisted over the 1st year. To explain these abnormalities, we used RT-PCR to amplify the complete coding regions of *ASS* and *SLC25A13*. Direct sequencing of the RT-PCR products with confirmation in genomic DNA revealed 3 novel exonic *ASS* mutations. Patient 1 was a compound heterozygote for D124N and R272L; patient 2 was a heterozygote for a 3 bp deletion S247 (S247). We did not find these *ASS* alleles in 68 controls nor did we find a second pathological allele in patient 2. To determine the functional consequence of these mutations, we utilized an intact cell assay to measure the incorporation of ^{14}C-citrulline into protein bound ^{14}C-arginine. Cells from patient 1 showed a severe deficiency (3.6% of control) while cells from patient 2 had an intermediate value (51% of controls).We conclude that *ASS* mutations are responsible for the abnormal urea cycle function in both patients and that patient 2 is either a heterozygote for a dominant-negative *ASS* allele or a compound heterozygote for S247 and an allele we have not yet detected. Family studies to distinguish between these possibilities are in progress.

Identification of novel mutations in patients with medium-chain acyl-CoA dehydrogenase deficiency. *B.Z. Yang, J.H. Ding, L. Sweetman, C.R. Roe.* Institute of Metabolic Disease, Baylor University Medical Center, Dallas, TX.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common inherited defect of fatty acid -oxidation, characterized by episodes of illness in early childhood. The disorder may present after fasting with symptoms resembling Reye Syndrome, coma, hypoglycemia, hyperammonemia, fatty liver, and sudden death. The reported cases show significant phenotypic heterogeneity of MCAD deficiency, even with the same genotype. Recently, we identified eight novel MCAD mutations in our group, including the patients detected by newborn screening in our institute. The diagnoses were based on the dried blood spot acylcarnitine profile that showed highly elevated octanoyl carnitine and decenoyl carnitine, indicating MCAD deficiency. All babies with MCAD deficiency detected by newborn screening were asymptomatic prior to testing. To investigate the molecular aspect, the common mutation 985A>G had been tested, which presented in 84% of all defective alleles in our group. To screen for unknown mutations within the MCAD gene, all 12 exons and their flanking intronic sequences were amplified from probands DNA. The PCR products were purified and sequenced. Sequence analysis revealed eight novel mutations, including E43K and R349X. All novel mutations were verified by the PCR/restriction tests, but were not detected in the normal control subjects. In addition, the correlation of genotype to clinical phenotype was discussed.

Novel Mutations Underlying Argininosuccinic Aciduria. *F. Imtiaz[1], M. Al-Sayed[2], O. Alsmadi[1], H. Khalil[1], M.S. Rashed[2,3], B.F. Meyer[1].* 1) Aragene, KFSH, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, KFSH, Riyadh, Saudi Arabia; 3) Department of Genetics, KFSH, Riyadh, Saudi Arabia.

Argininosuccinic aciduria (ASA) is common in Saudi Arabia as a consequence of extensive consanguinity. It is the most common urea cycle disorder identified by the Metabolic Screening Laboratory of our Institution. Affected patients are confirmed biochemically by Tandem Mass Spectrometry, which whilst sensitive, cannot be used for carrier detection. Establishment of the range and incidence of mutations underlying ASA in this population were not previously established. We utilized Whole Genome Amplification, PCR and direct sequencing to identify the molecular lesions underlying ASA. A missense mutation (Q354X) that accounts for 50% of Saudi patients with ASA was recently reported by our laboratory. In this study we report a further four novel mutations (D115Y, G157R, R186W and G361X) found in Saudi patients with ASA. The missense and one nonsense mutation were confirmed by their absence in ~300 chromosomes from the normal population. Cross species conservation of amino acid residues was observed in some but not all instances. Where parental and other familial DNA samples were available, segregation of the mutation in an autosomal recessive pattern of inheritance was confirmed. Together the five mutations described above cover ~90% of ASA patients in Saudi Arabia. This coverage provides efficient molecular diagnosis of ASA in the Saudi population and lays the foundation for preventative measures including inductive screening in extended families, counseling, and regional pre-marital screening. In addition, identification of these mutations enables provision of pre-implantation and prenatal diagnosis as appropriate.

Neonatal presentation of adenylosuccinate lyase deficiency. *M. Zikanova, J. Krijt, L. Dvorakova, H. Hartmannova, J. Zeman, S. Kmoch.* Inst. for Inh. Met. Disorders, Charles University, Prague 2, Czech Republic.

Adenylosuccinate lyase (ADSL) deficiency (OMIM 103050) is an inherited metabolic disease affecting predominantly central nervous system. Affected patients show first combination of hypothony and epileptic seizures and later progress with psychomotor retardation, muscular wasting and behavioural changes such as autism, aggressiveness or self-mutilation. The clinical symptoms develop gradually, usually within the first months of life. Recently we diagnosed two patients born after uneventful pregnancies at 40th and 38th week of gestation who presented with atony, acrocyanosis, bradycardia and pharmacoresistant epileptic seizures at birth. Both patients died at age of 9 and 6 weeks, respectively. Selective metabolic screening was positive for urinary SAICAR (TLC) and the ADSL deficiency was confirmed by presence of S-Ado and SAICAr in urine and cerebrospinal fluid (S-Ado/SAICAr ratios were 0,5 in both patients) and reduced ADSL activity in fibroblasts. Mutation analysis of ADSL gene showed that both patients were compound heterozygotes for Y114H/R426H and Y114H/E376D mutations, respectively. Expression studies performed in E.coli revealed that Y114H mutation leads to profound protein instability (Y114 is a residue essential for enzyme subunits assembly), while the R426H and E376D mutations substantially reduce the protein activity. The Y114H/R426H and Y114H/E376D combinations however represent the most severe genotypes observed in our serie of thirteen ADSL deficient patients. Its association with neonatal presentation and early death corroborates our previous finding that predicted residual ADSL activity, calculated as a mean of homoalelic in-vitro expressed enzyme activities, may correlates with the severity of clinical symptoms. Our work further allowed successful prenatal diagnosis in one of the families and shows that ADSL deficiency must be considered also in neonates with neurological presentation.

Apparent B_{12} Responsive *mut^0* Methylmalonic Acidemia in Two Patients. *M.M. Martin[1], G.M. Enns[2], T.M. Cowan[3], D.S. Rosenblatt[4], S. Packman[1], R.C. Gallagher[2], K. Weisiger[1].* 1) Department of Pediatrics, University of California, San Francisco; 2) Department of Pediatrics, Stanford University; 3) Department of Pathology, Stanford University; 4) Department of Human Genetics, McGill University.

Introduction: Isolated methylmalonic acidemia (MMA) is due to deficient activity of methylmalonyl-CoA mutase and is caused by either a defect in the apoenzyme or in the synthesis of its cofactor, cobalamin (Cbl). Defects in the apoenzyme are divided into two types based on the amount of enzyme activity detected in cultured fibroblasts; *mut^0*, with undetectable activity, and *mut$^-$*, with residual activity. Responsiveness to supplemental Cbl, is generally thought not to occur in *mut^0* patients and only rarely in *mut$^-$*. We present two patients with *mut^0* MMA who both appear to be responsive to vitamin B_{12}. **Case 1** is an Asian male infant who presented on day 4 with tachypnea and lethargy. He was found to have neutropenia, acidosis and hyperammonemia (1,227 M, normal <50). Initial MMA level was 1,477 M (normal <0.3) with a normal total homocysteine. Hemodialysis (HD), hydroxocobalamin (OHCbl), and IV carnitine were started with good response. OHCbl was continued at 2 mg IM daily and MMA levels have ranged from 10 to 150 M. At 7 months of age, he has had nor further hosptializations. **Case 2** is an Asian male infant who presented on day 4 with increasing lethargy, poor feeding and hypothermia. He was found to have hyperammonemia (NH_3 795 M), metaoblic acidosis, lactic acidemia and neutropenia. Initial MMA level was 362 and total homocysteine was normal. He responded well to HD and CVVHD, nutritional support, ammonia-scavaging medications, and supplementation with carnitine, vitamin C and OHCbl (1 mg IM daily). His MMA levels range between 20 and 50 M. At 6 months of age, he had mild hypotonia. Complementation studies and propionate uptake on skin fibroblasts were consistent with *mut^0* status in both cases. **Conclusion:** Though *mut^0* MMA is classically Cbl unresponsive, our patients have shown acceptable and stable MMA levels while reciving Cbl supplementation. The mechanism for this responsiveness is unclear at this time. Mutation analysis may help to shed some light on this phenomenon.

An overview of ophthalmologic findings seen in Cobalamin C deficiency. *P. Tanpaiboon[1], B.P. Brooks[2], J. Slaon[1], N. Braverman[3], C.P. Venditti[1].* 1) National Genome Research Institue/NIH, Bethesda, MD; 2) National Eye Institute/NIH, Bethesda, MD; 3) Institute of Genetic Medicine and Dept. of Pediatrics,Johns Hopkins Medical Center,Baltimore, MD.

Cobalamin C deficiency (*cbl*C) is a rare autosomal recessive metabolic disorder of intracellular cobalamin (vitamin B12) metabolism. The defect impairs the synthesis of adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl) and features methylmalonic acidemia and homocysteinemia. Ophthalmologic findings are varied and include horizontal nystagmus; decrease visual acuity; macular pigment abnormalities, often with a bulls eye appearance; progressive peripheral pigmentary retinopathy; and optic nerve atrophy. The evolution of the eye lesions is unknown. Seven patients with *cbl*C defect, including two sets of sibs where the index case was diagnosed symptomatically, underwent dilated eye examination and retinal photography in addition to metabolic studies. All seven patients had macular pigmentary abnormalities and/or atrophy. Four patients had strabismus and two had significant refractive errors. Two patients had optic atrophy. One patient treated prenatally and one treated presymptomatically appeared to have a milder ocular phenotype than their sibs; prenatal treatment, however, did not halt the macular changes. One patient had dysmorphic maculae indicating that a prenatal component may underlie the optic pathology in a subset of patients. The oldest individual (age 12) previously had macular changes similar to those observed in younger patients, but progressed to develop pan-retinal pathology and optic atrophy. These observations suggest that the metabolic derangement affects all areas of the retina and may have a defined evolution which first involves the macula, then the periphery and later the optic nerve. A large collection of retinal photographs with clinical correlations may help generate a staging schema for the eye lesions seen in this disorder and provide a marker of disease evolution.

Identification of Propionate Metabolic Genes in C. elegans: Functional Characterization of Methylmalonyl-CoA Mutase. *M. Tsai[1], R.J. Chandler[1], V. Aswani[1,2], M. Falk[3], M. Sedensky[3,4], P. Morgan[3,4,5], C.P. Venditti[1].* 1) GDRB, NHGRI, NIH, Bethesda, MD; 2) Marshfield Clinic, Marsfield WI; 3) Dept. of Genetics, CASE School of Medicine; 4) Dept. of Anesthesiology, University Hospitals of Cleveland; 5) Dept. of Pharmacology, CASE School of Medicine.

Methylmalonic acidemia is an autosomal recessive inborn error of metabolism caused by a defect in the conversion of L-methylmalonyl-CoA to succinyl-CoA. Its etiology is heterogenous, due to either defects in the apoenzyme or impaired cofactor synthesis. In an attempt to develop a tractable experimental system to study this group of conditions, we have performed genomic and biochemical characterization of the putative propionate to succinate conversion pathway in C. elegans. Homologues of PCCA, PCCB, MMAA, MMAB, MCM, and MMCR, which are involved in propionate metabolism in humans, were identified in C. elegans and cloned for functional studies. Loading of C. elegans with propionic acid caused the animals to produce methylmalonic acid and secrete propionylcarnitine. A variable biochemical response to RNA interference was seen. To further examine the functional properties of the C. elegans methylmalonyl-CoA mutase enzyme, the protein was over-expressed in yeast and kinetic analysis was performed. C. elegans mitochondrial preparations were studied in parallel to demonstrate native enzymatic activity and verify the observed kinetic constants obtained in the yeast system. The native enzyme is present as >70% apoenzyme, with the remainder existing as holoenzyme, indicating that C. elegans makes functional enzyme as well as adenosylcobalamin. Retroviral correction of cells derived from muto mice using the C. elegans MCM cDNA was similar to that achieved with the murine gene. In toto, the combined findings suggest that C. elegans has an active methylmalonyl-CoA mutase and can synthesize adenosylcobalamin, possibly utilizing the same pathways that mammalian cells do. This biological system might be used to identify unknown genes that are mutated in selected cobalamin disorders and to create a model of methylmalonic acidemia amenable to high-throughput genetic and genomic analysis.

The spectrum of methylmalonic acidemia detected by MS/MS newborn screening in North Carolina. *A. Basinger, S. Pendyal, D. Frazier, J. Koepke, M. Gucsavas-Calikoglu, J. Muenzer.* Department of Pediatrics, University of North Carolina, Chapel Hill, NC.

Since 1997, North Carolina (NC) has screened >900,000 newborn infants using tandem mass spectrometry. Ten cases of methylmalonic acidemia were identified after confirmatory testing of neonates who had both an elevated C3-carnitine (CN) and C3:C2-CN ratio. These fall into three distinct groups. Three African-American infants had mut^0 methylmalonic acidemia (group I), 2 Hispanic infants had mild, persistent elevation of methylmalonic acid (MMA) in both blood and urine without elevation of homocysteine (HCY) (group II), and 5 had both elevated MMA and HCY (group III). The group I patients all presented clinically in the first week of life. They have had typical courses involving multiple hospitalizations for acidosis, poor feeding, neutropenia, and delayed development. The group II patients are both healthy, receive no supplementation, are on unrestricted diets, and are being monitored. Of the five group III patients, none were B-12 deficient. Four had complementation studies consistent with cobalamin (cbl) C defect. A Caucasian female developed lethargy, poor feeding, and hypothermia on day of life 11 and died on day of life 21 from intracranial hemorrhage. A Caucasian male with hydrocephalus died at 5 months from a pulmonary hemorrhage. Three Hispanic children have milder disease and are developing normally with treatment. None have had acidosis or decompensation with illness. Treatment has included 1 mg intramuscular (IM) hydroxycobalamin 2-3 times per week and mild protein restriction using a metabolic formula. They have had normalization of HCY and reduction of MMA to near normal. The siblings of one of these three Hispanic patients were recently tested, and a 9 year old asymptomatic sister with normal development was found to be affected. A trial of oral hydroxycobalamin in this mildly affected patient did not lower her HCY or MMA. The subgroup of patients with cbl C defect and a mild presentation may represent a mutation which is more prevalent in the NC Hispanic population.

Modeling central nervous system alterations in human glycerol kinase deficiency (GKD) using the glycerol kinase (Gyk) knockout (KO) mouse. *N. MacLennan[1], C. Shin[1], L. Kim[1], L. Rahib[2], K.M. Dipple[1,2,3], E.R.B. McCabe[1,3].* 1) Pediatrics, UCLA, Los Angeles, CA; 2) Biomedical Engineering, UCLA, Los Angeles, CA; 3) Human Genetics, UCLA, Los Angeles, CA.

GKD is an X-linked inborn error of metabolism associated with central nervous system (CNS) deterioration. We showed previously that the Gyk KO mice accurately model the human phenotype. The purpose of these investigations was to elucidate alterations in mRNA expression in brain compared to other tissues in Gyk KOs. We performed microarray analyses on brain, liver, kidney and brown fat mRNA and modeled genes with altered expression using pathway analysis. Gyk gene expression was significantly down-regulated in all tissues. In brain, kinase activity and receptor signaling protein activity were the most significantly upregulated gene functional categories ($p<0.01$), while in liver, kidney and brown fat, the gene groups most significantly upregulated related to metabolism. In all four tissues, the gene groups most significantly downregulated were cell cycle and proliferation, reflecting the severity of the phenotype. Brain KO samples clustered together and away from brain wildtype (WT) samples in both unsupervised and supervised clustering. In unsupervised clustering, the brain was the most different of the tissues. An elaborate network of genes specifically altered in KO brain microarray data were identified by pathway analysis. Notable genes included midkine (-1.7 of WT), stimulated by retinoic acid 13 (-1.4 of WT) and calreticulin (-1.5 of WT), all believed to play a role in cell survival in developing brain. Calreticulin interacts with the DNA-binding domain of the glucocorticoid receptor and prevents receptor binding which is intriguing given GK's involvement in nuclear uptake of the glucocorticoid receptor. In conclusion, Gyk KO brain has a different pattern of altered gene functional categories and gene expression compared with liver, kidney and brown fat. These alterations in brain along with Gyk ablation may contribute to the CNS deterioration in GKD. Further studies of Gyk's role in murine brain development will provide critical insights into mechanisms of CNS deterioration in GKD.

Free radicals and antioxidant defenses in X-linked adrenoleukodystrophy patients. *M. Deon[1,3], A. Barschak[1,3], A. Sitta[1,3], S. Landgraff[1], G. Oliveira[1], T. Terroso[1], M.H. Oliveira[1], D.M. Coelho[1], M. Wajner[1,3], L. Jardim[1], R. Giugliani[1,3], C.R. Vargas[1,2].* 1) Medical Genetics Service, HCPA, Porto Alegre, Brazil; 2) Dep. of Clinical Analysis, Pharmacy Faculty, UFRGS, Porto Alegre, Brasil; 3) Dep. of Biochemistry, ICBS, UFRGS, Porto Alegre, Brazil.

X-linked adrenoleukodystrophy (X-ALD) is a peroxisomal disorder, biochemically characterized by the accumulation of very long chain fatty acids (VLCFA), particularly hexacosanoic acid (C26:0) and tetracosanoic acid (C24:0) in tissues and biological fluids. Patients affectted by this disorder present predominantly central and peripheral demyelination in addition to adrenal insufficiency. The mechanisms underlying the brain damage in X-ALD are poorly known. Considering that free radical generation is involved in various neurodegererative disorders, like Parkinson disease, multiple sclerosis and Alzheimer's disease, in the present study we evaluated some oxidative stress parameters, namely tiobarbituric acid reactive species (TBA-RS) and total antioxidant reactivity (TAR) in plasma of X-ALD symptomatic patients. It was verified a significant increase of plasma TBA-RS, reflecting induction of lipid peroxidation, as well as a decrease of plasma TAR, indicating a deficient capacity to rapidly handle an increase of reactive species. Therefore, we may conclude that oxidative stress contributes at least in part to the pronounced neurological dysfunction found in X-ALD. In this scenario, it has been proposed that the neurological damage that occurs in X-ALD could be mediated by astrocyte activation and cytokines pro-inflammatory induction. Since free radicals are also involved in inflammatory response, our findings may reflect the same phenomenon. It is therefore proposed that oxidative stress may be involved in pathophysiology of X-ALD. Finally, since so far no therapy for X-ALD symptomatic patients has been proven to be successful, it may also be presumed that the administration of antioxidants should be considered as a potential therapy for the patients affected by X-ALD.

Genomics of Glycogen Storage Disease type Ia (GSDIa):Global gene expression analysis in glucose-treated and untreated glucose-6-phosphatase knock-out mice. *T.V. Damodaran, A. Schneider, A. Bird, Y.-T. Chen, D.D. Koeberl.*
Div of Medical Gen, Dept Peds, Duke University Med Ctr, Durham, NC.

GSDIa (Von Gierke Disease), is caused by a deficiency of glucose 6-phosphatase (G6Pase) activity and accompanying glycogen accumulation in the liver and kidney. Clinical manifestations include growth retardation, hypoglycemia, and increased risk for hepatocellular carcinoma. G6Pase knockout (G6Pase-KO) mice (Gift from J.Y. Chou, NICHD) showed all of the clinical characteristics of GSD-Ia. Using this model, we explored the global gene expression changes in glucose-treated (GT) and untreated (UT) G6Pase-KO mice. We hypothesized that pathway-specific microarrays concurrently might help us to identify key glucose-response and G6Pase system-response genes, including: A) Insulin, B) Signal transduction, C) Cell cycle, and D) Apoptosis (Superarray Biosciences, Bethesda, MD). G6Pase-KO (-/-) mice and wild-type siblings (+/+) were analyzed at 10 days old. Affected (-/-) mice were treated with 10% glucose, 1 gm/kg twice a day, which was stopped at 7 days old for UT affected (-/-) mice. RNA from liver, kidney, brain and heart was analyzed, and validation was performed for selected genes from each pathway that confirmed the gene expression patterns identified. Salient findings include the following: A) The expression profiles were distinctly different for GT and UT groups for all tissues studied; B) Liver and kidney showed similar expression profiles in GT mice, and frequently showed opposite trends from UT mice; C) Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was over-expressed in both GT and UT groups, and represented a potential biomarker for GSDIa. Increased GAPDH may be involved in non-enzymatic moonlighting activities such as transcriptional regulation, thereby playing major role in pathogenesis; D) Alterations related to increased incidence of malignancy in GSD1A liver included altered expression of genes involved in cell cycle control (eg. Ccne1, Ccnd1). Pathway-targeted microarray analysis of GSDIa mice revealed biomarkers that will be informative regarding pathogenesis, responsiveness to experimental therapies, and potential screening strategies for GSDIa in humans.

Mitochondrial disease genetics: mito-myths and mito-facts in 329 children with definite respiratory chain disorders. *D.R. Thorburn, A. Boneh, S. Walsh, E. Oldaker, D. DuSart, M. Smith, H.H. Dahl, D.M. Kirby.* Murdoch Childrens Research Institute and Genetic Health Services Victoria, Royal Children's Hospital, Melbourne, VIC, Australia.

We are referred almost all suspected cases of childhood-onset mitochondrial disease (minimum prevalence 6.2/100,000) in Australia and New Zealand. We sought to highlight a number of common misconceptions that may impede optimal investigation and management. We performed a retrospective review of records of 329 children diagnosed by our centre with definite respiratory chain defects since 1990. Results: Histochemical investigations were diagnostic in less than 10% of children. Most diagnoses are based on finding a respiratory chain enzyme defect in a skeletal muscle biopsy. However, over 40 patients, mostly with hepatoencephalopathies, had nondiagnostic muscle investigations with the diagnosis based on liver enzymology. Pathogenic mitochondrial DNA (mtDNA) mutations were identified in 84 patients from 72 families (14 mtDNA rearrangements, 29 MTTL1, 1 MTTK, 21 MTATP6, 3 MTND1, 4 MTND3, 5 MTND5, 7 MTND6); the most common diagnoses being Leigh disease, MELAS and CPEO. A family history suggesting maternal inheritance was the exception rather than the norm and many of the children had de novo mtDNA mutations. Pathogenic nuclear gene mutations were identified in 40 patients (31 families) in 9 different genes (2 NDUFS2, 1 NDUFS4, 3 NDUFS6, 2 NDUFV1, 16 SURF1, 1 SCO2, 7 POLG, 2 DGUOK, 6 TAZ) causing complex I, complex IV or combined enzyme defects. In these patients the most common diagnoses were Leigh disease, Lethal Infantile Mitochondrial Disease and Alpers disease. Enzyme-based or molecular prenatal diagnosis was performed in ~50 pregnancies at risk for nuclear or mtDNA mutations and 7 affected pregnancies were identified. Conclusion: The approach to diagnosis of mitochondrial disease in children varies depending on clinical presentation. We achieved a molecular diagnosis in 38% of patients but most children require muscle and/or liver biopsy to obtain an enzyme diagnosis and to guide molecular analysis of the 34 mtDNA and 41 nuclear genes with pathogenic mutations identified to date.

New strategies for the rapid identification and quantification of mitochondrial DNA mutations in patients with respiratory chain defects. *V. Procaccio[1,2], S. Bannwarth[3], V. Paquis-Flucklinger[3,4], N. Neckelmann[5], R. Jimenez[1], A. Davila[1], J. Poole[1], M. Simon[1], D.C. Wallace[1,2].* 1) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, USA; 2) Department of Pediatrics, University of California, Irvine, USA; 3) Department of Medical Genetics, Archet 2 Hospital, CHU Nice, France; 4) FRE CNRS/UNSA 2720, Medicine School, University of Nice-Sophia Antipolis, France; 5) Transgenomic, Inc. Omaha, NE, USA.

Molecular analysis of mitochondrial DNA (mtDNA) is a critical step in the diagnosis of mitochondrial disorders. We are currently developing a two-tier strategy for the comprehensive analysis of the entire mitochondrial genome. First, we score for the presence of the most common heteroplasmic and homoplasmic mutations that are known to be pathogenic. Scoring is accomplished by using an innovative and sensitive HPLC-mediated restriction fragment analysis process. This method does not only detect the presence of specific mutations, but also quantifies the relative percentage of mutant DNA in the sample. Mutations at levels as low as 1% can be detected and quantified. If none of the specific known mutations are found at this stage we revert to a rapid scanning procedure that is designed to detect unknown and known heteroplasmic mutations. The scanning method is based on the use of a new mismatch-specific endonuclease known as Surveyor Nuclease.We have shown that in heteroplasmic samples known and unknown mutations can be detected at levels as low as 3%. These methodologies have been used to detect mtDNA mutations in DNA samples extracted from patients blood. Using these approaches we have been able to discover mutations that have not been reported previously or because conventional techniques failed to detect them. We anticipate that positive mutation detection in blood or other tissues may avoid the need for invasive muscle biopsies in numerous cases, and will enhance our ability to detect low levels of mtDNA mutations in potential carriers, crucial for genetic counseling.

The mitochondrial DNA point mutation at the discriminator base of tRNA-Glutamate is necessary to cause benign infantile cytochrome c oxidase deficiency. *M. Mimaki[1,2], H. Komaki[1], Y. Kirino[3], T. Suzuki[3], Y. Goto[1].* 1) Mental Retardation/Birth Defec, National Inst Neurosci, Tokyo, Japan; 2) Department of Pediatrics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Department of Chemistry and Biotechnology, Graduate School of Engineering, University of Tokyo, Tokyo, Japan.

Benign infantile cytochrome c oxidase (COX) deficiency is distinct because of its unusual course with clinical and pathological improvement. We experienced 6 patients with this disease, which is characterized by weakness, feeding and respiratory difficulties, mitochondrial myopathy, and lactic acidosis. Only skeletal muscle appears to be affected, and this condition improves spontaneously at 6 to 9 months of age. COX activity is severely reduced in skeletal muscle, but return to a normal level after 1 to 3 years. This disease was thought to be attributed to a nuclear DNA mutation, however, we identified T14674C or T14674G homoplasmic mutation in the mitochondrial DNA in all of the 6 patients. It is located at the end of the aminoacyl acceptor stem of the tRNA-Glu, which plays an important role in tRNA identity as the discriminator base. The nucleotide changes were not found in 200 normal individuals. Partial RNase T1digestion of total RNA from the patient confirmed the mutation in the tRNA itself corresponding to the DNA mutation. Although acid PAGE analysis of RNA extracted from myoblasts of the patient showed normal aminoacylation of tRNA-Glu, northern blot analysis using muscle specimens revealed reduction of tRNA-Glu molecules as compared with normal infants. From these facts, we think the mutation at nucleotide position 14674 is essential cause of this disease. Early differential diagnosis between fatal and benign infantile COX deficiency by detection of this mutation is critically important for management of these infants, because the benign form is initially life-threatening but reversible. However, the mechanism of the recovery remains to be explained. A developmental change in physiological demand of tRNA-Glu quantity or a switch of enzyme from the defective fetal isoform to a normal adult one could account for the improvement.

Histological Abnormalities and Mitochondrial Dysfunction in *Klotho* and Natural Aging Mice. *K. Hirata[1,2,3], Y. Akita[2,3], Y. Koga[2,3].* 1) Department of Living Environment, Saga Junior College, Saga, Japan; 2) Pediatrics and Child Health, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 3) Kurume University, Cognitive and Molecular Research Institute, Kurume, Fukuoka, Japan.

Klotho (Kl) mouse is known as a premature aging model showing a short lifespan, infertility, arteriosclerosis, hypogonadism, skin atrophy, osteoporosis, emphysema, and growth retardation including sexual development at 3-4 weeks of age to expire at 8-9 weeks of age. Kl gene products express especially in kidney and brain. Kl mouse induce abnormal calcium metabolism to cause notable calcification in kidney, however we still do not know the precise mechanism. We focused in kidney and cerebrum to analyze histological properties and the mitochondrial function such as respiratory chain enzyme activities and oxygen consumption in mitochondrial and synaptosomal fractions to examine whether Kl mice show the same properties as natural aging mice. We performed the biochemical analysis of natural aging (CD-1, averaged 84 weeks of age) and Kl (7 weeks of age) mice. The impaired mitochondrial respirations and histological abnormalities in Kl mice bore some resemblance to natural aging mice. The mitochondrial impairment by abnormal calcium metabolism of Kl mice induced senescence, as natural aging mice, but the histomorphometrical changes and the some changes of respiratory enzyme activities in kidney and cerebrum were different with natural aging mice. We elucidated that the defect of Kl gene expression in Kl mice cause the abnormal mitochondrial energy metabolism in both tissue and the histological abnormalities with some differences such as retardation of cerebral development and abnormalities of cerebral synaptic vesicles in Kl mice between Kl and natural aging mice. It is suggested that the defect of Kl gene expression induce the abnormal mitochondrial homeostatic system to make the developmental disabilities in cerebrum and kidney, and the sign of senescence for Kl mouse.

A new mitochondrial DNA mutation in ND3 gene is associated with isolated complex I deficiency and Leigh syndrome in 3 independent families. *E. SARZI[1], D. CHRETIEN[1], S. LEBON[1], A. ROTIG[1], A. MUNNICH[1], M. BROWN[2], V. PROCACCIO[3].* 1) INSERM U393, Genetics Department Necker Hospital, Paris, France; 2) Mercer University School of Medicine, Macon, GA, USA; 3) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, USA.

NADH:ubiquinone oxidoreductase (complex I) is the largest complex of the mitochondrial respiratory chain and this complex accounts for most cases of respiratory chain deficiency in human. Complex I contains at least 46 subunits and 7 of which are encoded by mitochondrial DNA (mtDNA). Previous studies have shown that at least 20% of respiratory chain complex I deficiencies are related to mtDNA mutations. Here we report three unrelated families with Leighs syndrome (LS). The mother of the first family of French origin reported difficulties in walking and headaches. She had 3 children, who developed in the first weeks of age, LS associated with a complex I deficiency identified in muscle or liver. Sequence analysis of mitochondrial complex I genes revealed an homoplasmic G to A mutation at nt G10197A in ND3 gene in patient muscle DNAs. The mothers leukocytes showed 50% of heteroplasmy. Two patients from a second family of French origin also presented LS and a complex I deficiency in liver and fibroblasts. The G10197A mutation was found to be homoplasmic in those tissues whereas the asymptomatic mother presented 70% of mutant mtDNA molecules in leukocytes. The mother of the third family was affected with generalized dystonia with childhood onset and bilateral basal ganglia lesions. She had 3 affected children with LS. An isolated complex I deficiency was found in muscle associated with the heteroplasmic G10197A mutation. The G10197A mutation modifies a hydrophobic amino acid alanine residue into a hydrophilic threonine (A47T) in a highly conserved part of ND3 subunit. The discovery in 3 unrelated families of the G10197A mutation with a similar phenotype establishes the pathogenicity and demonstrates that the A47T is important for the function of complex I.

Natural history of mild elevations of C5OH detected by newborn screening. *G.L. Arnold, E.M. Howell, L.R. Mead.*
Div Pediatric Genetics, Univ Rochester Sch Medicine, Rochester, NY.

Introduction: Newborn screening (NBS) by TMS was recently expanded in New York State to include 3-Methylcrotonyl CoA Carboxylase (3MCC) deficiency using the marker C5OH. In New York a C5OH level 0.6 molar triggers an urgent referral to a metabolic center.

Methods: We reviewed the clinic charts of all 11 patients referred by the state NBS program for critical elevations of C5OH in the first 6 months of the expanded program.

Results: Four infants were pre-term (range 29-36.5 weeks) and seven were term; mean gestational age (GA) was 36.8 weeks. Median age at initial screen was 2 days (range 1-16). Mean birthweight (BW) was 2960 gm (range 1415-3816). Mean initial NBS C5OH level was 1.03 molar (range 0.79-2.54). Initial C5OH level was not correlated with GA, BW, or the age at NBS.

All infants are clinically well. Follow-up acylcarnitine and urine organic acid (OA) analyses were performed at the initial clinic visit. On follow-up six infants now had C5OH levels within the reference range for the laboratory (0.09) and normal OA; no further testing was done. Of the remaining 5 infants the follow-up C5OH level was 0.16-0.4. Two infants had normal OA and C5OH levels of 0.23-0.3 (including one whose mother was found to have a mild persistent elevation of C5OH with normal plasma carnitine levels); no further testing was done. Two others had mild elevations of 3-isovalerylcarnitine and 3-methylcrotonylglycine on OA analysis. On serial testing one of these infants normalized the C5OH level by month 2. However at age 4 months one remains with mild elevation (0.39); this is also the infant with the highest NBS C5OH level of 2.4 molar.

Discussion: Mild elevation of C5OH can be found in both pre-term and healthy term newborns; most have normal OA and the C5OH elevations usually resolve within weeks. Infants having low-grade abnormal metabolites on urine OA analysis may take longer to resolve blood C5OH levels or may have persistent mild elevations of unclear significance.

Whole blood and leukocyte intracellular glutathione levels are low in organic acidemias. *G.M. Enns[1], K.R. Atkuri[2], T.M. Cowan[1,3], S.M. Huegenin[3], M. Lyons[1], L.A. Herzenberg[2], L.A. Herzenberg[2].* 1) Dept. Pediatrics, Divs Med. Genet; 2) Dept. Genetics; 3) Dept. Pathology, Stanford University, Stanford, CA.

Primary disorders of organic acid metabolism may cause secondary mitochondrial dysfunction, leading to increased production of intracellular reactive oxygen species (iROS) and depletion of intracellular antioxidants. The glutathione system is the main natural defense mechanism that helps to combat oxidative damage, but it has not been studied systematically in individuals with organic acidemias. In this report, we analyzed intracellular and whole blood glutathione levels in three patients with methylmalonic acidemia (*mut*^{0}) and one with propionic acidemia using Hi-D fluorescence activated cell sorting (FACS) and tandem mass spectrometry (MS/MS). Peripheral blood buffy coats were treated with monochlorobimane (MCB), then stained for leukocyte subset markers and subjected to FACS. When compared to normal controls (n=27), iGSH levels in CD4 (MCB ratio 1.12 $\pm$ 0.15 v. 1.66 $\pm$ 0.27 in controls, p=0.002) and CD8 (MCB ratio 1.04 $\pm$ 0.20 v. 1.52 $\pm$ 0.21 in controls, p=0.003) T lymphocyte subsets and neutrophils (MCB ratio 2.15 $\pm$ 0.85 v. 2.65 $\pm$ 0.61, p=0.044) were significantly lower in subjects with organic acidemias. iGSH levels tended to be lower in monocytes (p=0.054), but a significant difference in B cells was not observed. Consistent with FACS results, the mean whole blood glutathione level in organic acidemia patients was 60% of normal controls when analyzed by MS/MS. Immunodeficiency, in addition to neutropenia, has been reported in patients with organic acidemias. The pathogenesis of immune dysfunction in organic acidemia patients may in part be explained by low leukocyte iGSH levels leading to damage of specific immune cell subsets. Because N-acetylcysteine (NAC) restores iGSH levels by providing the cysteine necessary for its biosynthesis, NAC therapy may be beneficial in both acute and chronic treatment of organic acidemias.

Characterization of two patients with mut^0 methylmalonic acidemia after combined liver-kidney transplantation: failure to normalize CSF metabolism. *J.L. Sloan[1], M. Merideth[1], T. Bunchman[2], J.J. Gargus[3], R. Koch[4], C.P. Venditti[1].* 1) NHGRI, NIH, Bethesda, MD; 2) DeVos Children's Hospital, Grand Rapids, MI; 3) UCI, Irvine, CA; 4) Childrens Hospital LA, Los Angeles, CA.

Methylmalonic acidemia (MMAemia), caused by deficiency of the methylmalonyl CoA mutase is a devastating disorder, recalcitrant to medical management in many cases. Several patients have received kidney, liver and combined liver-kidney transplantation as a treatment, with mixed results. We describe the metabolic phenotype of two patients with mut^0 class MMAemia s/p liver and kidney transplantation who were studied in the inpatient setting. Case 1, a 19 year-old female, was diagnosed at 2 days following an episode of hypothermia and lethargy. At age 12, she received a cadaveric renal transplant and subhepatic heterotopic auxiliary liver transplant. Case 2, a 27 year-old female, was diagnosed in the neonatal period. At age 22, she received an orthotopic liver transplant, followed by a kidney transplant two years later. Transplantation has protected the patients from ketoacidotic crises. Both have persistent MMAuria, range 1197-2266 mg/gCr (nl<3). Other parameters were essentially identical, including plasma MMA concentration (260-270 M) [nl<0.27] and whole body MMA output (14 mg MMA/kg/d). Case 2 demonstrated reduced MMA output and decreased plasma MMA levels (268 M vs. 181 M) with dietary protein restriction. The concentration of MMA in the CSF of both patients was >500 M [nl<0.59], more than two-fold that of the plasma MMA. 2-methylcitrate was also increased in the CSF > plasma. Creatinine clearance was normal. CONCLUSIONS: Persistent elevations of MMA and 2-methycitrate and modulation by precursor intake indicate that combined liver-kidney transplantation is not curative for MMAemia. High levels of MMA in the CSF s/p LKT may increase the risk to develop a metabolic stroke or CNS dysfunction. The possibility of further renal injury post-transplant must also be considered given the massive MMAemia/uria. Nutritional control and CSF monitoring may be required for optimal management. Further studies on the post-transplant state are needed, particularly on outcome and metabolic characterization.

Characterization and identification of mitochondrial cobalamin binding proteins in patients with methylmalonic aciduria. *E. Moras[1,2], D. Watkins[2], D.S. Rosenblatt[1,2].* 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) Division of Medical Genetics, Department of Medicine, McGill University Health Centre, Montreal, QC, Canada.

Vitamin B_{12} (Cbl) is necessary for the function of two human enzymes: methylmalonyl CoA mutase (MCM) and methionine synthase (MS). The mitochondrial enzyme, MCM, catalyzes the conversion of L-methylmalonyl-CoA to succinyl-CoA and uses adenosylcobalamin (AdoCbl) as a cofactor. Defective MCM enzyme (complementation group *mut*) or a deficiency in the synthesis or utilization of AdoCbl (*cblA*, *cblB*, and *cblH*) results in methylmalonic aciduria (MMA). In the cytosol, methylcobalamin is utilized as a cofactor for MS in the conversion of homocysteine to methionine. The *cblC*, *cblD*, and *cblF* disorders result from defects in the synthesis of both cofactors and therefore present with combined MMA and homocystinuria. In man, Cbl has been shown to bind to MCM in mitochondria and to MS in the cystosol. Using fibroblast cell lines from patients with different inborn errors in AdoCbl synthesis, we attempted to determine if other mitochondrial Cbl binding proteins involved in AdoCbl synthesis and/or metabolism exist. We also tried to understand how known mutations in these patients might affect Cbl binding to accessory proteins. Fibroblasts were incubated with [^{57}Co]CNCbl and mitochondrial fractions were obtained. Using gel filtration chromatography, proteins were separated based on molecular weight. In control cells, the majority of radioactivity (65%) eluted with an apparent molecular weight of 150kD, corresponding to MCM. Unbound Cbl (1355D) was also identified (16.2 %). Six per cent of the radiolabelled Cbl eluted with a previously unidentified protein having an apparent molecular weight of 30kD. Extracts from *cblA* fibroblasts showed a Cbl binding profile similar to that of controls. In the *cblB*, *cblH*, *mut* and *cblC* complementation groups, the unidentified peak represented a large amount of the radiolabelled Cbl (28%, 41%, 54% and 73% respectively). These results indicate the presence of an as yet unknown Cbl-binding protein in the mitochondria of human fibroblasts.

Overexpression of Mouse MethylmalonylCoA Mutase in Yeast: Use to Study Interallelic Complementation and Kinetic Characterization of a Novel Km Mutant. *V. Aswani[1,2], R. Chandler[1], L. Worgan[3], D. Rosenblatt[3], C.P. Venditti[1].* 1) NIH, NHGRI, Bethesda, MD; 2) Marshfield Clinic, Marshfield, WI; 3) Dept of Human Genetics, McGill University.

Studies were undertaken to examine the kinetic properties of the murine MCM enzyme and a series of site-directed mutants that changed homologous amino acids seen in various patients with mut-class MMA, including two that participate in interallelic complementation and one associated with partial impairment of enzymatic function. The R93H, G717V, and G642R mutations were introduced into the mouse gene at homologous positions. The G642R change was identified in a patient with residual propionate incorporation and a mild infantile course. The mutations were cloned under the control of the GAL4 promoter with either URA or TRP markers and introduced into yeast with single or double auxotrophic selection. Antibodies against the mouse protein were generated and used to verify galactose-regulated expression. Activity was measured with the succinate thiokinase linked assay. Km and Vmax parameters and their distribution-free confidence limits were determined by direct linear plots. Robust activity exceeding 2000 nmol/mg/hr was routinely achieved in the yeast extracts, allowing kinetic studies to be conducted with ~15 ml of log-phase yeast as starting material. The WT murine enzyme had native properties when over-expressed and was entirely apoenzyme. The G640R change produced a pure cobalamin Km effect, approximately 10 fold increased vs WT, milder than that previously reported for the human G717V mutation, and may be suitable for expression in the murine model to produce a mut- state. The R91H/G715V double mutant possessed mixed kinetic parameters, intermediate between wild type and the individual mutants, demonstrating that interallelic complementation can be replicated in yeast by co-expression of two mutant subunits. Detailed kinetic analysis has also allowed cofactor administration in the affected patient with the G642R mutation to be reconsidered. The natural mutations seen in patients with mut class MMA should be studied in greater detail to allow genotype-enzymatic correlations to be examined.

The molecular basis of atypical methylmalonic aciduria: Search for mutations in the methylmalonyl-CoA mutase and methylmalonyl-CoA epimerase genes. *A.B. Gradinger[1,3], L.C. Worgan[3], J.P. Lerner-Ellis[1,3], D. Watkins[3], E. Moras[1,3], D. Roquis[2], C. Doré[2], D.S. Rosenblatt[1,3].* 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 3) Division of Medical Genetics, Department of Medicine, McGill University Health Centre, Montreal, QC, Canada.

The methylmalonic acidurias occur due to a defect in methylmalonyl-CoA mutase (MCM) (*mut*) or due to inborn errors in the metabolism of vitamin B_{12} (cobalamin) that result in a block of the synthesis of adenosylcobalamin (AdoCbl) (*cblA*, *cblB*, *cblC*, *cblD*, *cblF*, or *cblH*). D-methylmalonyl-CoA is generated during the catabolism of branched chain amino acids, odd chain fatty acids and cholesterol. Methylmalonyl-CoA epimerase racemizes D-methylmalonyl-CoA to L-methylmalonyl-CoA, which is then converted to succinyl CoA by MCM, using AdoCbl as a cofactor. It has been suggested that defects in epimerase will also result in methylmalonic aciduria (MMA), but no confirmed cases of epimerase deficiency have been identified. We have sequenced the *MUT* and *MCEE* genes (coding for MCM and epimerase respectively) from 30 patients with mild MMA, who could not be assigned to any of the known disorders causing MMA. Their cultured fibroblasts showed reduced incorporation of labeled propionate into cellular macromolecules (a measure of functional MCM activity). Patients ranged from being clinically unaffected to having severe presentations such as muscular hypotonia, acidotic crises and developmental delay. Analysis of the *MUT* gene revealed a heterozygous missense mutation in one patient (c.1091A>C, p.Y364S). As well, a heterozygous silent base change (c.711A>G, p.P237P) was present in two patients. Neither of these changes was seen in 48 CEPH controls. Sequencing of the *MCEE* gene showed two patients to be homozygous for a nonsense mutation (c.139C>T, p.R47X). Another patient was shown to be heterozygous for a deletion in the 3 untranslated region (c.*+120_121delTG). Neither of these changes was seen in 70 CEPH controls. Thus, in this subset of patients, it is possible that the changes found in the *MUT* or *MCEE* genes contribute to their mild MMA.

Combined methylmalonic and malonic aciduria with cerebral organic acidosis in a 52 year old man. *K. O'Brien[1], J. Sloan[1], C. Whitley[2], I. Bernardini[1], A. Gropman[3], C. Venditti[1].* 1) NHGRI/NIH,Bethesda,MD; 2) University of MN,Minneapolis,MN; 3) Georgetown University,Washington, DC.

Combined methylmalonic and malonic aciduria (CMAMMA is a rare metabolic disorder with an unknown etiology. Metabolic findings include increased malonic acid (MA) and methylmalonic acid (MMA) in the urine. We describe the case of a 52 year old white male with progressive neuropsychiatric complications, no history of metabolic decompensation, and methylmalonic acidemia. Over an eight year period he developed progressive cognitive decline with labile moods, and began experiencing seizure-like episodes. He was treated for a seizure disorder based on his history and an abnormal baseline electroencephalogram (EEG), but did not respond to anti-epileptic therapy. Intramuscular hydroxycobalamin failed to lower his plasma MMA level or improve symptoms. Neurocognitive assessment revealed memory loss, attentional difficulties, motor asymmetry, a sensory neuropathy, and bilateral coordination deficits. Magnetic resonance imaging of the brain demonstrated a right choroid plexus cyst and punctuate lesions in the cerebellar hemispheres. Magnetic resonance spectroscopy of brain white matter, cortical and deep gray matter, and cerebrospinal fluid (CSF), was unremarkable. Laboratory studies showed an elevated plasma MMA level of 11 uM with normal vitamin B12 and homocysteine levels. Fibroblast MalonylCoA decarboxylase activity was normal. His urine organic acid (OA) profiles demonstrated increased MMA (9-111 mmol/mol Cr, normal <4) and MA (9-16 mmol/mol Cr, normal<2) without other propionate-derived metabolites. The plasma MMA levels ranged between 10.0-15.3 uM. CSF analysis showed increased MMA, MA and detectable ethylmalonic acid, with a CSF to plasma MMA gradient greater than 5-fold. This patient appeared to have the CMAMMA syndrome based on urine OA analysis. However, his CSF organic acid profile is compatible with a combined semialdehyde metabolic perturbation. In some patients the natural history of the CMAMMA syndrome may feature altered central nervous metabolism and a predisposition to neuropsychiatric complications. The natural history of this syndrome needs further delineation.

Pearson syndrome with abnormal urine organic acids and a novel mitochondrial DNA deletion. *Y. Qu[1], H. Bass[2], M. Jamehdor[1], R. Mardach[2,3].* 1) Dept. of Genetic Testing, Kaiser Permanente, Los Angeles, CA; 2) Dept. of Genetics, Southern California Permanente Medical Group, Los Angeles, CA; 3) Regional Metabolic Service, Kaiser Permanente, Los Angeles, CA.

Pearson marrow-pancreas syndrome is a rare mitochondrial deletion syndrome characterized by refractory anemia with pancreatic dysfunction. The phenotypic presentation is variable depending on the amount of mitochondrial DNA deletion found in different tissues. Without identification of a mutation, the diagnosis can be difficult. We report a patient with Pearson syndrome who had abnormal urine organic acids and a novel mitochondrial DNA deletion.

The patient is the fourth child born prematurely at 35-week gestation to a non-consanguineous couple. Family history was unremarkable. During the neonatal period, the baby was found to have pancytopenia and hepatomegaly. A metabolic work-up revealed normal plasma amino acids and acylcarnitines but aminoaciduria. Urine organic acid (UOA) analysis showed lactic aciduria with ketosis. The most notable excretion of organic acids (in mmol/mol creatinine) are: lactate, 2157 (N=0-150); 2-hydroxybutyrate, 125 (N=0-3); 2-hydroxyisovalerate, 52 (N=0-1); 3-hydroxybutyrate, 565 (N=0-15); 3-hydroxyisobutyrate, 1079 (N=0-75); 3-hydroxypropionate, 934 (N=0-15); propionylglycine, 8 (N=0); fumarate, 201 (N=0-17) and malate, 518 (N=0-62). However, 3-methylglutaconic acid, which may be found in patients with mitochondrial disorders, was within normal range. Branched-chain amino acid in-vitro probe assay was conducted on fibroblasts, and no specific defects were detected. Analysis of mitochondrial DNA revealed a novel 5.2 kb deletion confirming the diagnosis of Pearson syndrome.

Relevant clinical symptoms and the presence of lactic aciduria, ketosis, together with increased excretion of branched-chain amino acid and TCA cycle metabolites, should prompt mitochondrial DNA testing. More data should be collected to analyze if a correlation exists between an abnormal UOA pattern and a mitochondrial DNA mutation on a clinical background.

A novel quantitative method for detection of allele-specific RNA expression. *E. Klootwijk, E. Gottlieb, C. Ciccone, P.J. Savelkoul, M.S. Sun, D. Krasnewich, W.A. Gahl, M. Huizing.* MGB, NHGRI, NIH, Bethesda, USA.

Hereditary Inclusion Body Myopathy (HIBM) and sialuria are two distinct disorders resulting from mutations in the same gene, *GNE*, coding for the bifunctional, rate-limiting enzyme in sialic acid biosynthesis, i.e., UDP-GlcNAc 2-epimerase (GNE)/ManNAc kinase (MNK). Sialuria is caused by autosomal dominant missense mutations in the allosteric site of GNE/MNK, leading to a loss of feedback-inhibition and increased excretion of sialic acid. In contrast, HIBM is caused by autosomal recessive *GNE* missense mutations outside the allosteric site, resulting in decreased GNE/MNK enzyme activity and decreased production of sialic acid. Both sialuria and HIBM exhibit variable clinical phenotypes. We examined whether there exist mutation-dependent variations in allelic expression of *GNE*, since these could account for the variable disease phenotypes. We developed a real-time RT-PCR method that rapidly and accurately detects and quantifies allele-specific expression. The procedure is based on the use of a combination of two allele-specific fluorescent reporter probes and real-time amplification kinetics. We first tested the validity of each allele-specific assay across a concentration range obtained by mixing cell-free transcribed normal and mutated *GNE* RNA. Each of the assays proved to be accurate and mutation-specific, allowing us to study allelic expression of *GNE*. Next, we applied the assays to RNA obtained from fibroblasts of sialuria or HIBM patients. No patient showed a significant difference in mutation-dependent allelic *GNE* expression, indicating that allelic expression did not cause the variable phenotypes in these patients with sialuria or HIBM. This novel, allele-specific RNA quantifying method is convenient and rapid, and requires minimal concentrations of RNA (<25ng). The procedure is attractive for various applications, including validation of SI-RNA silencing experiments. In fact, we have demonstrated the methods validity for allele-specific RNA gene silencing using SI-RNAs in sialuria fibroblasts. In addition, this method can be employed for studies of X-chromosomal inactivation, genetic imprinting, and epigenetics.

Use of knockout mouse models to elicit the pathophysiology involved in obesity and hypertension in Bardet-Biedl syndrome. *M.A. Fath[1,3], K. Rahmouni[2], M. Andrews[1,3], C.D. Sigmund[2], V.C. Sheffield[1,3].* 1) Department of Pediatrics, Division of Medical Genetics; 2) Department of Internal Medicine; 3) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetic disorder with the cardinal features of obesity, retinopathy and polydactyly. We have developed mouse BBS models for BBS2 (*Bbs2*$^{-/-}$) BBS4 (*Bbs4*$^{-/-}$) and BBS6 (*Bbs6*$^{-/-}$) whose phenotypes closely resemble that of humans. We sought to use these models to dissect the mechanisms involved in the metabolic and cardiovascular disorders associated with BBS. We found that BBS null mice develop obesity due to both hyperphagia and a decrease in activity. We examined whether the obesity in the BBS null mice is associated with the loss of leptin action or leptin resistance. Leptin is an adipocyte-derived hormone that promotes weight loss by decreasing appetite and increasing energy expenditure. We found high circulating levels of leptin in the BBS null mice. As expected, injections of leptin caused a decrease in body weight and food intake in the wild type mice. Leptin failed to reduce appetite or body weight in both *Bbs2*$^{-/-}$and *Bbs4*$^{-/-}$adult mice but had a modest effect on young animals. This indicates that the hyperleptinemia observed in the BBS null mice increases with age and adiposity. Next we compared arterial pressure between wild type and BBS null mice. *Bbs4*$^{-/-}$and *Bbs6*$^{-/-}$mice exhibited ~12 mmHg higher arterial pressure than their wild type controls. However, *Bbs2*$^{-/-}$mice had normal arterial pressure. Increased sympathetic nerve activity is considered to be an important mechanism of obesity-associated hypertension. Consequently, we recorded the renal sympathetic nerve activity in the knockout mice. *Bbs4*$^{-/-}$ and *Bbs6*$^{-/-}$mice showed higher baseline renal sympathetic nerve activity as compared to the wild type mice but the *Bbs2*$^{-/-}$mice did not, consistent with the normal arterial pressure findings. All 3 mouse models of BBS exhibit obesity however only 2 exhibit hypertension. This suggests a role for the renal sympathetic nervous system in the high arterial pressure associated with BBS and a unique opportunity to understand the mechanisms of obesity-associated hypertension.

Genetic disruption of *RanBP2* in the murine impairs glucose catabolism and retinal function. *P. Ferreira[1], A. Aslanukov[1], R. Bhowmick[1], J. Oswald[1], D. Raz[2], R. Bush[2].* 1) Departments of Ophthalmology, Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC 27110; 2) National Institutes of Health, NIDCD/NEI, Bethesda, MD 20892.

The Ran-binding protein 2 (RanBP2) is a large mosaic protein unique to vertebrates. Selective domains of RanBP2 interact specifically with a diverse set of molecular partners. RanBP2 has been implicated in multiple cellular functions. Yet, the biological relevance and implication/s of these in physiological and pathological processes remain elusive. To probe the function of RanBP2 in animal physiology and disease, we generated a mouse model harboring the disruption of *RanBP2*. Analysis of the Mendelian ratios of the offspring produced from $RanBP2^{+/-}$ x $RanBP2^{+/-}$ crosses supports that $RanBP2^{-/-}$ mice are early embryonic lethal. The *RanBP2* locus was also haploinsufficient. $RanBP2^{+/-}$ mice exhibited a number of physiological phenotypes that were dependent on the age and genetic background. $RanBP2^{+/-}$ males 6 months old in an inbred 129ola, but not in a 129ola/C57Bl6 mixed genetic background, exhibited significant deficits in glucose catabolism upon glucose challenge and when placed on a high fat diet, without impairment of gluconeogenesis and glucose uptake. This was accompanied by a reduction of the levels of hexokinase I (HKI), a partner of RanBP2, and its delocalization in photoreceptors. $RanBP2^{+/-}$ males had decreased body weight beginning at ~4 month of age, but exhibited similar levels of food consumption. $RanBP2^{+/-}$ male mice had ERG deficits. These were manifested by a reduction of the scotopic *b*-wave and a trend towards a reduced photopic *b*-wave and scotopic *a*-wave. Finally, there was no difference in the average of the density of nuclear pores (NPC) at the nuclear envelope (~ 3-4 NPC/m2) between wild type and heterozygous *RanBP2* litters (P0). Altogether, the data support that haploinsufficiency of *RanBP2* causes deficits in glucose catabolism by a RanBP2-mediated reduction in HKI and genetic modifiers modulate this process. Hence, the *RanBP2* mouse model serves as a disease model to complex metabolic disorders such as diabetes type II and allied retinopathies.

A conditional knockout mouse model for Gaucher disease. *G.B. Sinclair[1], K.E. Colobong[2], F.Y.M. Choy[3], L.A. Clarke[2].* 1) Department ofPathology , Children's and Women's Health Center of British Columbia, Vancouver, Canada; 2) BC Research for Children's and Women's Health, Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 3) Centre for Biomedical Research, Department of Biology, University of Victoria, Victoria, Canada.

Gaucher disease (OMIM 230800), the most common lysososomal storage disorder, results from an inherited deficiency of the enzyme glucocerebrosidase (GBA) (EC 3.2.1.45). Enzyme replacement regimes (ERT) have been effective in altering the disease course in non-neuronopathic (type I) forms. There still remains though a very poor understanding of the pathologic mechanisms underlying the extreme heterogeneity of type I patients, the etiology of neuronopathy in type II and III patients, and the role of ERT across this spectrum. Mouse models for this disease have been attempted using traditional gene knockout, point mutation, and chemical induction approaches, with varying degrees of success. We have utilized Cre and Flpe recombinases in a novel approach to conditionally inactivate the murine GBA locus, allowing for the removal of selectable markers at the ES cell stage, and adding only targeted recombination sites. Non-recombined animals develop normally, while early ubiquitous recombination leads to significant tissue glucocerebroside storage and recapitulates the perinatal lethal phenotype observed with traditional GBA knockout. Hematopoietic and endothelial cell-specific recombination was achieved using the Tie2Cre system. Conditional KO animals are viable but have significant pathology. These animals display 33% of normal GBA activity in the liver, 10-15% in the bone marrow and spleen, and had undetectable activity in peripheral mixed white cells. Tissue glucocerebroside storage was evident with isolated lipid laden "Gaucher" cells in the liver, rafts of these cells in the spleen and measurable splenomegaly by 26 weeks of age. While this current model resembles type I Gaucher disease, this system allows for spatiotemporal control of GBA activity and the modeling of a wide array of Gaucher phenotypes leading to greater understanding of the pathophysiology of disease and further potential therapeutic approaches.

Linkage analysis in one Chinese family with congenital fibrosis of extraocular muscles and mutation screening of candidate gene. *S. Lu, C. Zhao, N.D. Li, K.X. Zhao.* molecular genetics lab, TianJin Eye Hospital, TianJin, TianJin, China.

Objective To describe the clinical phenotype in a Chinese family with congenital fibrosis of extraocular muscles. To identify the chromosomal location of the disease locus and to sequence the candidate gene in the critical region. Methods The clinical feature of all affected members in this family were examined. A genome-wide linkage screening was conducted. Direct genomic sequencing was used to evaluate the candidate gene KIf21A. Results Four affected members in the pedigree were born with classic phenotype of CFEOM. By linkage analysis the disease gene was mapped to chromosomal region 12p11.2-q12 defined by microsatellite markers D12S1648 and D12S1668. The maximum Lod Score was 2.12 (D12S1090). Direct sequence showed no mutation in all exons and exon-intron boundaries of the candidate gene KIF21A , a polymorphism substitution occurred in the exon 21. Conclusions The disorder in this family should be referred as CFEOM1which was inherited as an autosomal dominant trait. The candidate gene was linked to CFEOM1 locus on chromosome 12p11.2-q12, between marker D12S1648 and D12S1668. It's more likely that KIf21A is not the disease causing gene in this family.

Nonlinear Transmission/Disequilibrium Test. *M. Xiong[1], J. Zhao[1], E. Boerwinkle[1], C. Amos[2].* 1) Dept Human Genetics, Univ Texas Health Science, Houston, TX; 2) Dept Epidemiology, MD Anderson Cancer Institute, Houston, TX.

With the imminent completion of the International HapMap Project, and the availability of efficient and cost-effective genotyping technologies, genome-wide TDT for linkage and association analysis of complex diseases is feasible. In its original form, the TDT may not optimally reveal information and therefore we introduce nonlinear TDT statistics to amplify the difference in the frequencies of the transmitted and nontransmitted alleles/haplotypes in order to increase statistical power. In this report, we develop theoretical foundations and a general statistical framework for the construction of nonlinear TDT statistics. The type I error rates of the nonlinear TDT statistics in both homogeneous and admixture populations are validated through extensive simulation studies. By analytical methods, we show that several nonlinear TDT statistics have higher power than the original TDT statistics. Using approximation to the noncentrality parameters, we unravel the relationship between the measure of nonlinearity of the nonlinear function and the power of the nonlinear TDT statistic. We also show that a class of similarity measure-based TDT statistics can be derived as nonlinear TDT statistics. Finally, to further evaluate the performance of the nonlinear TDT statistics, the presented nonlinear TDT statistics are applied to two real data examples to test the linkage of the RET gene with Hirschsprung disease the and FC receptor genes with systemic lupus erythematosus. The results show that several nonlinear TDT statistics can reach stringent p-values to ensure genome-wide significance.

Exploiting Grid Computing for the Analysis of Genetic Linkage Disequilibrium. *W.W.S. Lau, A.R. Collins.* Human Genetics, Southampton General Hospital, Mailpoint 808, Duthie Building, University of Southampton, SOUTHAMPTON, Hampshire, United Kingdom.

Linkage disequilibrium (LD) maps are analogous to linkage maps in that map distances are additive but for disease association mapping they provide potentially much higher resolution. LDMAP is a program for constructing LD maps from single nucleotide polymorphism (SNP) data from large population samples. It employs a sequential algorithm which selects the informative SNP pairwise data for each interval between adjacent SNPs, and models the decline of association with distance centered on each interval. From the HapMap project and other sources, millions of SNP genotypes are now available for constructing the LD maps. However the volume of data imposes a considerable computational load which can be addressed effectively utilizing the computational Grid. Grid computing provides a distributed high-throughput alternative to manage the large scale data processing in which the computing resource is made available on demand transparently. The LDMAP algorithm has been integrated into the Condor system - a cycle stealing scheduler, and has been evaluated on a cluster of more than 1600 nodes. The Grid-Enabled LDMAP has been prototyped, and the LD maps of entire chromosomes are constructed from HapMap samples. An online interface which will allow external users to build maps on remote Grid resources is planned. High resolution LD maps constructed from the high density HapMap samples (3 million SNPs per population projected) will have a substantial impact on the efforts to map complex trait genes and for the study of selection, frequent chromosome rearrangements and other phenomena.

Merging microsatellite data II: methodology and software to increase power in association studies. *A.P. Presson*[1], *E. Sobel*[2], *J.C. Papp*[2]. 1) Dept Statistics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Correctly merged data sets can increase statistical power in association studies. However, alleles from microsatellite data sets genotyped with different experimental protocols or platforms cannot be accurately matched using base pair size information alone. In a recent publication we introduced MicroMerge, software that merges microsatellite data by matching allele frequencies between data sets. In the current presentation we discuss an alternate algorithm, which produces data sets that can be analyzed by all standard genetic analysis software. The new model considers unique alleles that are observed at only one laboratory to be missing from the other laboratory's data set. This view differs from the previous method that ascribed missing alleles to allele-calling differences, i.e., lumping more than one true allele under a single allele name. In addition to the current, alternate algorithm, we now present extensions of both algorithms to (1) align multiple data sets simultaneously, (2) align data sets that each contain samples from more than one ethnic group, (3) enable user supplied population allele frequency vectors, so that small data sets can be combined, and (4) reject poorly aligned allele pairs instead of entire markers. Finally, we discuss a maximum likelihood approach for assessing alignment quality. These new features extend the application of MicroMerge to a greater variety of data sets and improve the merge yield by preserving all confidently aligned alleles. Preliminary results indicate that the new algorithm successfully aligns data sets, and that the new features will be an asset to the association analysis.

***In silico* fine-mapping of genetic loci for mammary metastasis in mice.** *P. Liu, H. Vikis, Y. Wang, M. You.*
Department of Surgery, Washington Univ. in St. Louis, St. Louis, MO.

Metastasis is a process by which tumors spread from the primary organ of growth to secondary sites in the body. This process is of tremendous clinical importance, since the majority of cancer mortality is associated with metastatic diseases rather than the primary tumors. In this study, we performed a whole-genome linkage disequilibrium (LD) analysis *in silico* for the metastasis efficiency of mammary (MEM) tumors in mice. Genotypic data on 8,868 evenly distributed single nucleotide polymorphisms (SNPs), spanning the mouse genome at an average density of 288kb per SNP, were downloaded from the Novartis Research Foundation (GNF) SNP database. Twenty five inbred strains with different genealogies and distinct metastatic potentials were used for our analysis. We identified two new genomic regions (MEM1 and MEM2) on chromosomes 5 and 9, respectively, which were potentially associated with mammary tumor metastasis (p ¡Ö 0.0006). Potential candidate genes in these two regions were carefully assessed based on previous studies and the gene ontology (GO) inference. We prioritized a small list of candidate genes, including Eif2ak1, Pms2, and Ocm for future confirmation studies. Our study provides important clues toward the identification of the MEM genes.

Mapping of Autosomal Dominant Progressive Myopathy of a Limb-Girdle Distribution and Bone Fragility to Chromosome 9p21-p22: Identification of a Novel Locus for a Musculoskeletal Syndrome. *G. Watts[1], S. Mehta[1], C. Zhao[2], S. Ramdeen[1], S.J. Hamilton[3], S. Mumm[4], M.P. Whyte[4], B. McGillivray[3], V.E. Kimonis[1].* 1) Division of Genetics, Childrens Hospital, Harvard Medical School, 300 Longwood Avenue, Fegan 10, Boston, MA 02115; 2) Center for Medical Genetics, Molecular Genetics Laboratory, 1000 North Oak Avenue, Marshfield, WI, USA; 3) Provincial Medical Genetics Programme, Children's and Women's Health Centre of British Columbia C234, 500 Oak Street, Vancouver, British Columbia V6H 3N1; 4) Division of Bone and Mineral Diseases, Washington University School of Medicine, and Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO, USA.

Autosomal dominant progressive myopathy of a limb-girdle distribution and bone fragility is a rare and complex disorder of unknown etiology. In this report we present clinical studies and mapping of this disease utilizing a genome-wide scan. Affected individuals in the large family we describe demonstrate the phenotypic variability of this disease, developing combinations of progressive muscle weakness, susceptibility to fractures and poor healing of long bones. Additional features seen in the family include thin, prematurely grey hair, thin skin and hernias. Electromyograms and muscle biopsies show non-specific myopathic changes, and radiographs reveal coarse trabeculation, patchy sclerosis, cortical thickening, and narrowing of the medullary cavity. We identified linkage to chromosome 9p21-p22, with a maximal LOD score of 3.74 for marker DS91121. Haplotype analysis narrowed the disease locus to a 15Mb region flanked by markers AGAT142P and GATA5E06P. This new region contains the locus for Diaphyseal Medullary Stenosis with Malignant Fibrous Histiocytoma (DMS-MFH). Although DMS-MFH lacks the myopathy and causes malignant fibrous histiocytoma in 35% of affected individuals, the skeletal similarities to the family presented are striking. Identification of the gene for this unique disorder will facilitate our understanding of the complex interaction between bone and muscle pathogenesis in this and other related debilitating disorders.

Bivariate linkage of cortical bone thickness and skeletal age to chromosome 3p. *D.L. Duren[1], J. Blangero[2], T. Dyer[2], S.A. Cole[2], R.M. Siervogel[1], B. Towne[1].* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX.

Skeletal growth, maturation, and mineralization are highly coordinated, yet distinct, processes of bone development. The genetic regulation of each process is also distinct, but at the same time it is likely that they have some shared genetic basis. In this study, we analyzed radiographic cortical thickness of the second metacarpal and skeletal maturation of the hand-wrist using the FELS method (Roche et al., 1988) in 600 children from the Fels Longitudinal Study examined at chronological age 10 years. These individuals are from 144 nuclear and extended families. An initial set of 440 of these individuals have been genotyped for some 400 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to obtain uni- and bi-variate multipoint LOD scores. Univariate linkage analysis of cortical bone measures revealed three significant LOD scores (> 3.0) for linkage to markers on chromosomes 2 and 3. We followed this with a bivariate linkage analysis of lateral cortical thickness and skeletal age, and found significant linkage (LOD = 3.98) to markers on chromosome 3p at 32 cM (between markers D3S1304 and D3S1263), an increased linkage signal over that of lateral cortical thickness alone (LOD = 3.67) to the same chromosomal position. One potential positional candidate gene residing in this region is the oxytocin receptor gene (OXTR). Because the oxytocin receptor was recently found to be functional in both osteoblasts and osteoclasts, and has binding affinity to both oxytocin and estrogen, OXTR is a plausible candidate gene for childhood bone accrual. Future work will seek to identify other specific genes that influence the accrual of bone mass at different stages of childhood development. Supported by NIH grants HD36342, HD12252, and MH59490.

A gene for Autosomal Dominant Childhood Onset Proximal Spinal Muscular Atrophy with Lower Limbs Predominance maps to chromosome 14q32.3. *L. Viollet[1], A. Toutain[2], L. Guyant-Marechal[3], J.M. Pedespan[4], C. Laroche[5], B. Fouquet[6], D. Lacombe[7], I. Maystadt[8], P. Saugier-Weber[3], A. Munnich[1].* 1) INSERM U-393, Hopital Necker, Paris, France; 2) Service de Génétique, Hôpital Bretonneau, Tours, France; 3) Service de Génétique, Hôpital Charles Nicolle, Rouen, France; 4) Service de Neuropédiatrie, Hôpital Pellegrin, Bordeaux, France; 5) Service de Neuropédiatrie, Hôpital Dupuytren, Limoges, France; 6) Service de Medecine Physique, Hôpital Bretonneau, Tours, France; 7) Service de Génétique, Hôpital Pellegrin, Bordeaux, France; 8) Centre de Génétique Humaine, UCL, Bruxelles, Belgique.

Spinal muscular atrophies (SMA) are characterized by progressive anterior horn cell degeneration, leading to motor weakness, muscular atrophy and denervation. Numerous SMA phenotypes have been reported, differing by the distribution of paralysis, the age at onset and the mode of inheritance. Here we report on a phenotype of autosomal dominant SMA in a large European pedigree, characterized by childhood onset and benign evolution. In all of patients, walking ability was delayed and weakness predominated at the pelvic girdle muscles. A symmetrical atrophy of the thigh and leg muscles was noted, contrasting with normal or slightly weak scapular girdle muscles. No chest deformity was noted, scoliosis was absent and patients were still ambulant at adulte age. Osteotendinous reflexes were preserved and/or brisk in the lower and upper limbs. Diagnosis of motor neuron disease was suspected on neurological assays, showing muscle denervation with normal motor and sensory nerve conduction velocities. SMN gene deletion was excluded in the DNA of probants. We performed genetic analysis in this pedigree by whole genome scanning and we identified a common haplotype in the 14q32.3 region located between loci D14S973 and D14S1007, cosegregating with the disease. (Zmax: 3,85 at ?=0.00), corresponding to a large physical distance of 13 megabases. Recruitment and genetic analysis of other cases of autosomal dominant SMA would be very helpful to narrow the critical region. Testing candidate genes in this region will probably allow identifying a new gene involved in motor neuron degeneration.

Focal dystonia not linked to DYT6, DYT7 and DYT13 loci in two French families. *M.Y. Frederic[1], C. Dhaenens[2], C.M. Monino[1], S. Schraen[2], M. Martinez[3], M. Claustres[1], S. Tuffery-Giraud[1], B. Sablonniere[2], G. Collod-Beroud[1].* 1) Laboratoire de Genetique Moleculaire, IURC, Montpellier, France; 2) Laboratoire de Biochimie et de Biologie Moléculaire, CHU de Lille, Lille, France; 3) Inserm, EMI00-06, Evry, France.

Dystonia is a neurological movement disorder characterized by involuntary muscle contractions, which force certain parts of the body into abnormal, sometimes painful, movements or postures. Idiopathic torsion dystonia (ITD) includes adult onset dystonia which usually remains focal, affects one body part and occasionally spreads to adjacent regions. Commonly described forms of focal ITD (FITD) include cervical dystonia (spasmodic torticollis), blepharospasm, oromandibular dystonia, laryngeal dystonia (spasmodic dysphonia), and limb dystonia (among which task-specific dystonia such as the writers cramp). FITD are genetically heterogeneous. Three loci, DYT6, DYT7 and DYT13, have been already reported but no gene has been identified to date. We studied 2 large French families presenting with varied symptoms of FITD: spasmodic torticollis, postural tremor, blepharospasm, task-specific cramp and dysphonia. The first family, DYST143, is composed of 26 subjects (5 definitely affected, 2 with partial phenotype). The average of onset is 4320 years. The second family, DYST154, included 21 subjects (3 definitely affected, 2 with partial phenotype). The average of onset is 3216 years. DYST 143 and DYST154 were studied for the three loci known to be implicated in FITD by genotyping all individuals with markers spanning these regions. Haplotype construction showed no common haplotype shared among all definitely affected family members within the 3 regions. These results were confirmed by lod scores -2 for DYST 143. For DYST154, non informative lod scores for DYT 7 were obtained, but the implication of this locus would lead to a change of status for three subjects currently aged of more than 32 years old and scored as unaffected. These results illustrate the great genetic heterogeneity of FITD and indicate the existence of one or more unassigned genes for this pathology in the French population.

Complete genomic screen for Parkinsons disease in Tunisia and evidence for the involvement of PARK8. *L. Ishihara[1], L. Warren[2], R. Gibson[2], S. Thomas[2], N. Hattori[3], A. Akkari[2], R. Elango[2], R. Amouri[4], M. Kefi[4], S. Belal[4], N. Gouider-Khouja[4], S. Ben Yahmed[4], A. Nelsen[2], C. Stapleton[2], D. Kelly[2], D. Leppert[2], L. Middleton[2], C. Brayne[1], F. Hentati[4].* 1) Public Health & Primary Care, University of Cambridge, United Kingdom; 2) Glaxo Smith Kline, RTP, NC and United Kingdom; 3) Department of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 4) Institut National de Neurologie, Tunis, Tunisia.

The etiology of Parkinsons disease (PD) is complex, with evidence suggesting that both genetic and environmental factors influence disease risk. Monogenic forms of the disease, including dardarin (PARK8), have been identified from familial linkage studies, and they have provided clues into the pathogenesis of PD and possible modes for therapeutic intervention. In an attempt to identify additional genetic causes of PD, a family-based genetic linkage study has been carried out as a collaboration between the pharmaceutical company GlaxoSmithKline and investigators from Tunisia. Eighty multiplex PD families were recruited from the Institut National de Neurologie in Tunis, which provides a specialized neurological service to the entire country. Due to the socio-cultural conditions and high rate of consanguineous marriage, the frequency of neurodegenerative disorders (including PD) is much higher in Tunisia than in other countries. These families provide a unique and powerful opportunity for performing genetic linkage studies. PD was diagnosed using UK PD Society Brain Bank Clinical diagnostic criteria, but postural instability was not considered to validate the diagnosis. Interrater confirmation of diagnosis was carried out, and clinical data and DNA collection methods were standardized. A whole genome scan was performed in these families with an average marker density of 4 centiMorgans. Preliminary analysis has shown a peak in the PARK8 region in a subset of families. One individual from each family will be sequenced for a mutation in PARK8 (G2019S), which has recently been reported to be much more frequent in North Africans than Caucasians. Linkage and sequencing results for PARK8 will be presented along with a detailed clinical review of relevant phenotypes.

Genome-wide search for the *CLN7* gene. *E. Siintola[1], M. Topcu[2], A.-K. Anttonen[1], A.-E. Lehesjoki[1].* 1) Folkhälsan Institute of Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland; 2) Department of Pediatrics, Hacettepe University Faculty of Medicine, Section of Child Neurology, Turkey.

The neuronal ceroid lipofuscinoses (NCLs) are autosomal recessive neurodegenerative disorders characterized by the accumulation of autofluorescent storage material in many cells types, especially in neurons. At least seven subtypes of childhood-onset NCLs have been identified of which the late infantile onset forms (LINCLs) are genetically most heterogeneous with three underlying genes identified (*CLN2*, *CLN5*, and *CLN6*). A variant form of LINCL (vLINCL) present in Turkish patients has been considered a distinct clinical and genetic entity (CLN7). Clinical features in Turkish vLINCL patients include age of onset at 2-7 years, epileptic seizures, myoclonus, motor impairment, mental regression and loss of vision. On electron microscopy, condensed fingerprint profiles or a mixture of curvilinear and condensed fingerprint profiles are seen in many tissues.

We previously showed that in a subset of patients, Turkish vLINCL is caused by mutations in either the *CLN6* or the *CLN8* gene. In seven consanguineous families we excluded all known human NCL loci as well as three loci homologous for genes underlying NCL-like phenotypes in animal models (*CTSD*, *CLCN3*, and *CLCN7*), suggesting that these families represent "true" Turkish vLINCL. We undertook a genome-wide scan in these seven families using 378 microsatellite markers covering the human genome (modified Applied Biosystems LMS-2/MD10 marker set, Finnish Genome Center, University of Helsinki) and looked for regions with shared homozygosity between the families. No single genomic region showed overlapping homozygosity in all families. A region on chromosome 3 with overlapping homozygosity in six families was excluded after fine mapping in all but two families. We are currently analyzing regions with shared homozygosity between four or more families. These regions also show positive LOD scores in multipoint linkage analysis. Our data suggest the existence of more than one NCL-causing, novel genes in the Turkish patients.

Genomewide-scan results for a large family affected with intracranial aneurysms. *D.J. Verlaan[1,2], A. Noreau[1], J. St-Onge[1], G.A. Rouleau[1].* 1) Faculté de Médecine, Centre Hospitalier de l'Université de Montréal-Hôpital Notre-Dame, Montréal, Québec, Canada; 2) Department of Human Genetics, McGill University, Montréal, Québec, Canada.

Background: Intracranial aneurysms (IA) are dilations of intracranial arteries that occur most commonly at arterial bifurcations. Unruptured IAs are present in approximately 1-2% of the population aged older than 30 years old. Aneurysms are only rarely symptomatic unless they rupture, which typically results in a subarachnoid haemorrhage that is associated with high morbidity and mortality. The purpose of our study is to map a gene that predisposes to IA.
Methods: A French Canadian family containing 8 affected individuals with IA was identified. Six affected cases and 5 unaffected individuals were sent for an 8 cM genomewide scan at deCODE (Reykjavik, Iceland). The disease segregation within the family was compatible with a Mendelian inheritance pattern, and a parametric LOD score approach was used to test for linkage. Multipoint LOD scores of the autosomes were calculated using GENEHUNTER version 2.1_r5 beta and two-point linkage for the X chromosome was calculated using MLINK from the FASTLINK 3.0P package. An affecteds-only approach was performed, using an autosomal dominant model, a phenocopy frequency of 0.01, a penetrance of 0.8, a disease allele frequency of 0.001 and deCODE allele frequencies.
Results: Preliminary multipoint analyses suggest five possible regions of linkage on chromosomes 4q22-34, 5q22-23, 8q21-22, 12p13 and 15q26. None of these regions have previously been implicated in the pathogenesis of IA, except for the 5q22-23 region, which as already been reported.
Conclusion: Further genotyping will permit us to determine the inclusion or exclusion of these positive regions. Genotyping of additional FC families may also help us determine where this susceptibility locus lies.

X-linked lethal infantile spinal muscular atrophy (XL-SMA): Progress in disease gene identification. *M. Ahearn[1], J. Ramser[2], K.O. Yariz[1], D. Dressman[3], M. Barmada[4], E.P. Hoffman[3], M. Farrer[5], M. Hulihan[5], A. Meindl[2], L. Baumbach[1].* 1) Univ Miami Medical Sch, Miami, FL; 2) Ludwig Maximilians Univ, Munchen, Germany; 3) Children's National Med Ctr, Washington, DC; 4) Univ of Pittsburgh, Pittsburgh, PA; 5) Mayo Clinic, Jacksonville, FL.

X-linked lethal infantile motor neuron disease (MIM 301830), resembles Werdnig-Hoffman disease, with the additional features of early onset or congenital contractures and/or fractures. Fourteen unrelated families have been identified from North or Central America and Western Europe. Of these, nine families have been tested for X-chromosome linkage; all families mapped to the same Xp11.3-Xq11.2 region. One family is thought to represent a new mutation. The cumulative LOD score is 8.71 at a =0.0 at DXS1003. In the past year we have focused on the two largest families using more microsatellite repeat markers and SNPs. Markers were run on the ABI 3100 and allele calls made with GeneMapper. SNPs were selected from the ABI Assays-on-Demand and run on the ABI 7000. This has not yielded new recombination events however, new LOD score data has been generated which confirms the region of linkage. The highest LOD score region spans DXS8080 to DXS1055 with LOD score of 3.61-3.63 based on these two families. Analysis of these data and LOD score calculations has been independently verified by a second laboratory. Mutation screening through genes in the region has proceeded jointly between University of Miami (UM) and Ludwig Maximilians University (LMU) pursuing complimentary approaches. UM screening has focused on study of candidate disease genes based on presumed protein functions that relate to RNA processing, neuronal or muscle development, cell to cell communication and apoptosis. Growing knowledge concerning the molecular and cellular basis of autosomal SMA is used for selection many of these candidates. At LMU, all cDNAs in the disease gene region are being tested for mutations in XL-SMA samples using high-throughput methodologies. In total, approximately 80 genes within the candidate region have been tested with no mutations found in affected males or carrier females. Gene screening will be completed by October 2005.

Mutational and linkage analysis in three families from Southern Italy with Autosomal Dominant Nocturnal Frontal Lobe Epilepsy. *E.V. De Marco[1], F. Annesi[1], S. Carrideo[1], P. Forabosco[2], I.C. Cirò Candiano[1], P. Tarantino[1], F.E. Rocca[1], D. Civitelli[1], P. Spadafora[1], A. Gambardella[3], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone (Cosenza), Italy; 2) Institute of Population Genetics, National Research Council, Alghero (SS), Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

ADNFLE is caused by mutations in the 4 subunit of the neuronal nicotinic acetylcholine receptor (CHRNA4) gene. More recently we identified a second gene coding for the 2 subunit (CHRNB2)in a large Italian family. However, only a minority of ADNFLE families carry a mutation of either gene. Here, we investigated nine brain-expressed genes, encoding distinct neuronal nicotinic acetylcholine receptor (nAChR) subunits, in three additional ADNFLE families from Southern Italy. We first analysed DNAs from three probands, belonging to these families, that showed the typical ADNFLE phenotype. Exon 5 of CHRNA4 and CHRNB2 genes, harboring all the known mutations, were sequenced. Then, we performed a linkage study on 11 affected and 29 non affected individuals. Microsatellite markers encompassing the chromosome localization of the nAChR subunit genes and RFLPs were used for the linkage study. The following chromosome regions were examined: 1q21 (CHRNB2), 8p21 (CHRNA2), 8p11.2 (CHRNA6, CHRNB3), 15q14 (CHRNA7), 15q24 (CHRNA5/A3/B4), 20q13.2 (CHRNA4). Two point and multipoint linkage analyses were performed by LINKAGE and GENEHUNTER. No mutations in exon 5 of CHRNB2 or CHRNA4 were found. Moreover, linkage analysis excluded the involvement of these genes in ADNFLE in two families. The third family showed a not significant LOD score value for CHRNA4 markers. As regards the remaining loci, negative LOD scores values (less than -2) were obtained for all markers by parametric linkage analysis in one family, while the study is still in progress in the other two families. Our preliminary results further illustrate the considerable genetic heterogeneity for such a syndrom. It is reasonable to hypothesize that either new genes not belonging to nAChR gene family or yet unidentified brain-expressed nAChR genes are involved in the pathogenesis of ADNFLE.

A new locus for temporal lobe epilepsy maps to chromosome Xp11-q21. *L. Patry[1], D.J. Verlaan[2,3], D.K. Nguyen[1], P. Major[1], A. Lortie[1], L. Carmant[1], I. Rouleau[1], G.A. Rouleau[2], P. Cossette[1].* 1) Service de Neurologie, Université de Montréal, Montréal, Québec, Canada; 2) Faculté de Médecine, Université de Montréal, Montréal, Québec, Canada; 3) Department of Human Genetics, McGill University, Montréal, Québec, Canada.

Background: Thirty members of a French-Canadian family segregating temporal lobe epilepsy (TLE) were studied over 4 generations. All affected individuals (n=6) were male who developed stereotypical complex partial seizures between 2 and 14 years of age. All seizures were triggered in the course of showering or bathing (reflex epilepsy), which is also known as hot-water or bathing epilepsy.
Methods: The X chromosome was genotyped using 10 evenly distributed microsatellite markers because genealogical analysis of the family was compatible with a recessive X-linked pattern of transmission. Two-point parametric LOD scores were calculated using MLINK from the FASTLINK 3.0P package using a penetrance of 0.8, a disease allele frequency of 0.00001, a phenocopy frequency of 0.0001 and equal allele frequencies. Fine mapping was performed using 14 additional markers located within the linked region.
Results: Evidence for linkage was found on chromosome Xp11-q21. Fine mapping of the region revealed key recombinants at markers DXS8042 and DXS6799, delimiting the candidate region to a 27 cM interval. Linkage analysis of the region revealed a maximum LOD score of 3.08, at = 0, for markers DXS1003, DXS6949, DXS1125 and DXS8092.
Conclusion: We mapped a new locus for TLE on chromosome Xp11-q21. To our knowledge, this is the first locus identified for TLE on the X chromosome. Although X-linked inheritance has been rarely described for idiopathic epilepsy, a male predominance has been observed for some epileptic syndromes, including benign partial epilepsy of adolescence (3:1).

Follow-up study of the 5q23 candidate region for Parkinsons Disease: Fine-mapping linkage results in the PROGENI-EU consortium data. *M. Martinez[1,2], N. Pankratz[3], A. Durr[4], B. Nichols[5], N. Wood[6], T. Faroud[3], PROGENI-EU consortium.* 1) INSERM EMI 00-06, Evry, France; 2) Northwestern University, Evanston, IL; 3) Indiana University School of Medicine, Indianapolis, IN; 4) INSERM,U289, Paris, France; 5) Cincinnati Childrens Hospital Research Center, Cincinnati, Ohio; 6) Institute of Neurology, London, UK.

The chromosome 5q23 region has provided evidence of linkage to PD susceptibility genes in 4 independent PD samples [Scott et al., 2001; Hicks et al., 2002; Prankratz et al., 2002; Martinez et al., 2004]. It has also been shown positive for linkage to age of onset to PD [Li et al., 2002]. The reported linkage peaks were, however, individually modests (lods=1.0-1.6), suggesting that the locus may have only modest effects, and/or may act in a subset of families. We have formed an International Parkinsons research group (PROGENI-EUGSPD), combining data from the 2 United States studies and several European centers. This leads to the largest family sample (528 families,~1 000 PD subjects and >420 Affected Sib Pairs) ever been made available for linkage analyses to PD. Here, we present results on the follow-up study of the 5q23 region (~79cM) using a common set of 20 microsatellite markers. Evidence for linkage to PD susceptibility was not significant whether a narrow or a broad definition of the disease was used. Linkage to AOO of PD was significant under the broad (lod=1.75, P=0.005) but not under the narrow (lod=0.51, P=0.13) phenotype. Altogether, the hypothesis of a 5q23 susceptibility PD gene is unlikely in the consortium data. Yet, genetic heterogeneity within our sample will be investigated. Our data supports the hypothesis of a 5q23 gene contributing to AOO variability. The results remain, however, puzzling. Inconsistent results can be explained by a decrease in power of the smaller sample of narrow PD cases, but also by a higher rate of false positive linkage finding resulting from some distributional properties of AOO under the broad model. The sensitivity of our linkage results to these factors will be evaluated using simulations to derive appropriate significance levels.

Linkage and association study of Alzheimer disease families linked to 9p21.3. *C.R. Leon-Guerrero, S. Zuchner, P. Xu, C. Browning, P. Bronson, E. Martin, J.R. Gilbert, J.L. Haines, M.A. Pericak-Vance.* Duke University Medical Center, Center for Human Genetics, Durham, NC.

In a genome wide microsatellite-based linkage screen on Caucasian Alzheimer disease (AD) families we mapped a new chromosomal locus to 9p21.3. The peak lod score occurred in the subset of families with at least one autopsy confirmed AD case. This linkage was independently confirmed in AD families from a consanguineous Israeli-Arab community suggesting a recessive mechanism. Using an updated clinical sample of our 197 autopsy confirmed AD families, we genotyped 88 SNPs within the chromosomal region of approximately 20 Mbp. Analysis of multiple SNPs surrounding the original peak region generated further support for linkage with peak two-point lod scores of 2.59 at rs6475797 and 2.45 at rs6475797. These data potentially narrowed the region of interest to 2.7 Mbp with several AD candidate genes. Association analysis showed consistently significant results (p0.05 - 0.005) in the genes cyclin-dependent kinase inhibitor 2A and 2B (CDKN2A, CDKN2B). Changes in expression of CDKN2A have repeatedly been reported in Alzheimer brains and a number of cyclin-dependent kinases are elevated in neurons prone to dedifferentiation and degeneration. We conclude that CDKN2A and CDKN2B are promising new candidate genes potentially contributing to AD susceptibility on chromosome 9p.

Finding genes that influence complex disorders, such as schizophrenia, is one of the biggest challenges of present day human/medical genetics. The objective of this study was to map and identify, in a mouse model, microsatellite markers associated with amphetamine (AMPH)-induced locomotor activity, a rodent behavioral trait that models the hyperdopaminergic state postulated in schizophrenia. Two panels of recombinant congenic strains (RCSs) of mice derived from A/J (A) and C57BL/6J (B) were used in this experiment. The RCSs were informative for 620 microsatellite markers covering the whole genome. A total of 433 animals from 38 congenic and parental strains were tested. AMPH-induced total distance traveled (AMPH-TDIST) was recorded and used as the target phenotype for QTL analysis. Two strains were identified in the A/J background (A52 and A63) which significantly elevated AMPH-TDIST compared to their parental A/J strain. These strains behaved similarly to C57BL/6J, showing higher AMPH-TDIST, AMPH-TDIST peak values and AMPH-TDIST longer time to peak when compared to A/J. Markers on chromosomes 1, 2, 3, 4, 5, 6, 8, 9, 10, 19 and 20 were significantly associated with AMPH-TDIST in the A background. Within the B background, four strains significantly deviated from the parental (B81, B74, B69 and B75). Two of these strains had significantly higher and two significantly lower AMPH-TDIST than the parental C57BL/6J. Markers associated with AMPH-TDIST in the strains with the B background mapped to chromosomes 5 and 20. Data from this approach combined with other genetic (mapping data in humans) and functional sources may help to identify candidate genes relevant to schizophrenia.

Human substance abuse vulnerability loci: confirmation and fine mapping of rSA7 on chromosome 4q. *J.P. Gong, H. Ishiguro, G. Uhl.* Molecular Neurobiology Branch, NIDA, Baltimore, MD.

We have used pooled association genome scanning to identify differences in allelic frequencies at the SNP markers including rs1857 (WIAF-3821) between polysubstance abusers and controls in European-American (abuser/control allelic frequency ratio 0.85) and African-American (abuser/control ratio1.63) samples (Uhl et al, 2001). Sullivan et al (2005) have recently reported linkage to cocaine dependence to nearby markers. We now report confirmation of this association in individually-genotyped European- (minor allele frequencies 0.137 vs 0.175) and African-American (0.077 vs 0.019) samples. rs1857 lies between the 3 ends of annotated genes that encode the sprouty 1 antagonist of fibroblast growth factor signaling (SPRY1) and an apparent soluble guanylate cyclase (LOC441039). Alignments of BAC sequences and HapMap data from the central 95 kb segment of this region reveal nine haplotype blocks ranging from 2 - 24 kb. Dinucleotide repeat polymorphisms within three of these blocks of restricted haplotype diversity each display nominally-significant allelic associations with addiction vulnerability. SPRY1, LOC441039 and other interesting genes near these blocks of restricted haplotype diversity including FGF2 and NUDT6 are thus good candidates to contain allelic variants that influence vulnerability to substance abuse and contribute to the association signals in rSA7, at and near rs1857.

Haplotype Analysis of the human Dopamine Receptor D4 (DRD4) Gene in the Japanese Schizophrenia. *H. Mitsuyasu, H. Kawasaki, L. Gotoh, Y. Kobayashi, N. Maeda, S. Kanba.* Dept Neuropsychiatry, Graduate School of Medical Sciences, Kyushu Univ, Fukuoka, Japan.

Schizophrenia is the most prevalent of the major psychotic disorders with 1% of the population affected worldwide. Although genetic factor is suggested to be involved in the etiology of schizophrenia, the underlying pathophysiologic mechanisms leading to the development of schizophrenia are still unclear. Several lines of evidence suggest the possible involvement of dopaminergic neurotransmission systems in the pathogenesis of schizophrenia. Thus,'gdopamine hypothesis'h emerges from the observation of altered dopamine levels in various regions of schizophrenic brains and the finding that some antipsychotic drugs block dopamine receptors. Dopamine receptors have been a focus of genetic studies with schizophrenia. In particular, DRD4, a member of the D2-like dopamine receptor family, has been suggested to be a strong candidate because of the finding of high affinity of clozapine for DRD4 and the elevation of DRD4 protein and mRNA expression postmortem in the brain of schizophrenia patients. In order to investigate the contribution of DRD4 dopamine neurotransmission systems to schizophrenia, we carried out a haplotype analysis of DRD4. We genotyped 216 schizophrenic patients (121 men and 95 women) and 243 healthy controls (138 men and 105 women) with 26 polymorphisms by direct sequencing method. Uni- and multivariable analysis showed significant gender-specific association between DRD4 polymorphisms and Japanese schizophrenia patients. Three SNPs (-809G/A, -713C/T, and -521T/C) are significantly different between female schizophrenia patients and controls. In contrast, -603del/T showed a significant difference only in male schizophrenia patients. Haplotype analysis using unphased data also showed significant differences. Our results indicate that the DRD4 gene might be involved in gender-specific pathophysiologic mechanisms that contribute to the development of schizophrenia. This study was approved by and performed in accordance with the guidelines of the Ethics Committee of the Graduate School of Medical Sciences, Kyushu University.

Association analysis of adenosine A1, A2A, A2B, dopamine D1, and D2 receptor genes with schizophrenia in the Japanese population. *L. Gotoh, H. Mitsuyasu, H. Kawasaki, Y. Kobayashi, N. Maeda, S. Kanba.* Department of Neuropsychiatry, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Fukuoka, Japan.

Antipsychotic agents used for the treatment of schizophrenia affect dopamine D2 receptor (DRD2) mediated neurotransmissions, suggesting that dopaminergic dysfunction plays an important role in the pathophysiology of schizophrenia. It is known that SCH23390, a se-lective dopamine D1 receptor (DRD1) antagonist, inhibited PCP-induced schizophre-nia-like behaviors. It is also reported that adenosine neurotransmitter system has functional interaction with dopaminergic neurotransmission. Therefore, it is possible to hypothesize that the functions of adenosine A1, A2A and A2B receptors (ADORA1, ADORA2A and ADORA2B) could be some part of the pathophysiological mechanisms of schizophrenia. To clarify the relationship between five receptors and schizophrenia, the polymorphisms (SNPs) of these five receptor genes were analyzed in both schizophrenia patients and nor-mal controls. Total 30 fragments for genotyping experiments were amplified by PCR from each subject consisting of the schizophrenia patients (n=100) and normal controls (n=100). Primers were designed based on the positions of SNPs based on the database of JSNP (Japanese Single Nucleotide Polymorphisms). Using the amplified DNA fragements, all the subjects were genotyped with 27 SNPs and 2 deletions in ADORA1 gene, 4 SNPs in ADORA2A gene, 1 SNP in ADORA2B gene, 1 SNP in DRD1 gene, and 18 SNPs in DRD2 gene. Based on the results, genotyping and allele frequencies were calculated. Association analysis of each polymorphism was performed between schizophrenia patients and normal individuals. So far, no significant difference was identified. Haplotype prediction, linkage disequilibrium calculation, and multi-variate statistical analysis are carried out. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University.

Association analysis of human cAMP-GEFII gene polymorphisms with Japanese schizophrenia patients. *H. Kawasaki, H. Mitsuyasu, Y. Kobayashi, L. Gotoh, N. Maeda, S. Kanba.* Dept Neuropsychiatry, Graduate School of Medical Sciences, Kyushu Univ, Fukuoka, Japan.

We have previously reported novel genes of second-messenger regulated Rap1-GEF (guanine nucleotide exchange factor) gene family whose GEF activities are positively regulated by the binding of second-messenger molecules such as cAMP, calcium and diacylglycerol (DAG), indicating that three major second messengers transduce their signals to target molecules different from protein kinases. A part of this gene family includes cAMP-GEFI and cAMP-GEFII, CalDAG-GEFI and CalDAG-GEFII. Both cAMP-GEFI and cAMP-GEFII have binding domains for cAMP as well as GEF domains. Since antipsychotics have antagonistic actions for dopamine receptors regulating intracellular cAMP concentrations in central nervous system, cAMP-GEFs can be good candidates for molecular studies of schizophrenia. In order to investigate the contribution of cAMP-GEFII to the pathophysiological mechanisms of schizophrenia, we carried out a genetic analysis of single nucleotide polymorphisms (SNPs) of the cAMP-GEFII gene. Information of a total 21 SNPs was collected based on the databases of both dbSNP and JSNP and our genotyping experiments, which included 3 coding SNPs and 17 intron SNPs and one regulatory SNP. We found two novel non-synonymous ones. We genotyped 96 schizophrenic patients and 112 healthy controls with the 21 SNPs by direct sequencing method. The results of haplotype prediction, linkage disequilibrium calculation, and multi-variate statistical analysis are now being analyzed. Although there was slightly different distribution of the regulatory SNP between schizophrenia and controls, no statistical significant association were found. All subjects were given informed consent based on the ethical regulations of Kyushu University.

An oligogenic segregation and linkage analysis of non-P53 Li-Fraumeni syndrome families. *E.W. Daw, C.C. Wu, S.E. Olufemi, J. Ma, L.L. Bachinski, C.I. Amos, R. Krahe, L.C. Strong.* Univ Texas MD Anderson CA Ctr, Houston, TX.

Li-Fraumeni syndrome is a rare inherited disorder that increases the risk of developing certain types of cancer, especially in the childhood to early adult years. The spectrum of cancers include soft tissue sarcoma, breast cancer, osteosarcoma, breast cancer, and others. Genetic mutations have been identified that cause this disorder, including mutations in the P53 and Chek2 loci. In four families we have identified, causative mutations have not yet been identified in either of these loci nor is there evidence for linkage to them. We undertook an oligogenic simultaneous segregation and linkage analysis of these families to identify other genes that might cause Li-Fraumeni syndrome. Our analysis used Bayesian Monte Carlo Markov chain methods (implemented in Loki) to simultaneously estimate the number, location and effect of genes that contribute to cancer liability, as measured through age-at-onset. There were 358 individuals included in the 4 families we studied, with 168 men and 190 women. The families ranged in size from 65 to 112. Phenotype and covariate data were available on 340 individuals, including 87 cancer-affected and 253 unaffected individuals. We used age-at-onset as a censored trait so that both affected and unaffected individuals contributed information to our analysis. The covariates included were sex and birth-year cohort (assigned categorically in 20-year intervals). Initially, we screened 373 markers across the genome in 57 individuals. These were followed up by 67 additional markers in regions of interest, typed on a slightly larger group of individuals. In the segregation part of our analysis, we found a > 99% posterior probability that at least one gene contributing to Li-Fraumeni syndrome was segregating in these families, and a >75% posterior probability that two or more genes were segregating. Both sex and birth-year effects were found, with the younger cohorts found to be at greater risk. Two chromosomes were identified as having a high posterior probability of linkage: Chromosome 6q25 (Bayesian L-score of 32.0) and chromosome 1q31 (Bayesian L-score of 35.2).

High density mapping studies on chromosomal regions 1, 3, 6, 12, 13 and 17 in 28 families with chronic lymphocytic leukemia. *D. Ng[1], G.E. Marti[2], L. Fontaine[3], J.R. Toro[1], N. Caporaso[1], L.R. Goldin[1].* 1) Genetic Epidemiology Branch, DCEG, NCI, National Institutes of Health, DHHS, Bethesda, MD, USA; 2) Laboratory of Medical and Molecular Genetics, Division of Cell Gene Therapy, Food and Drug Administration, Bethesda, MD, USA; 3) Westat Research Inc., Rockville, MD, USA.

B-cell chronic lymphocytic leukemia (CLL) is the most prevalent form of leukemia in adults living in western countries. There is accumulating evidence that a subset of CLL is due to genetic susceptibility. Population and family studies have shown an increased risk of lymphoproliferative disease among relatives of patients with CLL. To date, a causative factor has not been identified for familial CLL. Since 1974, the Genetic Epidemiology Branch (Division of Cancer Epidemiology and Genetics, National Institutes of Health) has enrolled families with two or more living cases of CLL. In 2003, we reported results of a genome wide scan of 18 CLL families. Lod scores of 1.0 or greater were detected on chromosomes 1, 3, 6, 12, 13 and 17. In an ongoing effort to identify genetic susceptibility loci for familial CLL, we performed a fine mapping study of chromosomal regions identified by the whole genome scan with 28 CLL families. Results from the fine mapping study showed no evidence of linkage at 1p22.1-p21.2, 3q22.1, 3q26.2, 6q22.31-q23.2, 12q24.23, 14q32.13, 17p13.3. Chromosome 13q22.1 remains a region of interest with a p-value of 0.014 and warrants additional molecular investigation as a susceptibility locus for CLL.

A genome-wide linkage scan for left ventricular outflow tract malformation susceptibility loci. *K.L. McBride[1], S.D. Fernbach[2], G.A. Zender[1], S.M. Leal[2], D.W. Stockton[2], J.A. Towbin[3], J.W. Belmont[2].* 1) Center Molecular & Human Gen, Columbus Child Research Inst, Columbus, OH; 2) Dept of Mol & Human Genetics, Baylor College of Medicine, Houston TX; 3) Pediatric Cardiology, Baylor College of Medicine, Houston TX.

Malformations of the left ventricular outflow tract (LVOT) are relatively common (birth prevalence of 1/1000 live births) and carry high mortality. LVOT malformations include congenital aortic valve stenosis (AVS), coarctation of the aorta (CoA), and hypoplastic left heart syndrome (HLHS), which are related developmentally by obstruction of blood flow through the left side of the heart. Previous inheritance analysis of these malformations demonstrated both high heritability and sibling recurrence risks. Complex segregation analysis was compatible with an autosomal dominant inheritance in some families and an overall pattern of inheritance involving from 1 - 6 genes. These findings suggested linkage analysis may be successful in mapping susceptibility genes. 25 families comprising multiple members affected with AVS, CoA or HLHS were recruited. A total of 132 individuals were genotyped at 380 autosomal microsatellite markers spaced an average of 10 cM over the genome using the ABI Prism Linkage Mapping Set V2.5. Parametric linkage analysis under an autosomal dominant model was executed under FASTLINK, with additional analysis assuming heterogeneity performed with HOMOG. Regions with lod scores > 1.0 were considered suggestive of linkage. The highest lod scores were found on chromosomes 2p25.1 (HLOD = 1.95), 15q13.3 (1.44), 13q22.1 (1.17), and 10q21.2 (1.12). The region around 2p25.1 contained an interesting candidate gene, SMYD1. Knock out of this transcription factor gene in the mouse is characterized by left ventricular hypoplasia. Sequencing the coding region of SMYD1 in this cohort, however, did not uncover any segregating causative mutations. This study has identified several genomic regions where further research may reveal susceptibility loci for LVOT malformations. To this end, an additional 10 families (total 192 individuals in study) have been recruited for genotyping.

Neuropeptide Y gene variants are linked to and associated with premature coronary artery disease in two independent datasets. *S.H. Shah[1,2], L. Wang[2], J. Rose[2], D.C. Crossman[3], C.B. Granger[1], J.L. Haines[4], C.J. Jones[5], V. Mooser[6], C. Haynes[2], B. Pedersen[2], P. Goldschmidt-Clermont[1], J. Vance[2], E.R. Hauser[2], W.E. Kraus[1].* 1) Duke University Department of Medicine, Durham NC; 2) Duke University Center for Human Genetics, Durham NC; 3) University of Sheffield School of Medicine, Sheffield, United Kingdom; 4) Vanderbilt University School of Medicine, Nashville TN; 5) University of Guelff, Cardiff, United Kingdom; 6) GlaxoSmithKline, Inc., Philadelphia PA.

Neuropeptide Y (NPY) has cardiovascular activity. NPY gene variants have been associated with obesity and vascular disease. We sought to investigate NPY variants in sporadic and familial premature coronary artery disease (CAD), based upon its location within a linkage peak in the GENECARD study of premature CAD. Linkage analysis was performed in 420 GENECARD families with microsatellite markers. Ordered subset analysis (OSA) using age-of-onset and lipids was done to reduce heterogeneity. Four NPY single-nucleotide polymorphisms (SNPs) (1 nonsynonymous (rs16139); 2 synonymous (rs5572, rs5574); 1 non-coding (rs5573)) were tested for linkage and association. To validate, an association study was done in an independent dataset of sporadic premature CAD (461 cases, 310 controls). We had previously shown linkage to chromosome 7p15 in GENECARD (multipoint LOD 1.04). OSA using microsatellites revealed a multipoint LOD of 4.22 in this region (p=0.004 for LOD increase) in 97 families with earliest age-of-onset (mean 37.8 years), who also had higher cholesterol. Two NPY SNPs were linked to premature CAD (rs5573 and rs5574, two-point LODs 1.87 and 2.18). Pedigree-disequilibrium testing showed these SNPs were also associated with CAD in GENECARD (p=0.04, 0.01). In the independent dataset of sporadic CAD, rs5573 and rs5574 were also associated with premature CAD (allelic OR 1.3 (p=0.03) and 1.3 (p=0.01); genotype OR 1.5 (p=0.02) and 1.6 (p=0.007)). Therefore, NPY variants appear to be linked to and associated with premature CAD. The nonsynonymous SNP was not associated; therefore, these SNPs may play a regulatory role. Evaluation of other SNPs and functional assessment are ongoing.

Genetic loci on chromosome 3q are associated with variations in HDL cholesterol levels in a study of coronary artery disease. *E.R. Hauser[1], S.H. Shah[1,2], L. Wang[1], C. Nelson[3], P. Goldschmidt-Clermont[2], J. Vance[1], W.E. Kraus[2].*
1) Duke University Center for Human Genetics, Durham NC; 2) Duke University Department of Medicine, Durham NC; 3) Duke Clinical Research Institute, Durham NC.

Coronary artery disease (CAD) and dyslipidemia have genetic components. We have shown linkage to premature CAD on chromosome 3q13 (multipoint LOD=3.5), also shown to map to HDL cholesterol (HDLC). We then performed association fine-mapping in an independent dataset with two case groups (old (OA) and young (YA) CAD subjects) and a control group (ON). This revealed association of multiple single-nucleotide polymorphisms (SNPs), primarily in OA. The greatest clinical difference between the groups was in HDLC. We therefore sought to evaluate relationships between HDLC and SNPs in this region. Seventy-seven SNPs spanning 2 megabases (Mb) were genotyped in 169 OA, 301 YA, and 205 ON. Measured genotype analysis was performed using mean HDLC by genotype separately for each group, using linear models adjusted for sex and race. We found that HDLC was lower in YA (mean 38.9 mg/dL, SD 11.5) than OA (mean 44.3 mg/dL, SD 15.2), and lower in OA than ON (mean 49.3 mg/dL, SD 17.4). Significant measured genotype results were found primarily in OA. Seven SNPs showed significant (p0.05) differences in HDLC by genotype in OA: RS6788787 (mean HDLC(SD) by genotype (11, 12, 22, respectively): 15.0(14.1), 44.1(17.7), 41.3(13.1), p=0.02); RS6438389 (24.1(11.7), 45.6(15.3), 41.9(13.9), p=0.01); RS2927275 (40.7(20.7), 45.1(15.2), 37.5(13.4), p=0.05); RS1501881 (55.0(17.8), 42.2(15.5), 36.2(10.7), p=0.007); RS1910040 (53.0(31.6), 43.3(14.0), 38.2(14.6), p=0.04); P0356 (89.0(n=1), 42.7(12.2), 40.9(15.2), p=0.0002); and RS9861188 (52.7(18.6), 36.6(13.3), 43.7(13.6), p=0.01). Seven more SNPs were borderline significant (p<0.10). Trends were consistent in YA and ON. These SNPs clustered within 0.4 Mb in multiple linkage disequilibrium blocks. We conclude that variants in a 2 Mb region of chromosome 3q13, residing in a linkage peak for premature CAD, are associated with HDLC in sporadic CAD. We are evaluating whether this is a gene-environment interaction, a QTL for a primary CAD risk factor, or pleiotrophy.

Searching for a gene on chromosome 11q influencing age-related blood pressure variation in Mexican Americans. *S. Rutherford, G. Cai, J.W. MacCluer, J. Blangero, L.D. Atwood, A.G. Comuzzie, S.A. Cole.* Dept Genetics, SW Foundation Biomed Research, San Antonio, TX.

Hypertension is a common disease and a well-known predisposing risk factor for stroke, renal failure and cardiovascular disease (CVD). Unraveling the genetic basis of common diseases of complex inheritance and unknown etiology such as hypertension has been complicated by genetic heterogeneity, incomplete penetrance, and the contributions from multiple environmental factors and their interactions. Despite these obstacles, we detected strong evidence for linkage (LOD score = 5.4) to age-related blood pressure (BP) traits near the marker D11S4464 on chromosome 11q24.1 in Mexican Americans from the San Antonio Family Heart Study (SAFHS). We are currently extending our initial linkage results by investigating single nucleotide polymorphisms (SNPs) within known genes located in the 1-LOD score interval surrounding the linkage peak near the D11S4464 marker and conducting association analyses to identify the most promising candidate genes. To date, we have genotyped 30 SNPs in 25 genes, of which 19 are reasonable BP candidates, within an 8.7 Mb region. Although additional SNPs within known genes are currently being genotyped to more thoroughly investigate this region, preliminary analysis of the current 30 SNPs shows association with age-related BP variation for a SNP located in the intron for the ubiquitination factor E4A gene (UBE4A; P value = 0.012) and another located in the intron for the Rho guanine nucleotide exchange factor 12 gene (ARHGEF12; P value = 0.016). Although a search of the literature could not produce previous studies implicating UBE4A to BP variation, a study with the stroke prone spontaneously hypertensive rat indicates that the Rho guanine nucleotide exchange factors may contribute to increased activation of the RhoA/Rho-kinase pathway, which regulates vascular tone and is implicated in hypertension. The SNP association result obtained in our Mexican American family provides additional motivation for our continuing search to identify an age-related BP variation gene on chromosome 11q.

COMPLEX DISEASES IN ISOLATED POPULATION OF CILENTO: STUDY OF HYPERTENSION IN CAMPORA. *M. Ciullo[1], C. Bourgain[2], T. Nutile[1], C. Bellenguez[2], V. Colonna[1], M. Astore[1], A. Calabria[1], O. Guardiola[1], G.L. Iovino[3], B. Trimarco[3], M.G. Persico[1].* 1) IGB-ABT, CNR, Naples, Italy; 2) INSERM U535, Villejuif, France; 3) Department of Internal Medicine, Federico II University of Naples, Italy.

Essential hypertension (EH), is a major predisposing factor to renal failure and cardiovascular diseases. To identify genes involved in EH, we studied the population of Campora, an isolated village from Cilento, South Italy, with a few founders and inbreeding. The clinical assessment of a 443 random individual sample revealed that 39% were affected. All 443 individuals that related through a 2947-member pedigree spanning 15 generations, were genotyped for 1122 microsatellites on the genome (average marker distance: 3.6 cM). To perform non parametric linkage analysis, the pedigree was broken into 37 families with the maximum partitioning approach of Falchi et al (2005). A strong evidence for linkage (max Zlr score = 3.66) was found on chromosome 8q22-23. To protect from possible spurious linkage signals due to the pedigree breaking, significance was assessed with simulations taking this pedigree breaking step into account (genome-wide P-value = 0.08). Finally, the robustness of the signal to the breaking method is validated using a new method based on factor analysis. These results suggest that we identified a new hypertension-susceptibility locus on chromosome 8q22-23, a region with interesting candidate genes involved in vascular remodeling and angiogenesis.

Auriculo-condylar syndrome: confirmation of wide intrafamilial clinical variability and mapping of the disease gene. *M.R. Passos-Bueno[1], F. Poerner[2], C. Masotti[1], K. Oliveira[1], R.M. Zechi-Ceide[3], M.L. Guion-Almeida[3], A. Splendore[1], R.S. Freitas[2].* 1) Dept Genetics and Evol Biol, Univ De Sao Paulo, Sao Paulo SP, Brazil; 2) CAIF, Centre for Integral Care to Cleft Lip and Palate patient,Curitiba, PR, Brazil; 3) Hospital de Reabilitação de Anomalias Craniofaciais, São Paulo, SP, Brazil.

Auriculo-condylar syndrome (ACS) is an autosomal dominant condition, characterized by malformed years (mostly characterized as question mark ears), micrognathia, glossoptosis, microstomia, condylar agenesis and cleft palate. To date there are very few reports of the syndrome in the literature, but ACS is clearly a branchial arch disorder, which is a group of disorders still very poorly characterized. The identification of the ACS gene will certainly contribute for a better understanding of the molecular events that take part in the development of the first and second branchial arches. In this report, we will describe an additional large Brazilian family, which includes 10 affected individuals with vertical transmission of the disease in 4 generations. We also noticed a wide spectrum of clinical variability, where the mildest cases present only the question mark ears while the most severe ones present the full phenotype. It is also our aim to map and identify the ACS gene. For this purpose, we have obtained DNA samples of affected and healthy individuals of this family as well as from another ACS Brazilian family, which clinical data was previously reported (Guion-Almeida ML et al, Am J Med Genet., 2002 112(2):209-14). We have first performed segregation analysis for chromosomal regions that contain genes associated with diseases of the first and 2nd branchial archs: 5q31-33, contains TCOF1, the gene for Treacher Collins syndrome; 16q12.1, includes the gene SALL1, responsible for Townes-Brocks syndrome; 14q32, candidate region to hemifacial microsomia. No evidence of linkage was observed with any of the markers tested in these regions, therefore, we excluded SALL1, TCOF1 and the 14q32 region as responsible for ACS. We are currently doing a genome scan, and 7 chromosomes have been excluded. FAPESP, CNPq, CEPID.

QTLS controlling morphology in the domestic dog. *K. Chase[1], N.B. Sutter[2], D.R. Carrier[1], F.R. Adler[1], H.G. Parker[2], V. Oza[2], E.A. Ostrander[2], K.G. Lark[1].* 1) Department of Biology, University of Utah, Salt Lake City, UT; 2) Naional Human Genome Reserach Institute, NIH, Building 50 Bethesda MD 20892.

An early promise of the dog genome project was that we would identify genes important in morphology, as are reflected in the enormous variation in size, body proportion, and skull shape observed between established breeds of domestic dog. Towards this end we have used principal component analysis of skeletal variation in a population of Portuguese Water Dogs (PWDs) to reveal systems of traits defining skeletal structures. Morphological variation segregating within this breed, the breeds recent creation from few founders, and the availability of excellent pedigree records make possible a quantitative genetic analysis. Skeletal measurements from radiographs and a genome wide microsatellite scan were collected on 463 dogs. Based on 42 metrics from the pelvis, fore- and hind-limbs we have estimated size as the first principal component of skeletal variation. A total of 21 percent of variation in skeletal size of PWDs results from differences between females (smaller) and males. More than half of this sexual dimorphism results from an interaction between a QTL associated with CHM on the X-chromosome and a QTL associated with FH2017, linked to IGF1 on CFA15. In females, the small size associated CFA15 haplotype is dominant. In males the large size associated haplotype is dominant. These data suggest a genetic mechanism for the evolution of size sexual dimorphism in other species consistent, with the 1950 postulate termed Rensch's Rule. Positional cloning of the underlying genes and identification of relevant variants is underway using SNP-based haplotype approaches. Thus far, SNP haplotypes associated with large and small PWD have been established and studies are currently being extended to additional breeds.

Linkage Analysis with Markers in Linkage Disequilibrium. *R. Pruim[1,2], M. Boehnke[1], G. Abecasis[1].* 1) Center for Statistical Genetics, Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI; 2) Department of Mathematics and Statistics, Calvin College, Grand Rapids, MI.University of Michigan, Ann Arbor, MI.

Single-nucleotide polymorphisms (SNPs) are rapidly replacing microsatellites as the marker of choice for genetic linkage studies. With the advent of ever denser SNP panels, it is inevitable that datasets will include markers that are in linkage disequilibrium. The standard analyses of these data, however, are based on an assumption of linkage equilibrium, and a violation of this assumption has been shown to distort linkage evidence in certain study designs. Recent work of Abecasis and Wigginton describes an efficient approach for modeling linkage disequilibrium between markers during multipoint analysis of human pedigrees. This method allows for rapid estimation of allele and haplotype frequencies within clusters of tightly linked markers but requires that the markers be partitioned into such clusters, and that the clusters have modest size (generally at most ~20 markers).

Here we describe a flexible, efficient algorithm for partitioning markers into clusters suitable for this kind of analysis. Our algorithm takes a greedy approach and attempts to maintain as much information for linkage as possible, even when some markers must be removed to achieve acceptable cluster sizes. Our algorithm estimates information loss based on marker counts, heterozygosity, or entropy measures. As an illustration of the method and of the dangers of ignoring linkage disequilibrium, we examine real and simulated data from dense sets of SNPs and microsatellites on chromosome 14.

MCMC-based multipoint linkage analysis for two loci plus a polygenic component and general pedigrees. *Y. Sung, E. Thompson, E. Wijsman.* University of Washington, Seattle, WA.

Complex traits are influenced by multiple genes. Linkage analysis can be carried out with model-free approaches, but these have lower power for linkage detection than model-based approaches. Most programs for parametric linkage analysis (lod score analysis) allow only a single gene. PAP allows one gene plus a polygenic component, and TMLINK allows two genes for discrete traits. Modeling two linked genes as one can lead to incorrect inference about location; two-locus models have higher power for linkage detection and provide more accurate localization. However, two-locus analyses are computationally challenging and practical issues limit the number of markers and pedigree sizes.

We describe a new MORGAN program, lm_twoqtl, for parametric linkage analysis of a quantitative trait model having one or two linked genes and a polygenic component. We compute the likelihood with MCMC realization of segregation indicators at trait loci conditional on marker data, summation over founder genes at trait loci, and peeling of the polygenic component. Adding a polygenic component models additional genetic variability from other genes. This is the first two-locus lod score program that allows a polygenic component, and allows any number of markers and general pedigrees. It has been verified against exact computation, using PAP and an independent implementation in R.

Two simulated examples, both consisting of 100 nuclear families, show that two-locus analysis correctly identifies the locations of two linked genes with one large peak lod score (Z) near the true bivariate position and no misleading peaks. In the first example, where two genes contribute equally to the trait, one-locus analysis gave Z = 4.6 and Z = 5.9 near the true loci and a misleading peak with Z = 4.6 midway between them, whereas two-locus analysis gave a correct bivariate peak with Z = 19.8. In the second example, where two genes contribute unequally to the trait, one-locus analysis gave Z = 8.7 and Z = -1.3 near the true loci, thus missing the latter locus, whereas two-locus analysis gave a correct peak with Z = 22.5.

Comparison of the information content of 100,000 SNPs, haplotype blocks and tag SNPs. *C. Rosenow.* Systems Biology, Agilent, Santa Clara, CA.

Agilent has developed a novel software tool for the analysis of genotyping data. GeneSpring GT 2 has been tested using more than 100,000 SNPs and 500 samples for linkage (> 21 bits) and association applications. It contains an integrated pedigree viewer with de novo pedigree building capabilities, solely based on raw genotype information, and can deduce haplotypes from genotype information. For family based applications we support parametric and non-parametric linkage analysis and transmission disequilibrium test (TdT). For unrelated individuals we provide quantitative and qualitative case control analysis, ANOVA and multivariate regression algorithms. We used the published genotype data from the HapMap project in GeneSpring GT 2 to deduce haplotype blocks and identified tag SNPs which are representative for each block. A case control analysis was performed on an unrelated Caucasian data set with i) the tag SNPs; ii) the deduced haplotype blocks and iii) the raw genotype data. The results of this comparison will be presented.

EM2: Enhanced Computational Algorithm for Haplotype-Based Association Analysis in Case-Control Studies. *I. Amundson, K. Bradley, B. Yaspan, J.R. Smith.* Vanderbilt University Medical Center, Departments of Medicine and Cancer Biology, Nashville, TN.

Haplotype-based association analysis within a case-control study design is broadly anticipated to offer a powerful approach to identify genetic variants causing common disease. Accurate assignment of phase to enable tests of heterogeneity between case and control haplotype profiles is computationally very demanding. Use of permutation testing to estimate exact P values compounds this demand. This can limit the feasibility of large studies. We describe modification of algorithms implemented in the sliding window program of Fallin and Schork (AJHG 67:947-959, 2000) to facilitate large-scale studies. This enhanced version employs parallel-processing, enables use of multi-allelic as well as bi-allelic markers, and places no intrinsic limit on the number of markers or samples. Improved computational algorithms will be crucial for large-scale genome-wide association studies using a case-control design.

Ordered subset analysis: new software and reporting guidelines. *B. Browning.* Genetic Data Sciences, GlaxoSmithKline, Research Triangle Park, NC.

Ordered Subset Analysis (OSA) [Hauser et al 2004] identifies subsets of families ordered by a trait-related covariate that give maximum evidence of linkage. Families are rank-ordered by a trait-related covariate, the ordered subset of families yielding the strongest evidence of linkage is identified, and the p-value is estimated using a permutation test.

The FLOSS (Flexible Ordered Subset) software package provides a new, flexible framework for OSA. FLOSS can be used with any linkage software package that reports NPL z-scores for each locus and family. In addition, linear ASM LOD scores can also be used in place of z-scores when using MERLIN. P-values are estimated using the efficient Besag-Clifford permutation test [1991]. FLOSS also includes a flexible program for calculating family covariate scores. FLOSS is written in Java for easy portability, and includes user documentation. The source code is documented, extensible, and freely available from the author.

Reporting Guidelines: We propose the following analysis and reporting guidelines:

1) Report the rationale for the specific covariates used in the analysis.

2) Report statistics describing the number of individuals with covariate data per family that were used to assign the family covariate scores.

3) Determine a significance threshold prior to analysis, and report all significant Monte Carlo p-values. The Monte Carlo p-values, not the increase in LOD score, should be emphasized.

4) Report the total number of regions tested using OSA and the covariates used in each region.

5) When two or more covariates yield significant p-values in the same region, give an appropriate measure of the correlation of the family covariate values.

Genome scans for nonsyndromic cleft lip with or without cleft palate in families from seven countries. *M.L. Marazita[1], J.C. Murray[2], A. Lidral[2], M.E. Cooper[1], T. Goldstein McHenry[1], B.S. Maher[1], L. Moreno[2], S. Daak-Hirsch[2], L.L. Field[3], M. Arcos-Burgos[4], C. Valencia[4], J. Risk[5], J.T. Hecht[6], K. Doheny[7], E. Pugh[7], C. Boehm[7].* 1) Ctr for Craniofacial and Dental Genet, U of Pittsburgh; 2) U of Iowa; 3) U of British Columbia, Canada; 4) U of Antioquia, Colombia; 5) U of Liverpool, U.K; 6) U of Texas, Houston; 7) CIDR, Johns Hopkins U.

In recent years there has been substantial progress in identifying genetic factors that contribute to nonsyndromic cleft lip with or without cleft palate (NSCL/P). A combination of the evaluation of candidate genes and regions with genome-wide scans has proven fruitful. To identify genetic regions likely to include NSCL/P susceptibility loci, we performed genome-wide scans of 6,565 individuals (4,373 genotyped of whom 1,514 were affected) from 820 families ascertained from seven countries (Philippines, Colombia, China, India, Turkey, U.S.A., U.K.). Genotyping of the 10 cM genome-scan microsatellite markers in all study participants was performed by the Center for Inherited Disease Research (CIDR). The data was analyzed by a combination of linkage approaches: two-point and multipoint, parametric (LOD, HLOD under both dominant and recessive models) and non-parametric (NPL). A Bayesian approach utilizing the posterior probability of linkage (PPL) was also applied (see Govil et al, this meeting). A number of regions had genome-wide significant HLOD results (i.e. multipoint HLOD > 3.2): chromosome 1q22.3-41 (max multipoint HLOD=3.3, dominant model), 2p13 (3.2, dom), 3q26-q28 (4.1, dom), 9q22-q33 (5.4, dom), 14q24-q31 (4.2, rec), 16 (3.6, rec). The multipoint NPL results supported regions on chromosomes 1, 2, 6, 9, 12, 14 with p-values < 0.05 for each. The two-point PPL approach supported the chromosome 1, 2, 6, 9 and 12 regions (Govil et al). Follow-up studies including fine-mapping and candidate gene analysis of each of these positive regions is underway (see Mishima et al, Hart et al, this meeting). NIH grants DE09886, DE12472, DE08559, DE13076, DE14667, DE016148, DE016215, RR-00084; CIDR NIH contract N01-HG-65403.

Coincident linkage of type 2 diabetes, metabolic syndrome, and cardiovascular disease in the Diabetes Heart Study. *C.D. Langefeld, J. Ziegler, J. Carr, B. Freedman, S. Rich, L. Wagenknecht, D.W. Bowden.* Wake Forest Univ. School of Medicine, Winston-Salem, NC.

Cardiovascular disease (CVD) is a major contributor to morbidity and mortality in type 2 diabetes (T2DM). The Diabetes Heart Study is a single center study of >450 T2DM-enriched families extensively phenotyped for measures of CVD, including calcified coronary plaque (CCP), in addition to T2DM, and metabolic syndrome (MS). 982 Caucasian subjects from 358 pedigrees (575 T2DM relative pairs) with at least two individuals with T2DM were included in a microsatellite-based a 10cM genome scan performed at the Mammalian Genotyping Center. Relationships and Mendelian errors were examined using the entire dataset with PREST and PEDCHECK. Sample meanSD age and BMI was 619 and 32.67.5, respectively. The sample was 53% female and 80% of the subjects have a diagnosis of T2DM and 80% have detectable CCP. Prevalent CVD was measured using 2 definitions: CVD1 based on self-reported history of CVD (463 subjects) and CVD2 defined as CVD1 and/or CCP greater than 600 (696 subjects). Additional qualitative traits evaluated in this analysis are +/- presence CCP and +/- carotid calcified plaque (CarCP). Multipoint nonparametric linkage analysis using the NPL(pairs) statistic identifies several chromosomal regions with suggestive evidence of linkage. Of particular interest is evidence for coincident mapping of each trait T2DM, MS, CVD1, CVD2, CCP, and CarCP to three different regions. All 6 traits map to 3q13 (peak 128 cM, nearest marker D3S4523) with LOD scores ranging between 1.15-2.51 with the highest LOD score with CVD2. A second locus is at 4q31 (peak at 146 cM, nearest marker D4S1625) with LOD scores ranging between 0.90-2.41 with the highest LOD score with T2DM. A third locus is on chromosome 14 (peak 23 cM, nearest marker ATA77F05) with LOD scores ranging between 0.58-2.31 with the highest LOD score with MS. A fourth locus at 86-94 cM on chromosome 3 shows evidence of linkage to T2DM/MS and CVD2/CCP with the highest LOD= 2.71 for CVD2. This comprehensively phenotyped sample of families provides the ability to map novel combinations of traits of great biomedical interest.

Pleiotropic QTLs on chromosomes 5p13-p15, 16q22 and 19p13 influencing blood pressure and body composition measures: The NHLBI Family Heart Study. *M.F. Feitosa[1], M.A. Province[1], K.E. North[2], D.K. Arnett[3], R.H. Myers[4], J.S. Pankow[5], P.N. Hopkins[6], I.B. Borecki[1].* 1) Washington Univ, St. Louis, MO; 2) Univ North Carolina, Chapel Hill, NC; 3) Univ Alabama, Birmingham, AL; 4) Boston Univ, Boston, MA; 5) Univ Minnesota, Minneapolis, MN; 6) Univ Utah, Salt Lake City, UT.

Obesity is a risk factor for hypertension, and both are predictors of coronary heart disease. To identify locations of quantitative trait loci (QTLs) influencing variation of both blood pressure (systolic (SBP), diastolic (DBP) and mean arterial pressure (MAP)) and body composition (fat free mass (FFM), percent of body fat (PBF), waist circumference, waist-to-hip ratio and body mass index (BMI)), bivariate variance component linkage analyses were employed on 2,766 subjects within 397 Caucasian pedigrees from the NHLBI Family Heart Study using 402 polymorphic markers. African American sample will be analyzed once genotyping has been conducted. All phenotypes were adjusted for age and sex effects. Bivariate LOD scores of 3.53 for FFM-SBP and 2.93 for FFM-MAP were found on chromosome 5p13-p15. These bivariate linkage peaks were substantially higher than the corresponding univariate linkage results for these traits at this location (FFM: LOD = 1.48, SBP: LOD = 0.88; MAP: LOD = 1.23). On chromosome 16q22, LODs of 3.08 for BMI-MAP and 2.85 for BMI-SBP were detected, which were higher than the respective univariate LODs (BMI: LOD = 1.00, SBP: LOD = 0.74; MAP: LOD = 0.77). Another pleiotropic QTL was observed on chromosome 19p13. The bivariate LODs of 3.01 for PBF-DBP and 2.80 for PBF-MAP were higher than the univariate LODs (PBF: LOD = 1.32, DBP: LOD = 2.55; MAP: LOD = 2.22). Despite evidence of linkage on 5p13-p15, 16q22 and 19p13 from several studies for metabolic syndrome phenotypes, pleiotropic QTLs influencing blood pressures and body composition measures have been largely unexplored. Chromosomes 5p13-p15, 16q22 and 19p13 harbor several plausible candidate genes, including NPR3, AGRP, HSD11B2, CHD10, CHD12, CHD6, CHD1, CHD8, CHD15, FOXC2, RETN, INSR and LDLR.

Genome-wide scan for hypertension: Taiwan Young-Onset Hypertension Genetic Study. *W.H. Pan[1], C.M. Chung[1], C.S.J. Fann[1], J.W. Chen[2], C.L. Hsu[1], Y.S. Jong[3], H.M. Lo[3], F.M. Ho[3], C.S. Kang[4], C.C. Chen[5], H.C. Chang5[5].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 3) Tao-Yuan General Hospital Department of Health, Taiwan; 4) Min-Sheng Hospital, Taoyuan, Taiwan; 5) Lin-Shin Hospital, Chung-Li, Taiwan.

Efforts to map hypertension genes have been proven difficult without large sample size and phenotype with strong genetic component. Therefore, we carried out a multi-centered genome-wide linkage study with young-onset hypertension as the phenotype. We have recruited 1447 individuals, including 675 affected patients from 464 families. There were 253 affected sibpairs with hypertension and 172 pairs with young-onset hypertension, respectively. The maker set of deCODE genetics that defines a ~10 cM resolution was typed. Evidence of linkage was assessed with a non-parametric linkage method using GENEHUNTER. Two point linkage analyses were calculated, using the SIBPAL program. Indication of linkage signals were demonstrated consistently by two methods for regions on chromosome 1, 2, 3, 4, 6, 7, 8, 19, and 22. Among them, a region on chromosome 2 (140-170 cM) with a NPL score over 2 overlaps with findings of several other studies. There are several other novel positions identified by our study, including three with NPL score over or close to 1.5. In the second stage, we performed fine mapping with 32 markers spanning 40 cM (115-155) on chromosome 2. The NPL score was raised from 2.06 to 2.21. We then used tag SNPs selected from public HapMap database for all genes in this candidate region to pin down the hypertension susceptibility gene. Genotyping for a total of 20 SNPs in ten genes was obtained using mass spectrometer-based detection implemented on a Sequenom MassARRAY system. Transmission disequilibrium test analysis implemented in GENEHUNTER was performed for fine mapping. A significant association was found between hypertension and a haplotype constructed by 3 markers flanking the region for POLR1B, CHCHD5, SLC20A and FLJ40629 (P=0.000037). SLC20A, a sodium-dependent phosphate transporter, is the most likely culprit gene for hypertension.

From genomewide scan to QTL fine mapping for ACE activity with young-onset hypertension patients. *R.Y. Wang[1], C.M. Chung[2], C.S.J. Fann[2], J.W. Chen[3], Y.C. Liu[2], Y.S. Jong[4], H.M. Lo[4], C.S. Kang[5], C.C. Chen[6], H.C. Chang[6], W.H. Pan[2].* 1) School of Public Health, China Medical University, Taichung, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 4) Tao-Yuan General Hospital Department of Health, Taiwan; 5) Min-Sheng Hospital, Taoyuan, Taiwan; 6) Lin-Shin Hospital, Chung-Li, Taiwan.

Genetic variation in ACE has been associated with hypertension and related diseases. The purpose of this study was to map QTL for ACE activity, a highly heritable intermediate phenotype for blood pressure or hypertension. We recruited 1168 individuals from 305 young-onset (onset age 40 years) hypertension pedigrees. The marker set of deCODE genetics that defines a ~10 cM resolution in human index map was typed for the study subjects. Normalized ACE activity as a quantitative trait was analyzed using SOLAR package. The heritability of ACE activity trait was estimated 0.52 after covariates were adjusted. Two-point analysis showed the highest LOD score at 89.6 cM (LOD=5.28 for D17S957) and multipoint linkage analysis at 83 cM (LOD=4.76) of chromosome 17, respectively. We also identified other loci with LOD3 located at 143.91 cM on chromosome 9 (LOD=5.22 for D9S1863) and at 68.82cM on chromosome 22 (LOD=3.73 for D22S1169) by two-point analysis and at 187 cM on chromosome 1 (LOD=3.29) and at 144 cM on chromosome 9 (LOD=4.59) by multipoint analysis. These results support that the ACE gene or nearby loci on 17q were among the strongest candidate genes influencing the ACE activity. Subsequently, 23 informative SNPs marker spanning the ACE locus were genotyped. FBAT and TRANSMIT softwares were performed to relate high ACE activity (80th percentile) to individual SNPs and haplotype blocks constructed with 3-consecutive SNPs. Individual SNPs and haplotype blocks nearby the 3 end of ACE locus in intron 20-24 have the largest (-log(P)=14.43). We have disclosed multiple QTLs for ACE activity. Our data suggest that the QTL on ACE gene locate between intron 20 to 24. This finding may lead to understanding on how ACE expression is regulated.

Genomic localization of a locus on chromosome 4 linked with variation of HDL Cholesterol. *Z.Y.H. Wong, K.J. Scurrah, A. Lamantia, S.B. Harrap.* Department of Physiology, University of Melbourne, Victoria 3010, Australia.

Plasma concentrations of high-density lipoprotein cholesterol (HDL-C) are inversely correlated with the risk of cardiovascular disease.[1] Genetic factors account for 57% of the variance of HDL-C.[2] In this study we undertook a 3 stage genotyping analysis in white healthy adult families from the Victorian Family Heart Study.[2] In 274 adult sibling pairs of average age 24 year a genome-wide scan revealed a locus on chromosome 4 at 170 cM with suggestive genome-wide evidence (Z score = 3.34, 1 Z confidence interval: 34 cM) of linkage to HDL-C. Linkage results were not materially affected by adjustment for covariation with age, sex, weight, height, and body mass index. In 233 of the sibling pairs and their parents we undertook fine mapping of the chromosome 4 locus with 11 microsatellite markers with average intermarker distances of 1.34 cM. This analysis based on genotypes and phenotypes from both generations strengthened our preliminary findings with a peak probability (Z score = 3.9) at 169 cM (1 Z estimated confidence interval: 17 cM). Our linkage data strongly suggests a genetic location around 169 cM on chromosome 4q32.3 is linked with HDL-C. In this region exists the gene encoding the carboxypeptidase E. The third stage involves association tests of single nucleotide polymorphisms (SNPs) and haplotypes in and around candidate gene(s) or selected loci of this region with HDL-C to elucidate the functional variants. Groups of genetically unrelated males & females having high (mean 2.37 mmol/L) or low (mean 0.77 mmol/L) HDL-C levels were mapped initially with 18 SNP markers spanning 33.4 Kb. 5 SNPs showed evidence of association with HDL-C with and/or without genotype-sex interactions. These preliminary data demonstrated the feasibility of our scientific strategy and methodology, and add further credence to this specific locus on chromosome 4q32.3 for HDL-C control.

Developing a Laboratory Information Management System (LIMS) in a high-throughput genotyping facility. *C. Boyce, J. Romm, B. Craig, C. Bark, M. Zilka, Y. Sun, M. Barnhart, C. Boehm, R. King, J. Goldstein, E. Pugh, K. Doheny.* Center for Inherited Disease Research, Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) is a centralized facility established to provide genotyping and statistical genetics services for investigators seeking to identify genes that contribute to human disease. As the demand for services increased, CIDR was required to alter the way operations were performed. Included in this need for change was the migration from the Applied Biosystems (AB) 3700 to the AB 3730 and GeneMapper software. Due to the increase in capacity and change of platform, CIDR needed to implement a new LIMS to replace the existing LIMS that had been developed in-house over the years. A new data transfer system, customization of GeneMapper software, and a web interface between CIDRs Project Management and the Principal Investigator (PI) was also required. CIDR spent about two years working with the AB Professional Services group (formerly known as Rapid Integrated Solutions) to design, develop, test and integrate a new LIMS system, custom WebLIMS, and data release process, all driven by a new relational database, SQL*LIMS, LSL and other custom functionality. Based on CIDRs experience developing a LIMS in-house versus hiring an outside contractor to develop a LIMS, there are several conclusions that can be made. From a constructive viewpoint, there was a steep learning curve for CIDR staff to learn the core capabilities of the new system and for CIDRs Informatics group to learn to manage, maintain and further customize the new system. The database administrative duties are much more complex and the programmers must modify source code written by others. However, the new LIMS is more highly integrated and relational than the existing in-house LIMS, tracking and record keeping is unsurpassed, the system is more organized and it allows for better lab and workflow management. The overall experience was satisfactory and the new well-integrated LIMS has been implemented successfully and is currently being used for production genotyping.

Using a Utah pseudo isolate population to identify predisposition genes for prostate cancer. *L.A. Cannon-Albright, J. Farnham, N.J. Camp.* Dept. Medical Informatics, Univ Utah Sch Medicine, Salt Lake City, UT.

Using a retrospective approach to study design, we have identified multiple pseudo isolate populations in Utah, originating from the Utah Mormon pioneers (Cannon-Albright et al., in press). We have defined several birth-country pseudo isolates in the Utah Population Dababase (UPDB), selecting Utah Mormon pioneer founders with a specific birthplace from among all pioneers, and restricting the pseudo isolate population to include only descendants of the founder-matings, and their descendants. That is, from a selected set of founders, and allowing no immigration, we identify a smaller, pseudo isolate sub-population . We hypothesize that pedigrees identified in these pseudo isolate populations represent a genetically homogeneous, informative resource for complex disease predisposition gene mapping. We present an example of a single pseudo England isolate high risk prostate cancer pedigree, which alone provides compelling evidence for linkage of prostate cancer predisposition on chromosome 18. We have identified 8 high risk England pseudo isolate prostate cancer pedigrees with 6 or more prostate cases representing a significant excess of prostate cancer among the isolate descendants of the pedigree founder. One of these 8 pedigrees was previously genotyped in a genome wide linkage study for prostate cancer. The England isolate pedigree contained 6 purely English prostate cancer cases, with 5 of the cases genotyped or inferred from spouse and offspring. Four regions on chromosomes 1, 5, 13 and 18 showed evidence for linkage in this English pedigree (multipoint hetLOD > 1.0), all with a dominant model, with the chromosome 18 evidence being the most compelling (multipoint LOD>1.70, $p<0.002$ for several sequential markers). All 5 of the genotyped prostate cancer cases in the England isolate pedigree share a chromosome 18 haplotype. Subsequent genotyping of prostate cases in 2 additional Utah English isolate pedigrees has identified haplotype-sharing in the same region.

Estimating joint informativeness of markers in a haplogroup. *H. Lee, X. Sheng, R. Chakraborty.* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

With more genetic markers available, closely linked markers are jointly utilized as a haplogroup. When markers in such a haplogroup are to be used together, inter-locus allelic dependency needs to be considered in computing haplotype frequencies. Since this dependency is influenced by mutation rate, population demographic history, and physical distance between the markers, any attempt of estimating haplotype frequency, and haplotype diversity (as an index of joint informativeness) using analytical method becomes computationally involved. Alternatively, when haplotypes are identifiable by direct laboratory methods, such population genetic parameters are estimated empirically using the gene count method. However, as the number of markers in a haplogroup increases, the number of possible haplotypes quickly outnumbers the sample size, making the estimated parameters more dependent on the sample size. Consequently, with the fixed sample size, increased number of markers does not necessarily lead to an elevated joint informativeness. In order to investigate the optimal number of markers that would produce the maximum informativeness given the conventional DNA database size, we analyzed haplotype data consisting of 19 Y-chromosomal microsatellites, from US black (N=260) and US Caucasian (N=244) populations. The results show that, in the US black population, only six markers were needed to reach the haplotype diversity of 0.999, while additional 10 more markers were necessary to elevate the value into 0.9997. Sequential addition of markers, ordered by their gene diversity did not necessarily produce the optimum improvement in joint informativeness, but in general, this approach provided better results than randomly selected set of markers. Data from the US Caucasians demonstrated the similar results. Our study indicates that, extending over conventional minimal set of nine Y-chromosomal markers will only marginally improve the joint informativeness. Also, for a set of closely linked markers, determining reference database size requires different guidelines from that of autosomal markers. (Research supported by a federal training grant on research in biothreat agents).

Genome wide linkage scan of 758 affected sibling pair families with rheumatoid arthritis using the Illumina Linkage IV set of ~5,600 SNP markers. *C.I. Amos[1], W. Chen[1], A.T. Lee[2], M.F. Seldin[3], L.A. Criswell[4], D.L. Kastner[5], E.F. Remmers[5], W. Li[2], M. Kern[2], P.K. Gregersen[2].* 1) Dept Epidemiology,MD Anderson Cancer Ctr, Houston, TX; 2) NSLIJ Research Institute, Manhasset, NY; 3) Rowe Program in Human Genetics, UC Davis, CA; 4) Department of Medicine, UCSF, San Francisco, CA; 5) NIAMS/NIH, Bethesda, MD.

The North American Rheumatoid Arthritis Consortium (NARAC) has assembled a large collection of affected sibling pairs with rheumatoid arthritis (www.naracdata.org). In addition to a strong signal in the HLA region, previous microsatellite genome screens on 512 of these families have revealed modest evidence linkage (LOD 1.5-2.5) at several other chromosomal locations. We have now performed a complete genome wide linkage scan using ~5,600 informative SNP markers on 758 NARAC families containing 931 affected sibling pairs. Linkage analysis was carried using a call to MERLIN from SNPLINKer. Allowance for linkage disequilibrium between SNP markers (D<0.7) required the removal of approximately 17% of the genotypes, and eliminated an apparently spurious linkage peak at the extreme telomeric portion of chromosome 6q. The data confirm a very strong and broad linkage peak on chromosome 6p, centered on the HLA region (max NPL score =18.9 at 32.9 cM), but extending from 13 cM on 6p out to 80cM on 6q with LOD scores >3. This 67 cM linkage interval suggests the likely involvement of multiple loci on this chromosome in RA susceptibility. In addition, previously identified regions with very modest evidence linkage on chromosomes 4, 5 and 11 now show more compelling evidence of linkage (LOD scores > 2.8, >2.8 and >3.5 respectively). Finally, we have been able to narrow a previously observed linkage peak on chromosome 18q to a region around 52cM, consistent with the results of a recent dense association mapping study of this region (Remmers et al, abstract submitted). These results greatly refine regions of linkage we previously have reported and demonstrate that significant additional linkage information can be extracted from multiplex families by using a suitably dense set of informative SNP markers across the genome.

Fine-mapping of a diabetic nephropathy locus on 3q24-q27 and association analysis with the candidate gene *PRKCI*. *J.K. Wolford[1], M.P. Millis[1], K.A. Yeatts[1], S. Rais[1], R.G. Nelson[2], W.C. Knowler[2], R.L. Hanson[2].* 1) TGen, Phoenix, AZ; 2) NIDDK, Phoenix, AZ.

Diabetic nephropathy is the major cause of end-stage renal disease (ESRD). In the Pima Indians of Arizona, who have very high rates of ESRD attributable to diabetes, a genome scan found evidence for linkage for nephropathy on 3q24-q27 (LOD=2.14). To fine-map the linkage interval, we genotyped 14 microsatellite markers in addition to the 34 from the original genomic scan, yielding a final mean map density (SE) of 2.50.7 cM. The information content was 0.57-0.67 with the original markers and increased to 0.67-0.73 with the additional markers. Linkage analysis was performed using the S_{all} function in GENEHUNTER-PLUS in 98 diabetic sibpairs concordant for nephropathy in whom linkage had been originally detected. In the original analyses, the strongest evidence for linkage (LOD=2.14) was found between markers *D3S1763* and *D3S3053* at map location 181 cM. With the additional markers, the evidence for linkage on 3q increased to LOD=2.63. Association analyses of candidate genes in this region are being conducted in 107 cases with diabetic ESRD and 108 controls with diabetes >10 years and no evidence of nephropathy and in the families from the original linkage study (148 diabetic individuals with nephropathy and 458 without nephropathy in 264 sibships). Initial analyses focused on the protein kinase C-iota (*PRKCI*) gene. We sequenced all 18 exons, exon-intron boundaries and 2 kb of the 5 regulatory region in 36 Pimas and identified 13 SNPs. None of the SNPs showed a statistically significant association in either study group (P>0.05). The strongest results were seen with SNP133631, where the minor allele had a frequency of 0.22 in cases and 0.12 in controls (OR=1.61 per copy of the minor allele, 95% CI=0.98-2.63, p=0.06); the corresponding OR in the family study was 1.41 (95% CI=0.88-2.27, p=0.15): these ORs correspond to an effect of ~1% on the variance in liability to nephropathy, which is unlikely to explain the linkage signal. These analyses support the presence of a locus for diabetic nephropathy at 3q24-27, but suggest that variation in *PRKCI* does not explain this finding.

Fine-mapping and characterization of the mouse autoimmune diabetes locus Idd21.1. *T. Merriman, S. Hook, J. Hollis-Moffatt.* University of Otago, Dunedin, New Zealand.

Mouse *Idd21.1*, on distal Chr18, maps to a region orthologous to human *IDDM6*. The aims of this work were to fine-map *Idd21.1* and to test whether *Idd21.1* operates through a T lymphocyte-mediated immune pathway.

Beginning with the congenic strain NOD.ABH-(*D18Mit8-D18Mit4*) (with 11cM of distal Chr18 ABH diabetes-resistant DNA on the non-obese diabetic (NOD) background), two novel mouse strains were created (NOD.ABH-(*D18Mit8-D18Mit46*) and NOD.ABH-(*D18Mit8-D18Mit216*), containing 3 and 9cM of distal Chr18 ABH DNA, respectively) and diabetes incidences determined. NOD.ABH-(*D18Mit8-D18Mit46*) had a reduced diabetes incidence vs NOD (57% and 85% at 7 months respectively, $P<0.0001$), providing evidence for *Idd21.11* in the 47-50cM region. Given there was no significant difference between NOD.ABH-(*D18Mit8-D18Mit46*) and NOD.ABH-(*D18Mit8-D18Mit216*) (57% and 63% respectively, $P=0.24$), there was no evidence for an Idd locus in the 50-56cM interval. NOD.ABH-(*D18Mit8-D18Mit216*) had an increased diabetes incidence vs NOD.ABH-(*D18Mit8-D18Mit4*) (63% and 48% respectively, $P=0.02$), providing evidence for *Idd21.12* in the 56-58cM interval. A third congenic strain, NOD.ABH-(*D18Mit8-Madh2*), provided further support for *Idd21.11* (67% diabetes incidence, $P=0.0001$ vs NOD). A fourth strain, NOD.ABH-(*D18Nds1-D18Mit4*), provided further support for *Idd21.12* (75% diabetes incidence, $P=0.01$ vs NOD). Thus, *Idd21.1* consists of two subloci (*Idd21.11* and *Idd21.12*).

Adoptive transfer of splenocytes from NOD and NOD.ABH-(*D18Mit8-D18Mit4*) into lymphocyte-deficient NOD.*scid* and NOD.*scid*.ABH-(*D18Mit8-D18Mit4*) mice was done. The NOD splenocytes were equally efficient at transferring diabetes to NOD.*scid* and NOD.*scid*.ABH-(*D18Mit8-D18Mit4*) ($P=0.24$), suggesting that *Idd21.1* does not influence intrinsic resistance of -cells to immune attack. NOD.ABH-(*D18Mit8-D18Mit4*) splenocytes were more efficient at transferring diabetes to NOD.*scid* than to NOD.*scid*.ABH-(*D18Mit8-D18Mit4*) ($P=0.002$), consistent with the hypothesis that *Idd21.1* may regulate diabetes through interaction between the adaptive and innate immune systems.

Bivariate linkage analysis of TNF-alpha and Body Mass Index in Type 2 Diabetes. *J. Zhou, G. Chen, A. Adeyemo, Y. Chen, C. Rotimi.* Pharm, Natl Human Genome Ctr, Howard Univ, Washington, DC.

Bivariate linkage analysis of TNF-alpha and Body Mass Index in Type 2 Diabetes Guanjie Chen, Adebowale A. Adeyemo, Jie Zhou, Yuanxiu Chen, Charles Rotimi National Human Genome Center at Howard University College of medicine, Washington D.C Obesity is one of the biggest generators of silence inflammation. The cytokine TNF-alpha produced by adipocytes is a key component of the insulin - resistant state in obesity and contribute to the development of type 2 diabetes. Bivariate linkage analyses of correlated traits provide greater statistical power to identify genetic loci with effects too small to be detected in single trait analyses. We conducted genome wide bivariate analyses of TNF-alpha and Body Mass Index (BMI) using a sample of sib pairs (321 sibling pairs and 36 half sibling pairs) affected with T2DM from the Africa America Diabetes Mellitus (AADM) study. Participants were genotyped with a panel of 372 autosomal microsatellite markers with an average intercal of 9cM and multipoint linkage analysis done using the variance components approach. Three suggested linkage evidence regions (two regions, LOD = 3.02 (142cM), near marker D2S1334 and LOD = 3.33 (173cM), at marker D2S1776 on Chromosome 2, and one region with LOD = 3.23 (131cM), near marker D11S912 on Chromosome 11) were identified and one tentative linkage evidence region (LOD = 2.19 (146cM), near marker D1S1631 on chromosome 1) was identified. By conducting bivariate linkage analyses for each measure of TNF-alpha level with a measure of obesity (BMI), the combination provides additional advantage in searching for TNF-alpha linkage regions in type 2 - diabetic patients.

A dense SNP map of human chromosome 20q13.1: linkage disequilibrium, haplotype analysis, and association with type 2 diabetes in a 6.0 Mb interval. *D.W. Bowden, J..L. Bento, M. Zhong, C.D. Langefeld, B.I. Freedman, J.C. Mychaleckyj.* Ctr Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC.

Human chromosome 20q12-13.1 is linked to type 2 diabetes mellitus (T2DM) in multiple studies. To identify T2DM susceptibility gene(s) in this region, a SNP map has been constructed across a 5.83 Mb region (HG Build 35: 41.4 - 47.2 Mb), which contains 75 genes including the candidate diabetogenic genes, adenosine deaminase (ADA), hepatocyte nuclear factor 4 alpha (HNF4A) and glucose transporter 10 (GLUT10). Verified SNPs from the NCBI dbSNP and Appelera/Celera Discovery System databases, with minor allele frequency ranging from 0.04-0.49, were genotyped using a mass spectrometry based genotyping system and placed on the map at an average density of 1 SNP per 17 kb. A total of 337 SNPs were genotyped on 310 Caucasian controls and 300 Caucasian cases with T2DM and end stage renal disease (ESRD). Inter-SNP linkage disequilibrium (LD) was calculated using D as a measure of LD. 226 SNPs (67% of all SNPs on map) fall into 83 LD blocks. Evaluation of LD across the map comparing T2DM cases to controls reveals higher levels of LD in the case population. Within regions of significant high LD (D 0.70, P-value 0.05), haplotypes were constructed using HAPLO.SCORE and Dandelion. In single SNP analysis 53 SNPs (15.7% of 337 total) showed nominal evidence of association in one or more point marker tests of association (P 0.05), and 9 SNPs (0.03%) retained test significance at P 0.005. These latter SNPs lie in 4 perigenic regions, including SLC12A5 (potassium-chloride cotransporter), NCOA5 (nuclear receptor coactivator 5), CDH22 (cadherin-like 22), and PRex1 (phosphatidylinositol 3,4,5-triphosphate-dependent RAC exchanger 1). After adjustment for multiple tests at a Family Wise Error Rate (FWER) < 0.05, two T2DM-associated SNPs in the PRex1 region retained map-level significance. In addition, LD haplotype blocks encompassing the associated single SNPs in SLC12A5/NCOA5 and PRex1 regions were significantly associated with the T2DM (P<0.005 for both).

Fine mapping a locus for early-onset type 2 diabetes in African American families. *M.M. Sale[1,2], T.S. Leak[1], C.D. Langefeld[3], C.J. Valis[3], C.J. Gallagher[1,4], B.I. Freedman[2], D.W. Bowden[1,4].* 1) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC.

To identify susceptibility loci for type 2 diabetes mellitus (T2DM) and diabetic nephropathy in African Americans, a genome wide screen was performed on 638 African American affected sib-pairs (ASPs) with T2DM from 247 families; 206 ASP from 166 families were concordant for end-stage renal disease (ESRD)/nephropathy. Ordered subsets analysis (OSA) revealed a linkage peak on chromosome 7p in the subset of T2DM families with an early age of diagnosis (29% of pedigrees, max. LOD=3.85, p=0.0034 for the change in LOD score). T2DM-ESRD subsets with lower BMI (64% of pedigrees, max. LOD=3.93, p=0.01) and longer duration to ESRD (37% of pedigrees, max. LOD= 3.59, p=0.01) also showed evidence for linkage. Nonparametric linkage regression (NPL) analyses provided evidence for interactions with early age at T2DM diagnosis (p=0.0039), duration of diabetes to onset of ESRD (p=0.0281), and low BMI in T2DM-ESRD ASP (p= 0.0143). We genotyped eleven additional polymorphic markers in the region of interest, with an average spacing of 4 cM, in the same pedigrees. OSA supported evidence of linkage at 28 cM on chromosome 7p, closest to D7S3051, in early-onset T2DM families (21% of pedigrees; max. LOD= 3.61, p=0.0025; mean age at diagnosis 29.5 3.0 years). In T2DM-ESRD families, the evidence for linkage in subsets with lower BMI (64% of pedigrees; max. LOD= 2.20, p=0.11) and longer duration of diabetes before onset of ESRD (56% of pedigrees; max. LOD=2.81, p=0.20) diminished. There are several plausible diabetes candidates in this region, including interleukin-6, neuropeptide Y, and phosphodiesterase 1C. Refining the linkage peak on chromosome 7p provides substantial evidence of susceptibility gene(s) for early-onset T2DM in our African American sample.

Evidence for multiple distinct obesity/type 2 diabetes mellitus loci under a single peak of linkage on chromosome 11q23: replication in ethnically diverse populations. *L. Baier[1], Y. Muller[1], L. Ma[1], M. Traurig[1], P. Kovacs[2], A. Bottner[2], S. Stone[3], K. Timms[3], C.J. Groves[4], M. McCarthy[4], M. Erdos[5], K. Conneely[6], M. Boehnke[6], K. Miyake[7], L. Atwood[8], L. Johansson[9], M. Ridderstale[9], W. Knowler[1], R. Hanson[1], C. Bogardus[1].* 1) NIDDK/NIH, Phoenix, AZ; 2) Leipzig, Germany; 3) Salt Lake City, UT; 4) Oxford, UK; 5) Bethesda, MD; 6) Ann Arbor, MI; 7) Chicago, IL; 8) Boston, MA; 9) Malmo, Sweden.

A prior genomic linkage scan in Pima Indians indicated an obesity susceptibility locus on chromosome 11q23-24 (LOD=3.6). There was also evidence that the same genomic region contained a susceptibility locus for type 2 diabetes mellitus (T2DM)(LOD=1.7). Bivariate linkage analysis for the combined phenotype diabesity gave the strongest evidence for a disease locus (LOD= 5.2). The region of linkage spans 24 Mb. To narrow this region, single nucleotide polymorphisms (SNPs) are being genotyped at a 10 kb density, across the entire 24 Mb, for linkage disequilibrium (LD) mapping. To date, more than 2000 SNPs have been genotyped and tested for association with either BMI or T2DM in 1229 Pima Indians. LD mapping using this genotypic data shows three distinct regions (Regions 1-3), each spanning approximately 500 kb, that contain multiple SNPs significantly associated ($p<0.01$) with BMI in Pima Indians. SNPs within two of these regions have been further genotyped in other, ethnically diverse populations. SNPs in Region 1 are modestly associated with BMI in two groups of Finns (FUSION study and Malmo), USA Caucasians (Framingham) and German Caucasian children (Leipzig School Children) (all $p<0.05$ after adjusting for age and sex). SNPs in Region 1 are also associated with T2DM in Pima Indians ($p<0.001$), Mexican Americans (Starr County; $p<0.05$) and Finns (Helsinki; $p<0.02$). SNPs in Region 2 are associated with BMI in two Caucasian populations (Framingham and Utah; $p<0.001$ and $p<0.05$, respectively, after adjusting for age and sex) and are also associated with T2DM in Utah Caucasians. In contrast, none of the SNPs that were tested from either region were associated with BMI or T2DM in Caucasians from the UK. We are currently attempting to replicate associations in Region 3.

Fine-mapping the MKS3 locus for Meckel-Gruber syndrome. *U.M. Smith[1], N.V. Morgan[1], E.R. Maher[1], P. Cox[2], C. Bennett[3], T. Attie-Bitach[4], C.A. Johnson[1].* 1) Medical and Molecular Genetics, University of Birmingham, Birmingham, UK; 2) Dept. of Pathology, Birmingham Womens Hospital, Birmingham, UK; 3) Clinical Genetics, St. James Hospital, Leeds, UK; 4) Departement de Genetique et Unite INSERM U-393, Hopital Necker-Enfants Malades, Paris, France.

Meckel-Gruber syndrome (MKS) is a lethal autosomal recessive developmental disorder characterised by encephalocele, large multicystic kidneys, polydactyly and fibrocystic changes to the liver. The incidence of MKS varies between different populations, and MKS shows genetic heterogeneity with three known loci. *MKS1* is on chromosome 17q21-q24, *MKS2* on chromosome 11q13 and *MKS3* on chromosome 8q. Here we report the fine-mapping of *MKS3*. We have used a new cohort of Pakistani consanguineous families to redefine the critical interval for *MKS3*. Linkage to *MKS1* and *MKS2* was formally excluded with microsatellite markers. Our cohort of patients showed distinct phenotypic similarities, such as cleft palate and low set ears, in addition to the standard diagnostic criteria. Six families underwent a combination of Affymetrix 10k SNP chip genome-wide linkage analysis and microsatellite linkage analysis. This yielded a two-point cumulative LOD score of 5.24 for = 0 at marker D8S1988, corresponding to the centre of the region. A family that is multiply consanguineous with two affected second cousins, has narrowed the critical interval due to an obligate recombination in an unaffected sibling. Further fine-mapping using novel microsatellites has reduced the interval to chromosome 8q21.2-23, between secure boundaries. We are in the process of sequencing candidate genes in this interval for causative mutations.

Linkage analysis in families with generalized epilepsy with febrile seizures plus. *A.M. Madsen, Y. Wang, M.R. Winawer, W.A. Hauser, C. Barker-Cummings, R. Ottman.* Sergievsky Ctr, Columbia Univ, New York, NY.

Generalized epilepsy with febrile seizures plus (GEFS+) is a familial epilepsy syndrome with variable phenotypes, including typical febrile seizures (FS), febrile seizures plus (FS+) (i.e., FS persisting beyond age six or accompanied by afebrile generalized-tonic seizures), and generalized and focal epilepsy. Mutations in SCN1B (19q13), GABRG2 (5q31), SCN1A (2q24) and SCN2A (2q24), have been identified in GEFS+ families. We sought to evaluate evidence for mutations in these known genes, and to localize other genes for the syndrome. We selected, from a set of 88 families containing 2 individuals with idiopathic or cryptogenic epilepsy collected for genetic linkage analysis, a subset of 16 families that appeared consistent with GEFS+ (i.e., those containing two or more individuals with febrile seizures). We typed all available family members at 390 microsatellite markers spaced at an average of 10cM intervals across the genome. The families contained an average of 13.5 (range 3-32) genotyped individuals, of whom 5.9 (range 3-14) were affected with idiopathic or cryptogenic epilepsy or febrile seizures. In initial analyses, we assessed the evidence for linkage to markers within 5cM of the previously identified genes, assuming a dominant model with 75% penetrance. In analyses of all families combined, linkage was excluded at theta < 0.10 for each of the markers. In analyses of individual families, however, two families gave suggestive linkage evidence (lod scores of 1.67 and 1.01 respectively) for D2S1776, located 4cM telomeric to SCN1A. Each of them contained 13 or more affected individuals, five or more of whom had FS+. None of the other families had a lod score exceeding 1.0 for any of the markers near the other three genes. These results suggest that SCN1A mutations may underlie the GEFS+ phenotype in two of the 16 families; mutation screening in these families is warranted. In the remaining families, mutations in the four previously identified genes are less likely, and we are continuing to screen for linkage in other chromosomal regions.

Screening for DFNB1, DFNB2, DFNB3, DFNB4, DFNB9 and DFNB21 loci in the Iranian patients with autosomal recessive non-syndromic hearing loss. *Y. Riazalhosseini[1], N.C. Meyer[2], A. Daneshi[3], M. Mohseni[1], N. Bazazzadegan[1], M. Avenarius[2], P. Imanirad[1,4], M. Farhadi[3], K. Kahrizi[1], R.J.H Smith[2], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences,Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 3) Department of Otolaryngology, Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran; 4) Molecular-Cellular Biology Department, Khatam University, Tehran, Iran.

Autosomal recessive non-syndromic hearing loss (ARNSHL) is the most common form of severe inherited hearing impairment. To date, at least 45 loci for ARNSHL have been identified, indicating it as an extremely heterogeneous disorder. These loci are referred to as DFNB loci. Although, mutations at the DFNB1 locus (including GJB2 and GJB6 genes) are the most common cause of ARNSHL in populations originating from Northern Europe, we have shown that mutations in GJB2 and the (GJB6-D13S1830) do not play a significant role in the etiology of deafness in Iran. In this study, we assess the contributions made by other loci to the ARNSHL genetic load in Iran. We have selected 50 consanguineous families with normal GJB2 and GJB6 alleles to be screened for linkage to the DFNB2, DFNB3, DFNB4, DFNB9 and DFNB21 loci. Linkage analysis is applied using, in average, 3 short tandem repeat (STR) markers for each locus. These loci have been excluded in 18 families but two families; each has been localized to DFNB4 and DFNB21. We are screening these families for mutations in SLC26A4 and TECTA, respectively. Our results suggest that other loci may have the major causative roles in ARNSHL in Iran. This hypothesis will be confirmed by including more families and screening additional loci.

Mapping a third locus for familial TAAD (TAAD3) using samples from a single family with multiple affected individuals and determining the contribution of this locus to familial disease. *N. Avidan[1], V. Tran Fadulu[1], J. Chen[1], J. Yuan[1], A. Braverman[3], R. Yu[2], S. Shete[2], D.M. Milewicz[1].* 1) Department of Internal Medicine, The University of Texas Medical School at Houston, Houston, TX; 2) Department of Epidemilogy, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 3) Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO.

Familial thoracic aortic aneurysms and dissections (TAAD) is an autosomal dominant condition with reduced penetrance and variable expression. Genes predisposing to TAAD have been mapped to 5q13-14 (TAAD1), 11q23 (FAA1), and 3p24-25 (TAAD2). We collected a large family, TAAD216, with a unique phenotype of dissections involving both the ascending and descending aorta and young age of onset in women. The disease phenotype was not linked to any of the known loci for familial TAAD or MFS, suggesting that the disease was due to a novel locus. The family consists of 134 individuals, 71 males and 63 females, with enough power to map a locus using only this family. We applied whole genome linkage analysis to 10K mapping SNP chip (Affymetrix) data, using a sliding window of 180-200 SNPs and the Allegro program on a sub-family with a pedigree of 24 individuals. Of these, 12 individuals were classified as affected, 5 as unaffected, and 7 as unknown. Parametric as well as non-parametric options were used to calculate the LOD scores. Initial analyses gave suggestive peaks on chromosomes 2 and 8 ranging from 1.5 to 2.0, and a peak on chromosome 15q that was over 4.0 with both parametric and non-parametric analysis. The three genomic regions were screened with microsatellite markers using 32 members from the extended family. No shared haplotype was found on chromosome 2 and 8, however a shared haplotype was found in 4 affected and 4 possibly affected individuals between D15S1046 and D15S130 with a maximum LOD score of 3 at marker D15S127. We screened 54 additional families with three or more affected individuals, and found 8 families linked to this locus, suggesting that this locus might contribute to 10-20% of familial TAAD. We propose to name the new locus TAAD3.

Bayesian genome scan for cleft lip with or without cleft palate (CL/P). *M. Govil[1], J.C. Murray[1], M.L. Marazita[2], A. Lidral[1], L.L. Field[3], M. Arcos-Burgos[4], L. Moreno[1], C. Valencia[4], J. Risk[5], J.T. Hecht[6], K. Doheny[7], E. Pugh[7], C. Boehm[7], V.J. Vieland[1].* 1) U of Iowa; 2) U of Pittsburgh; 3) U of British Columbia, Canada; 4) U. of Antioquia, Colombia; 5) U of Liverpool, UK; 6) U of Texas, Houston; 7) CIDR.

Non-syndromic CL/P is one of the most commonly occurring congenital anomalies and has a complex etiology with birth prevalence that varies with geographic origin. There has been some recent progress in testing and identifying candidate genes and regions for CL/P, but given its complex etiology and epidemiology, large sample sizes across multiple populations and a variety of analytical approaches to address expected heterogeneity and identify multigenic causes are necessary. One such approach, the posterior probability of linkage (PPL), is designed to handle the complexity observed for CL/P. It integrates out the trait model parameters; allows explicitly for both intra- and inter-sample heterogeneity; and accumulates evidence for or against linkage across multiple heterogeneous datasets using Bayesian sequential updating. A two-point Bayesian 10 cM genome scan (markers genotyped by the Center for Inherited Disease Research) computing the PPL was carried out for 487 informative families drawn from 8 populations from 7 countries sequentially updated over population of origin. These families have been analyzed with multipoint parametric and nonparametric linkage approaches with several regions reaching genome-wide signifiance (see Marazita et al, this meeting). The following regions have two-point PPLs 10%: 1q23.3, 2p21, 6q16.1, 9q32, 12p12.3 and 12q13.13. While these 2-point PPL results support the multipoint HLOD and/or NPL results (Marazita et al), they also allow narrowing the overall region for further analysis to a total of 50 cM (approx.) with an 80% probability of a gene on at least one of chromosomes 1, 2, 6, 9 and 12. It is expected that multipoint PPL analyses currently underway will further reduce the region for fine mapping. Dyslexia gene identifyed in an Icelandic sample. *H. Stefansson[1], A. Ingason[1], J. Halldorsson[2], G. Thorleifsson[1], T. Thorlacius[1], O. Rolfsson[1], G. Bjornsdottir[1], G. Sveinbjornsdottir[2], B. Richardsson[1], K. Kristjansson[1], A. Kong[1], U. Thorsteinsdottir[1], J.R. Gulcher[1], K. Stefansson[1].* 1) Dept Population Genomics, Decode Genetics, Reykjavik, Iceland; 2) National Blood Collection facility, Nóatún, Iceland.

Dyslexia is the most common learning disorder in individuals of normal intelligence affecting approximately 5% of those who have access to satisfactory educational resources. Contribution of genetic factors to the risk has been demonstrated by twin studies, segregation analysis and extended families have been used to identify loci linked to dyslexia. Current studies indicate locus heterogeneity as several different loci have been identified although only some have been replicated in independent cohorts. We have analyzed 82 Icelandic pedigrees where dyslexia segregates and our results are in line with previous studies indicating locus heterogeneity. No genome-wide linkage signal was achieved but supportive linkage was found to previously reported loci. Fine-mapping one locus, however, gave significant association to dyslexia in a cohort of 412 dyslectic individuals with a relative risk of 1.9 to a single marker ($p = 4.6x10-7$, PAR = 10.6% after correcting for relatedness) supported by surrounding markers and haplotypes. For 218 of the 412 genotyped dyslectic individuals both parents were genotyped. Of 62 informative transmissions studied 42 were transmissions of the at-risk variant to a dyslectic offspring ($p = 0.00014$).

Genome-wide linkage scan of obsessive-compulsive disorder: significant evidence for susceptibility loci on chromosomes 3q21-27. *Y. Yao[1], JF. Samuels[1], V. Willour[1], A. Pinto[2], J. Knowles[3], J. McCracken[4], S. Rauch[5], D. Murphy[6], M. Riddle[1], B. Cullen[1], M. Grados[1], B. Greenberg[2], A. Fyer[2], P. Davis[5], J. Bienvenu[1], G. Nestadt[1].* 1) Dept Epidemiology, Johns Hopkins Univ, Baltimore, MD; 2) Brown University, Providence RI; 3) Columbia University, New York, NY; 4) Unversity of California at Los Angeles, CA; 5) The Massachusetts General Hospital, Boston, MA; 6) National Institute of Mental Health, Bethesda, MD.

Introduction: Obsessive-compulsive disorder (OCD) is a disabling psychiatric disorder characterized by obsessions and/or compulsions. Previous twin and familial aggregation studies support a genetic etiology. Here we present the first large scale model-free linkage analysis of OCD. Methods: 219 extended and nuclear families were assessed in the OCD Collaborative Genetics Study using standard diagnostic methods. A genome-wide microsatellite marker panel was genotyped at CIDR. Non-parametric linkage analyses were conducted using both broad (definite and probable diagnoses) and narrow definitions (definite only) of OCD. Results: Using a p-value of 0.01 as a cut point, significant linkage signals were observed on chromosome 3q (multipoint Kong and Cox LOD-ALL =2.62, p-value = 0.0003), 1p (multipoint Kong and Cox LODALL= 1.46, p-value =0.004), 7p (Kong and Cox LODpairs =1.97, p-value =0.0013), and 15p (Kong and Cox LOD-pairs =1.36, p-value =0.006). Empirical p values were calculated for the NPLall scores via simulation of 10,000 replicates using Merlin. These results strongly suggest evidence for linkage on chromosomes 3. Conclusions: We are currently pursuing candidate gene studies as well as SNP-based fine mapping in all significant regions, with particular focus on 3q21-27.

Gemone wide linkage scan of aggressive prostate cancer: Results from the International Consortium for Prostate Cancer Genetics. *S.K. McDonnell[1], L. Dimitrov[2], D.J. Schaid[1], and the International Consortium for Prostate Cancer Genetics.* 1) Mayo Clinic College of Medicine, Rochester, MN 55905; 2) Wake Forest University School of Medicine Center for Human Genomics, Winston-Salem, NC 27157.

A combined linkage scan of 1,233 prostate cancer (PC) families was recently reported by the International Consortium for Prostate Cancer Genetics (ICPCG), with suggestive linkage findings for chromosomes 5q12, 8p21, 15q11, 17q21, and 22q12 (Xu et al. AJHG, 2005). However, PC is one of the most common cancers among men, with few men having overtly aggressive disease, which may lead to a large number of phenocopies, and which may explain why genetic linkage results of this disease have been difficult to replicate. To overcome this heterogeneity in disease etiology, a number of investigators have recently restricted genetic linkage analyses to the most severely affected men, but are limited by a small number of such families. Fortunately, the resources of the ICPCG are sufficiently large and broad to overcome small sample sizes. The ICPCG Clinical Committee defined aggressive PC as a series of or criteria: 1) regional or distant stage (based on pathology if available, otherwise clinical stage, T3, T4, N1, M1), or 2) Gleason grade score of 7 or higher, or 3) poorly differentiated grade (if no Gleason available), or 4) level of prostate specific antigen at diagnosis of 20 or higher, or 5) death from metastatic prostate cancer before age 65 years. We have recently completed a genome wide linkage scan of 189 families with three or more aggressive PC using both parametric heterogeneity (HLOD) and nonparametric allele sharing (Kong and Cox (KC-LOD)) methods, and find suggestive linkage results on chromosomes 5q (KC-LOD = 2.43), 6p (KC-LOD = 2.32), 11q (Recessive HLOD = 3.56), and 20q (Dominant HLOD = 2.50).

Evidence for a prostate cancer predisposition locus on chromosome 22q in the Utah pedigrees. *N.J. Camp, J.M. Farnham, L.A. Cannon Albright.* Dept of Medical Informatics, Univ of Utah School of Medicine, Salt Lake City, UT.

We have pursued a hint of linkage for prostate cancer on chromosome 22, previously reported in a genome linkage scan in extended Utah pedigrees. A meta analysis of genome-wide screening data from the International Consortium for Prostate Cancer Genetics has reported significant evidence for linkage of this same region. The evidence for this region was contributed to, in part, by the Utah pedigrees, but included supporting evidence from other pedigree collections. Fifty-nine Utah pedigrees with at least 4 prostate cancer cases and no more than 2 meioses separating the prostate cancer cases were analyzed using the CIDR genomic search STRP marker set. We previously performed parametric linkage analyses using dominant and recessive models on four datasets resulting from a pedigree splitting algorithm. Three regions of interest (LODs > 1.9) were identified on chromosomes 1p, 5q, and 22q, with a maximum dominant TLOD of 2.09 at marker D22S685. Twelve of the Utah pedigrees had multipoint LODS > 0.588 ($p<0.05$) on chromosome 22 under the dominant model. Two previous studies reported hints of linkage within 15 cM of our peak. We have added fine mapping markers to a resolution of ~5cM on chromosome 22 in the 12 Utah pedigrees showing evidence of linkage. With this additional genotyping, 8 of these pedigrees maintain evidence of linkage (LOD > 0.588). Six flanking recombinants in these pedigrees, both telomeric and centromeric, strongly support an 8cM region, consistent with previous linkage reports for this chromosome.

The search for cluster headache susceptibilty genes: genomewide scan and HCRTR2 candidate gene analysis. *L. Baumber[1], H. Harty[1], C. Sjostrand[2], J. Hillert[2], M. Leone[3], G. Bussone[3], M.B. Russell[4], R.C. Trembath[1].* 1) Dept Genetics, Univ Leicester, Leicester, United Kingdom; 2) Department of Neurology, Karolinska University Hospital, Sweden; 3) Carlo Besta National Neurological Institute, Milan, Italy; 4) Head and neck research group, Akershus University Hospital, Norway, and Faculty division Akershus University Hospital, University of Oslo, Norway.

Cluster headache (CH), a primary headache characterized by recurrent, unilateral, short-lived painful episodes, often with regular periodicity. CH prevalence has been estimated to be 1 per 500 of the adult population displaying a marked sex bias (female:male ratio 1:2.5-3.5). Whilst most frequently a sporadic disorder, twin concordance and familial studies support a genetic predisposition to CH. Segregation analysis favours an autosomal dominant disease trait. We have commenced a series of studies to elucidate the molecular genetic basis of predisposition to CH. We performed a polymorphic STR based genome-wide linkage analysis upon the five most informative multiplex families (ELOD 3.2) ascertained in Denmark. Despite no single chromosome generating a significant LOD score, evidence for suggestive linkage (NPL 2 or >) was observed for four putative disease loci. Investigation in additional families failed to confirm linkage for any nominal locus suggesting disease or locus heterogeneity in this disorder. We next assessed hypocretin receptor 2, a specific candidate gene recently implicated through a cohort association study. HCRTR2 encodes a G protein coupled receptor to orexin peptides, regulators of neuro-endocrine function. DNA sequence analysis of eight independent familial CH patients revealed no deleterious variants of HCRT2 in coding sequence and exon-intron junctions. Genotyping of two HCRTR2 SNPs in an extended cohort of European sporadic CH cases (n= 235) revealed no statistically significant difference in allele or genotype frequencies between cases and controls. These combined data emphasize the likely genetic complexity underlying CH and highlight the requirement for larger cohorts for replication of association studies in the condition.

Linkage to 22q12 for a Nicotine Dependence Quantitative Trait in Australian and Finnish Samples. *S.F. Saccone[1], A. Agrawal[1], M.L. Pergadia[1], D.M. Dick[1], A. Todorov[1], A.-M. Loukola[4,2], U. Broms[2], H. Maunu[4,2], E. Widen[2], K. Heikkila[2], K. Morley[3], A. Baxter[3], M. Campbell[3], J.P. Rice[1], G.W. Montgomery[3], N.G. Martin[3], J. Kaprio[2], L. Peltonen[2,4], A.C. Heath[1], P.A.F. Madden[1].* 1) Washington University School of Medicine, St Louis, MO, USA; 2) University of Helsinki, Finland; 3) Queensland Institute of Medical Research, Australia; 4) National Public Health Institute, Helsinki, Finland.

Past research into the genetics of nicotine addiction has produced a variety of linkage signals with little concordance among results. This study used two samples, one Finnish and one Australian, where data collection and genotyping were completed separately in each country. For both samples, the genetic analysis of a quantitative trait, the maximum number of cigarettes smoked in a 24-hour period, found the maximum genome-wide evidence of linkage to occur at 22q12. The Australian sample consisted of 289 nuclear families containing probands for a heavy smoking phenotype which were genotyped at the Australian Genome Research Facility. In parallel, 155 nuclear families were identified in Finland and genotyped at the Finnish Genome Center. A regression of IBD sharing on the sum and difference of the trait values was performed using MERLIN-REGRESS. In each sample linkage peaks were detected at precisely the same location on chromosome 22. The maximum genome-wide multipoint LOD scores for the Australian and Finnish samples were 2.46 at 27 cM and 3.19 at 28 cM respectively. Combining the samples results in a multipoint LOD score of 5.16 at 27 cM. The marker D22S315 yields a singlepoint LOD score of 5.53 with an empirical p-value of 0.004 from 1000 singlepoint simulations. These results suggest genes involved in nicotine dependence lie in this region. One possible candidate is GRK3 (a.k.a. ADRBK2), the gene encoding the G protein receptor kinase 3, which has been shown to be associated with bipolar disorder. Build 35.1 of the NCBI physical map indicates D22S315 is intronic to GRK3. Funded by NIH grant DA12854, the Australian National Health and Medical Research Council, the European Union (QLG2-CT-2002-01254) and The Center of Excellence of the Academy of Finland.

A Genome Scan for Retinal Pigmentary Abnormalities and Geographic Atrophy. *C.L. Thompson[1], G. Jun[1], B.E.K. Klein[2], R. Klein[2], J. Capriotti[1], K.E. Lee[2], S.K. Iyengar[1].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, WI.

Genetic studies of age-related macular degeneration (AMD) often involve individuals with both choroidal neovascularization (CNV) and geographic atrophy (GA), but few genome-wide scans (GWS) have differentiated between these two distinct end points. In order to comprehend the genetics influencing pigmentary abnormalities (PA) and GA in AMD, we reanalyzed the data from our previous GWS on AMD (FARMS sample of 34 extended families including 346 sibling pairs) looking only at PA and ignoring CNV-related phenotypes. We also present a new GWS in the full Beaver Dam Eye Study (BDES) cohort (4,926 individuals and 1526 sibships), which includes data at baseline, 5 year and 10 year follow-up. Fundus photographs were taken for each subject and were graded on a new six-step retinal PA/GA scale ranging from absence to pure GA. Scores were adjusted for age. A model-free linkage analysis for PA/GA was performed on both samples for 338 markers covering all autosomes. Multipoint linkage analysis of the FARMS sample provided evidence for linkage with p-values < 0.01 in the 1q25, 5p13, 6q21-23 and 11q14 regions. The most significant peak was found on chromosome 1, in the region of Complement Factor H and Hemicentin-1 (empirical p-value of 4.38x10-3). Concordance with previous GWS for GA was found on 5p13. The loci on 1q25 and 6q21-23 have been observed in other GWS for AMD and may represent more general susceptibility genes. Linkage analysis in the BDES sample using the rate of change as a measure of progression replicated the peaks on chromosomes 5 and 6, suggesting that these loci may contribute to the rate of progression of pigmentary abnormalities toward GA. These findings suggest a complex, heterogeneous model for PA/GA.

A high-density single-nucleotide-polymorphism (SNP) genomewide screen on extended autism families. *D.Q. Ma[1], J. Jaworski[1], I. Konidari[1], R.K. Abramson[2], H.H. Wright[2], M.L. Cuccaro[1], J.R. Gilbert[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) University of South Carolina School of Medicine, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Autism is a common neurodevelopmental disorder with a significant genetic component and locus heterogeneity. A genome-wide linkage analysis was performed on 26 extended autistic families (total 67 affecteds). Each family has 2 to 4 affecteds generating either avuncular or cousin pairs. For analysis, we used a high-density single-nucleotide-polymorphism (SNP) genotyping assay, the Affymetrix GeneChip Human Mapping 10K array. Two-point parametric linkage analysis demonstrates suggestive linkage evidence (HLOD>2.0) in regions at 1q23.3 (156-160 cM in the decode genetic map); 2q35-36.3 (210-230 cM); 5q23.2 (127 cM); 6p25.3 (16 cM); 11q14.1-21 (83-100 cM); 12q11-14 (56-80 cM); 12q22 (102 cM); and 14q11.2 (20 cM). Using a set of SNPs with R^2 <0.16 in the above peak region on chromosome 12, both multipoint parametric and non-parametric analysis displayed significant evidence for linkage in the region of 12q14.2 (76 cM to 81 cM) with the Max LOD score at 78 cM (HLOD=3.27 [REC]; LOD^*=3.59). Families with only affected males may represent a specific subgroup of autism. The linkage evidence on Chromosome 12 increased with a 2-point Max HLOD of 3.36 [REC] in the 17 extended families with only affected males. Multi-point non-parametric analysis supported this linkage with improved linkage evidence (Max LOD^2=3.93) between 76-78 cM. The novel linkage peak on chromosome 12 in this genome-wide screen further supports the hypothesis that there is substantial locus heterogeneity in autism and that extended families, along with gender effects, may help delineate these different loci.

Genetic linkage analysis with affected relative pairs and their covariates: Application to prostate cancer linkage.

D.J. Schaid[1], J.P. Sinnwell[1], S.N. Thibodeau[2]. 1) Dept Health Sciences Research; 2) Dept Lab Med and Pathology, Mayo Clinic Col Med, Rochester, MN.

Genetic linkage analysis of complex traits is complicated by heterogeneity of disease etiology, requiring statistical methods to account for non-genetic factors, or for gene-environment interaction, or perhaps for a primary gene when scanning for linkage with a secondary gene. To date, most linkage methods that account for covariates for affected relative pairs tend to be restricted to sib pairs, with the exception of the LODPAL method in S.A.G.E. This method is built on a conditional logistic model for the relative risk for different types of relatives (Goddard and Olson, AJHG, 2001). Although this method is appealing because it can be applied to arbitrary pedigrees, at times it can be difficult to maximize the likelihood due to model constraints, and it does not account for the dependence among the different types of relative pairs in a pedigree. To overcome these limitations, we have developed a new approach, based on score statistics for quasi-likelihoods. We have developed two types of tests: 1) a combined test for both linkage and heterogeneity, and 2) a test for heterogeneity, adjusted for linkage. Furthermore, we have developed robust methods that account for the dependence among different relative pairs within a pedigree. Fortunately, the methods can be formulated in terms of weighted least squares regression, with a special type of scaled covariate that accounts for the relationship of the members of a pair of relatives. One type of scaling leads to a first-order Taylor series approximation of the LODPAL method. Other types of scaling could be considered, implying that our proposed methods can be easily extended to improve power for different types of genetic mechanisms leading to disease. Application of our methods to prostate cancer linkage, and simulations, suggest that our approach is likely to be useful for a broad range of genetic linkage heterogeneity analyses.

Linkage analysis of familial prostate cancer with recursive partitioning. *J. Sinnwell[1], D. Schaid[1], T. Therneau[1], W. Isaacs[2], International Contortium for Prostate Cancer Genetics.* 1) Dept Health Sci Res, Mayo Clinic Col Med, Rochester, MN; 2) Johns Hopkins University, School of Medicine, Baltimore, MD.

A family history of prostate cancer (PC) is one of the strongest risk factors for this disease, yet genetic linkage analysis of prostate cancer has been exceptionally challenging, with weak to moderate linkage signals and difficulty replicating linkage findings. To overcome these difficulties, the International Consortium for Prostate Cancer Genetics (ICPCG) has pooled 1,233 PC pedigrees with completed genome wide scans by microsatellite markers and with the following pedigree-specific covariates: mean age at diagnosis, number of men with PC, pattern of hereditary prostate cancer, and pattern of X-linked inheritance. To evaluate whether these covariates can be used to determine subsets of linked families, we implemented novel recursive partitioning (RP) methods for both parametric and model-free linkage analyses. The RP methods were implemented in the S-PLUS programming language, which grows and prunes a tree, with the leaves of a tree defined to be as homogeneous as possible. Here, we attempted to create leaves that are homogeneous with respect to linkage. The RP algorithm requires the following key measures which are applied recursively during the construction of a tree: 1) a goodness of split, with a larger value indicating a better way to split the data into subsets based on a covariate; and 2) a deviance, with a smaller value indicating a more homogeneous tree node. For the goodness and deviance measures, we used maximum heterogeneity lod scores for the parametric methods, and we used the Kong-Cox linear allele sharing method for the model-free approach. These methods were applied to the ICPCG data to determine homogeneous linkage subsets.

Linkage analysis of familial prostate cancer with pedigree covariates by regression of nonparametric linkage scores. *K. Zarfas[1], D. Schaid[1], S. McDonnell[1], W. Isaacs[2], International Consortium for Prostate Cancer Genetics.* 1) Dept of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN; 2) Johns Hopkins University, School of Medicine, Baltimore, MD.

Although prostate cancer (PC) has long been recognized as familial, with family history of this disease one of the strongest risk factors, genetic linkage analysis of prostate cancer has been exceptionally challenging. Because PC is one of the most common cancers among men, heterogeneity in disease etiology is likely a major reason why genetic linkage analyses have produced weak to moderate linkage signals, and replication has been difficult. To overcome these difficulties, the International Consortium for Prostate Cancer Genetics (ICPCG) has pooled 1,233 PC pedigrees with completed genome wide scans by microsatellite markers and with the following pedigree-specific covariates: mean age at diagnosis, number of men with PC, pattern of hereditary prostate cancer, and pattern of X-linked inheritance. To evaluate whether these covariates are associated with linkage to a chromosomal region, the pedigree-specific NPL scores calculated by Genehunter were regressed on the covariates by a series of linear regression models. A reduced model with an intercept-only was used to test for linkage; a full model with an intercept plus covariates was used as a combined test for both linkage and heterogeneity; and a test for heterogeneity, adjusted for linkage, was accomplished by contrasting the full versus reduced models. Permutations of the covariates were used to compute p-values for the combined and adjusted tests. Results from these analyses suggest interesting regions. The advantages of this approach are that it offers a mechanism to account for pedigree-specific covariates in pooled data, and provides rapidly computation of permutation p-values for both the combined test and the adjusted tests.

Multifactorial genetic models for posterior subcapsular cataract using a genome scan. *G. Jun[1], B.E.K. Klein[3], R. Klein[3], K.E. Lee[3], S.K. Iyengar[1,2].* 1) Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, Ohio; 2) Ophthamology, Case Western Reserve University, Cleveland, Ohio; 3) Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, Wisconsin.

Posterior subcapsular cataract (PSC) is an age-related cataract whose etiology is incompletely understood and is influenced by environmental and genetic factors. We conducted a genome-wide scan (GWS) using 2252 individuals (N = 1015 sibpairs; 33 concordantly affected, ASPs; 160 discordantly affected, DSPs; and 822 concordantly unaffected sibpairs, USPs) from 487 pedigrees in the Beaver Dam Eye Study (BDES). The amount of PSC was graded within grid segments overlaid on a retro-illuminated photograph of the lens using standard protocols. We performed a model-free linkage analysis using PSC affection status (defined as 5 % of any grid segment). Of the most significant regions in the GWS, we assessed gene-gene and gene-environment interactions. We obtained evidence for linkage on 6q12 (D6S1053; $p=1.8x10^{-4}$), 9p21 (GATA187D09; $p=2.2x10^{-5}$), 12p11.23 (D12S1042; $p=1.2x10^{-6}$), 13q13.2 (D13S1439; $p=8.3x10^{-5}$), and 19q13.11 (D19S245; $p=3.8x10^{-5}$) in the GWS. These regions showed excessive mean allele sharing among ASPs and USPs, but decreased sharing among DSPs. The locus on 6q12 is shared with our previous GWS for cortical cataract. Different families were linked to 6q12 for PSC and cortical cataract. Linkage signals that were best explained by the interaction with heavy drinking and smoking were on 1q23 (main effect (ME): 0.28, interaction (I): $3x10^{-7}$) and 13q14 (ME: 0.52, I: $3.0x10^{-5}$), respectively. Significant gene-gene interaction with the marker D6S1053 was observed on 1q42 (ME: 0.84, I: $7x10^{-5}$), 9p21 (ME: 0.11, I: $1x10^{-4}$), and 10p11 (ME: 0.30; I: $1x10^{-4}$). In conclusion, genetic factors involved in PSC are multifactorial and shared with other cataracts.

Genome-wide linkage screen of quantitative traits loci for autism. *C. Li[1,2], L. Jiang[1], G. Crockett[1], S. Anderson[1], J.L. Haines[1,3], J.S. Sutcliffe[1,3].* 1) Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Department of Biostatistics, Vanderbilt Univ, Nashville, TN; 3) Department of Molecular Physiology and Biophysics, Vanderbilt Univ, Nashville, TN.

Autism is a neurobehavioral spectrum of phenotypes characterized by deficits in the development of language and social relationships and by patterns of repetitive, rigid and compulsive behaviors. Twin and family studies have provided strong evidence for a genetic component in autism. Although many groups have performed genomic linkage screens using autism as a dichotomized trait, there havent been any systematic screening for autism-related quantitative traits. Using SOLAR, we performed a genome-wide linkage scan over the 22 autosomes on seven previously defined (Tadevosyan-Leyfer et al. 2003; Cuccaro et al 2003) autism-related quantitative traits in 356 combined Vanderbilt and AGRE (Autism Genetics Research Exchange) multiplex autism families. The seven quantitative traits are spoken language, social intent, compulsions and rigidity, developmental milestones, savant skills, sensory aversions, and insistence on sameness. The scores were transformed as necessary before analysis to conform to the normality assumption of the variance components method employed by SOLAR. We adjusted for the potentially different genetic effects between male and female subjects by including gender as a covariate in all analysis. In addition to gender, we also adjusted for other factors that may influence the outcome: age at interview for social intent and savant skills and birth order for spoken language. We carried out both two-point and multi-point analyses. Multi-point LOD scores of >3 were obtained for compulsions/rigidity and social intent on chromosomes 2q and 16p, respectively. All factors except insistence on sameness demonstrated LOD scores >2 on at least one chromosome. Results on 1q, 2q, 5q, 16p, and 17q overlapped with previous regions of interest based on linkage analyses of the dichotomous trait. These data support the utility in applying quantitative autism-related traits to the genome-wide search for susceptibility loci.

High density whole-genome scan using single nucleotide polymorphisms for Fuchs Dystrophy. *Y.J. Li, N.A. Afshari, L. Zhang, E.R. Martin, S.G. Gregory, G.K. Klintworth.* Duke University Medical Center, Durham, NC.

Fuchs corneal dystrophy (FD) is a common late onset bilateral slowly progressive ocular disorder, which leads to a loss of corneal endothelium and development of guttae on Descemets membrane. It causes corneal edema and a severe impairment of visual acuity in the elderly population. The genetic basis of FD is not well studied. To date linkage screens have not been performed for FD. The only identified gene known to be responsible is COL8A2 on chromosome 1p, which was first found with a missense mutation in one early-onset FD family and one posterior polymorphous corneal dystrophy family. Further investigation showed associated mutations in late-onset FD. Analyses of COL8A2 in other cases of FD have been inconsistent. In order to identify the underlying genetic etiology of FD, we performed a genome-wide linkage scan using the Illumina linkage panel IV with 6144 SNPs markers on a set of 22 multiplex FD families. We used FASTLINK for parametric two-point linkage analysis with both recessive (REC) and dominant (DOM) affecteds only models and Allegro for multipoint analysis of interesting chromosomes (twopoint LOD scores > 1.5). We identified five regions with positive linkage signals from all analyses on chromosomes 1, 7, 15, 17, and X. The peak two point LOD score for the screen was found on chromosome 15q (LOD=3.26 for REC and 2.48 for DOM). Chromosome 17q (~107 to 126cM region) conatins our most overall significant results with LOD scores greater than 2 by both twopoint and multipoint analyses. The X chromosome result (LOD=1.80) is interesting given the preponderance of females with FD. Finally, the peak chromosome 1p region result (LOD >2) is located near the COL8A2 gene suggesting that at least a subset of families may have mutations in this gene warranting mutation screening of COL8A2 in these data. In summary, we report the first genome wide SNP screen in FD, provide evidence for the involvement of COL8A2 and identify novel regions for the location of FD risk genes.

Fine mapping of the region on the chromosome 5q32 in Scandinavian families with celiac disease. *S. Adamovic[1], Å. Naluai[1,2], S. Nilsson[2,3], Å. Hellqvist[2], A.H. Gudjonsdottir[4], H. Ascher[4,5], J. Wahlström[1].* 1) Clinical genetics, Gothenburg, Sweden; 2) SWEGENE Genetics and Bioinformatics Core Facility, Göteborg, Sweden; 3) Chalmers University of Technology, Göteborg, Sweden; 4) Dept. of Pediatrics, The Queen Silvia Children's Hospital, Göteborg, Sweden; 5) Nordic School of Public Health, Göteborg, Sweden.

We performed a genome wide scan in 106 Scandinavian multiplex families with celiac disease (Naluai et al, EJHG 2001). After typing additional markers in the region on chromosome 5q31-33 the NPL score reached a significant level of 4,2. We continued our study by fine mapping a part of this region (approximately 6 cM) between markers D5S2017 and D5S434 in order to perform an association analysis. For this study we analysed 54 SNPs and 8 microsatellites. The SNPs were chosen with consideration to their validation status and position in the region. We focused on possible candidate genes, like genes involved in immunoreactions, cell cycling or apoptosis. SNPs chosen had minor allele frequencies above 0,1. The average distance between the markers was approximately 100-200 kb, except for two minor regions directly beneath the linkage peak where we increased the density of markers to 1 per 50kb. The analysis indicated some haplotypes that showed a nominal association ($p<0,001$). Although promising, it was not significant after correction and could not fully explain the linkage peak, so further investigation of the region is necessary.

A genome-wide scan of Gilles de la Tourette syndrome. *D. Pauls[1], Tourette Syndrome Association International Consortium for Genetics[2].* 1) Dept Psychiatry/Neurodev Gen, Harvard Med Sch, Charlestown, MA; 2) Tourette Syndrome Association, Bayside, NY.

Twin and family study suggest that there is a significant genetic component important for the expression of Gilles de la Tourette Syndrome (GTS) and a number of linkage studies have reported suggestive evidence for linkage regions on 4q, 8p, and 11q. The present report describes the second genome-wide scan conducted by the Tourette Syndrome International Consortium for Genetics. A genome wide scan using approximately 400 microsatellite markers was completed on 327 affected sib-pairs and 20 multigenerational families. Altogether, over 2,200 individuals were genotyped in these families. Non-parametric linkage analyses were completed with GENEHUNTER and SIMWALK2. using both a diagnosis of GTS and/or chronic tics as affected. Six chromosomal regions with heterogeneity NPL scores over 3.1 were observed on 2p, 3p, 3q, 11q, 18p and 20p. The two regions with the highest NPL scores were 2p (NPL=4.17, $p < 0.000066$) and 20p (NPL=4.63, $p < 0.000023$). Fine mapping results in most of these regions are consistent with the initial findings. Of note is that the region on 11q is very close to the region reported in two previous studies. The results from this genome scan provide strong evidence for at least two and possibly three susceptibility loci for GTS. The finding on 11q is of particular import since it appears to be a replication of two earlier reports.

Genome-wide scan for familial cutaneous malignant melanoma (CMM) susceptibility loci in a northeastern Italian population. *K.F. Kerstann[1], R. Steighner[2], M. Ter-Minassian[1], D. Calista[3], P. Minghetti[3], G. Landi[3], A.M. Goldstein[1], M.T. Landi[1].* 1) Genetic Epidemiology Branch, DCEG/NCI/NIH, Rockville, MD; 2) Core Genotyping Facility, Advanced Technology Center/NCI/NIH/DHHS, Gaithersburg, MD; 3) Dermatology Unit, Maurizio Bufalini Hospital, Cesena, Italy.

The incidence of CMM, the most severe cutaneous malignancy, has increased at a rate of 3-7% per year since the early 1960s in Western countries. Approximately 10% of all melanoma cases are familial. Several genetic susceptibility genes for CMM have been identified, including CDKN2A (9p21), CDK4 (12q14) -plus loci in the regions of 1p22 and 1p36, although the gene(s) within these regions have yet to be identified. These loci account for the genetic susceptibility in approximately 20-40% of familial CMM. Therefore, other genetic (and/or environmental) factors are likely involved in the majority of familial melanomas. To identify additional susceptibility loci for familial CMM we analyzed a racially homogeneous population from northeastern Italy. Sixty families with at least two cases of CMM were ascertained from the Bufalini Hospital in Cesena, Italy. Previous studies of Italian melanoma prone families found that approximately 33% of the families harbor CDKN2A mutations. However, only 7% (n=4) of our families had CDKN2A mutations. The families from Cesena were similar to other Italian families with CDKN2A mutations with regard to number of cases, pigmentation characteristics, and family members with multiple melanomas, dysplastic nevi or pancreatic cancer. Thus, we hypothesized that our families had an inherited susceptibility to CMM. We therefore, conducted a genome-wide scan of fifty-six families without mutations in any candidate gene for melanoma. We performed two-point linkage analyses based on a dominant model as well as multipoint and nonparametric analyses using 10cM microsatellite scan data. No evidence for linkage was observed for 12q14, 9p21, 1p22 or 1p36. Affecteds-only analyses identified three regions of interest (lod scores > 1.5), while pre-divided sample tests identified two additional regions (lod score >2). Follow-up analyses of these regions with increased marker density are underway.

Bivariate genome-wide scan for phenotypes related to the metabolic syndrome in non-diabetic Chinese subjects from the Stanford Asia-Pacific program of hypertension and insulin resistance family study. *Y. Chiu[1], L. Chuang[2], A. Hsiung[1], The SAPPHIRe Study Group[3,4,5,6,7].* 1) Biostatistics & Bioinformatics, National Health Research Inst, Zhunan, Miaoli, Taiwan; 2) National Taiwan University, Taipei, Taiwan; 3) Division of Endocrinology and Metabolism, Tri-Service General Hospital, Taipei, Taiwan; 4) Faculty of Medicine, School of Medicine, National Yang-Ming University and Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 5) the Executive Office, Taichung Veterans General Hospital, Taichung, Taiwan; 6) Department of Public Health Sciences and Epidemiology, School of Medicine, University of Hawaii and Pacific Health Research Insitute, Honolulu, Hawaii; 7) Department of Genetics, Stanford University, School of Medicine, Stanford, California.

Previously, we have identified regions with tentative evidence of linkage in the univariate genome-wide linkage scan for multiple correlated metabolic syndrome related traits. The common regions identified for the correlated traits might be due at least in part to the effects of pleiotropic genes. We therefore conducted bivariate linkage analyses for the correlated traits related to the metabolic syndrome (MS), aiming to dissect the genetic architecture affecting these traits. Results shown that the multiple traits analysis can improve the detection of quantitative-trait loci (QTLs), which have been found in the univariate linkage analysis. Further, QTLs whose effects were too small to be found in single-trait analyses were identified in the bivariate analyses.

Gene mapping and evaluation of memory traits in the Caribbean Hispanics with familial Alzheimer disease. *J.H. Lee[1], H.-S. Lee[1], V. Santana[1], J. Williamson[1], R. Lantigua[1], M. Medrano[2], B. Tycko[1], E. Rogaeva[3], Y. Stern[1], P. St. George-Hyslop[3], R. Mayeux[1].* 1) Taub Inst & Sergievsky Ctr., Columbia Univ, New York, NY; 2) Universidad Tecnologica de Santiago, Santiago, DR; 3) Centre for Research in Neurodegenerative Diseases, Univ of Toronto, Toronto, Ontario, Canada.

Alzheimer disease (AD) comprise a complex array of subphenotypes. To simplify the AD phenotype and improve genotype-phenotype relation, we examined memory traits as endophenotypes because memory traits may represent biological traits underlying AD, and they have high to moderate heritability. Here, we report findings from a genome scan. We studied 1066 individuals from 210 Caribbean Hispanic families with late-onset AD. We evaluated both affected and unaffected family members for a battery of neuropsychological tests to measure memory, abstract reasoning, language and visuospatial functions. We conducted a variance component linkage analysis as implemented in SOLAR using 430 microsatellite markers. We adjusted for age, sex, and education in the polygenic model, and corrected for ascertainment. Because we found significant linkage in 10q, 12p, and 18q in our earlier AD genome scan, we concentrated on these regions. We observed several regions with LOD2, and to some extent, the findings differed by trait. Delayed recognition, a cognitively simple test, was a sensitive marker for familial AD where linkage peaks for the two traits often overlap. On the other hand, non-verbal recall test with low heritability yielded low LODs, and the pattern of linkage differed from other traits. For long-term recall and long-term storage, the pattern of linkage across the genome was similar. In 12p13 where we previously had a strong signal for AD, we observed only modest linkage (LOD=1.66) for delayed recognition but not for others. For 10q where others found strong linkage, we observed only a weak signal (LOD~1). Further, we observe novel chromosomal regions such as 18p11 (LOD=3.13) that were linked to memory traits, but not to AD. Here we show that we may be able to enhance power to map genes that contribute to AD using memory traits. We also show that we may be able to localize genes that are related to memory independent of AD.

Genome-wide Scan for Schizophrenia in an Afrikaner Founder Population. *A. Woodroffe[1], J. Louw Roos[2], J.A. Gogos[3], G.R. Abecasis[1], M. Karayiorgou[4].* 1) Univeristy of Michigan, Department of Biostatistics, Ann Arbor, MI; 2) University of Pretoria & Weskoppies Hospital, Pretoria, RSA; 3) Columbia University Medical Center, Department of Physiology & Cellular Biophysics, New York, NY 10032; 4) Rockefeller University, Human Neurogenetics Laboratory, New York, NY 10021.

Schizophrenia is characterized by delusions, hallucinations, and disorganized speech or behavior. The disorder is very common, affecting 1 in every 100 people worldwide. Evidence for contribution from genetic factors include increased prevalence of schizophrenia in relatives of affected individuals. Twin studies indicate a 30-50% concordance rate for MZ twins and a 10-20% rate for DZ twins. For this study, we collected data from a sample of 481 Afrikaners. This is a founder population that has descended from about 2,000 Dutch founders. We carried out an extended, high-density genome-wide linkage scan using 2005 microsatellites at an average density of 2 cM. A maximum multipoint LOD score of 2.99 was observed at D13S1825 (133 cM), the most telomeric marker tested on chromosome 13q. The multipoint linkage peak extends from about 124 cM to the telomere. We also found a singlepoint LOD score of 2.92 at D13S285 (127 cM). These findings on 13q are consistent with the results of our previous lower density 10 cM scan which identified a multipoint LOD score of 2.23 at D13S285. The maximum singlepoint LOD score of 3.15 was observed at D1S2885 (45 cM). However, the observed multipoint LOD score at that marker was only 1.17. We have previously described a proband with paternal UPD of chromosome 1 in this population. We did not find any haplotype sharing between the UPD proband and other affected individuals at this marker density. Parent of origin linkage analysis to test for possible imprinting effects revealed suggestive evidence for maternal sharing on chromosome 1. In addition to the linkage analysis, we tested for association using the TDT. We did not find any disease associated alleles after correcting for multiple testing. We are currently employing large scale SNP genotyping to fine map candidate genes and regions on 13q and 1p.

Bipolar Disorder with Psychotic Features shows Evidence of Linkage to Chromosomes 5,6,and 18. *B. Kerner, N.B. Freimer.* Ctr Neurobehavioral Genetics, Univ California, Los Angeles, Los Angeles, CA.

Purpose: The heterogeneity of psychiatric disorders is one of the major obstacles in the attempt to identify underlying genetic mutations. The presence of some phenotypic features that occur across diagnostic boundaries, such as psychosis, provides additional challenges. The familial aggregation of such features independent of existing diagnostic categories suggested the utility of such phenotypes in linkage analyses. We undertook a reanalysis of the NIMH Bipolar Genetics Initiative data sets Wave 1,3,and 4 using psychotic features to define affected status. **Methods:** 55 pedigrees in Wave 1 (484 individuals, 136 affected)and 187 pedigrees in Wave 3 and 4 combined (1170 individuals, 440 affected)were included in a whole genome scan using microsatellite markers. Pedigrees were selected for multiple members affected with psychotic symptoms. Relatives without a diagnosis of bipolar disorder were included as affected if they had a lifetime history of psychotic symptoms. The NPL option in MENDEL was used to calculate IBD sharing in relatives. **Results:** The most significant finding in Wave 1 was located on chromosome 5q34 between markers D5S820 and GABRA1 at 163 cM. The most significant finding in Wave 3 was located on chromosome 6q22 between markers D6S474 and D6S1040 and in Wave 4 on chromosome 18p11 and 18q12. Combined analysis of Wave 3 and 4 increased the signal on chromosome 18. When Bipolar Disorder was used as phenotype, only the signal on chromosome 6 in Wave 3 was evident. **Conclusion:** Bipolar Disorder with psychotic features appears to be a useful phenotype for linkage analysis. All loci reported here showed evidence for linkage in other genome scans for both bipolar disorder and schizophrenia. These loci may contain susceptibility genes for psychotic symptoms across diagnostic categories.

Genome Screen for Atopic Dermatitis in the French EGEA families ascertained through asthmatic probands. *M. Dizier[1], M. Guilloud-Bataille[1], E. Bouzigon[2], C. Bétard[3], J. Bousquet[4], F. Gormand[6], J. Hochez[7], J. Just[8], A. Lemainque[3], N. Le Moual[9], R. Matran[1], F. Neukirch[1], E. Paty[1], I. Pin[1], D. Vervloet[5], F. Kauffmann[9], M. Lathrop[3], F. Demenais[2], I. Annesi-Maesano[9].* 1) INSERM U535, Villejuif, France; 2) INSERM EMI 00-06, Evry, France; 3) CNG, Evry, France; 4) INSERM U454, Montpellier, France; 5) Service de Pneumologie-allergologie, Hôpital Nord, Marseille, France; 6) Service de pneumologie, centre hospitalier Lyon-Sud, Pierre Benite, France; 7) INSERM U436, Paris, France; 8) Centre de diagnostic et traitement de l'asthme, Hôpital Trousseau, paris, France; 9) INSERM U472, Villejuif, France.

In the sample of 295 French EGEA families with at least one asthmatic subject, a genome screen was conducted to search for genetic factors specific to atopic dermatitis (AD) or shared by AD and asthma or by AD and allergic rhinitis (AR). The AD phenotype was based on self reporting AD status and age at onset. AR phenotype was based either on self reporting diagnosis or on symptoms while asthma phenotype was based on answers to a questionnaire plus the presence of bronchial hyper-responsiveness. The phenotype of non-specific organ allergic manifestations(NSOAM)defined by the presence of at least one of the allergic diseases (asthma, AR or AD) was also considered. Analyses were conducted using the Maximum Likelihood Binomial (MLB) method developed for linkage analysis in sibships. Evidence of linkage to the 11p14-q13 region was supported for AD (p=0.0001) as well as for NSOAM (p=0.0002) while linkage was only indicated to the 5q13 region for AD (p=0.002), when associated or not with asthma or AR, and to 5p13 (p=0.002) and 17q21 (p=0.003) for NSOAM. Detection of linkage to the 11p14-q13 region could be due to the presence of one or of more genetic factor(s), involved either specifically in AD or more generally in NSOAM. Further association studies with candidate genes in this region, may help to identify the underlying genetic mechanisms.

Genomewide scan in Ashkenazi families shows linkage of ocular refraction to a quantitative trait locus on chromosome 1p36. *R. Wojciechowski[1,2], G. Ibay[1], C. Moy[3], D. Stambolian[3], J.E. Bailey-Wilson[1].* 1) IDRB, NHGRI, Baltimore, MD; 2) Epidemiology, Johns Hopkins U, Baltimore, MD; 3) Ophthalmology, U of Pennsylvania, Philadelphia, PA.

Purpose: The development of refractive error is mediated by both environmental and genetic factors. We performed regression-based quantitative trait locus (QTL) linkage analysis on Ashkenazi Jewish families to identify regions in the genome responsible for ocular refraction. Methods: We obtained refractive error measurements on individuals in 49 multi-generational American families of Ashkenazi Jewish descent. The average family size was 13.7 individuals and was composed of 3 generations. Recruitment criteria specified that each family contain at least 2 myopic members. The mean spherical equivalent refractive error in the sample population was -3.46D (SD=3.29) and 87% of individuals were myopic. Microsatellite genotyping with 387 polymorphic markers was performed on 410 people. We performed multipoint regression-based linkage analysis for ocular refraction using the statistical package Merlin-regress. To minimize the impact of extreme values on linkage statistics we also conducted analyses on a normalizing (log) transformation of refractive error. We estimated genomewide significance levels for ocular refraction and the transformed trait by generating random genotypes at each marker in 100 replicates of our pedigrees. We estimated empirical significance levels as the number of replicates in which the maximum LOD score exceeded that of the test sample for each trait. Results: Maximum LOD scores of 9.5 for ocular refraction and 8.7 for log-transformed refraction were observed at 49.1 cM on chromosome 1p36 between markers *D1S552* and *D1S1622*. The corresponding empirical genomewide significance levels were $p<0.07$ for ocular refraction and $p<0.01$ for log-transformed refraction, providing strong evidence for linkage of refractive error to this locus. The inter-marker region containing the peak spans 11 Mb and contains approximately 189 genes. Conclusion: We found genome-wide significant evidence for linkage of refractive error to a novel QTL on chromosome 1p36 in an Ashkenazi Jewish population.

Type-1 Protein Phosphatase Inhibitor 4 (*I-4*) on Xp11.4-11.3 is Associated with Familial and Idiopathic Parkinsons Disease: The *Gene*PD Study. *G. Xu[1], J.B. Wilk[1], A.L. DeStefano[1], Q. Yang[2], J. Latourelle[1], S. Williamson[1], R. Prakash[1], J. Tobin[1], M. Sun[3], M.E. MacDonald[3], J.F. Gusella[3], R.H. Myers[1], for the GenePD investigators.* 1) Department of Neurology, Boston University School of Medicine, Boston, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 3) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Parkinson disease (PD), the second most common neurodegenerative disorder, is caused by degeneration of dopaminergic neurons in the substantia nigra and other areas of the brain. Mutations in five genes *parkin*, *-synuclein*, *DJ-1*, *PINK1*, and *LRRK2* have been identified to cause PD in a minority of families and more than ten PD linkage regions have been reported, with the susceptibility genes in these regions still under investigation. Three independent linkage analyses have provided compelling evidence for additional PD susceptibility genes on the X chromosome. We report modest evidence of linkage (multipoint LOD = 1.07) to PD affection status at 41Mb on the X chromosome in 283 affected sibling-pairs from the *Gene*PD Study. Thirty-seven SNPs, in or near possible PD candidate genes located from 40 to 47 Mb were evaluated for association to PD by chi-square tests and logistic regression in different genetic models. Association to PD affection was observed for c6231643 in two independent samples: Familial PD (p = 0.018) and Idiopathic PD (p = 0.016). C6231643 is 257 bp 3 of the type-1 protein phosphatase inhibitor 4 (*I-4*) gene. Haplotype analysis using three *I-4* SNPs (c2462683-c2462691-c6231643) also identified the evidence of association to PD in the two independent samples across genders. As a potentially important regulatory subunit of *PP1*, *I-4* may have impact on the phosphorylation processes triggered by dopamine, resulting in the development of PD.

Model-independent linkage analysis and tests of association on regions of chromosomes 9 and 16 linked to idiopathic scoliosis. *C. Justice[1], B. Marosy[2], M.H. Roy-Gagnon[1], K.F. Doheny[3], E.W. Pugh[3], A.F. Wilson[1], N.H. Miller[2].* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Orthopaedic Surgery, JHU, Baltimore, MD; 3) CIDR, IGM, JHU SOM, Baltimore, MD.

Idiopathic scoliosis (IS) is a structural lateral curvature of the spine present in the late juvenile or adolescent period in otherwise normal individuals. It affects 2-3% of the pediatric population, and 0.2-0.5% of the population require active treatment. Idiopathic scoliosis is believed to be a complex genetic disorder in which expression of the disease state may depend on several genetic and possibly environmental factors. Previous studies have suggested autosomal dominant, X-linked and multifactorial modes of inheritance. As part of a large collaborative study of familial idiopathic scoliosis, 202 families with at least two individuals with a lateral curvature greater than or equal to 10 degrees were ascertained and clinically characterized. Phenotypes include degree of lateral curvature, curve type, age of onset and sex. A genomic-wide screen identified candidate regions on chromosomes 6, 9, 16 and 17 (Miller et al. 2005). The candidate regions on chromosomes 9 and 16 were genotyped with SNPs using the Ilumina platform. SNP marker density was ~ 58 Kb, with 519 SNPs genotyped on 9q31.3-q34.2 and 805 SNPs genotyped on 16p12.3-q22.2. Idiopathic scoliosis was analyzed both as a quantitative trait and as a qualitative trait, in which the curvature determining the threshold for affectation status was set at values of 10 and 30 degrees. Model independent sib-pair linkage analysis was performed on these various subsets. Tests of association using FBAT were performed with IS as a quantitative trait and as a qualitative trait. Haplotypes of two, three and four SNPs were also analyzed for association using FBAT.

In search of the founder haplotype for the prostate cancer susceptibility locus on 7q11-21 in Jewish families using the Affymetrix 100K SNP chips. *D. Friedrichsen[1], J. Stanford[2], R. Wells[1], M. Janer[3], K. Deutsch[3], S. Kolb[2], H. Hung[1], P. Nelson[1], L. Hood[3], E. Ostrander[4].* 1) Dept Human Biol; 2) Public Health Sci, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Institute for Systems Biology, Seattle, WA; 4) Cancer Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD.

Hereditary prostate cancer (HPC) is a genetically heterogeneous disease with evidence for multiple loci contributing to overall susceptibility. One approach to reduce locus heterogeneity is to analyze HPC in Jewish families, which represent a more well-defined and genetically homogenous population. We previously reported a combined genome-wide scan of 36 Jewish HPC families where we identified a region of significant linkage on chromosome 7q11-21, with an empirical P value of 0.006. Our strategy for isolating this prostate cancer susceptibility gene is to identify the founder haplotype surrounding the founder mutation in at least a subset of these Jewish families. Previously reported founder haplotypes in Jewish families for susceptibility genes in other diseases have been 500 kb or larger. The Affymetrix 100K SNP chips have a SNP every 50 kb on average and chromosome 7 specifically has over 6,000 SNPs. The resolution of the 100K chips is potentially small enough to identify regions that may contain the founder haplotype. Currently, we are in the process of genotyping 90 members of the 18 Jewish PROGRESS families on the 100K SNP chips. This includes 51 affecteds and an additional 39 family members, which will be useful in determining chromosomal phase of the alleles. The data will be analyzed to determine regions where a specific haplotype pattern shared within families is also shared across several families for a large distance (greater than 500 kb) and where this pattern occurs more often in the shared affected haplotypes than in the other haplotypes in the families. After putative haplotypes are identified, SNPs from the HapMap project will be genotyped to confirm and further resolve the haplotypes identified. Finally, all exons in the remaining regions will be sequenced to discover the putative disease-associated mutation.

Genome-wide association studies in founder populations: adding value by simultaneously testing for linkage using large families. *R.J. Thomson[1], J. Stankovich[2], S. Quinn[1], J. McKay[1,3], T. Albion[1], M. Bahlo[2], J. Silver[2], L. Fitzgerald[1], J. Dickinson[1].* 1) Menzies Research Institute, University of Tasmania, Hobart, Australia; 2) Walter and Eliza Hall Institute Of Medical Research, Melbourne, Australia; 3) International Agency for Research on Cancer, Lyon, France.

In terms of numbers of cases required, association studies are more efficient than linkage studies for detecting common alleles that confer susceptibility to disease. However linkage analysis with large pedigrees remains an efficient method to detect rare susceptibility variants. When genome-wide association studies are conducted in founder populations, it will often be possible to construct large pedigrees linking the cases. Thus the possibility arises of analysing such datasets to test for linkage as well as association.

In linkage analysis with large families it is impossible to analyse jointly all genotypes from all individuals using exact algorithms. However as marker density increases it becomes less crucial to analyse all individuals genotypes simultaneously. We propose a multipoint, pair-by-pair analysis of case genotypes using *Merlin 1.0*. This technique will be demonstrated, using *Hapmap* data to simulate genotypes in families, at the marker densities required for genome-wide association studies. Results for *Affymetrix* 10K and 50K SNP chips will be presented. Even at these lower marker densities, inference of haplotype sharing patterns is almost as accurate in a pair-by-pair analysis, as it is in an exact, whole-pedigree analysis.

Genetic homogeneity in X-linked myopia locus at Xq28 (MYP1): Narrowing of the Critical Region and Exclusion of fifteen Known Genes Localized in the Interval. *S.K. Nath[1], U. Radhakrishna[2,3], R. Lyle[2], R. Raval[4], R. Singh[5], U.C. Patel[6], J.V. Solanki[6], V. Himabindu[7], S. Vishnupriya[7], V. Vittalrao[7], U. Ratnamala[3], S.E. Antonarakis[2].* 1) Arthritis & Immunology, Oklahoma Medical Res Fndn, Oklahoma City, OK; 2) Dept. of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) Green Cross Blood bank & Genetic Research Centre; 4) Dept. of Biochemistry, Gujarat Cancer and Res. Institute,; 5) Dr. P.L. Desai Eye Center,Ahmedabad; 6) Dept. of Animal Genetics & Breeding, Veterinary college, Anand,; 7) Dept. of Genetics, Osmania University, Hyderabad, India;.

Myopia is a common vision problem experienced by approximately one-third of the general population with a prevalence of 0.5-2.5% in Western Europe and US populations. The genes responsible for MYP1, MYP2, MYP3, MYP4, MYP5 and MYP6 have been mapped to chromosomes Xq28, 18p11.31, 12q21-q23, 7q36, 17q21-q22, and 22q12 respectively, but no specific gene mutations have yet been identified. We studied two large four-generation Indian pedigrees (UR006 & UR077) with isolated, non-syndromic myopia, with apparent X-linked inheritance (MYP1;MIM310460). The anomaly was only present in male members of the pedigree. The degree of myopia was variable ranged from -6 to -16.5 D with a mean of -13.33 D. In order to map the myopia locus in these families, we performed linkage analysis on 41 samples, 12 affected and 29 normals in both families, using polymorphic microsatellite markers covering the entire X chromosome. Marker DXYS154 which is located in pseudoautosomal (PAR) region in distal Xq28, showed no recombination with the phenotype with a combined maximum LOD score of 4.42 at theta = 0 under an autosomal recessive model. Other markers in the Xq28 region that showed no recombination with the phenotype included DXS1108, DXS8087 and F8i13. Observation of recombination in family UR006 refined the disease locus to 1.2 cM region flanked by markers DXS1073 and DXYS154. Mutations in the CTAG1B, CTAG2, GAB3, MPP1, F8Bver, FUNDC2, VBP1, RAB39B, CLIC2, TMLHE and (PAR) HSRY3, SYBL1, IL9R, SPRY3, CXYorf1 were excluded by direct sequence analysis.

Evidence of a Novel Postaxial Polydactyly Type B Locus in a Costarrican Family. *J. Peralta[1,2], P. León[1], H. Raventós[1], L. Almasy[2].* 1) Centro de Investigación en Biología Celular y Molecular, Universidad de Costa Rica, San José, Costa Rica; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Postaxial Polydactyly (PAP) is a congenital hand/foot malformation characterized by the presence of an extra ulnar/fibular digit. In PAP Type A (PAP-A) the digit is functional and articulates with the fifth metacarpal/metatarsal, but in Type B (PAP-B) it is present as an skin appendix without bone tissue. Both types segregate as autosomal dominant traits with incomplete penetrance, although there have been reports of recessive inheritance of PAP-B. Genetic and allelic heterogeneity are common features of PAP. Several loci have been linked with either PAP-A or the mixed type PAP-A/B. Allelic variants of one of those loci, *GLI3*, are responsible for PAP-A, PAP-A/B, Preaxial Polydactyly and Greig Cephalopolysndactyly. Our goal was to garther evidence regarding the involvement of known PAP loci in the development of PAP-B. Given the known genetic heterogeneity of PAP, we concentrated our analysis in one large family from Costa Rica (F01) that has affected individuals in all four generations and segregates only PAP-B as a dominant trait. *GLI3* (7p13), *PAP-A/B* (7q22), *PAP-A2* (13q21-q32) and *PAP-A3* (19p13.2-p13.1) as well as key genes involved in limb development, *IHH*, *SHH*, *dHAND*, and *HOXD13*, were selected as possible candidates. A total of 50 STRs located in the candidate gene regions, the HOXA, B, C and D gene clusters, and inside the ninth intron of GLI3, were genotyped in 17 of the 20 affected family members. Using an affected-only analysis and a disease allele frequency of 0.001, linkage was excluded (LOD-2) for all candidate loci. For the *GLI3* intragenic locus Z=-4.79@=0. Recently a balanced translocation t(4;7)(p15.2;q35) has been described in association with PAP-B [Galjaard, 2003]. STRs near the reported translocation breakpoints genotyped in F01 showed no evidence of linkage with PAP-B. Our results suggest the existence of a novel PAP locus responsible for the isolated PAP-B phenotype observed in F01. The calculated power of F01 (3expected LOD7) should be enough to localize this novel locus.

Fine mapping of candidate regions in African Americans with sarcoidosis: Confirmation of linkage to chromosome 5p15.2. *R. Sinha[1], S.K. Iyengar[1], B.A. Rybicki[2], M.C. Iannuzzi[3], R.C. Elston[1], C. Gray-McGuire[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Biostatistics and Research Epidemiology, Henry Ford Health System, Detroit, MI; 3) Division of Pulmonary, Critical Care, and Sleep Medicine, Mt. Sinai School of Medicine, New York, NY.

Sarcoidosis, a systemic granulomatous disease of unknown etiology, likely results from an environmental effect on a genetically susceptible individual. This disease is much more prevalent in women than in men and, in the United States, African Americans are both more commonly and more severely affected than Caucasians. This study is a follow-up of the recently published first genome scan for sarcoidosis susceptibility genes conducted in an African American sample comprising 229 African American nuclear families ascertained through two or more sibs with a history of sarcoidosis (Ianuzzi et al. Genes and Immunity, 2005). Areas of interest from the genome scan include chromosomes 5p15-13, 5q11, 5q35, 2p25, 3p25, 3q12, 9q34, 11p15 and 20q13. These fine mapping regions were analyzed using both the original Haseman-Elston regression (dependent variable is the squared sib-pair trait difference) and the weighted Haseman-Elston regression (dependent variable is a weighted average of the squared sib-pair trait difference and the squared mean-corrected sum) with two new improvements. The first improvement was inclusion of the available half sib pairs in the regression, which increased our sample size by 20%, and the second improvement was estimation of the mean correction term from the data. The marker with the strongest signal, D5S1486 on 5p15.2, had an initial p-value of 0.007, which decreased to 10^{-6} with the inclusion of half sibs. These results demonstrate the presence of a susceptibility gene on 5p15.2 as well as the utility of correctly including half sibs in the analysis.

Exclusion of candidate genes for a hereditary type of telangiectasia. *M. Amyere[1], L. Boon[2], MB. Mulliken[3], M. Vikkula[1].* 1) Lab Human Molec Genetics, Christian de Duve Inst, Brussels, Belgium; 2) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, Université Catholique de Louvain, Brussels, Belgium; 3) Center for Vascular Anomalies, the Childrens Hospital and Harvard Medical School, Boston, MA, USA.

Telangiectases are abnormal dilatation of end vessels, mainly venules, but occasionally involving capillaries and arterioles in the subpapillary plexus in the upper dermis. The Hereditary haemorrhagic telangiectasia (HHT or Rendu-Osler-Weber disease) is characterized by epistaxis, mucocutaneous telangiectases and visceral arteriovenous malformations (AVMs) caused by mutations in Endoglin (ENG) or activin receptor-like kinase-1 (ALK1, ACVRL1). Hereditary benign telangiectasia (HBT) is another, rare variant. Affected individuals present with cutaneous, punctate, radiating or arborising telangiectases. HBT is distinguished from HHT, by the lack of AVMs and absence of mucosal lesions. These two telangiectasias are inherited as an autosomal-dominant disorder with variable penetrance. Another similar hereditary disorder, CM-AVM, is caused by mutations in RASA1. These patients have more homogeneous, round-to-oval pinkish-red cutaneous lesions, atypical capillary malformations, which are sometimes associated with AVMs. We report a family with cutaneous telangiectasias with an autosomal dominant pattern of inheritance. The affected individuals develop large, heteregenous telangiectasias that are not associated with AVMs. This condition could be a more extensive variant of HBT. We performed a genome-wide linkage analysis using microsatellite markers and SNP genotyping assay with the GeneChip Human Mapping 10K Array. The analysis excludes the three candidate genes, endoglin, ALK-1 and RASA1. This provides evidence for existence of a different causative gene for this type of hereditary telangiectasia. Genome wide linkage analysis of a novel hereditary progressive hyperpigmentation disorder. *T. Vogt[1], M. Amyere[2], M. vikkula[2].* 1) Dept Dermatology, Univ Regensburg, Regensburg, Germany; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université Catholique de Louvain, Brussels, Belgium.

Familial progressive hypermelanosis is a new variant of a hereditary pigmentation disorders without associated symptoms. This phenotype has so far been observed only in five families, all living in close proximity in a small town in south-east of Germany (Zanardo et al., 2004). The phenotype, with an autosomal dominant inheritance with reduced penetrance, consists of progressive diffuse, partly blotchy hyperpigmentation, multiple café-au-lait spots, intermingled with scattered hypopigmented appearing maculae, and lentigenes. Histological and ultrastructural section from the hyperpigmented spots display strong basal hyperpigmentation of the epidermis with numerous melanophages containing large amounts of pigment. In contrast, the hypopigmented appearing macula show a slight basal hyperpigmentation of epidermis, but virtually no melanophages in the upper dermis. The restricted area of occurrence of the disease and the extreme rarity of the phenotype suggest a common origin and thus a founder effect for this genetic defect. Based on this hypothesis, we performed a genome-wide linkage analysis in the five families using the GeneChip Human Mapping 10K Array SNP genotyping. The results demonstrate the presence of significant linkage peaks with maximal LOD of 2.28 assuming the smallest genetic distance between the five families, on the long arm of chromosome 12. All affected individuals shared the same haplotype in this locus. This finding suggests that a gene involved in melanin distribution is located on chromosome 12. (http://www.icp.ucl.ac.be/vikkula); (vikkula@bchm.ucl.ac.be).

Linkage analysis of ocular refraction as a quantitative trait in an adult population. *A.P. Klein[1,2], P. Duggal[3], K. Lee[4], R. Klein[4], J.E. Bailey-Wilson[3], B.E.K. Klein[4].* 1) Departments of Oncology and Pathology Johns Hopkins School of Medicine, Baltimore MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore MD; 3) Statistical Genetics Section, NIH/NHGRI/IDRB, Baltimore, MD; 4) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison WI.

Ocular refraction refers to the power of the external lens to bring images into focus on the retina. Refractive errors, myopia (nearsightedness) and hyperopia (farsightedness) are common conditions that require corrective lenses. It has been well established that myopia clusters within families and linkage to regions on chromosome 12q, 17q, 18q and 22q has been demonstrated through studying highly myopic individuals. The potential for genetic effects through the entire range of refraction has been less well studied. In a study of 221 dizygotic twin pair, regions on chromosomes 3q, 4q, 8p and 11p have been reported to be linked to refraction. Using data collected as part of the Beaver Dam Eye Study, we previously demonstrated substantial positive correlation for refraction as a quantitative trait between siblings (0.39), parents and offspring (0.26) after adjustment for age, sex. In order to localize the genes influencing refraction in this population non-parametric genome-wide linkage analyses was conducted on 881 sibling pairs within 487 extended pedigrees (2231 genotyped individuals) using 385 autosomal microsatellite markers. Sibling pair linkage analysis (singlepoint and multipoint) using SIBPAL (S.A.G.E version 4.5) was performed on quantitative refraction, and refraction adjusted for age, education and nuclear sclerosis. Refraction was adjusted for nuclear sclerosis because nuclear lens opacity has been shown to decrease refraction (more myopic). Both asymptotic and empirical p values using Monte Carlo permutations were obtained. Three novel regions meet the Lander-Kruglyak criterion for suggestive evidence for linkage ($p<0.00074$). Additionally, our results replicated two of the previously reported linkage regions. Linkage analysis of the extended pedigree data will also be presented.

Linkage Analysis for Laterality Genes in Pedigrees Ascertained for Autism. *A. Lu[1], S.J. Spence[2], N. Kono[1], R.M. Cantor[1], D.H. Geschwind[2].* 1) Dept Human Genetics, David Geffen School of Medicine, Univ of California, Los Angeles, CA; 2) Dept of Neurology, David Geffen School of Medicine, Univ of California, Los Angeles, CA.

Human brain asymmetry for language is strongly associated with handedness, and typical patterns of brain and behavioral asymmetry are reported to be disrupted in a number of neurodevelopmental disorders. For example, an excess of non-right-handed individuals has been observed among a sample of 78 children with Autism (Gillberg, 1983). We observed the same pattern in a sample of 275 children with Autism and 53 of their unaffected siblings, from the Autism Genetic Research Exchange (AGRE), a cohort of approximately 500 nuclear families ascertained for at least two children with Autism Spectrum Disorder. A GEE logistic regression model, used to account for the dependence among siblings, revealed an increased frequency of 24% left-handed or ambidextrous individuals versus 4% right-handed, ($p<0.006$). We reasoned that non-right-handedness could serve as an Autism endophenotype, and whole genome multipoint linkage analysis was conducted in the AGRE sub-sample of 91 genotyped pedigrees containing 420 individuals and at least one non right-handed member, including parents. Handedness was modeled as the result of a single recessive gene with a frequency of 0.45 and 50% penetrance, consistent with the 10% population prevalence, and the analyses were conducted using the parametric option of the GENEHUNTER software. Only 2 regions had a lod score greater than 1.0 in this preliminary study: 8q24.21 at 140 cM with a lod score of 2.4 and 20q13.12 at 62 cM with a lod score of 1.3. These findings, while not significant at the genome-wide level, warrant additional analyses in independent samples of a larger size.

Chromosome 10 in Late-onset Alzheimer Disease. *X. Liang[1], B. Anderson[1], N. Schnetz-Boutaud[1], J. Bartlett[1], B. Lynch[1], P.C. Gaskell[1], H. Gwirtsman[1], L. McFarland[1], M.L. Bembe[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1].*
1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Late-onset Alzheimer disease (LOAD) is a complex neurodegenerative disorder resulting from multiple genetic and nongenetic factors. Several genome screens have consistently suggested that chromosome 10 harbors at least one locus for LOAD. However, the region on chromosome 10 is still large. To narrow down the peak region and make association analysis more feasible, we analyzed our large family-based dataset using both covariate and subset analyses to increase the homogeneity.

36 SNPs evenly spaced across 80.2 Mb region on chromosome 10 were genotyped in 725 multiplex families (1204 affected sib pairs). We analyzed the data using Ordered Subset Analysis (OSA), and a two point LOD score of 2.50 was obtained at marker rs1319013, p=0.002 in 45% families when the families were ordered from low to high by ApoE LOD score. Marker rs14327 generated two point LOD score of 1.94 in 13% families when the families were ordered from low to high using covariate of the linkage signal on chromosome 12 (p=0.009). In the autopsy confirmed subset, rs10826594 generated the peak of LOD=2.07 in OSA multipoint analysis when the covariate ApoE LOD score ranked families from low to high. In the ApoE all4 subset (all AD patients have at least one ApoE 4 allele), marker rs3127242 generated two point LOD of 1.40 when families were ordered by linkage signal on chromosome 12 from high to low (p=0.04). In the ApoE non4 subset (none of AD patients has ApoE 4 allele), marker rs3750686 generated parametric two point LOD score of 1.54. This marker also had a two point LOD of 2.30 in OSA using the linkage signal on chromosome 12 from low to high as a covariate.

Our data suggest that there is a locus associated with LOAD in the region near rs1319013 (62 cM) and rs3750686 (103 cM) on chromosome 10. These two regions most likely contain gene(s) related to late-onset Alzheimer Disease.

Identification of granuloma-loci through lead-overlap in 100K genome wide association experiments in Sarcoidosis and Crohn Disease. *J. Hampe[1], A. Franke[1], C. Becker[2], R. Valentonyte[1], M. Krawczak[3], J. Müller-Quernheim[4], M. Schürmann[5], S. Nikolaus[1], T. Kühbacher[1], P. Nürnberg[2], S. Schreiber[1].* 1) Institute of Clinical Molecular Biology, Christian Albrechts University, Kiel, Germany; 2) Cologne Center for Genomics, University of Cologne, Germany; 3) Institute of Medical Statistics and Biometry, Christian Albrechts University, Kiel, Germany; 4) Department of Pneumology, University Hospital Freiburg, Germany; 5) Institute of Human Genetics, University of Lübeck, Germany.

Crohn disease (CD) and Sarcoidosis share granulomas as a pathognomonic histological feature of tissue inflammation and do cluster clinically. The spectrum of involved organs and the disease course are quite different on the other hand. The joint analysis of the genetic risk profile gives the chance to investigate common etiological pathways possibly specific for the overlapping granuloma trait. The age- and sex-matched samples from 393 CD patients, 400 sarcoidosis patients and 399 control individuals were genotyped on the 100K Affymetrix GeneChip system. Single point genotypic and allelic association tests were performed for markers fulfilling the following criteria in controls: i) no evidence of departure from Hardy-Weinberg-Equilibrium at the p=0.05 level, ii) minor allele frequency >1% and iii) Call rate >95%. Out of the 83,268 SNPs meeting these criteria, 2466 SNPs showed significant association at the p=0.05 level in CD and 3135 in sarcoidosis. 364 markers overlapped between the two analyses, which is significantly more ($p<0.001$) than expected by random selection alone. Similar results were obtained when choosing a significance threshold of $p<0.001$ for the association signals to compare. A total of 34 SNPs for CD (including *CARD15*) and 132 for sarcoidosis fulfilled this more stringent criterion with an overlap of 3 SNPs on chromosomes 11, 13, and 19 between both diseases, which is again much more than expected by chance. We conclude that the overlapping association leads might represent common susceptibility variants predisposing to granulomatous inflammation while other loci and environmental factors lead to the different tissue distribution in the two disorders.

Cytogenetic Characterization and Molecular Association of Patients with the Silver - Rusell Syndrome (SRS). *G. Vasquez[1], C. Muneton[1], A.H. Campo[2], A. Ruiz-Linares[3], H. Bedoya[2], F. Quintero-Rivera[4], J.L. Ramirez-Castro[1].* 1) Dept Genetics, Antioquia Univ, Medellin, Colombia; 2) Laboratorio de Genética Molecular, Sede de investigación Universitaria (SIU), Universidad de Antioquia. Med., Colombia; 3) The Galton Laboratory, Department of Biology (Wolfson House), University College London, Stephenson Way, London, UK; 4) Center for Human Genetic Research, MGH, Boston, MA.

Silver-Russell syndrome (SRS) is a heterogeneous genetic disorder mainly characterized by several clinical findings, in which patients show prenatal and postnatal growth retardation. SRS is genetically sporadic, but several reported cases demonstrate dominant or recessive patterns of inheritance, suggesting a genetic cause. On the other hand, maternal uniparental 7 chromosome disomy, and maternal imprinting have shown to play an important role in some SRS patients. In the present study we found a SRS affected child in each of seventeen studied families. All the patients and their families were from Antioquian population (Colombia). All of them had a normal karyotype. For the microsatellites markers assays, the D7S2422 and D7S813 markers for the 7p11.2-p13 chromosome showed a biparental segregation. For the Hardy-Weinberg equilibrium test, the same markers were in equilibrium in the population (parents and patients). The Linkage Disequilibrium and Association Tests (TDT) for the markers D7S2422 and D7S813 applied first to parents and them to the whole population of parents and children showed that no association exist among these markers and the GRB10 related SRS gene. In conclusion, the transmission analysis of haplotypes and respective genealogies suggests an autosomal recessive type of inheritance; in which affected SRS descendant and normal parents are present.

Following up genome scans for plasma apolipoprotein E (apoE): analysis of chromosome 17q positional candidate genes in GENOA families. *M.S. Leduc[1], L.C. Shimmin[1], K.L.E. Klos[1], C.F. Sing[2], E. Boerwinkle[1], J.E. Hixson[1].* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Plasma apoE plays a central role in metabolism of several lipoproteins that are important CVD risk factors (triglycerides, LDL, HDL). The common apoE isoforms only explain about one-fourth of the genetic variation in apoE levels. To identify other genes that influence apoE levels, we performed a genome-wide search in families from the GENOA study (Genetic Epidemiology Network of Atherosclerosis). To increase genetic and environmental homogeneity, we performed linkage scans in families stratified by ethnicity, lipoprotein levels, and BMI. We found significant evidence for linkage on chromosome 17q in Hispanic families for two strata including low cholesterol (LOD=3.32 at 103cM) and low cholesterol-high HDL (LOD=3.20 at 110cM). This linkage signal was replicated in African-American families, with evidence for linkage on 17q for 2 strata including low cholesterol-high HDL (LOD=1.76 at 73cM) and low BMI-low TG (LOD=1.89 at 85cM). In this study, we are following-up these 17q linkage signals using a positional candidate gene approach. We identified 10 candidate genes that are located in the linked region with known roles in metabolic pathways of lipoproteins or other CVD risk factors. We selected 32 SNPs for genotyping in the GENOA families. We used FBAT to find associations between plasma apoE levels and the common ApoH isoforms in Caucasians (APOH*H1, p=0.02) and Hispanics (APOH*H3w, p=0.02), but in unstratified families. We also found associations for ACE1 in unstratified Hispanics (p=0.02), as well as in Hispanics stratified by low cholesterol (p=0.02). In addition to these single SNP analyses, we are directly determining multi-SNP haplotypes using hybrid cell lines that are monosomic for chromosome 17. These molecular haplotypes will greatly facilitate accurate haplotype estimation in the GENOA families for multi-SNP association studies, as well as conditional linkage analyses to ascertain whether associated haplotypes are responsible for the original linkage peak on chromosome 17q.

Linkage to GABR cluster with exclusion of GABRG2 and GABRA1 genes in a large Colombian family with GEFS+. *N. Pineda-Trujillo[1], J. Carrizosa[2], R. Mehon[1], W. Arias[3], C. Alzate[3], G. Bedoya[3], W. Cornejo[2], A. Ruiz-Linares[1,3].* 1) University College London, London-United Kingdom; 2) Servicio de Neurologia Infantil, Facultad de Medicina, Universidad de Antioquia Medellin-Colombia; 3) Grupo de Genética Molecular, Universidad de Antioquia, Medellín-Colombia.

Generalized epilepsy with febrile seizures plus (GEFS+) is a clinical and genetically heterogeneous disorder. Four genes (SCN1B, SCN1A, SCN2A and GABRG2) and four loci (FEB1-FEB4) have been associated with the disorder. However, the exclusion of these GEFS+ candidate genes/loci in large families has suggested that other genes may play a role in the aethiology of this disorder. Our purpose was to evaluate candidate GEFS+ genes/loci in a large Colombian family with the disorder, by typing tightly linked polymorphic microsatellites. Results indicated linkage to GABR cluster (GABRG2, GABRA1, GABRA6 and GABRB2). However, sequencing of the GABRG2 coding region resulted in failure of identifying a mutation in this gene. Typing additional polymorphic markers in the GABR cluster revealed a recombinant individual for marker SHGC-132760, located in between GABRG2 and GABRA1, confirming exclusion of GABRG2 as responsible for the disorder in this family. Furthermore, a clear disease segregating haplotype was identified. GABRA1, which previously was associated to Juvenile myoclonic epilepsy was also excluded by sequencing its coding region. Sequencing of the GABRB2 and GABRA6 genes, the two remaining genes in this cluster, is underway. Our results suggest that high likely either GABRB2 or GABRA6 will present a mutation responsible for GEFS+ in our family, which would provide evidence of a second g-aminobutiric acid receptor associated with GEFS+. N. P-T. is funded by a COLCIENCIAS studentship.

Sex matters: an example of differential oligogenetic control of induced oncogenesis in male and female rats. *C. Fischer[1], B. Koelsch[2], A. Kindler-Rohrborn[2].* 1) Human Genetics, University of Heidelberg, Heidelberg, Germany; 2) Department of Neuropathology, University of Bonn, Medical Center, Bonn, Germany.

The inbred BD rat strains provide a suitable model system for the genetic dissection of susceptibility and resistance to the development of nervous system tumors, as they exhibit a broad spectrum of reactivity to tumor induction by the alkylating carcinogen N-ethyl-N-nitrosourea (EtNU). Among these BDIX and BDIV rats are highly susceptible and completely resistant, respectively, to the development of peripheral nervous system (PNS) tumors, (malignant schwannomas) which arise predominantly in the trigeminal nerves. We previously reported on the genetic mapping of 7 loci controlling tumor incidence and/or survival time in segregating (BDIX x BDIV) crosses on chromosomes 10 (Mss1) chromosomes 1 (Mss2), 3 (Mss3), 6 (Mss4), 13 (Mss5) and 15 (Mss6) as well as 10 (Mss7, centromeric portion). Interestingly, most of these loci mediate allele- and sex-specific effects of variable strength ranging from minor influences on tumor development to complete tumor resistance. This is reflected by the fact that male (BDIX x BDIV) F2 rats exhibit a two fold higher incidence of EtNU-induced schwannomas than females as well as a shorter survival time. The sex effect is even more striking when analysing gene-gene interactions. We found numerous interactions of which the most striking one was in female animals between two completely independent loci that displayed also main effects. For interaction analysis the false discovery rate to control statistical errors has been used. A number of human tumors too arise with a marked sex bias. Our study serves as a model for diseases with sex-specific oligogenetic susceptibility mechanisms. Fine mapping in nuclear families using linkage and linkage disequilibrium (LD) information: Dissection of linkage signals according to parental genotype. *J. Wicks.* ARC Ctr Complex Systems, Univ QLD, St Lucia, Australia.

Gene mapping studies use linkage and LD information to try to locate genetic variants which influence a phenotype. Defining and distinguishing between linkage and LD information has been a focus of research for some years, as scientists attempt to locate variants showing the strongest LD signal, and thereby determine causal variation, or variation in perfect LD with causal variation. Without functional studies of some kind, gene mapping studies cannot distinguish between variation which is directly causal and that in perfect LD with a causal variant. This defines the limit of what is possible with gene mapping studies, and also sets the ultimate aim of association mapping - which is to locate causal variants and those in perfect LD with causal variants. A major challenge, then, is to determine as much as possible about the hidden pattern of LD between an *observed* variant associated with a phenotype, and an *unobserved* causal variant responsible for the association. Addressing this question in the case of nuclear family genetic data, and with sibling phenotypic data for a qualitative or quantitative trait, it can be shown that LD and linkage information can be dissected by considering the linkage signals from the subsets of the data defined by the different possible genotypes in the parents. By subsetting the data in this way, very distinctive patterns emerge which provide a basis for distinguishing between *perfect* LD ($r^2 = 1$, $|D'| = 1$), *complete but imperfect* LD ($r^2 < 1$, $|D'| = 1$), and *incomplete* LD ($r^2 < 1$, $|D'| < 1$) (Wicks et al. 2005). Using these ideas and borrowing from the ingenious Homozygous Parents Affected Sib Pair and Marker Association Segregation Chi-Squares methods, as well as numerous other authors, two novel methods emerge. One is a parametric method of analysis of the underlying LD pattern, and the other is a very simple and elegant non-parametric method for choosing the most likely variant for causality, or for perfect LD with a causal variant, from a collection of genotyped variants in and around a gene. Application of the methods to simulated data sets shows that they provide useful results when compared to other LD mapping methods.

Interaction between AGT and ACE in Alzheimer disease. *P.G. Bronson[1], N.N. Wall[1], K. Welsh-Bohmer[2], J.L. Haines[3], J.R. Gilbert[1,2], M.A. Pericak-Vance[1,2], E.R. Martin[1,2].* 1) Center for Human Genetics, Duke Univ Med Center, Durham, NC; 2) Dept of Medicine, Duke Univ Med Center, Durham, NC; 3) Center for Human Genetics Research, Vanderbilt Univ Med Center, Nashville, TN.

We previously examined the effect of the intron 16 insertion/deletion and 7 single nucleotide polymorphisms (SNPs) in the angiotensin-converting enzyme gene (ACE) on chromosome 17. Several markers were significantly associated with AD, but it is unclear which contribute to risk due to strong linkage disequilibrium (LD) between markers. ACE is part of the renin-angiotensin system (RAS), which regulates blood pressure; hypertension is a risk factor for AD (Amouyel et al. 2000). Angiotensinogen, encoded by the AGT gene on chromosome 1, is part of the RAS pathway. Because of the biological interaction between ACE and AGT (Bis et al. 2003), we examined effects of 5 tagging SNPs in and around AGT. The SNPs were genotyped in a family dataset (371 families with 1,234 phenotypically discordant sibling pairs) and an independent case-control dataset (595 cases and 967 controls). We did not find significant association in the family dataset using the pedigree disequilibrium test (PDT) and the genotype-PDT. However, we did find significant association in the independent case-control dataset. The SNP1 G allele had an odds ratio (OR) of 1.34 (95% CI, 1.02 to 1.74; p=0.033). This association remained when we adjusted for age at exam, sex and number of APOE4 alleles (OR=1.42; 95% CI, 1.03 to 1.95; p=0.033). Carriers of the SNP1 AG genotype were at greater risk than carriers of the AA genotype in the crude (OR=1.39; 95% CI, 1.06 to 1.82; p=0.019) and adjusted (OR=1.45; 95% CI, 1.05 to 2.01; p=0.025) genotypic models. We found significant interaction between AGT and ACE in our crude and adjusted logistic regression models, with p-values ranging from 0.010 to 0.040. Although several AGT and ACE markers showed significant main and interactive effects on AD, different levels of significance in different analyses may reflect LD with an undiscovered functional variant. Further study is necessary to understand the interaction of AGT with ACE in AD.

Association between Alzheimer disease and Nicastrin. *N.N. Wall[1], P.G. Bronson[1], K. Welsh-Bohmer[2], J.L. Haines[3], J.R. Gilbert[1,2], M.A. Pericak-Vance[1,2], E.R. Martin[1,2].* 1) Center for Human Genetics, Duke Univ Med Center, Durham, NC; 2) Dept of Medicine, Duke University Medical Center, Durham, NC; 3) Center for Human Genetics Research, Vanderbilt Univ Med Center, Nashville, TN.

Several studies have found an association between the Nicastrin gene (NCSTN) on chromosome 1 and Alzheimer's disease (AD). Nicastrin interacts with presenilins 1 & 2 in the -secretase complex involved in proteolysis of -amyloid precursor protein (-APP). The lysis of APP causes the formation of amyloid plaques, a hallmark of AD pathology. We examined the effect of 5 intronic single nucleotide polymorphisms (SNPs) in the NCSTN gene on AD. SNPs were genotyped in a large AD family dataset (371 families with 1,234 phenotypically discordant sibling pairs) and an independent case-control dataset (595 cases and 967 controls). We did not find any significant allelic association in the family dataset using the pedigree disequilibrium test (PDT). However, we found significant genotypic association in one of the SNPs using the genotype-PDT. Specifically for SNP3, the G allele trended toward significance (p=0.052) and the GG genotype was significantly associated with AD (p=0.031). We found significant allelic and genotypic association with one of the SNPs in the independent case-control dataset. The SNP5 G allele had an odds ratio (OR) of 1.37 (95% CI, 1.11 to 1.69; p=0.003). This association remained when we adjusted for age at exam, sex and number of APOE4 alleles (OR=1.31; 95% CI, 1.03 to 1.68; p=0.03). Carriers of the SNP5 GG and AG genotype were also at increased risk in crude and adjusted linear (AA vs. AG vs. GG) and genotypic (GA vs. AA and GG vs. AA) models (p-values between 0.002 and 0.044). We found no linkage disequilibrium (LD) (r^2 =0.01) between SNP3 and SNP5 in the family or independent case-control dataset. Since both SNP3 and SNP5 are intronic with no known functional significance, it is likely that the association with AD is due to yet undiscovered functional variant(s) in LD with these SNPs. Further study is necessary to understand the genetic involvement of specific polymorphisms of NCSTN as well as the biological mechanism affecting AD risk.

No evidence of interaction between chromosomes 1q31 and 10q26 in age-related maculopathy (ARM). *Y.P. Conley[1, 2], J. Jakobsdottir[3], D.E. Weeks[2, 3], T.S. Mah[4], R.E. Ferrell[2], M.B. Gorin[2, 4].* 1) Department of Health Promotion & Development, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, PA; 3) Department of Biostatistics, University of Pittsburgh, PA; 4) Department of Ophthalmology, University of Pittsburgh, PA.

We recently discovered susceptibility genes for ARM on chromosome 10q26 of similar importance to ARM risk as the Complement Factor H (CFH)gene on 1q31 that has been replicated by several groups. We performed high density SNP genotyping on 1q31 and 10q26 and found very strong associations of the CFH and PLEKHA1/LOC387715/PRSS11 loci with ARM; we also detected a weaker signal over the GRK5/RGS10 loci. We employed the genotype-IBD sharing test as well as logistic regression to test for an interaction between SNPs from CFH and each of the genes on 10q26. We found no significant interaction between the two chromosomal regions. We tested several models: the baseline model including only the mean, three additive models which assumed an additive effect at first, second or both loci, three dominant models which incorporated dominant effects and three interaction models of additive/additive, additive/dominant and dominant/dominant interaction. Using the Akaike information criteria we compared the models; in the case of PLEKHA1, LOC387715 and PRSS11 an additive model including CFH was the best fitted model but when considering GRK5/RGS10 and CFH, an additive model including CFH only was the best fitted model. These results suggest that the effects of PLEKAH1/LOC387715 and CFH act independently towards ARM susceptibility, irrespective of the form of endstage ARM disease, and the possible effects of GRK5/RGS10 on ARM risk are very weak at best. We have found no interaction between CFH, PLEKHA1, LOC387715 or PRSS11 with self-reported smoking information, but our preliminary results suggest that there might be an interaction between GRK5/RGS10 and smoking in ARM. We are continuing to investigate these potential interactions.

Comprehensive Association analysis of genetic polymorphisms in the cell division cycle 2 (CDC2) gene with late-onset Alzheimer's disease. *J. Bartlett[1], X. Liang[1], N. Schnetz-Boutaud[1], B. Anderson[1], B. Lynch[1], P.C. Gaskell[2], H. Gwirtsman[1], L. McFarland[1], M.L. Bembe[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Alzheimer disease is a progressive complex neurodegenerative disease, characterized by neurofibrillary tangles in the neurons of the cerebral cortex and hippocampus and the deposition of amyloid within senile plaques and cerebral blood vessels. Several genome scans have indicated that chromosome 10 has at least one locus for this disease. Recent evidence has shown linkage between Alzheimers disease and two loci on chromosome 10 (marker D10s1255 and D10S583). Our association analysis focused on the cell division 2 gene (CDC2) which is close to one of the linkage regions (2Mb from D10S1225) and has previously been associated with risk in AD with an odds ratio of 1.78. Biologically, CDC2 is thought to be one of the main candidate kinases involved in PHF-tau formation because it can phosphorylate normal tau in vitro, compromising the ability of tau to stimulate microtubule assembly in AD. Five single nucleotide polymorphisms spanning the entire gene were selected and examined for association for late onset AD. A family-based dataset including 1337 discordant sibpairs and an independent dataset of 745 cases and 998 controls were collected in a Caucasian population in which the affected individuals were diagnosed at an age greater than or equal to 60 years of age. These datasets have >80% power to detect an odds ratio of 1.38. Neither dataset demonstrated any association with late-onset AD in our samples with all p-values >0.16. We conclude that the contribution of common genetic variants in CDC2 to the risk of developing AD is likely to be non-existent or very low.

Patterns of linkage disequilibrium are consistent within and between ethnic groups: sampling vs. ancestry in the HapMap project data. *F.C.L. Hyland, C.R. Scafe, H. Isaac, F.M. de la Vega.* Applied Biosystems, 850 Lincoln Centre Dr., Foster City, CA 94404, USA.

The recent release of the HapMap data raises important questions about the extent to which similarities and differences observed in the patterns of sequence variation between populations are an effect of sampling rather than due to intrinsic differences; and whether results from the Yoruban African population are predictive for African Americans. We computed metric linkage disequilibrium (LD) maps (expressed in LD units, or LDUs) for 104,824 SNPs on chromosomes 6, 21 and 22 in four HapMap populations. We compared these to 28,155 SNPs previously genotyped using TaqMan SNP Genotyping Assays on samples of 45 unrelated individuals from comparable Caucasian, Chinese and Japanese populations, and from African Americans. 12,206 SNPs were in common across the two data sets. The correlation of minor allele frequency (MAF) between two independent samples within an ethnic group is much higher than correlation between ethnic groups. The correlation between MAF in African Americans and Yorubans is similar to that within any other ethnic group. In contrast, LDU patterns are highly consistent between as well as within ethnic groups. The mean correlation between LDU across ethnic groups is 0.9993 (SD 0.0006). The mean correlation between LDU within samples of an ethnic group is 0.9992. This is consistent with the hypothesis that LD is largely driven by recombination rate; hence the fixed locations of steps and plateaux in the LD map. Correlation between LD across ethnic groups is 10 times higher than the correlation between LDU and physical locations (mean 0.9935, SD 0.0016), and highly significant. The length and LDU locations of the African American and Yoruban LD maps are consistent. These results confirm that differences in MAF or patterns of LD between ethnic groups observed in the HapMap data reflect underlying differences rather than sampling effects, and that the patterns inherent in the LD maps are largely consistent within and between ethnic groups. This raises the possibility of developing a standard LD map for association mapping in all populations if suitably scaled.

A Genome-wide Search for Susceptibility Genes for Intraocular Pressure: The Africa America Diabetes Mellitus (AADM) Study. *C. Rotimi[1], G. Chen[1], A. Adeyemo[1,2], K. Agyenim-Boateng[3], B. Eghan[3], J. Acheampong[3], A. Doumatey[1], J. Zhou[1], O. Fasanmade[4], T. Johnson[4], F. Akinsola[4], T. Rufus[4], G. Okafor[5], J. Oli[5], F. Ezepue[5], A. Amoah[6], S. Owosu[6], S. Akafo[6], Y. Chen[1], F. Collins[7].* 1) Natl Human Genome Ctr, Howard Univ, Washington, DC; 2) University College Hospital Department of Pediatrics and Chemical Pathology, Ibadan, Nigeria; 3) University of Science and Technology Department of Medicine, Kumasi, Ghana; 4) University of Lagos, College of Medicine, Endocrine and Metabolic Unit, Lagos, Nigeria; 5) University of Nigeria Teaching Hospital, Department of Medicine and Ophthalmology, Enugu, Nigeria; 6) University of Ghana Medical School Department of Medicine and Surgery, Accra, Ghana; 7) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Glaucoma is one of the leading causes of blindness worldwide. High intraocular pressure (IOP) is the major risk factor for glaucoma. Populations of recent African origin including West Africans and African-Americans have demonstrated increased risk for glaucoma. A genomic scan was conducted to identify loci linked to IOP in 246 type 2 diabetes sib-pairs from two West African ancestral populations of African-Americans. A total of 390 microsatellite markers were scored for an average spacing of 9 cM with no gaps greater than 20 cM. Multipoint linkage analyses were performed using the SOLAR package. Evidences of significant linkage was observed on chromosomes 5q22 with a LOD score of 3.4 (p=0.000038). Suggestive linkage was also observed on chromosome 14q22 with a LOD of 2.5 (p=0.000348). The strong signal on chromosome 5 is reinforcing previous studies and provides additional evidences that chromosome 5 may indeed contain susceptibility loci for glaucoma in multiple human populations. The evidence provided in this study is particularly important given the evolutionary history of these West African populations and the recent ancestral relationship to African Americans; a population with one of the highest rates of diabetes and associated complications including glaucoma in the world.

Genome-Wide Scan for Schizophrenia in the Molecular Genetics of Schizophrenia (MGS1) Collaboration Pedigrees Suggests Linkage in 8p23.3-p12 and 11p11.2-q22.3. Results of Fine Mapping. *P.V. Gejman[1], B.J. Mowry[2], R. Freedman[3], D.F. Levinson[4], F. Amin[5], J.M. Silverman[6], C.R. Cloninger[7], D.W. Black[8], W.F. Byerley[9], R.R. Crowe[8], A.L. Hinrichs[7], A.R. Sanders[1], C.H. Jin[7], J. Duan[1], C. Hou[1], N.G. Buccola[4], N. Hale[8], A. Olincy[3], J.P. Rice[7], B.K. Suarez[7].* 1) ENH & Northwestern Univ, Evanston, IL; 2) Univ Queensland, Queensland, Australia; 3) Univ Colorado Health Sciences Center, Denver, CO; 4) Univ Pennsylvania, Philadelphia, PA; 5) Emory Univ, Atlanta, GA; 6) Mount Sinai School of Medicine, NY, NY; 7) Washington Univ, St. Louis, MO; 8) Univ Iowa, Iowa City, IA; 9) Univ California, San Francisco, CA.

We report the clinical characteristics of a schizophrenia sample of 413 pedigrees, 266 of European Ancestry (EA) and 147 of African-American (AA) ancestry together with the results of a genome scan (STRP interval: 9 cM) and of follow-up fine-mapping. A family was required to have a sibling proband with schizophrenia (SZ), plus one or more additional siblings with SZ or schizoaffective disorder. Linkage analyses included 357 independent full-sibling ASPs (256 EA; 101 AA) and 101 all possible half-sibling ASPs (15 EA; 86 AA). Non-parametric multipoint linkage analysis of all families detected two regions with suggestive evidence for linkage on 8p23.3-p12 and 11p11.2-q22.3 (empirical Zlr ? 2.65), and a third region on 4p16.1-p15.32 in AA families in an exploratory analysis. The most significant linkage peak was in 8p; its signal was mainly driven by the EA families. Zlr scores >2.0 in 8p were observed from 29.4 cM to 60.4 cM (CIDR map). The maximum evidence was a Zlr = 3.35 (equivalent Kong-Cox LOD = 2.43) at D8S1771 (50 cM); there appear to be two peaks, both telomeric to NRG1. There is a paracentric inversion common in Europeans within this region whose effect on the linkage evidence remains unknown in this and in other previously analyzed samples. We have performed SNP based fine-mapping of chromosome 8p and of several other regions. Fine mapping of 8p has not significantly altered the significance or length of the peak. Fine mapping data for other chromosomal regions is under analysis.

Evidence for linkage of serum alkaline phosphatase levels: a genome-wide scan in the Framingham Offspring Study. *J-P. Lin[1], A. Cupples[2], C. O'Donnell[3].* 1) Office of Biostatistics Research, National Heart, Lung and Blood Institute, Bethesda, MD; 2) Dept. of Biostatistics, Boston University School of Public Health, Boston, MI; 3) Framingham Heart Study, National Heart, Lung and Blood Institute, Framingham, MI.

The serum activity of alkaline phosphatase (ALP), produced mainly in the liver, bone, kidney, intestine and placenta, correlates with bone formation rates and bone densities. Twin studies have shown that serum ALP variation is largely determined by genetic factors with heritability estimates ranging from 40-80%. A genome scan on serum ALP activity in mice revealed three major quantitative trait loci (QTL) on chromosomes other than those where the genetic loci known to be involved in the production of ALP isoforms are located. To date, no linkage analysis on serum ALP levels in humans has been reported. We carried out a 10 cM genome-wide scan in a community-based Caucasian cohort, the Framingham Heart Study. ALP was measured in the first examination of the offspring cohort (mean age = 36 years). Our study population consisted of 330 families with 1255 individuals being both genotyped and phenotyped, including 1322 full sibling pairs, 52 half sibling pairs, 665 cousin pairs, and 89 avuncular pairs. Using variance-component linkage methods implemented in SOLAR, the heritability was estimated as 39%; after age, sex, serum bilirubin, serum albumin and total serum protein adjustment. The genome-wide linkage analysis demonstrated evidence of linkage of ALP levels to chromosome 11p with a LOD score of 2.9 at 22 cM and to chromosome 1q with a LOD score of 2.0 at 233 cM. Human ALP isoforms have been previously mapped to chromosomes 1p36-34 and 2q34-37. Our study suggests that there may be QTLs that control serum ALP levels residing on chromosomes 11p and 1q, in regions that differ from those containing the genes encoding ALP isoforms.

A QTL on 12q Influencing a Marker of Inflammation and Body Mass Index in Women: NHLBI Family Heart Study. *J. Wu[1], J.S. Pankow[2], R. Tracy[3], K.E. North[4], L. Djoussé[5], R.H. Myers[5], M.A. Province[1], I.B. Borecki[1].* 1) Division of Biostat, Washington Univ Schl Med, St. Louis, MO; 2) Div Epidemiol Community Health, Univ MN; 3) Univ VT; 4) Dept Epidemiol, Univ NC; 5) Boston Univ Schl Med.

It has been recognized that obese individuals are intrinsically in a state of chronic inflammation, as indicated by positive correlations between serum levels of the inflammation marker C-reaction protein (CRP) and various anthropometric measures of obesity. To explore the hypothesis that a gene(s) may underlie this relationship, we conducted bivariate linkage analyses of body mass index (BMI) and CRP in Caucasian families of the NHLBI Family Heart Study. A set of 404 highly polymorphic markers with map density of ~10 cM were genotyped by the NHLBI Mammalian Genotyping Service (Marshfield, WI). Genotyping in African-American families is underway. CRP was log transformed to normalize its distribution, and both CRP and BMI were adjusted for age, age^2, age^3, sex, and field center. Variance components linkage analysis as implemented in SOLAR was performed in the combined data (1982 subjects) and within gender (892 men and 1092 women). CRP exhibited significant genetic correlations with BMI in women ($_G$=0.59, p<0.001) and the combined sample ($_G$=0.40, p<0.001), but not in men ($_G$=0.19, p=0.39). We detected a maximum bivariate LOD score of 3.64 on chromosome 12q24.2-24.3 (at 138 cM) in women. Within this region exists an interesting candidate gene, AMPK-BETA1 (AMP-activated protein kinase -1), whose product is a regulatory subunit of AMPK. Activation of hypothalamic AMPK was shown to block leptin's effects on food intake and body weight. Recent findings also suggest that AMPK activation could influence CRP production by modulating adipocyte secretion of interleukin-6. A suggestive linkage signal (lod=2.83) was found in the combined sample on chromosome 8q22.3 (118 cM). The highest peak (lod=1.96) obtained in men was localized on chromosome 16p13.3-p12 (20 cM). The above bivariate peaks were substantially higher than their respective univariate lods at the same locus for each trait. In summary, our results indicate that chromosom12q24.2-24.3 may harbor a QTL jointly regulating BMI and CRP in women.

Localization of candidate regions for a novel gene for situs inversus/Kartagener syndrome. *I. Gutierrez-Roelens[1], Th. Sluysmans[2], M. Amyere[1], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, Christian De Duve Institute of Cellular Pathology, Brussels, Belgium; 2) Division of Pediatric Cardiology, Cliniques universitaires St Luc, University of Louvain Medical School, Brussels, Belgium.

Asymmetric positioning of internal organs is characteristic to vertebrates. The normal left-right anatomic positioning, situs solitus, sometimes does not occur normaly leading to laterality defects, situs inversus, consisting of a complete inversion of the global left-right axis. Studies in animal models have shown that laterality decisions are mediated by a cascade of genes that lead to asymmetric expression of Nodal, LEFTA, LEFTB and PITX2 in the lateral plate mesoderm. Search for mutations in genes implicated in left-right patterning in animal models allowed to identify genes associated with heterotaxia defects in man. However, these genes explain only a small percentage of human situs defects suggesting that other genes must play a role. In this study, we report a consanguineous family composed of two unaffected parents and three children, two of which presented situs inversus with or without Kartagener syndrome. On the basis of the family history, we hypothezise autosomal recessive mode of inheritance. Genotype analysis with polymorphic markers did not show linkage with the known genes or loci causing laterality disorders. Array CGH did not detect a duplication or a microdeletion to be the cause of the affection either. Thus, genome wide screening using 10K Affymetrix SNP chips was performed allowing the identification of two regions of autozygosity, one in chromosome 1 and the other on chromosome 7. In the chromosome 1 locus, the strong candidate gene encoding the kinesin associated protein 3 (KIF3AP) was not mutated based on SSCP/heteroduplex analysis. The data give the basis for the identification of a novel situs determining gene, which is also implicated in the Kartagener syndrome. (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.be/vikkula).

An Application of the IBS-IBD Method to the Genetic Analysis of Alcoholism. *Q. Yue[1], V. Apprey[1], R. Taylor[2], G.E. Bonney[1].* 1) National Human Genome Ctr, Howard Univ, 2216 6 Street Room 206 NW Washington, DC 20059; 2) Department of Pharmacology, Howard Univ, Washington, DC 20059.

Our IBS-IBD transformation method uses the probabilistic relationship between identical by state and identical by descent sharing in sib-pairs to calculate the test for linkage. This method was particularly designed for sib-pair data without parental genotypes. In this paper, we applied this method to the Genetic Analysis Workshop (GAW) 14 COGA microsatellite data on alcoholism. We find that the markers D2S1329, D2S1333, D6S495, D7S1790, D7S820, D7S1799, D11S4464, D17S975, D21S1440 and D22S1267 have LOD scores of 5.96, 2.11, 2.93, 2.01, 2.25, 2.06, 2.79, 3.16, 2.71 and 3.43 respectively. Some of the markers listed above were also reported by other researchers, for example, the marker D7S820 was also reported by Nsengimana et al (GWA 14, 2004) with a LOD score of 2.04. Interestingly, the regions franked the markers D21S1440 and D6S495, were reported by Zhang et al (GWA 14, 2004) using SNPs, not microsatellite markers. However, the marker D2S1329 with the highest LOD score of 5.96 was not reported by any of the papers in GWA 14 meeting. In conclusion, using our IBS-IBD method on sib-pairs with microsatellite markers without parental genotypes, one can still find most of the linkage regions found by using sibling and parental genotypes or even SNPs data, and one may also find some additional interesting regions that may be caused by the population hypotheses in our IBS-IBD method.

High density genome scanning using Affymetrix chips: Indications of genome coverage and capture of variation based on the HapMap ENCODE regions. *M.R. Barnes[1], T.K. Bhinder[1], R. Elango[1], N. Goodgame[1], M.G. Ehm[2], S. Chissoe[2], E. Lai[2].* 1) Molecular Genetic Informatics, GlaxoSmithKline, Harlow, Essex, United Kingdom; 2) Discovery and Pipeline Genetics,GlaxoSmithkline, 5 Moore Drive, Research Triangle Park, North Carolina, 27709.

High density genome wide association studies have for many years been a long-term technological and analytical goal for human genetics. The new generation of SNP-based oligonucleotide arrays offers one technical solution to achieving this goal. In this study we evaluated the gene coverage and capture of variation by the commercially available, 117,000 SNP, Mapping 100K array from Affymetrix and the early access version of the soon to be commercially available, 528,000 SNP, 500K Mendel array. We have summarized the information captured by the SNPs in these maps using the ten HapMap-ENCODE regions as a model to estimate genome-wide map performance. We stratified measures of map performance in several ways, firstly in terms of gene coverage, secondly in terms of overall capture of information on variation, thirdly in terms of capture across the spectrum of SNP allele frequencies, and finally in terms of capture of potentially functional variation. The results of these analyses suggest that these technologies may indeed offer effective genome coverage at a cost that decreases substantially with map scale. However some of these benefits come at a price: as map scale increases many more markers are used than are needed to adequately scan the genome based on the criteria evaluated. This results in unnecessary resources and time being spent on the storage, analysis, and interpretation of these markers. Further still this will give rise to an increase in nominally significant associations. A very large proportion of these associations are likely to be false. This emphatically shifts the challenge of whole genome association studies from the technological to the analytical domain.

Genomewide linkage scan for intraocular pressure among Mongolian families shows evidence of linkage on chromosome 7p. *H. Kim[1], J. Kim[2], S. Cho[3], M. Lee[4], S. Jung[1], J. Seo[4,5].* 1) Biochemistry, Ewha Womans University, Seoul, Korea; 2) Dept Biochem, Coll Medicine, Hallym Univ, Chuncheon, Korea; 3) Graduate School Public Health, Seoul National Univ, Seoul, Korea; 4) Ilcheon Instit Molecular Medicine, Seoul National Univ,Seoul, Korea; 5) Dept Biochem, Coll Medicine, Seoul National Univ, Seoul, Korea.

High intraocular pressure (IOP) is the strongest known contributing factor causing glaucoma, a group of diseases in which retinal ganglion cell death and optic nerve degeneration lead to blindness. IOP is under both genetic and environmental influences. With age it is known that the IOP increases among western population, while that decreases in orient. It suggests that the loci regulating the IOP might be different to the glaucoma loci known so far. IOPs were measured by air tonometer for 475 individuals (37 Mongolian families, the average family number is 13), most of them are Khalkh tribes living Orhontol Som in Selenge Imac, Mongolia. The genotyping was performed using the ABI PRISM linkage mapping Sets MD-10. Initial analysis was carried out for the 189 genotyped individuals with the largest family numbers. The Pedigree Relationship Statistical Test (PREST) was used to identify pedigrees. The initial nonparametric multipoint analysis gave evidence of linkage on chromosomes 4p, 7p, and 15q with LOD scores exceeded 2.5. Maximum multipoint LOD score of 3.2 was observed at marker D7S519. These results suggest that a locus on chromosome 7p12 may contain a gene with a large effect on IOP in this popuation. Identification of a susceptibility locus in this region may eventually lead to a better understanding of gene-environment interactions in the regulation of IOP.

Segregation analyses and genome linkage scan of Bone Mineral Density in a European sample of families selected through a male osteoporotic subject. *C. Pelat[1], I. Van Pottelbergh[2], M. Cohen-Solal[3], J.M. Kaufman[2], M.C. de Vernejoul[3], M. Martinez[1,4].* 1) INSERM EMI00-06, Evry , France; 2) Endocrine department Gent University, Belgium; 3) INSERM U349, Paris, France; 4) Northwestern University, Evanston, IL.

Bone Mineral Density is one of the most important clinical predictors of osteoporotic fracture risk. BMD is a high heritable trait but the genes responsible are incompletely defined. The aim of this study was to assess the genetic determinism of BMD, as determined by segregation analyses under the regressive models. In addition, we performed a genome-wide linkage scan in order to identify chromosomal regions influencing these phenotypes. We have ascertained a sample of 100 extended pedigrees originating from France and Belgium. Families were selected through a male relative with osteoporosis (Zscore<-2 either at the Lumbar Spine or the Femoral Neck). Epidemiological data and BMD measures were collected for all living relatives accepting to participate in the study. Prior to segregation and linkage analyses, we constructed trait-residuals to adjust for the effects of age, sex and BMI. The best fitting segregation models included the effects of both a major gene and residual family correlations. Major gene effects were found more significant for BMD-FN than for BMD-LS. In addition, these analyses identified highly significant gene-environment interactions for BMD-FN (gene-age) and for BMD-LS (gene-age and gene-BMI). The genome-wide scan was performed using 458 microsatellites markers in our family data (85 families informative for linkage; 430, 321 and 325 sib, cousins and avuncular pairs respectively). We used model-free linkage analyses based on the variance component approach, as implemented in the computer program Merlin. Linkage analyses revealed a number of regions linked to either BMD-LS or BMD-FN. The positive regions did not overlap much across the two phenotypes. Altogether, the stronger signals were observed on chromosomes 11, 13, 17 and 22 (Lod=4.3, P=10-5; Lod=2.05, P=0.001; Lod=3.15, P=0.00007; Lod=2.72, P=0.0002).

Combined Analysis from Eleven Linkage Studies of Bipolar Disorder Provides Strong Evidence for Susceptibility Loci on Chromosomes 6q and 8q. *M.B. McQueen[1], N.M. Laird[2], Genetic Determinants of Bipolar Disorder Working Group.* 1) Epidemiology, Harvard School of Public Health, Boston, MA; 2) Biostatistics, Harvard School of Public Health, Boston, MA.

Several independent studies and meta-analyses aimed at identifying genomic regions linked to bipolar disorder have failed to find clear and consistent evidence for linkage regions. Our hypothesis is that combining the original genotype data provides benefits of increased power and control over sources of heterogeneity that outweigh the difficultly and potential pitfalls in the implementation. We conducted a combined analysis using the original genotype data from eleven bipolar disorder genomewide linkage scans comprised of 5179 individuals from 1067 families. Heterogeneity among studies was minimized in our analyses by using uniform methods of analysis and a common, standardized marker map, and was assessed using novel methods developed for meta-analysis of genome scans. This collaboration is the largest and most comprehensive analysis of linkage samples involving a psychiatric disorder to date. We demonstrate that combining original genome scan data is a powerful approach for the elucidation of linkage regions underlying complex disease. Our results establish genomewide significant linkage to bipolar disorder on chromosomes 6q and 8q, providing solid information to guide future gene finding efforts relying on fine-mapping and association approaches.

Multiple QTLs Influencing Triglyceride and HDL Cholesterol Levels Identified in Families With Atherogenic Dyslipidemia. *Y. Yu[1], D.F. Wyszynski[1], D.M. Waterworth[2], S.D. Wilton[3], P.J. Barter[4], Y.A. Kesäniemi[5], R.W. Mahley[6], R. McPherson[7], G. Waeber[8], T.P. Bersot[6], Q. Ma[1], S.S. Sharma[2], D.S. Montgomery[2], L.T. Middleton[2], S.S. Sundseth[2], V. Mooser[2], S.M. Grundy[9], L.A. Farrer[1].* 1) Boston University; 2) GlaxoSmithKline; 3) Australian Neuromuscular Research Institute; 4) The Heart Research Institute, Australia; 5) University of Oulu; 6) Gladstone Institute of Cardiovascular Disease; 7) University of Ottawa Heart Institute; 8) Lausanne University Hospital; 9) University of Texas Southwestern.

High triglyceride (TG) and low high density lipoprotein cholesterol (HDL-C) levels are prevalent features of the metabolic syndrome and increase risk for cardiovascular disease. We conducted a genome-wide scan (448 STR markers) using variance components linkage analysis to localize quantitative-trait loci (QTLs) influencing TG and HDL-C levels in 3071 subjects from 459 families with atherogenic dyslipidemia (TG > 75th percentile and HDL-C < 25th percentile). To obtain proper marker allele frequencies, families were classified on the basis of their ethnic background as European, Finns, and Turkish. The most significant evidence for linkage to TG levels was found in a subset of Turkish families at 11q22 (LOD=3.34) and at 17q12 (LOD=3.44). We carried-out sequential oligogenic linkage analysis to examine if multiple QTLs jointly influence TG levels in the Turkish families. These analyses revealed loci at 20q13 which showed strong epistatic effects with 11q22 (conditional LOD=3.15) and 7q36 which showed strong epistatic effects with 17q12 (conditional LOD=3.21). We also found linkage on the 8p21 region for TG in the entire group of families (LOD=3.08) with most evidence contributed by the European families (LOD=2.80). For HDL-C levels, evidence of linkage was identified on 15q22 in the Turkish families (LOD=3.05) and on 5p15 in the entire group of families (LOD=2.83). These QTLs provide important clues for the further investigation of genes responsible for these complex lipid phenotypes. These data also indicate that a large proportion of the variance of TG levels in the Turkish population is explained by the interaction of multiple genetic loci.

Identification of new loci for early onset obesity by a genome wide 10K SNP scan in 298 nuclear families from Germany. *F. Ruschendorf[1], K. Saar[1], C. Becker[2], A. Hinney[3], K. Reichwald[3], G. Brönner[3], S. Friedel[3], A. Scherag[4], P. Nürnberg[2], J. Hebebrand[3].* 1) Gene Mapping Center, Max-Delbrueck Center, Berlin-Buch, Germany; 2) Cologne Center for Genomics, University of Cologne, Germany; 3) Department of Child and Adolescent Psychiatry, Rheinische Kliniken Essen, University of Duisburg-Essen, Essen, Germany; 4) Institute of Medical Biometry and Epidemiology, Philipps-University Marburg, Germany.

Background & Aims: Several genome scans have been performed for adult obesity but only one for childhood and adolescent obesity. Our previous scan was performed with a small number of families and a low-density marker set. Therefore, we decided to recruit more families with obese children in order to replicate the study with a high-density marker panel. This should enable us to identify loci particularly involved in early-onset obesity. Methods: A total of 298 families with two or more obese children were collected (1235 individuals). DNA samples were genotyped using the Mapping 10K version 2 from Affymetrix (10204 SNPs). Data were analysed using the programs ALOHOMORA, Genehunter, Genhunter-Modscore, Merlin, and Allegro. Results: The average information content of the SNP array scan was 0.97. Within the subset of families (89) previously analysed by microsatellites the higher information content resulted in higher NPL scores for the linkage signals on chromosomes 8 and 11. Based on the whole data set we revealed other regions of linkage on chromosomes 4, 5, 6, 7, 9, 10, 11, 14, 15, 17, and X. Only a few of them coincide with linkage signals from genome scans in adult obesity. The highest NPL score (>3.0) was obtained for a locus on chromosome 17. The second highest value was obtained for chomosome 4 (NPL=2.95). On chromosome 9 the program Modscore revealed a score of about 3 for a recessive model without any parent-of-origin influence. Conclusion: Our data suggest particular gene loci to predispose to early-onset obesity rather than the adult form while others seem to be involved in both, early- and late-onset obesity.

Dilated Cardiomyopathy with Ataxia (DCMA) syndrome, a novel autosomal recessive Barth syndrome-like disorder, maps to chromosome 3q. *K. Davey[1], J.S. Parboosingh[1], D.R. McLeod[1], A. Chan[2], R. Casey[1], P. Ferreira[3], F.F. Snyder[1], P.J. Bridge[1], F.P. Bernier[1].* 1) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 3) Alberta Children's Hospital, Calgary, AB, Canada.

Dilated Cardiomyopathy with Ataxia (DCMA) Syndrome is a novel autosomal recessive mitochondrial condition in the Canadian Dariusleut Hutterite population. The main clinical features include a severe early-onset dilated cardiomyopathy, long QT syndrome, non-progressive cerebellar ataxia, testicular dysgenesis, mild development delays and growth failure. In addition, all affected patients have elevated 3-methylgluatoconic and 3-methylglutaric acid levels in both plasma and urine. DCMA shares some similarities with the X-linked Barth syndrome and the other classes of 3-methylglutaconic acidurias, however the clinical features and pattern of inheritance distinguish it from these other conditions. Using a homozygosity mapping approach, a complete genome scan was performed on 5 severely affected patients from consanguineous Hutterite families. We identified an extended disease associated haplotype of 23.9 cM on chromosome 3q26.2-q27.3. Fine mapping using additional markers and patients, as well as unaffected family members, narrowed this region to a minimal candidate region of 2.2 megabases of 3q27.2.

Genome Wide Scan of Exfoliation syndrome in a large Finnish family. *S. Lemmela[1], E. Forsman[2], A. Eriksson[2], H. Forsius[2], I. Järvelä[1,3].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Population Genetics Unit, Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Laboratory of Molecular Genetics, Helsinki University Hospital, Helsinki, Finland.

In Exfoliation Syndrome (XFS) greyish fibril like material is detected on the anterior surface of the lens and along the pupil margin and same kind material is also found in many extraocular tissues. XFS is a confirmed risk factor for open angle glaucoma. XFS is rare under 50 years of age and as highest approximately 30 % among population over 80 in Scandinavia. The etiopathogenesis of XFS is unknown but there is evidence for a genetic component. The mode of inheritance of XFS has proposed to be autosomal dominant with incomplete penetrance or mitochondrial transmission. We have studied the prevalence and inheritance of XFS in the Åland archipelago, in the south-western coast of Finland, since 1961. In a large pedigree XFS seems to be transmitted as a dominant trait with incomplete penetrance. During the last 40 years a total of 76 patients with XFS have been detected including more than 500 ophthalmologically examined persons. We have performed a genome wide scan with 1000 microsatellite markers for a total of 29 patients and 36 other family members belonging to this pedigree. The analysis was made under assumption of an autosomal dominant mode of inheritance with a low phenocopy rate (0.001, 0.999, 0.999) and a rare disease allele frequency (0.0001). Five markers extending a region of 31 cM at chromosome 18q resulted in positive 2-point lod scores: D18S468 (Zmax= 3.446, =1.00), D18S64 (Zmax=1.695, =0.840), D18S1147 (Zmax=1.682, =0.830), D18S1135 (Zmax=1.385, =1.00) and D18S450 (Zmax=1.491, =1.00). In addition, some positive lod score values were obtained at chromosome 17 (D17S849, Zmax=1.911), chr2 (D2S117, Zmax=1.725), chr 5 (D5S2049,Zmax 1.605) and chr X (DXS7108,Zmax=1.519). None of the loci identified in this study overlap with the previously identified genetic loci for primary open angle glaucoma, suggesting different genetic background of these overlapping eye diseases. We speculate that due to isolation of the study population a predisposing gene has enriched to this island.

A QTL on chromosome 3p influences the tempo of skeletal maturation in Nepali children. *B. Towne[1], J. Blangero[2], D.L. Duren[1], K.D. Williams[1], T. Dyer[2], M.J. Aivaliotis[2], C.R. Cottom[1], S. Lawrence[1], B. Jha[3], J. Subedi[4], J.L. VandeBerg[2], S. Williams-Blangero[2].* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Tribhuvan University Institute of Medicine, Kathmandu, Nepal; 4) Miami University, Oxford, OH.

Knowledge of genetic influences on skeletal development comes mainly from studies of monogenic disorders. Few studies have examined genetic influences on normal variation in skeletal development, and fewer still have examined the skeletal development of children in non-Western populations. We present here results from an initial whole-genome linkage scan for QTL influencing the tempo of skeletal maturation in children from the Jirel ethnic group in eastern Nepal. The Jirel population numbers ~5,000 individuals, most of who are in one large extended pedigree. More than 1,000 Jirel children are in the Jiri Growth Study, and at their annual exam a hand-wrist x-ray is taken from which skeletal age (SA) is estimated. For these analyses, SA data were selected from a subset of 368 Jirel children (182 boys and 186 girls) aged 6 to 18 years who have each been genotyped for ~400 autosomal markers. Each childs SA was subtracted from their chronological age at the time of their exam to obtain an overall measure of their relative skeletal maturation. A variance components-based linkage analysis method was used to analyze these data and obtain multipoint LOD scores. The heritability of tempo of skeletal maturation from ages 6 to 18 years was highly significant ($h^2 = 0.92$; $p < 7x10^{-4}$). Significant linkage was found of tempo of skeletal maturation to markers on chromosome 3p at 27 cM between markers D3S1304 and D3S1263 (LOD score = 3.32). Plausible positional candidate genes in this region include known and as yet unidentified genes involved in the 3p deletion syndrome. Future work will use an expanded sample of genotyped children in the Jiri Growth Study, and will seek to identify specific genes that influence different aspects of normal skeletal development during childhood. Supported by NIH grants HD40377, AI37091, AI44406, and MH59490.

Fine mapping of Obesity QTL on 5q14 in a Cohort of Type 2 Diabetes Patients from West Africa. *G. Chen, A. Adeyemo, J. Zhou, Y. Chen, C. Rotimi.* Natl Human Genome Ctr, Howard Univ, Washington, DC.

Previous linkage analysis identified QTL for three obesity phenotypes: BMI (LOD = 2.8), FM (LOD = 3.5) and PBF (LOD = 2.5) on 5q14 (Max location = 98cM, 1 LOD score region 74cM ¨C 117cM) in West Africans with Type 2 diabetes (321 siblings and 36 half siblings with 392 primer pairs with average spacing of 8.9cM throughout the genome). In order to localize the loci more precisely, we added 29 markers throughout the linkage region. We found LOD scores 3.66, 4.06, and 3.16 for BMI, FM, and PFM, respectively, Max location 98cM, and 1 LOD score region 75cM ¨C 108cM. In conclusion, our findings provide evidence that obesity susceptibility genes reside on chromosome 5q14.

Genome-wide SNP chip homozygosity mapping defines critical region for Native American Myopathy. *D. Stamm[1, 2], C. Powell[2], S. Kahler[3], A. Aylsworth[2], K. Deak[1], S. West[1], D. Craig[4], D. Lince[4], D. Stephan[4], J. Gilbert[1], M. Speer[1], Duke University Medical Center.* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Department of Genetics, UNC-CH, Chapel Hill, NC; 3) Little Rock, AR; 4) Translational Genomics Research Institute, Phoenix, AZ.

Native American Myopathy (NAM) is an autosomal recessive congenital myopathy first reported in the Lumbee people of North Carolina (OMIM 255995). Features include congenital weakness, cleft palate, ptosis, and susceptibility to malignant hyperthermia provoked by anesthesia. We hypothesize the affected individuals have alleles that are shared identity-by-descent (IBD) inherited from common ancestry. We used a SNP genome-wide screen on Affymetrix Gene Chip Mapping 10K Array platform that was performed by Translational Genomics (TGen, Phoenix, AZ). The SNP screen demonstrated shared regions of homozygosity between two affected Lumbee individuals from families Duke Family 2118 and Duke Family 2281 in four regions on chromosome 12. To follow up this screen in order to confirm previously identified regions and narrow the candidate interval, twenty-three microsatellite markers were selected to cover the four regions. Markers were prioritized based on the highest heterozygosity values and spacing within the region. The microsatellite marker data narrowed the region of homozygosity to one region spanning D12S398 to D12S1610 of 11.8 MB (7.6 cM) between the two affecteds. The overall results confirm homozygosity in region 12q13.13 to 12q14.2 in the two affected individual, supporting our hypothesis that the affected individuals share genetic material in an IBD fashion. Biologically plausible candidate genes in the 12q13.13 to 12q14.2 region identified by NCBI and Ensembl include integrin 7, PIP5K2C, KIF5A, MLC1SA, among others. We are currently evaluating candidate genes via sequencing to identify the genetic variant responsible for NAM. Sequencing of exons 1-5 and 7-27 in candidate gene integrin 7 showed no evidence for a mutation; exon 6 is in progress. These findings demonstrate the power and utility of SNP screens to perform homozygosity mapping in rare autosomal recessive diseases using only a few affected individuals.

A novel Gene for Enlarged Vestibular Aqueduct Syndrome (EVA-Syndrome) ? *R. Birkenhager, A.J. Zimmer, T. Klenzner, A. Aschendorff, R. Laszig, J. Schipper.* Department of Otorhinolaryngology, Head and Neck Surgery, University Hospital Freiburg, Killianstrasse 5, D-79106 Freiburg.

Background: Pendred syndrome (MIM 274600), an autosomal-recessive disorder is characterized by sensorineural deafness and goiter. This syndrome is one of the most common forms of syndromic deafness. Hearing loss is prelingual in the majority of the cases, only a subset of patients have a progressive hearing loss later in life. The deafness is associated with temporal bone abnormalities ranging from isolated enlargement of the vestibular aqueduct (EVA) to Mondini dysplasia, a more complex malformation that also includes cochlear hypoplasia. Both, EVA and Mondini dysplasia are easily recognized by computer tomography. PDS is caused by mutations in the SLC26A4 gene. This gene product, a transmembrane protein, is called pendrin. Functional studies in Xenopus laevis oocytes and Sf9 cells have shown that pendrin is a transporter of iodide and chloride. In this study we analyzed several multiplex families with EVA and hearing loss to distinguish between the Pendred- and EVA-Syndrome (MIM 603545). Methods: Individual exon and intron transitions of the SLC26A4 gene of patients were PCR amplified. Direct automatic sequencing of variant fragments was performed with the same primers, on an automatic genetic analyzer. A genomewide linkage analysis was undertaken using the Affymetrix 10K GeneChip mapping 10K Xba SNP array. Results: We identified 15 different mutations in the SLC26A4 gene so far, 6 of these mutations are novel. In 30 % of our patients we could not identify any mutation. These patients carry potential mutations in regulatory domains such as promotor regions, or alternatively the possibility of a distinct locus for a gene of autosomal recessive deafness with enlarged vestibular aqueduct. With a genomewide linkage analysis it was possible to identify genome regions where a gene is located which is, in addition to the SLC26A4 gene, responsible for the development of the Enlarged Vestibular Aqueduct Syndrome. Conclusions: Our results indicate evidences of a second gene which is involved in the development of the Enlarged Vestibular Aqueduct Syndrome.

High-resolution SNP maps in the genomic regions corresponding to drug-related genes. *A. Iida[1], S. Saito[2], A. Sekine[3], Y. Nakamura[1,2,4].* 1) Laboratory for Pharmacogenetics, SNP Research Center, RIKEN, Tokyo, Japan; 2) Laboratory for SNP Analysis, SNP Research Center, RIKEN, Tokyo, Japan; 3) Laboratory for Genotyping, SNP Research Center, RIKEN, Yokohama, Japan; 4) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

One of major goals in our laboratory is to establish 'gpersonalized medicine'h on the basis of single nucleotide polymorphisms (SNPs) regarding responsiveness or adverse effects to drugs and susceptibility to common diseases. To archive this aim, we have been two different screening programs to detect genetic variations in the Japanese population. One approach was intended to identify up to 150,000 SNPs within transcription units in the Japanese population; more than 195,000 SNPs have been identified already and that information is freely available via our worldwide website (http://snp.ims.u-tokyo.ac.jp/). Second, we have focused on genetic variations in the genomic regions that corresponding to genes encoding drug metabolizing enzymes, transporters, and G-protein coupled receptors. So far, we constructed comprehensive SNP maps of 265 gene loci that contain more than 7,500 genetic variations. Here we introduce the molecular features of each of those loci, such as regional distributions of SNPs, non-synonymous substitutions, insertion/deletion polymorphisms within exonic sequences, and genetic variations of other types. This database constructed in our laboratory should provide a fundamental molecular basis for understanding the pharmacokinetics or pharmacodynamics of drugs used to treat individual patients.

Pooled DNA sequencing: A fast, reliable and cost-effective method for comprehensive analysis of common SNPs in genetic association studies. *V. Kodavali[1], A. Northup[1], Y. Joo[1], L. Pless[1], J. Wood[1], B. Devlin[1], V.L. Nimgaonkar[1, 2].* 1) Department of Psychiatry; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA 15213.

Introduction: We have shown that re-sequencing is a precise method for estimating SNP allele frequencies in pooled DNA. We have now adapted this method for genetic association studies. Our strategy involves rapid, comprehensive screening of all common polymorphisms in a defined region by pooled DNA sequencing. Suggestive associations are followed up by individually genotyping SNPs using the samples composing the DNA pools. If confirmed, the associations are tested further in independent samples. Here, we report genetic analysis of ACSL6 (Acyl-CoA synthetase long-chain family member 6, 5q31, 43kb) and SIRT5 (sirtuin 5, 6p23, 45kb), which are involved in the altered phospholipid metabolism and cell signaling and thus may mediate schizophrenia pathogenesis. Methods: DNA pools were made by measuring DNA concentrations using a Pico Green reagent. Pools of cases (n=200) and controls (n=200) were amplified in quadruplicate using the PCR. Peak heights of sequencing traces were used to estimate allele frequencies and were obtained from ABI Prism Sequencing Analysis software version 3.7. Resutls: We identified 38 SNPs at ACSL6 and 31 SNPs at SIRT5 genes, by pooled sequencing (minor allele frequency >10%). Comparison of traces from pooled samples of cases and controls revealed suggestive differences for nine SNPs, following comparisons of variances and estimated error rates. These SNPs were genotyped in individual samples (n=400). We thus detected suggestive trends for association with ACSL6 (rs 11743803, p values allele-wise =0.02 and genotype-wise =0.06). In an extended sample (448 cases and 554 controls) the association remained marginally significant. Conclusions: Our study clearly demonstrates the application of pooled DNA sequencing in identifying and estimating reliable SNP allele frequencies in case-control association studies. We conclude that pooled DNA sequencing is a fast, cost-effective and reliable approach for comprehensive analysis of defined chromosomal regions in association studies.

Diplotype trend regression (DTR) analysis on ADH gene cluster and ALDH2 gene in alcohol and drug dependent patients. *X. Luo[1,2], H.R. Kranzler[3], L. Zuo[1,2], S. Wang[4], J. Lappalainen[1,2], J. Gelernter[1,2].* 1) Dept Psychiatry, Yale Univ Sch Medicine, New Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT; 4) Dept Biostatistics, Columbia Univ Mailman Sch Pub Health, New York, NY, USA.

The alcohol metabolizing enzymes are genetically and functionally complex. The association of some alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) genes with alcohol dependence (AD) has been studied in many populations, generally with limited marker sets. To test for associations between six ADH genes, the ALDH2 gene, and AD and drug dependence (DD) in European-Americans (EAs) and African-Americans (AAs), we used a novel regression method, which includes an extension of the structured association (SA) method. Sixteen markers within the ADH gene cluster (including ADH1A, ADH1B, ADH1C, ADH5, ADH6 and ADH7) on chromosome 4, four markers within ALDH2 on chromosome 12, and 38 unlinked ancestry-informative markers (AIMs) were genotyped in a case-control sample of 925 subjects. All markers were in HWE in controls, but 11 markers were in Hardy-Weinberg Disequilibrium (HWD) in some case groups. Diplotype Trend Regression (DTR) analysis (Zaykin et al. Hum Hered. 2002;53:79-91), which allows departures from HWE, controls for population stratification and admixture effects, and takes gene-gene interaction into account, showed that ADH5 and ADH6 genotypes, and diplotypes of ADH1A, ADH1B, ADH1C, ADH7 and ALDH2, were associated with AD or DD in EAs and/or AAs. Each of these genes had at least one marker with a peak [a measure of linkage disequilibrium (LD)] that could localize risk alleles. We found that several genes encoding ADH isoforms, and the ALDH2 gene, were associated with both AD and DD. Some associations between genes and diseases are consistent in direction across different populations and phenotypes, while some are in opposite directions or are population-specific and phenotype-specific. LD studies showed that although there is substantial within-gene LD and limited intergene LD within the chromosome 4 cluster, these results are best explained by 7 independent risk genes.

Gene-environment interaction between matrix metalloproteinase-3 (MMP3) and education influences the risk for high myopia in Taiwanese. *S. Juo[1,4], C. Liang[2], K. Hung[3], A. Sun[3], H. Wang[2].* 1) Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Clinical Medical Sciences, Chang Gung University, Taiwan; 3) Department of Surgery, Chang Gung Memorial Hospital, Taiwan; 4) Genome Center, Columbia University, New York, NY.

Purpose: We conducted a case-control study to investigate the relationship between the MMP2, MMP3 and TIMP1 genes and high myopia. Methods: We recruited 225 high myopes (-6 D) as cases and 259 controls (-1.5 D). We genotyped 22 SNPs at the three gene, which includes 5 SNPs of the MMP3, 9 of the MMP2 and 8 of the TIMP1 genes. Two commonly studied functional promoter polymorphisms (-1612 5A/6A at MMP3 and -1306 C/T at MMP2) were included in our SNP list. Allele frequencies were tested for the Hardy-Weinberg equilibrium (HWE). The degree of LD was assessed by D and haplotype blocks were reconstructed using the HaploView program, and haplotype analysis was conducted by using PHASE. The association between genotypes and high myopia was assessed for each SNP. We also analyzed the data separately by the college education level as a test of gene x environment interaction. Results: The genotype distribution was not deviated from HWE in any SNP. Eight SNPs were monomorphic, and were excluded for further analyses. The pair-wise D was > 0.9 for each pair of SNPs. The overall genotypic or allelic distribution between cases and controls was not significant for any of the 14 SNPs. In the test of a gene-environment interaction, we found a significant p value of 0.02 for the association between the three genotypes of the 5A/6A polymorphism at MMP3 and high myopia among the subjects with college or higher education. The OR for 6A/6A compared with (5A/6A + 5A/5A) was 2.3(95%CI:1.2-4.2,p=0.008) for high myopia in the subjects of high education. The OR was not significant for subjects without college education. Haplotype analysis did not improve the statistical significance. Other SNPs did not yield significant interactions with education. Conclusion: The present study indicated that a potentially functional promoter polymorphism of the MMP3 gene may confer susceptibility to high myopia under a heavy near-working condition.

Genetic variation in genes related to endocrine function in European men. *S. John[1], S. Pye[1], M. Jiang[9], A. Pickles[1], G. Bartfai[2], I. Feges[2], F. Casanueva[3], M. Lage[3], G. Forti[4], L. Petrone[4], A. Giwercman[5], K. Kula[7], M. Punab[6], P. Korrowitz[6], S. Boonen[8], H. Borgs[8], R. Walczak-jedrzejowska[7], A. Silman[1], F. Wu[1], I. Huhtaniemi[9].* 1) Univ of Manchester, UK; 2) Univ of Szeged, Hungary; 3) Univ of Santiago de Compostela, Spain; 4) Univ of Florence, Italy; 5) Lund Univ, Sweden; 6) Univ of Tartu, Estonia; 7) Univ of Lodz, Poland; 8) Univ of Leuven, Belgium; 9) Univ of Turku, Finland.

The European Male Aging Study (EMAS) is a prospective random general population cohort study aimed at identifying risk factors which predispose to symptoms and diseases associated with aging. 3,200 men have been recruited in 8 countries. The aim of the current report was to determine the extent of genetic variation across Europe in 12 genes related to endocrine function. 76 SNPs (MAF >5%); in 12 genes (AR, CYP17, CYP19, ESR1, ESR2, IGF1, LHB, LHR, NPY, SHBG, SRD2A5 and VDR) were genotyped in 92 men from each country (n=736). The distribution of genotypes between countries was compared using a 2 test, linear regression was used to test for association between genotypes and height, weight or BMI and GLLAMM equations were employed to account for mean and variance differences between countries. 27 (35%) of SNPs in all genes except NPY and SHBG showed genotype differences between countries ($p < 0.05$). Pair-wise LD analysis appeared broadly similar between populations. However, there were differences in haplotype frequencies for some genes e.g. LHR, the most common haplotype in the Spanish and Italian populations had a frequency of 20%, but a frequency of < 8% in all other countries. 11 of these 27 SNPs were associated with height, weight and or BMI using linear regression with traits adjusted for age. However only 2 associations remained significant (ESR2, SRD2A5) after accounting for country, suggesting these results may be due to the presence of population substructure. These data emphasize the importance of understanding potential population substructure in genetic association studies even in the context of a purely European study group. The findings may partly explain why phenotypic associations of SNPs show variability between different populations.

A constrained likelihood approach to marker-trait association studies. *K. Wang[1], V.C. Sheffield[2].* 1) Program in Public, Health Genetics, Univ Iowa, Iowa City, IA; 2) Department of Pediatrics, Howard Hughes Medical Institute, Univ Iowa, Iowa City, IA.

Marker-trait association analysis is an important statistical tool for detecting DNA variants responsible for genetic traits. In such analyses, an analysis model on the mean genetic effects of the genotypes is often specified. For instance, the effect of the disease allele on the trait is often specified to be dominant, recessive, additive or multiplicative. Although it is powerful when the analysis model is correctly specified, it has been found that this model-based approach can have low power when the specified model is incorrect. We introduce an approach that does not require the specification of a particular genetic model. This approach is built upon a constrained maximum likelihood where the mean genetic effect of the heterozygous genotype is required not to exceed those of the two homozygous genotypes. The asymptotic distribution of the likelihood ratio statistic is derived in the case of continuous traits and in the case of dichotomous traits. Simulation study suggests that this new approach has power comparable to model-based methods where the analysis models are correctly specified. This approach uses one marker at a time (single-marker analysis). However, given the latest findings that powerful inferential procedures for haplotype analyses can be constructed from single marker analyses, we expect this approach to be useful for haplotype analyses.

Family-based association analysis in the presence of linkage (APL) with missing parental genotypes: A computer program for single-locus and haplotype tests. *R-H. CHUNG*[1], *E. MARTIN*[2]. 1) Bioinformatics Research Center, North Carolina State University, Raleigh, NC; 2) Department of Medicine, Duke University Medical Center, Durham, NC.

We have developed software for conducting the family-based association analysis method APL (Martin et al. 2003, AJHG), and present simulations to evaluate modifications of the test and robustness to deviation from assumptions. The APL method is based on observing parental allele transmissions to affected siblings. APL can infer missing parental genotypes using genotypes of siblings and properly adjusts for linkage by considering identity-by-descent parameters. In the APL software we used a bootstrap variance estimator, instead of the original robust variance estimator, to offer flexibility in handling different family structures. We further extended the APL algorithm from single-marker to haplotype analysis and provide a global test for haplotype association. We present simulations to verify that the new tests have the correct type I error rate. Power simulations were used to compare the APL to two alternative family-based association methods, PDT and FBAT/HBAT. The APL test consistently showed more power for both single-marker and haplotype analyses using nuclear family data sets. The APL statistic is normally distributed when the number of informative families is large, but this approximation may not be appropriate when the number of informative families is small. Our simulation results showed that rare alleles or rare haplotypes can cause inflated type I error rate for APL tests. We used simulations to provide practical guidelines for when the approximation is valid. In general, using statistics with estimated variance greater than 5 gives reasonable type I error rates. We also explored the effect of violating the assumption of Hardy-Weinberg Equilibrium in allele and haplotype tests. We simulated several data sets with different degrees of departure from HWE. We found that APL is not very sensitive to the departure and remains a valid test. This study shows that the APL software provides a robust and reliable tool for association analysis using single loci or haplotypes in family data.

Population Association Study of NCAM, ANKK1 and DRD2 Genes with Alcohol Dependence. *B. Yang[1,2], H. Kranzler[3], H. Zhao[4], JR. Gruen[5], X. Luo[1,2], J. Gelernter[1,2].* 1) Dept Psychiatry Yale Univ Sch Medicine, New Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Univ CT Health Center, Farmington, CT; 4) Dept EPH Yale Univ Sch Medicine, New Haven, CT; 5) Dept Pediatrics Yale Univ Sch Medicine, New Haven, CT.

DRD2 is a functional candidate gene for substance use disorders (SUDs), including alcohol dependence (AD), and several DRD2 markers, and an ANKK1 marker previously thought to map to DRD2 (rs1800497, previously known as DRD2 TaqI A) have been associated to various SUDs. DRD2 also maps molecularly close to NCAM1 (which encodes a neural cell adhesion molecule and is also a functional candidate for SUD risk). We therefore conducted a case-control association study of 743 European Americans (325 with AD, 418 controls) and SNPs mapped to the NCAM-ANKK1-DRD2 cluster. . We selected 7, 4, and 4 SNPs in NCAM, ANKK1 and DRD2, respectively, including two DRD2 SNPs known to be functional, and DRD2 TaqI D (rs1800498), DRD2 TaqI B (rs1079597), to investigate their possible association with AD. All SNPs were in Hardy Weinberg equilibrium. Individual SNPs associated with AD at the $p<0.05$ significance level were selected for haplotype analysis. The associated SNPs were ANKK1 (rs4938016, $p = 0.018$), DRD2 TaqI D (rs1800498, $p = 0.045$), and DRD2^141ins/del (rs1799732, a functional promoter variant, $p = 0.0089$). Although DRD2^C957T (rs6277) showed borderline significance ($p = 0.06$), it was also included in the haplotype analysis since it affects mRNA stability. After adjusting for sex ($p = 3.88 \times 10\text{-}12$) and age (p close to 0), the generalized linear model analysis of the four-SNP haplotype, consisting of ANKK1 (rs4938016)-DRD2^C957T-DRD2 TaqI D-DRD2^141ins/del, resulted in two significantly associated haplotypes, 1-1-1-1 (frequency=0.021, OR=5.53, CI=[4.29, 6.77], p=0.0069) and 2-2-2-2 (frequency=0.182, OR=1.56, CI=[1.16, 1.95], p=0.027). Population stratification was tested using a panel of 36 Short Tandem Repeat (STR) markers that we designed to differentiate major US populations, and was ruled out as a source of spurious association. We conclude that ANKK1 and functional DRD2 variants are associated to AD.

Candidate-gene association study of mothers with Pre-Eclampsia and their offspring, analyzing 758 SNPs in 187 genes. *K.A.B. Goddard[1], G. Tromp[2], R. Romero[4], J.M. Olson[1], Q. Lu[1], Z. Xu[1], J.K. Nien[4], R. Gomez[4,5], E. Behnke[5], M. Solari[5], J. Espinoza[4], C.J. Kim[4], J. Santolaya[4], T. Chaiworaspongsa[4], Y.M. Kim[4], G. Lenk[2], K. Volkenant[2], H. Kuivaniemi[2,3].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Center for Molecular Medicine & Genetics; 3) Dept of Surgery, Wayne State Univ, Detroit, MI; 4) The Perinatology Research Branch, NICHD, NIH; 5) The Center for Perinatal Diagnosis & Research, Sotero del Rio Hospital, P. Universidad Catolica de Chile, Santiago, Chile.

Pre-eclampsia (PE) affects 5-7% of pregnancies worldwide and is a leading cause of maternal death and perinatal morbidity and mortality. Genetic factors may account for more than half of the variability in liability to PE. We conducted a large-scale association study with candidate genes selected for a potential role in obstetrical complications. SNP discovery was performed by DNA sequencing at Genaissance Pharmaceuticals, Inc (New Haven, CT). Genotyping was carried out at Genaissance Pharmaceuticals, Inc. using the MassARRAY System (Sequenom, Inc., San Diego, CA). Women with PE (n=426) and their offspring (n=323) were compared with control women (n=512) and their offspring (n=486) from the same hospital-based population. Haplotypes were constructed using the EM algorithm, and empirical p-values were obtained for a logistic regression-based score test, adjusted for maternal age and offspring gender. Interaction and incompatibility models between maternal and offspring genotypes were evaluated. The maternal *LPL* (p=.0077), *TNF* (p=.009), and *COL1A1* (p=.041) genotypes and the offspring *REN* (p=.0067) genotype were associated with PE. Common candidate genes for PE, including *MTHFR* and *NOS3*, were not significantly associated with PE. For the interaction model, *PROS1* (p=.0008) and *FGF4* (p=.0009) gave the most significant results. For the incompatibility model, *VWF* (p=.0004) was associated with PE. This is one of the most comprehensive genetic association studies of PE to date. Identification of the genetic regulators of PE may have broad implications, since women with PE are at increased risk of cardiovascular diseases later in life.

Comparison of Linkage Disequilibrium Measurement Programs. *M. Britain, D.L. Koller.* Department of Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

Linkage disequilibrium (LD) between markers partly determines the placement of SNPs in the testing of candidate genes. Several programs are available to determine the extent of pairwise LD. Because the same data can produce variable results depending on the program used, comparison of LD programs was necessary.

Using Simla (v. 3.0), we simulated pedigree files consisting of 800 three-generational families. We specified biallelic markers, equally spaced. We compared the accuracy and precision of two programs for computing D as a measure of LD, Haploview (v. 3.11) and the package consisting of SimWalk2, HaploXT, and GOLD. SimWalk2 (v.2.82) was used to generate haplotypes, which were then used by Haploxt, (part of the GOLD software package, v. 1.1, Abecasis et al) to compute D.

In the extreme case of no LD (D=0), Haploview and Simwalk2/HaploXT generated mean D values of 0.02 and 0.026, respectively. With complete LD (equal to 1), Haploview and Simwalk2/HaploXT produced values of 0.99 and 1.0, respectively.

We then simulated an intermediate value of D. The four haplotype frequencies were 0.60, 0.30, 0.05, and 0.05, with SNP minor allele frequencies each of 0.35, leading to a D of 0.78022. For n = 10, the mean D values for Haploview and Simwalk2/HaploXT were 0.78 (SD = 0.009) and 0.804 (SD = 0.021), respectively. With respect to the true value of LD, Haploview was more accurate than Simwalk2/HaploXT. The mean D from Haploview was not significantly different from the simulated value ($p = 0.9412$). The mean D from Simwalk2/HaploXT was significantly different from the simulated value ($p = 0.0005$). In addition, Haploview was more precise, with a more narrow dispersion of values. Values calculated in Haploview ranged from 0.77 to 0.79 (variance = 8.89 x 10-5) while values calculated in Simwalk2/HaploXT ranged from 0.778 to 0.837 (variance = 4.64 x 10-4).

Linkage Disequilibrium Patterns in Inbred Mice and Implications for Fine Mapping of Disease Loci. *D. Wang, M. You.* Department of Surgery and the Siteman Cancer Center, Washington University, St Louis, MO.

Linkage disequilibrium (LD) patterns have been extensively studied as guidance for fine mapping of disease loci in humans. However, less attention has been paid to LD patterns in the population of inbred mice. Inbred mouse population has a very unique history owing to the fact that each inbred mouse strain was a product of artificial selection over 20 generations of inbreeding. In this study, we assessed the LD patterns that exist in the inbred mouse population using the Roche SNP data that contains ~153,140 SNPs for 18 inbred mouse strains. Our results show that average pairwise LD (r2, squared correlation coefficient of alleles at two loci) decays significantly over the first 32 kb of the distance range, which seems to be larger than observed in humans. Large variability was also observed for pairwise LD vs. physical distance. SNPs with similar allele frequencies have stronger LD than those with different allele frequencies, and SNPs with higher allele frequencies also tended to have stronger LD. With the cladistic method implemented in software CLADH, we also show that LD mapping for a dichotomous phenotype with high (~80%) to complete penetrance has sufficient statistical power and accuracy. However, LD mapping has only limited use in mapping a mutation with moderate penetrance (~60%) when the sample size is small. This study provides the fundamental understanding of LD patterns in the inbred mouse population, and the feasibility and effectiveness of LD mapping of candidate genes using inbred mouse strains.

The impact of missing and erroneous genotypes on tagging SNP selection and power of haplotype tests. *W. Liu, W. Zhao, G.A. Chase.* Division of Biostatistics, Penn State College of Medicine, Hershey, PA.

Single nucleotide polymorphisms (SNPs) are the most common type of genetic polymorphism in the human genome and serve as effective markers for localizing disease susceptibility genes. With the recent development of sequencing technology, the number of SNP markers is increasing so quickly that current genotyping technologies are inadequate for genotyping all available SNP markers for a typical linkage/association study. Much attention has recently been paid to methods for selecting the minimal informative subset of SNPs in identifying haplotypes, but there has been little investigation of the effect of missing or erroneous genotypes on the performance of these SNP selection algorithms and haplotype tests using selected tagging SNPs. Even with modern automated DNA analysis methods, the problem of missing allelic data or genotyping error is not uncommon. In this project, we explored the effect of missing genotype or genotyping error on the performance of three tagging SNP selection programs: Claytons diversity based program **htstep**, Carlsons linkage disequilibrium (LD) based program **ldSelect**, and Strams coefficient of determination based program **tagsnp.exe**. When randomly selected known loci were relabeled as missing, we found that the average number of tagging SNPs selected by all three algorithms changed very little and the power of subsequent haplotype tests using the selected tagging SNPs remained close to the power of these tests in the absence of missing genotype. When randomly selected known loci were converted to another genotype, we found that the average number of tagging SNPs selected by all three algorithms increased. Strams program had the largest and Claytons program had the smallest increase. The power of the haplotype tests from all three programs decreased quickly with the presence of genotyping error. These results have direct implications for designing genome-wide association studies.

Association study of Estrogen receptor-alpha gene with mineral bone density in a group of unrelated Italian females. *G. Malerba[1], E. Petrelli[1], A. Sangalli[1], L. Xumerle[1], V. Braga[2], P.F. Pignatti[1], M. Mottes[1].* 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) Rheumatology Unit, Univ of Verona,, Valeggio S/M, Italy.

Estrogen receptor-alpha (ESR1) gene has been suggested to be a candidate for variability in bone mineral density. We report the study of 2 polymorphisms (PvuII and XbaI) of the ESR1 gene in 657 peri and postmenopausal Italian women. ESR1 polymorphisms were analyzed separately or in haplotype combination. Association analysis of the single markers with BMD values at spine and femur did not show any significant association. Haplotypes were reconstructed and no significant association with BMD values at the 2 distinct sites was observed. Association analysis preformed in a subgroup of individuals having an elevated Body Mass Index (BMI > 35) showed a significant association of PvuII (p=0.04) or XbaI (p=0.005) polymorphism with femur BMD values. Haplotype analysis showed that the PvuII-XbaI T-A haplotype was associated to lower femur BMD values (p=0.01). In conclusion, these data suggest the ESR1 may be involved in BMD variability in women with an elevated BMI. These results should be confirmed in a larger sample.

Multiplexed Haplotype-Specific Extraction (HSE) of Genomic DNA. *J. Dapprich[1], V. McCarro[2], C. Turino[2], G.S. Scavello[2], N. Murphy[2], D. Monos[3, 4].* 1) Generation Biotech, Lawrenceville, NJ. USA; 2) GenoVision, West Chester, PA. USA; 3) Department of Pathology and Laboratory Medicine, The Childrens Hospital of Philadelphia, Philadelphia, PA. USA; 4) Deptartment of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA.

Haplotype-Specific Extraction, HSE, physically separates a diploid sample into its haploid components using magnetic bead technology without knowledge of familial information. Haplo-separated DNA is then analyzed with kits and assays currently used for DNA-typing. HSE improves the accuracy of tissue typing: It enables unambiguous HLA typing of diploid allele combinations that may otherwise fail to be resolved. Haplotyping can improve the power of Association Studies: The conversion of individual diploid samples into more informative haploid components can increase the power to find correlations between traits and shared variants in case-control studies. Probes for the HLA loci A, B and DRB1 were used to separate DNA fragments from a single tube containing 400 ng genomic DNA of known HLA type on the GenoM-6/EZ-1 HSE robotic system. The haploseparated DNA was amplified in three independent PCRs and confirmed as haploid by HLA-typing with the InnoLiPA reverse SSOP (sequence specific oligonucleotide probe) system. Multiplexed haploseparations provide DNA fragments that can allow the derivation of extended molecular haplotypes. Based on publicly available SNP information it should be possible to separate the entire MHC for one person in one run. The approach is to 1)SNP-genotype candidate regions, 2)Haploseparate based on this information, and 3)Assemble contiguous molecular haplotypes for DNA samples of interest. Routine haplo-separation of large genomic regions can simplify the fine mapping of chromosomal regions for susceptibility genes and validate statistically derived haplotypes. HSE can increase the resolution and quality of genetic analysis in other diagnostic applications such as oncology testing, metabolic profiling and should improve our understanding of multi-factorial diseases and disease classification.

ALBERT: A Likelihood-Based Estimation of Risk in Trios. *A.A. Mitchell[1], E.S. Emison[2], A. Chakravarti[2], E.A. Thompson[1].* 1) University of Washington, Departments of Genome Sciences and Statistics, Seattle, WA; 2) Johns Hopkins University School of Medicine, Baltimore, MD.

The original transmission disequilibrium test (TDT) developed by Spielman et al, is a popular test for linkage in the presence of association in case-parent trios. Two major problems with the TDT are that its false positive rate is inflated in the presence of undetected genotyping error and it suffers from low power, particularly when the penetrance of the disease of interest is not multiplicative with the number of copies of the risk allele.

Here, we present ALBERT, A Likelihood-Based Estimation of Risk in Trios. ALBERT tests for association between a diallelic marker and a dichotomous trait in case-parent trios. The method, which provides estimates of genotype relative risks, genotyping error rate and risk allele frequency, is more powerful than the TDT for most sample sizes, genotype relative risks, allele frequencies and genotyping error rates. It has a low false positive rate and is robust to the presence genotyping errors. We have implemented the method in a software package, ALBERT, which is freely available through our website.

We applied our method to 29 diallelic markers spanning the RET region on chromosome 10q11.12 in 130 trios ascertained through a child affected with Hirschprung disease. We found a stretch of nine consecutive markers showing significant association ($p < 10^{-4}$) with Hirschprung disease; the middle four of these markers were significant at $p < 10^{-9}$. Thus, ALBERT has shown itself to be an effective tool in identifying alleles associated with increased risk of disease.

DNA pooling enables cost-effective genome-wide SNP association studies. *A. Gutin, V. Abkevich, K.M. Timms, T. Tran, D. Shattuck, J.S. Lanchbury, M.H. Skolnick.* Myriad Genetics Inc, Salt Lake City, UT.

Recently, remarkable technical advances have occurred that now make it feasible to screen the entire human genome for 500,000 or more SNPs using various microarray-based technologies. A major barrier to widespread application of these technologies is cost. We have developed a robust cost-effective DNA pooling approach to genome-wide SNP analysis. The power to detect an association strongly depends on how precisely the hybridization intensities and the corresponding allele frequencies can be measured. For the Affymetrix Centurion microarray, the standard method of estimating the allele frequencies has a standard deviation (SD) of about 7.4% for a typical SNP. We have developed a new approach to estimate allele frequency with much higher precision. The main idea of this approach is to combine hybridization intensities from different oligo-nucleotide probes corresponding to the same SNP with weights reflecting the quality of the probes. In order to estimate the qualities of different probes, 100 individual DNA samples were run on Affymetrix Centurion microarrays. Within this approach the allele frequency for a typical SNP can be estimated with SD of 2.5%. We have compared the power to detect association using our DNA pooling approach with the power to detect association based on individual genotyping. The following refers to a dataset of 250 cases and 250 controls and a significance level of p-value=0.001. For a SNP with a minor allele frequency of 25%, the minimal detectable allele frequency difference between cases and controls is about 11% using our DNA pooling approach (corresponding to power to detect association of 50%). For the same dataset with individual genotyping, the minimal detectable allele frequency difference is about 9%. This comparison demonstrates that our DNA pooling approach does not significantly reduce the power to detect association. The minimal loss of power using the DNA pooling approach facilitates the widespread use of high content SNP microarrays for a variety of disease association and population genetics applications.

Identification of translation initiation factor eIF-2B gamma subunit (EIF2B3) on chromosome 1p for age at onset of Parkinson disease: A potential Park10 gene. *J.M. Vance, S.A. Oliveira, X. Qin, X. Huo, M.A. Pericak-Vance, Y.J. Li.* Duke Univ Medical Ctr, Durham, NC.

We previously reported a linkage region on chromosome 1p (LOD=3.41) for genes controlling age at onset (AAO) of Parkinson disease (PD). This AAO linkage peak is essentially identical to a risk linkage peak for PD (PARK10) reported by Hicks et al. (2002) in their study of the Icelandic population, thus providing strong evidence of a major PD gene lying in this region. We recently reported a fine-mapping study, called iterative association mapping, by genotyping 284 SNPs in a 19.2Mb region centered under the AAO linkage peak in a set of 267 multiplex families (at least two affected individuals). Two candidate genes were found to associate with AAO, in which EIF2B3 showed the strongest significant association with AAO (P=0.0003 at SNP rs546354) based on 11 SNPs genotyped in the gene. These results were further supported by families linked to D1S2134, the chromosome 1p linkage peak marker. Here, we followed up this gene in an increased number of multiplex families (308 families). In total, we examined 45 SNPs in the EIF2B3 region including genes located upstream and downstream of EIF2B3, that is, from KIF2C to TESK2. The average distance between markers was about 5kb within a gene. We used the Monks-Kaplan method (Monks and Kaplan 2000) implemented in the QTDT program to test association between markers and AAO. The HBAT program was used for haplotype association testing. We found two clusters of markers in strong LD ($r2 < 0.6$) with significant results. The first large LD-bin with the most significant results ($P< 0.001$) was found between exons 4 and 6 of EIF2B3 and extended to KIF2C. Interestingly, a significant marker (P=0.017) in the second LD-bin was located in the middle of the first LD-bin, between exons 5 and 6. Eight tagSNPs were selected based on a lower r2 threshold ($r2< 0.4$), of which one tagSNP was selected from one LD-bin. The pairwise haplotype analysis shows promising results for tagSNPs selected from these two LD-bins (P=0.002), indicating a potential disease locus that may be located between exons 5 and 6. Further sequencing of these two exons is underway.

Candidate gene analysis of myopia. *M.E. Cooper[1], S.E. O'Brien[2], K.S. Zandick[3], J.C. Murray[2], M.L. Marazita[1], D.O. Mutti[3].* 1) School Dental Med, Center for Craniofacial and dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) University of Iowa, Department of Pediatrics, Iowa City, IA; 3) Ohio State University, College of Optometry, Columbus, OH.

Myopia is a common condition acquired in childhood. Treatment includes corrective lenses or surgery but in rare cases, myopia can lead to debilitating conditions including retinal detachment and blindness. In this study we examine the role of 7 candidate genes and loci using association and linkage approaches on 123 pedigrees ascertained through one or more myopic individuals. 477 family members were genotyped; 42% of the families have multiple affected siblings (mean typed affecteds per family = 2.2+1.0). Seventeen SNPs in 5 genes and 12 microsatellite markers on chromosomes 4,11,12,18 and 21 were analyzed. Phenotypes analyzed included myopia, myopia with age of onset after 14, and axial length. The results for myopia are reported here; the results with the other phenotypes were similar. Statistical analyses included tests of association (TDT, haplotype TDT, and reverse TDT with tests of Hardy-Weinberg equilibrium to guard against false positives) and tests of linkage-parametric (95% penetrant dominant model with 0.134 disease frequency) and nonparametric. Two of the three SNPs within FGF2 on 4q27 showed significant findings from different analysis methods: one SNP had the common allele over transmitted (p=0.01) with a significant maternal effect (p=0.03), another had a parametric LOD score near 1.0. One SNP within BDNF on 11p14.1 had a parametric LOD of 1.2. On chromosome12, anonymous microsatellite marker D12S2076 (12q21.31) had one allele borderline significantly over transmitted (p=0.08) and another significantly under transmitted (p=0.03); D12S1051 (12q23.1) had an allele significantly over transmitted (p=0.04) and another borderline significantly under transmitted (p=0.06). The results on chromosome 12q are consistent with other myopia studies; our study suggests FGF2 involvement with the development of myopia. Further study to isolate specific etiologic variants is warranted. Support: NIH/NEI grants #U10-EY08893 and R24-EY744701, Ohio Lions Eye Research and EF Wildermuth Foundations.

Genetic Linkage Study of High-Grade Myopia in an Hutterite Population from South Dakota. *P.C. Paluru[1], S. Nallasamy[2], M. Devoto[3], N.F. Wasserman[1], J. Zhou[1], T.L. Young[1,2].* 1) Division of Ophthalmology and Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Ophthalmology, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Biomedical Research, Nemours Childrens Clinic, Wilmington, DE.

Myopia is a common complex disorder, and severe forms have implications for blindness due to increased risk of premature cataracts, glaucoma, retinal detachment, and macular degeneration. Autosomal dominant (AD) non-syndromic high myopia (myopia 5.00 diopters) has been mapped to chromosomes 18p11.31, 12q21-23, 17q21-23, 7q36, and 2q37.1. Here, we demonstrate linkage for non-syndromic high myopia in a large, Hutterite family to a new locus on chromosome 10q21.1. After clinical evaluation, genomic DNA was genotyped from 29 members of a Hutterite family from South Dakota (7 affected, 9 unknown). The average refractive error of affected individuals was -7.04 diopters (range = -3.75 to -12.25). Prior to proceeding with a genome screen, linkage was excluded for the known AD non-syndromic and syndromic high myopia loci, including Stickler syndrome types 1, 2, and 3; Marfan syndrome; Ehlers-Danlos syndrome type 4; and Juvenile glaucoma. A genome screen was then performed using 382 markers with an average inter-marker distance of 10 cM. SimWalk2 software was used for multipoint linkage based on AD and AR models with a 90% penetrance and a disease allele frequency of 0.001. Additional fine-point mapping yielded a maximum LOD score of 3.22 under an AD model at microsatellite marker D10S1643. Fine-point mapping and haplotype analysis defined a critical region of 2.67 cM on chromosome 10q21.1. Haplotype analysis demonstrated two distinct haplotypes segregating with high myopia, possibility indicative of two distinct mutations occurring in the same gene. A search for genes physically mapped in this region revealed only two known genes: PCDH15 (protocadherin 15) and ZWINT (ZW10 interactor). Mutational characterization of these genes resulted in 23 polymorphisms and none of these segregated with the affection status. We have identified a novel myopia locus, further demonstrating the genetic heterogeneity of this disorder.

High-density SNP association study of the autism susceptibility loci on chromosome 2q and 7q. *J. Lamb[1], E. Maestrini[2], L. Winchester[1], A. Morris[1], H. Butler[1], E. Bacchelli[2], F. Blasi[2], G. Barnby[1], N. Sykes[1], A.J. Bailey[3], A.P. Monaco[1], IMGSAC.* 1) Wellcome Trust Centre for Human Genetics, Oxford, UK; 2) Dept of Biology, University of Bologna, Italy; 3) University Department of Psychiatry, Park Hospital for Children, Oxford, UK.

Autism is a severe neurodevelopmental disorder, likely to arise on the basis of a complex genetic predisposition. The IMGSAC genome screen for linkage in affected sib-pair families identified two principal loci on chromosomes 2q and 7q, which have been independently replicated. These broad ~40Mb linkage peaks contain ~200 genes. Fine mapping has not significantly narrowed the linked region, and mutation screening of promising candidate genes has failed to conclusively identify any etiological variants. Therefore, we have undertaken a gene-based, high-density SNP typing and association study in the two regions of linkage to identify susceptibility variants.

We used data from the HapMap project to evaluate the distribution of linkage disequilibrium (LD) and haplotype blocks across the two ~40Mb regions. We selected haplotype-tagging SNPs using Haploview and the Gabriel algorithm for block definition from blocks overlapping all known genes and their putative regulatory elements, thereby reducing the amount of genotyping required and capturing the majority of common variation in approximately 80% of all gene regions. Following power calculations to maximize efficiency, we have genotyped 1536 SNPs (including controls for mis-typing and stratification) at each locus using the GoldenGate assay, on a sample of 576 individuals including 192 sex-matched controls and 125 trios from multiplex families selected based on their allele sharing status.

Preliminary bioinformatic analysis has been carried out with regard to SNP distribution, LD block and gap statistics, and intragenic haplotype tagging efficiency. Sample and SNP genotyping success rates are ~99% and 96% respectively. Analysis will be performed on haplotypes within each block using both family-based and case-control association tests, and the results presented.

Interpreting results from association studies using analytical and permutation based methods. *L. Li[1], P.L. St Jean[1], M.G. Ehm[1], M.E. Weale[2], D.B. Goldstein[3].* 1) Discovery&Pipeline Genetics, GlaxoSmithKline R&D, RTP, NC; 2) Institute for Human Genetics and Health, University College London, Darwin Bdg (Biology), Gower St, London WC1E 6BT, UK; 3) Center for Population Genomics and Pharmacogenetics, Duke Institute for Genome Sciences and Policy, Duke University, DUMC Box 3471, 4006 GSRB II, 103 Research Drive, Durham, NC 27710.

Attrition in drug development is a significant problem leading to escalating costs. Most drug targets are identified via animal models and lack human validation information. The HiTDIP program (high throughput human-disease specific target program) is designed to provide human target validation information for complex diseases in the form of association of SNPs with disease. We genotyped 4267 SNPs in 1405 tractable genes, in 3227 individuals in a two stage case/control design. Genotypic, allelic and haplotypic tests were performed and permutation p-values calculated. We identified genes as associated with type 2 diabetes if at least one test was significant ($p<0.05$) in the primary screen and gene based test was significant in the secondary study. We estimated the experiment false positive rate to be 0.14. We estimated the number of true signals using these data to help us interpret the importance of the results using both analytical and permutation based methods. Results indicate that the chance of identifying true signals is high based on the study design and at least 5 of the significant genes are truly associated with the disease at 5% level.

Linkage of TB and TNF- to IL10 and TNFR1 gene regions. *C.M. Stein[1,2], L. Nshuti[2,3], R.D. Mugerwa[2,3], D. Leontiev[1], C. Millard[1], W.H. Boom[2], C.C. Whalen[1,2], S.K. Iyengar[1].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Tuberculosis Research Unit, CWRU, Cleveland, OH; 3) Makerere University School of Medicine, Kampala, Uganda.

Tuberculosis (TB) is a growing global public health problem, particularly in the face of the HIV epidemic. Evidence for a role of host genetics in TB susceptibility is accumulating, but association studies of candidate genes have offered inconsistent results. Much of this variability in study results is likely due to inconsistency in phenotype definition and study design. To model the multifactorial nature of TB, we have developed expression of tumor necrosis factor- (TNFa) as an intermediate phenotype, and focused on candidate genes that might be involved in TNFa regulation and TB risk. We analyzed 398 individuals from 66 families from a household contact study in Kampala, Uganda. Culture confirmed disease defined TB disease, and TNFa expression in response to *M. tuberculosis* (Mtb) culture filtrate was measured as a continuous trait. Microsatellite markers were genotyped in 11 candidate gene regions, and model-free multipoint linkage analysis utilized Haseman-Elston (SIBPAL) regression and the conditional logistic affected sibpair (LODPAL) model. We found that the interleukin (IL)-10 gene and TNF receptor 1 (TNFR1) gene regions were linked to both Mtb antigen-induced TNFa expression and TB affection in HIV-seronegative relative pairs at the =.05 level. TNFa demonstrated linkage in the SIBPAL analysis (IL10: D1S256 p=.03, TNFR1: D12S1625 p=.05). Similar results were found using the LODPAL models (D1S256 LOD=1.35, D12S1625 LOD=.74). In addition, the interferon-gamma receptor 1 gene (IFNGR1) was linked to TB status using both statistical models (D6S1587 LOD=2.35 from LODPAL, D6S1675 p=.03 from SIBPAL). IL-10 and IFNGR1 have been associated with TB in previous molecular studies, but this relationship between TNFR1 and TB has never been demonstrated in a human population. Other candidate genes showed linkage to TB, but only in the conditional logistic analysis. Further analyses will be conducted to elucidate the susceptibility alleles and the direction of effect on TNFa expression.

Re-analysis of the AGRE autosomal linkage scan to account for potential imprinting effects. *M.D. Fallin[1], K. Cheslack-Postava[1], A. Feinberg[2], C. Newschaffer[1].* 1) Dept Epidemiology, Johns Hopkins Univ, Baltimore, MD; 2) School of Medicine, Johns Hopkins University, Baltimore, MD.

Although evidence clearly suggests that genetic factors play an important role in autism, no autism-related genes have been conclusively identified. This is likely due to a complex etiology that involves genetic, epigenetic, and environmental influences during development. Epigenetic influences, such as imprinting, have been implicated in related disorders including Angelmans syndrome and fragile X, although evidence for imprinting effects in autism is still equivocal, with findings of both paternal or maternal inheritance, depending on the study and genomic region. If imprinting is an important mechanism, linkage analyses that incorporate parent-of-origin effects should be a fruitful way of identifying regions that harbor autism genes. With this in mind, we have applied both parametric and allele-sharing linkage analyses that model imprinting to the genome scan data generated for the Autism Genetics Resource Exchange (AGRE) samples (1). We present results for GENEHUNTER-IMPRINTING (2) and GENEFINDER-POO (3) for all 22 autosomes in 195 families with at least two affected siblings where cases are defined as autism disorder, and 303 families with >1 case defined as autism, not quite autism, or a broad autism phenotype. Our strongest initial finding is on chromosome 5p under a maternal expression model, with an HLOD = 4.68 and a 1 LOD interval of 14.4 cM, according to parametric analyses. Additional findings are on chromosomes 7, 19, and 20. References: 1. Yonan et al (2003) Am J Hum Genet 73:886. 2. Strauch et al (2000) Am J Hum Genet 66(6):1945-57. 3. Linking candidate-genes to orofacial clefts in Lithuanian population. *V. Kucinskas[1], A. Morkuniene[1], D. Kasperaviciute[1], A. Utkus[1], L. Linkeviciene[2].* 1) Dept Human & Medical Genetics, Vilnius Univ, Vilnius, Lithuania; 2) Institute of Odontology, Vilnius Univ, Vilnius, Lithuania.

Nonsyndromic cleft lip and/or palate is one of the most common craniofacial malformations. It is composed of two separate entities: cleft lip with or without cleft palate (CL+/-P) and cleft palate only (CP). Both have a genetic background, and environmental factors probably disclose these malformations. We used the transmission/disequilibrium test (TDT) to investigate the relationship between orofacial clefts and microsatellite and biallelic markers associated with five candidate genes: *TGFA*, *TGFB3*, *RARA*, *GABRB3* and *BCL3* in the patients from Lithuania. 86 case - parent trios were ascertained through a child with a nonsyndromic oral cleft: 62 trios with the patient with cleft lip and palate (CLP), 10 trios with cleft lip (CL) and 14 trios with cleft palate (CP). Association was found between microsatellite D2S292 allele 6 (182 bp) in the *TGFA* gene and CL+/-P (TDT for allele - wise analysis: ^{2}= 16,808, 8 df, p = 0,032; TDT for genotype - wise analysis: ^{2}= 31,178, 19 df, p = 0,039). No association was found for this marker when all patients (CL+/-P and CP) were analyzed together, suggesting different role of *TGFA* gene in CL+/-P and CP. The inheritance of *Taq*I marker alleles (C1 allele is reference and C2 - variant, i.e. deletion of 4 bp in intron V) of the *TGFA* locus was analyzed in the sample of 40 informative case-parent triads out of 86 initially genotyped ones. We evaluated the presence of association between *Taq*I marker alleles in the *TGFA* gene and the risk of isolated CL+/-P. Our data provide no evidence of the role *TGFA* genotype in the *Taq*I site and susceptibility to cleft lip and/or palate. There is no evidence of significant linkage disequilibrium with the C2 allele in *Taq*I site and CL+/-P phenotype. No significant differences were found when comparing data by clefting type.

MHC association in multiple sclerosis is restricted to the HLA class II region by dense SNP mapping. *M.R. Lincoln[1], A. Montpetit[2], M.Z. Cader[1], J. Saarela[3], D.A. Dyment[1], M. Tiislar[2], V. Ferretti[2], P.J. Tienari[4], N.J. Risch[5], A.D. Sadovnick[6], L. Peltonen[3], G.C. Ebers[1], T.J. Hudson[2].* 1) Dept. of Clinical Neurology, University of Oxford, Oxford, UK; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 3) Dept. of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 4) Dept. of Neurology, University of Helsinki, Helsinki, Finland; 5) Center for Human Genetics, University of California San Francisco, San Francisco, USA; 6) Dept. of Medical Genetics and Faculty of Medicine (Division of Neurology), University of British Columbia, Vancouver, Canada.

Multiple sclerosis is the most common neurological disease affecting young adults in Northern European populations. The strongest candidate for genetic susceptibility is the MHC, particularly HLA-DRB1, where linkage and association have been consistently reported. There is evidence, however, for locus and allelic heterogeneity within the MHC and an important question has been whether HLA-DRB1 itself, nearby genes in the extended MHC, or combinations of these loci, underlie MS susceptibility. We attempted to resolve this challenging question by genotyping 4,203 individuals from two large Canadian and Finnish cohorts totaling 1,185 MS families with a high-density SNP panel spanning the MHC and flanking regions. Haplotype blocks were identified and assessed for association with MS. The strongest associations in Canadian samples were with blocks within the HLA class II region ($P4.9\times10^{-13}$), but none were greater than that of HLA-DRB1 itself ($P2.7\times10^{-13}$). These findings were corroborated in the Finnish cohort ($P1.8\times10^{-16}$). Conditioning on either HLA-DRB1 or the most significant HLA class II haplotype block, we observed no additional block or SNP association to suggest an MHC contribution to susceptibility independent of HLA-DRB1. This study therefore strongly argues that MHC-associated susceptibility to MS is determined by HLA-DRB1 alleles, their interactions and/or closely neighboring variants.

Whole genome association study for psoriasis using the Quebec LD Map custom genotyping chip. *J. Raelson, P. Croteau, Q. Nguyen Huu, B. Paquin, P. Van Eerdewegh, R. Little, J. Segal, B. Stojkovic, H. Fournier, R. Allard, V. Perepetchai, T. Nguyen, N. Laplante, J-M. Vidal, J. Hooper, T. Keith, A. Belouchi.* Genizon Biosciences, Vilee-St-Laurent (Montreal), PQ, Canada.

We previously performed a whole genome association study (WGAS) for Crohns disease using 500 individually genotyped trios from the Quebec Founder Population (QFP) and 165,000 SNP markers distributed evenly across the genome at a density of approximately 1 marker per 17 kb. We were able to detect highly significant association at the CARD15 locus, which has a lower extent of LD than 70 percent of the genome, using a SNP density as low as 1 marker per 47 kb for our QFP sample. We then mapped variation in LD across the genome using a multi-marker metric of LD and control haplotypes from the Crohn's study and used this information to construct the ~ 81,000 Quebec LD marker map (QLDM) with marker spacing of 1 SNP per 30 kb at LD levels equal to or greater than that of CARD15 and with increasing density as high 1 SNP per 10 kb in regions that were identified as having a lower extent of LD.

The QLDM was then used to perform a WGAS for psoriasis using 500 trios with affected members from the QFP. Fifteen hundred individuals were genotyped using a custom chip created by Perlegen Sciences for Genizon Biosciences containing the QLDM markers. We identified 17 regions that were associated with psoriasis at significance of P less than 10^{-5}, including the previously reported PSORS1 locus in the HLA region of 6p21, which was associated at a significance of P less than 10^{-20}. The average map density in this region was approximately 1 SNP per 30 kb. Newly discovered loci will be tested in a second population.

Analysis of Neuropilin-1 as a Candidate Gene for Diabetic Nephropathy. *Y. Wang[1], M. Slaughter[1], J.R. Schelling[2,3], J.R. Sedor[2,3], S.K. Iyengar[1].* 1) Epidemiology & Biostatistics, Case Western Reserve University, Cleveland OH; 2) Department of Medicine, Case Western Reserve University,Cleveland OH; 3) Rammelkamp Center for Research and Education, MetroHealth Medical Center, Cleveland OH.

Diabetic nephropathy (DN) is a multifactorial disease with strong evidence for a genetic cause of disease pathophysiology. Interval mapping in rat strains susceptible to glomerulosclerosis has demonstrated that multiple loci (Rf1-Rf5) contribute to the renal failure phenotype. Previously, we showed that the Rf5 orthologous region on human 10p was linked to DN. Bioinformatic mining revealed that the Neuropilin1 gene (NRP1) is within 1cM interval of the 10p linkage peak. NRP1 is a co-receptor for vascular endothelial growth factor (VEGF) and Semaphorin ligands. Kidney glomerulus-specific deletion or overexpression of VEGF causes glomerular disease in mice. NRP1 is also expressed in kidney, but transgenic mice with overexpression or targeted deletion of NRP1 are embryonic lethal prior to kidney development. Hence, the role of NRP1 in the kidney is not well understood. Since glomerulosclerosis is a hallmark of DN, three SNPs were identified in NRP1 and genotyped in 74 European American (EA) and 79 African American (AA) diabetic sib pairs phenotyped for the presence or absence of DN. In our analysis, the SNPs were coded as covariates in three different genetic models: additive, dominant, and recessive. A Haseman-Elston regression linkage analysis was performed using the S.A.G.E. program SIBPAL. Based on the sibling data, we discovered that when SNPs at NRP1 were added as covariates, the previously identified linkage signal in the EA population lost significance (P-value increased from 0.00565 to 0.0482), while we observed a small increase in the linkage signal for the AA (P-value decreased from 0.650 to 0.428). When a test of family-based association between these SNPs and the DN trait was performed with ASSOC, we observed no association with any of the SNPs in either the EA or AA populations. Our conclusion is that NRP1 is in close linkage disequilibrium with a gene for DN, but is not the causative gene in this population.

The Arg16Gly polymorphism in beta2-adrenoreceptor is associated with severe obesity in Pima Indian women. *T. Guo, Y. Muller, L. Ma, R. Valenzuela, R. Hanson, S. Kobes, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, 4212 N. 16th Street, Phoenix, AZ 85016, USA.

The beta-2 adrenoceptor (ADRB2) is a major lipolytic receptor in human fat cells and may be of major importance for obesity and energy expenditure. To investigate the impact of single nucleotide polymorphsms (SNPs) in the *ADRB2* gene on obesity, we sequenced 83 extremely obese Pima Indians (BMI 50 kg/m2). A total of 10 common SNPs were found. Four SNPs were located in the exonic region, of which one was a functional missense substitution (Arg16Gly, rs1042713). Four SNPs were located in the 5' promoter region, and two in the 3' flanking region. A Gln27Glu, reported to be associated with obesity in most populations was not found to be polymorphic in Pima Indians. Eight of the 10 SNPs were successfully genotyped in 489 full-heritage, non-first-degree-related adult Pimas (362 severely obese and 127 nondiabetic-nonobese subjects) for association analysis. Analysis of stratification by gender showed 7 SNPs, including Arg16Gly, had nearly complete allelic concordance (r^2=0.78-0.94), and were significantly associated with obesity only in females (recessive model p= 0.0046-0.0175). Our data suggest that ADRB2 may influence body weight through a sex-specific mechanism, and our results are in accordance with results which showed that Gln27Glu, a polymorphism in the same haplotype block as Arg16Gly in Caucasians, to be associated with obesity in women only from Sweden, Spain and Japan.

Lack of association between serotonin transporter gene and borderline personality disorder: a preliminary study. *X. Ni[1], K. Chan[2], N. Bulgin[1], T. Sicard[1], S. McMain[2], J. Kennedy[1].* 1) Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) Dialectical Behavior Therapy Clinic, Centre for Addiction and Mental Health, Toronto, Canada.

Borderline personality disorder (BPD) is a chronic, disabling, and high-risk mental disorder characterized by a pervasive pattern of instability in regulation of emotion, interpersonal relationships, self-image, and impulse control beginning in early adulthood. BPD affects about 1%-2% of the general population and has high mortality rate as a result of suicide and impulsive behaviour. Multiple lines of evidence suggest that serotonin transporter gene (5-HTT) plays an important role in suicide, impulsive behaviour, and emotional liability. To test for an association between 5-HTT and BPD, we genotyped two polymorphisms in 5-HTT, 5-HTTLPR and VNTR, in 63 Caucasian patients with BPD and 263 Caucasian healthy controls. The program COCAPHASE was used to compare allele frequencies between cases and controls and to perform haplotype analysis. There were no significant differences of allele and genotype frequencies of the 5-HTTLPR and VNTR markers between BPD patients and healthy controls ($p>0.05$). There was also a lack of association based on haplotype analysis. Our results suggest that serotonin transporter gene may not play a role in BPD. Naturally, the small sample of BPD patients may have limited our findings. The study of a large sample of BPD patients is warranted to substantiate these preliminary findings. This work is supported by Quick Action Small Grant Program of the Borderline Personality Disorder Research Foundation (BPDRF).

Nicotine dependence is associated with the serotonin transporter gene. *S.L. Santangelo[1,2,3], G.D. Papandonatos[4], J.M. McCaffery[5], M. Lyons[2,6], M.T. Tsuang[2,3,7], R. Niaura[8], S. Buka[3,9].* 1) Psychiat & Neurodevlop Genetics, Ctr for Human Genetic Resrch, Mass General Hosp, Boston, MA; 2) Dept Psychiat, Harvard Medical School, Boston, MA; 3) Dept Epidemiology, Harvard School of Public Health; 4) Center for Statistical Sciences, Dept Community Health, Brown Medical School, Providence RI; 5) Ctrs for Behavioral and Preventive Medicine, Dept Psych & Human Behav, Brown Medical School & Miriam Hosp, Providence, RI; 6) Dept Psychology, Boston University, Boston, MA; 7) Institute of Behav Genomics, UC San Diego, San Diego, CA; 8) Ctr for Transdiscip Resrch, Dept Psych & Human Behavior, Brown Medical Schl & Butler Hosp, Providence RI; 9) Dept Society, Human Develop & Health, Harvard School of Public Health, Boston MA.

Most candidate gene studies of smoking phenotypes have investigated only one or two specific mutations, functional polymorphisms, or SNPs. With such sparse coverage, it is difficult to know what if any inferences should be drawn from negative results of such studies. With the recent availability of large numbers of SNPs in public databases, it is now possible to fully characterize a candidate gene by saturating it with SNPs at high density. Recently, we undertook such an investigation of the serotonin transporter gene (SLC6A4). A case-control association study was conducted to test for association of SLC6A4 with DSM-IV nicotine dependence. The genotyped sample was comprised of 443 unrelated individuals, of whom 211 were nicotine dependent. SLC6A4 spans 31 kb on chromosome 17q. Sixteen SNP markers selected from public databases were genotyped across 96 kb, including 25 kb past the 3 and 5 ends of the gene, for an average density of 6 kb. The 11/16 markers retained after data cleaning fell into three blocks of linkage disequilibrium. We identified a 5 SNP haplotype in block 1 with a frequency of .33 that was nominally significantly associated with nicotine dependence. This was accounted for by two common SNPs in strong LD with one another, with frequencies of .52 and .51. A Cochran-Armitage test for trend in allele frequencies indicated both SNPs were significantly associated with nicotine dependence, with p-values of 0.018 and 0.008.

Psychosis and Mania: a 440-SNP screen of 65 candidate genes in Ashkenazi Jewish schizophrenia and bipolar 1 case/parent trios using two clinical conditions. *V.K. Lasseter[1], M.D. Fallin[2], G. Nestadt[1], P.S. Wolyniec[1], J.A. McGrath[1], D. Avramopoulos[1], N. Cheng[1], D. Valle[4,5], K.Y. Liang[3], A.E. Pulver[1,2].* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Department of Epidemiology, The Johns Hopkins Bloomberg School of Public Health; 3) Department of Biostatistics, The Johns Hopkins Bloomberg School of Public Health; 4) McKusick-Nathans Institute, The Johns Hopkins School of Medicine; 5) The Howard Hughes Institute, The Johns Hopkins School of Medicine.

Previously, we completed a SNP screen of 440 SNPs in 65 candidate genes for either bipolar 1 disorder or schizophrenia using Ashkenazi Jewish case/parent trios. The use of narrow phenotypes and a relatively genetically homogeneous population were strategies selected to increase power and the likelihood of success in identifying predisposing loci for these genetically complex psychiatric disorders. An overlap in genetic susceptibility for the two disorders has been hypothesized based on co-aggregation of familial risks and symptoms. From the sample of 323 bipolar 1 trios and the second sample of 274 schizophrenia trios, significant evidence (empirical $p<.01$) was previously shown for DAO, GRM3, GRM4, GRIN2B, IL2RB, and TUBA8 for bipolar 1 disorder and DPYSL2, DTNBP1, G30/G72, GRID1, and GRM4 for schizophrenia. We have now conducted exploratory genotype TDT association analyses (both single SNP and haplotype-based) using two new phenotypes based on consensus ratings of symptom-level data (manic episodes and psychosis) in these same Ashkenazi Jewish trios. For the mania phenotype (423 trios), we find significant ($p<.01$) evidence for 3 genes (KIF13A, BZRP, TUBA8). Similarly for the psychosis phenotype (494 trios), 6 candidate genes (KIF13A, SCA1, GRM4, ADRA1A, NOS1, and TPP2) had significant associations. These analyses address issues in heterogeneity and overlap in these severe psychiatric disorders and may be helpful in prioritizing future studies for other investigators.

Refinement of the chromosome 5q31 risk haplotype in inflammatory bowel disease. *S.A. Fisher[1], J. Hampe[2], M.J. Daly[3], C. Onnie[1], S. Purcell[3], C.M. Lewis[1], S. Schreiber[2], J.D. Rioux[3], C.G. Mathew[1].* 1) Department of Medical and Molecular Genetics, King's College London, Guy's, King's and St Thomas' School of Medicine, London, United Kingdom; 2) Department of General Internal Medicine, Christian-Albrechts-Universitat, Kiel, Germany; 3) Whitehead Institute of Technology, Center for Genome Research, Massachusetts, USA.

Strong association of a common haplotype spanning 250 kb on chromosome 5q31 with Crohns disease (CD) has been widely replicated. It has been proposed that two functional variants within the *SLC22A4* and *SLC22A5* genes at this locus contribute directly to CD susceptibility. However, extensive linkage disequilibrium across the region has complicated efforts to distinguish causal variants from the strong association of the general risk haplotype.

We have genotyped the *SLC22A4* and *SLC22A5* variants (L503F, G-207C) and four other single nucleotide polymorphisms (SNPs) from the risk haplotype (IGR2063, IGRX100a, IGR2230, IGR3236) in a total of 1,200 cases and controls from four populations of European origin. A haplotype regression based approach has been used to test for conditional association and to dissect the contribution of individual SNPs or haplotypes to disease risk.

The results show that the C2063G variant, rather than L503F or G-207C, provides the strongest single SNP association and that, conditional on a single L503F SNP effect, a haplotype effect with C2063G significantly improved the fit of the model. We conclude that variants in the *SLC22A4* and *SLC22A5* genes are not sufficient to explain the disease risk at this locus. Resolution of the identity of the causative susceptibility gene or mutations will require very large association studies and may not be possible by genetic studies alone.

Extension of the association probability to a quantitative trait. *W. Zhang, N. Maniatis, S. Rodriguez, I.N.M. Day, A. Collins, N.E. Morton.* Human Genetics Div, Univ Southampton, Southampton, United Kingdom.

The association probability was developed for haplotypes in case-control studies, extended to the transmission disequilibrium test, derived from the Malecot model and shown to be more efficient than alternative metrics to describe linkage disequilibrium (LD, Morton et al. 2001). From this foundation was extended to diplotypes and used to create the first LD maps. Recently a further extension was made to association mapping for affection status through the metric z = , where is the attributable risk in diplotypes. In the example of CYP2D6 data, no other model had performed as well in association mapping as the and z metrics, which are most powerful when LD is expressed in LD units (LDU, Maniatis et al. 2004). Here we present the theory and application of a quantitative trait association mapping using the z metric. The sample can be random, case-control, or case-hypernormal control. A quantitative trait is grouped into m classes and the class variable is expected to be robust to deviations from normality. Data with estimated z are fitted to the Malecot model and composite likelihood, 2 testing association obtained from the hierarchical models and location of the associated gene estimated. The method has been verified in the CYP2D6 data, where m = 2. We also applied the method to the IGF2 data comprising 2743 random samples from a UK multicentre study of cardiovascular risk. Weight, lean body mass (LBM), and the first principal component of these variables with body mass index (BMI) were analyzed. Preliminary results indicate that disease associated regions can be fine-mapped with high power by this approach. Disentangling linkage disequilibrium and linkage from dense SNP trio data. *G. Clarke, L. Cardon.* Wellcome Trust Center for Human Genetics, University of Oxford, Oxford, United Kingdom.

Parent-offspring trios are widely collected as part of disease gene mapping studies, and also being extensively genotyped as part of the International HapMap Project. With dense maps of markers on trios, the effects of LD and linkage can be separated allowing estimation of recombination rates in a model-free setting. Here we define a model-free multipoint method based on dense sequence polymorphism data from parent-offspring trios to estimate inter-marker recombination rates. We use simulations to show that this method has up to 92% power to detect recombination hotspots of intensity 25 times background over a region of size 10kb typed at a density 1 marker per 2.5kb and almost 100% power to detect large hotspots of intensity >125 times background over regions of size 10kb typed with just 1 marker per 5kb (=0.05). We found strong agreement at megabase scales between estimates from our method applied to HapMap trio data and estimates from the genetic map. At finer scales, using CEPH pedigree data across a 10Mb region of chromosome 20, a comparison of population recombination rate estimates obtained from our method with estimates obtained using a coalescent based approximate-likelihood method implemented in PHASE 2.0 shows detection of the same coldspots and most hotspots: The Spearman rank correlation between these estimates is 0.58 ($p< 2.2^{-16}$).

Fine mapping candidate genes in cleft lip loci at 1p22-p33, 3q26-q28, 15q12-q14 and 17q12-31. *H. Mishima[1], L.M. Moreno[1], T. Busch[1], M. Arcos-B.[8], C. Velencia[3], A. Hing[4], E. Lammer[5], M. Jones[6], N. Robin[7], B.S. Maher[2], M.E. Cooper[2], T. Goldstein McHenry[2], A. Mach[1], M.L. Marazita[2], A.C. Lidral[1].* 1) U. of Iowa, Iowa City, IA; 2) U. of Pittsburgh, PA; 3) U. of Antioquia, Medellin, Colombia; 4) Children's Hosp., Seattle, WA; 5) Children's Hosp., Oakland, CA; 6) Children's Hosp., San Diego, CA; 7) U. of Alabama, AL; 8) NIH, Bethesda, MD.

Recent candidate gene and genome scan studies from Colombian and Ohio populations indicated that loci at 1p22-p33, 3q26-q28, 15q12-q14 and 17q12-31 met the criteria for follow up studies (LOD>1.75 or p<0.0023) (Rao and Gu 2001). Molecular data and animal models support candidate genes in these loci including *LHX8*, *FOXD3*, and *TGFBR3* (1p22-p33); *TP63* and *EPHB3* (3q26-q28); *GABRB3* (15q12-q13) and *WNT3* and *WNT9B* (17q12-31). The purpose of this study was to fine map these loci in an extended sample. 32 SNPs were genotyped in 78 extended families and 85 trios from Colombia and 28 extended families and 99 trios from USA. Parametric, nonparametric and association analyses were conducted. Results showed population differences with 1p22-p33 being positive in the USA data, while 3q26-28 being positive only in the Colombian data. *FOXD3* and *ROR1* genes at 1p22-p33 do not appear to increase risk for NSCL/P. However, markers within 102-126 cM at 1p22-p33 were significant (p<0.01) with the most significant results centered at 114cM (multipoint NPL p=0.00003). *EPHB3* and *TP63* genes at 3q26-28 showed positive LD in the Colombian data (p=0.058 and p=0.02, respectively) but not in the USA data. Markers for *GABRB3* at 15q12 revealed weak LD in both populations. Finally LD was also observed at 17q12-31 from SNPs rs1999533 (p=0.017, 69cM; *NSF*) and rs70602 (p=0.024, 69cM; *WNT3*) in 292 Colombian nuclear trios and also, significant LD was observed for the entire data set USA and Colombia (521 nuclear trios) with the SNP rs1530364 (p=0.014, 65cM; *WNT9B*). In conclusion, results obtained confirm the presence of NSCL/P susceptibility loci in 1p22-p33 in the US data, 3q26-q28 in the Colombian data and 17q12-31 for both populations underscoring the population heterogeneity that characterizes this trait. Supported by NIH R01DE14677, K02DE015291, P60DE13076; MOD #6-FY01-616.

A Powerful and Robust Test of Transmission Disequilibrium for Quantitative Traits in General Pedigrees. *G. Diao, D.Y. Lin.* Dept Biostatistics, Univ North Carolina, Chapel Hill, NC.

Association mapping based on family studies can identify genes that influence complex quantitative traits while providing protection against population stratification. Among all the family-based tests of association, the one based on the variance-components model (Abecasis et al. 2000, Am. J. Hum. Genet. 66, 279-292) is the most flexible and most powerful. This test, however, relies heavily on the normality of the quantitative trait. Nonnormality can cause inflated type I error and reduced power. In most situations, the problems cannot be overcome by permutation. Although it is desirable to transform the trait values to achieve normality, it is difficult to specify the correct transformation, especially when there exist outlying trait values. We propose a novel extension of the variance- components model by allowing a completely arbitrary transformation function for the trait values, and present an efficient likelihood-based test for genetic association. Extensive simulation studies show that the proposed method provides accurate control of the type I error and is substantially more powerful than the existing methods. The advantages of our method are demonstrated through an application to the Collaborative Study on the Genetics of Alcoholism.

Towards a systematic screen of cytoplasmic dynein-dynactin genes and other candidates for association with motor neuron degeneration disorders by tagging SNP analysis. *P.R. Shah[1], A. Ahmad-Annuar[1], K.R. Ahmadi[2], N. Soranzo[2], C. Russ[3], P.C. Sapp[4], D. Kasperaviciute[1], H.R. Horvitz[4], R.H. Brown Jr.[3], D.B. Goldstein[2], E.M.C. Fisher[1].*
1) Dept.of Neurodegenerative Disease, Inst. of Neurology, London, UK; 2) Dept. of Biology, UCL, London, UK; 3) Day Laboratory for Neuromuscular Research, Mass General Hospital, MA, USA; 4) Howard Hughes Medical Inst., MIT, MA, USA.

The cytoplasmic dynein-dynactin complex, a molecular motor responsible for retrograde axonal transport, has been implicated in the aetiology of motor neuron degeneration in both mouse models and humans. For example, mutation of the human dynactin subunit *DCTN1* is a risk factor for familial lower motor neuron disease (Puls et al. Nat Genet 2003; 33:455) and sporadic amyotrophic lateral sclerosis (SALS) (Munch et al. Neurology 2004; 63:724). Consequently, as genes of this complex and other candidates are of interest as causal/susceptibility loci for motor neuron degeneration disorders, we have developed a strategy to economically represent and interrogate common variation across each gene for an association with disease. We have determined haplotype and linkage disequilibrium patterns for each gene of interest in northern Europeans, based on single nucleotide polymorphism (SNP) genotype data. We identified SNPs capable of tagging known/unknown variation (tSNPs) with an association threshold (r^2) 0.85 and assessed their performance using a SNP-dropping procedure. We genotyped tSNPs in 261 North American SALS cases and 225 matched controls to test for association with disease.

To date, we have analysed tSNPs in several genes and completed studies for both cytoplasmic dynein 1 heavy chain 1 (*DYNC1H1*) and intermediate chain 1 (*DYNC1I1*). For *DYNC1H1*, we found that two tSNPs (rs2251644 and rs941793) were sufficient to tag the majority of haplotypic variation at $r^2$0.85 but found no significant association with disease (p=0.538 and p=0.204 respectively, tSNP haplotype p=0.956). In addition, 9 tSNPs were sufficient to tag *DYNC1I* and no significant association with disease status was seen (p>0.08). We are currently investigating additional genes of the complex.

A Genome Variation Server for linkage disequilibrium analysis and tagSNP selection using genotype data from dbSNP. *M.J. Rieder, Q. Yi, P.D. Robertson, E. Calhoun, D.A. Nickerson.* Dept Genome Sciences, University of Washington, Seattle, WA 98195.

Selecting informative single nucleotide polymorphism (SNP) markers for genotype-phenotype studies requires genotype data from many individuals to assess the linkage disequilibrium (LD) between SNPs. The number of SNPs with genotype data submitted over the past year to dbSNP has increased dramatically (approximately 2 million SNPs) due to the efforts of the International HapMap Project and from genotypes generated by Perlegen (1.58 million SNPs across three populations). To provide a tool for rapid querying, data integration, and analysis of the genotype data in dbSNP, we have designed a web-accessible Genome Variation Server (GVS). This GVS allows users to query all SNPs with genotype data in the dbSNP database according to eithergenome coordinates, HUGO gene name, Entrez GeneID, or reference SNP identification number (dbSNP rs number). Each query returns the number of SNPs and genotypes by population (e.g. European, African-American, Asian, etc). Additionally, specific population data can be queried to extract and display genotype data in both text and graphical formats such as the visual genotype, a color-coded array of sample identifiers and their corresponding genotypes. Interactive queries, to select tagSNP sets based on user-defined thresholds forr minor allele frequency cutoffs and LD levels (using the r^2 LD measure), are used to generate summary text output and display LD plots graphically. GVS allows a simplified method for rapid retrieval, analysis and selection of customized tagSNP panels in specific populations.

Linkage Disequilibrium Mapping With Single Feature Polymorphisms. *S. Kim[1], K. Zhao[1], R. Jiang[1], J. Molitor[3], J. Borevitz[2], M. Nordborg[1], P. Marjoram[2].* 1) Department of Biological Sciences, University of Southern California, Los Angeles, CA; 2) Department of Ecology and Evolution, University of Chicago, Chicago, IL; 3) Department of Preventive Medicine, University of Southern California, Los Angeles, CA.

Single Feature Polymorphisms (SFP) are polymorphisms resulting from the use of high-density oligonucleotide tiling arrays for genotyping. For any feature (typically 25bp) on the array, any sequence differences between a particular chromosome and the reference genome will be revealed through a difference in hybridization intensities. The data are thus of the binary form same or different with respect to the reference genome. Because two chromosomes that both differ from the reference genome need not be identical and sensitivity and specificity are not identical, the data can be viewed as noisy SNP data with strange asymmetric errors. The advantage of SFPs over SNPs is their low cost. Here we examine the feasibility of using SFPs for linkage disequilibrium (LD) mapping. We compare the performance of tag SNPs to that of SFPs on simulated data with 2 different haplotype-based LD mapping methods. Our general conclusion is that for a given cost, SFPs will often have more power than SNPs as the former make up for quality with quantity.

The first genome wide linkage disequilibrium map. *W. Tapper, A. Collins, J. Gibson, N. Maniatis, S. Ennis, N.E. Morton.* Human Genetics, University of Southampton, Southampton, SO166YD, UK.

Two genetic maps describe patterns of recombination and can be used to identify genes affecting a particular phenotype, recombinogenic sequences, and evidence of natural selection. Recombination is measured in morgans over a single generation in a linkage map, but may cover thousands of generations in a linkage disequilibrium (LD) map measured in LD units (LDU). The HapMap Project has led to a huge increase in the genotyping of single nucleotide polymorphisms (SNPs) that are the main source of LD information. We have used a subset of the phase 1 HapMap data consisting of 2,885,936 SNPs from CEPH (CEU), Japanese (JPT), Chinese (HCB), and Yoruban (YRI) populations, to create the first genome wide LD map which covers 99.7% (2,934 Mb) of the euchromatin. Recombination accounts for 97.1% of the LDU variance in chromosome arms and 95.2% in their deciles. The Malecot model predicts that the ratio of corresponding distances in LDU and Morgans estimates the effective bottleneck time t in generations which is constant between chromosomes. The LD maps estimate t as 1472, 1483, 1648, and 2073 generations for CEU, JPT, HCB, and YRI respectively implying bottleneck times of between ~36,800 and ~51,825 years, assuming 25 years per generation. Presumably, this low estimate reflects the partly cumulative effect of bottlenecks since the out-of-Africa migration. Deeper analysis shows significant deviations in t between chromosome arms due to physical size, SNP density and holes in the LD map. These differences are the result of (1) the linkage map employing the Kosambi function which exagerates Morgan length for all chromosomes especially shorter ones; (2) the non-pseudoautosomal region of the X chromosome being subject to hemizygous selection; and (3) low SNP density in intervals of high recombination. These genome wide LD maps are available from our LD database (http:/cedar.genetics.soton.ac.uk/public_html/LDB2000/release.html) as integrated maps that can be viewed as tables or graphs to determine the pattern of LD in any genomic region. Other options on this site allow for identification of recombination hotspots, population comparisons and SNP selection based on LDUs.

Tag SNP selection for Finnish individuals based on the CEPH Utah HapMap database. *C.J. Willer[1], L.J. Scott[1], L.L. Bonnycastle[2], A.U. Jackson[1], P. Chines[2], R. Pruim[1,3], C.W. Bark[4], Y-Y. Tsai[4], E.W. Pugh[4], K.F. Doheny[4], L. Kinnunen[5], T.T. Valle[5], R.N. Bergman[6], J. Tuomilehto[5,7,8], F.S. Collins[2], M. Boehnke[1].* 1) Dept of Biostatistics, Univ Michigan; 2) Genome Technology Branch, National Human Genome Research Institute; 3) Dept of Mathematics and Statistics, Calvin College; 4) Center for Inherited Disease Research, School of Medicine, Johns Hopkins University; 5) Diabetes and Genetic Epidemiology Unit, Dept of Epidemiology and Health Promotion, National Public Health Institute, Finland; 6) Dept of Physiology and Biophysics, Keck School of Medicine, Univ of Southern California; 7) Department of Public Health, University of Helsinki, Finland; 8) South Ostrobothnia Central Hosp, Seinäjoki, Finland.

The Finland-United States Investigation of NIDDM Genetics (FUSION) study has sought to evaluate tag SNPs selected for the purpose of association testing in a region of linkage. In an 18 Mb region of chromosome 14, we selected SNPs with minor allele frequency 5% from the CEPH Utah HapMap database (May 2004) by applying a pairwise r^2 criterion of .8 and prioritizing selection of nonsynonymous SNPs and those with higher Illumina design scores. Genotypes for 1,425 Finnish samples at 956 SNPs were generated at CIDR. After matching of the reference allele, 90% of SNPs had an allele frequency difference .10 between the CEPH Utah and Finnish samples and 99% of SNPs had an allele frequency difference .15. The t-test revealed 7.7% of the SNPs had a significant difference (p .01) between allele frequencies in the CEPH Utah and Finnish samples. However, after examining pairs of adjacent SNPs, we found that the absolute difference between the r^2 estimates in the Finnish and CEPH samples was .10 in 76% of SNP pairs and .15 in 87% of SNP pairs. Haplotype frequency estimates for 180 bins of 3-20 SNPs also showed similarities between the Finnish and CEPH Utah samples; 94% and 98% of haplotypes had frequency differences .10 and .15, respectively. We conclude that use of the CEPH Utah linkage disequilibrium data allowed for efficient SNP selection in our Finnish sample.

Linkage disequilibrium and haplotype study at the Xq13-21 region in six Native American populations. *S. Wang[1], D. Labuda[2], G. Bedoya[3], A. Ruiz-Linares[1,3].* 1) Wolfson House, The Galton laboratory, Department of Biology, University College London, London, United Kingdom; 2) Université de Montreal, Montreal; 3) Laboratorio de Genética Molecular, Facultad de Medicina, Universidad de Antioquia, Medellín, Colombia.

Great interest exists in assessing patterns of linkage disequilibrium (LD) in human populations as these will impact on our ability to identify genes through association analyses. A region of the world that has been scantly examined in LD surveys is the American continent. Here we examined LD in six Native American populations at a region of the X chromosome (Xq13-21) that has been extensively studied in Europe and Asia. We typed seven microsatellite markers covering this 4cM region in six Native American populations (five from Colombia and one from Canada). Compared to other populations, Native Americans show low diversity and high LD. Similar levels of LD were observed in Native Americans as in certain European and Asian isolates, but with lower diversity in the Americas. The haplotype frequency distribution at the two markers in strongest LD shows that three haplotypes that are rare in Asia or Europe have a widespread distribution in the Americas, while the two most common haplotypes in Asia and Europe were not observed in the Americas. These results are consistent with strong drift in Native American populations and illustrate the potential of X-chromosome studies for probing the evolutionary history of the Americas. The low genetic diversity and high LD of Native American populations should facilitate association mapping of common diseases in these populations.

Association of IL4Ra gene with severity of lung disease in Cystic Fibrosis. *F. Belpinati[1], G. Malerba[1], L. Xumerle[1], C. Bombieri[1], R. Galavotti[1], C. Castellani[2], B.M. Assael[2], P.F. Pignatti[1].* 1) Sect Biol & Genetics, DMIBG, Univ Verona, Verona, Italy; 2) Cystic Fibrosis Veneto Regional Centre, Hospital of Verona, Italy.

Cystic Fibrosis is an autosomal recessive disease caused by mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene. Chronic lung disease is the most serious clinical expression of CF. The course of the lung disease is highly variable; this variability is explained only partially by allelic heterogeneity at the CFTR gene. The severity of pulmonary manifestations in CF may be correlated with other genetic factors. We report the study of three polymorphisms of the IL4Ra (IL4-receptor alpha) gene. This gene is involved in asthma and atopy and may represent a possible modifier of pulmonary disease in CF. Eigthy-three family trios were collected through a CF patient attending the Veneto Regional CF Centre of Verona. All the 83 patients were severe/severe CFTR mutation carriers and were clinically evaluated for respiratory parameters, gastrointestinal and nutritional status parameters, and other clinical variables. The patients and their parents were investigated for three functional polymorphisms (I50V, S503P and Q576R in exons 3 and 9) of the Il4Ra gene. The transmission disequilibrium test showed a significant association between Q576R (p=0.014) or S503P (p=0.035) polymorphisms with FEV1 values in the patients. The Q576R and S503P polymorphisms showed to be in strong linkage disequilibrium (D'=0.98, r2=0.79). The I50V was not in linkage disequilibrium with any of the other 2 polymorphisms. In conclusion, these data suggest that the IL4Ra gene might be a modifier gene for FEV1 variability in CF, mediating lung inflammatory processes.

Linkage Analysis for Bilaterial Perisylvian Polymicrogyria: a new locus mapped on Xq27-q28. *N. Santos[1], I. L. Brandão[1], R. Secolin[1], M. S. Silva[1], F. Cendes[2], M. M. Guerreiro[2], I. Lopes-Cendes[1].* 1) Dept Medical Genetics, UNICAMP, Campinas, SP, Brazil; 2) Dept Neurology, UNICAMP, Campinas, SP Brazil.

Introduction: Recently, familial forms of bilaterial perisylvian polymicrogyria (BPP) have been described and a candidate locus was mapped on chromosome (ch) Xq28, distal do marker DXS8103. The objective of this study was to describe clinical characteristics and to perform linkage analysis in 3 families segregating bilateral perisylvian polymicrogyria (BPP).

Methods: We studied 3 unrelated families segregating BPP. A total of 26 individuals, including 14 patients were evaluated in this study. All family members were examined by a neurologist and subjected to high resolution volumetric MRI scans with multiplanar reconstruction. Family members were genotyped for 14 polymorphic dinucleotide repeat markers: DXS1192, DXS1227, DXS8106, DXS8084, DXS8043, DXS8028, DXS1200, DXS998, DXS8091, DXS8086, DXS8069, DXS8103, DXS1073 and DXS8087, flanking a 42.3 cM interval on ch Xq27-q28. Two-point and multipoint linkage analysis was performed using the LINKAGE package.

Results: Clinical spectrum ranged from normal to mild neurological dysfunction, mainly pseudobulbar paresis, such as poor articulation and poor tongue movements. All 14 patients had BPP confirmed by MRI, in different anatomical distributions: 9 patients had only BP, 3 had posterior parietal BPP and 2 had frontoparietal BPP. Two-point linkage analysis yield a Zmax = 3.10 at = 0.00 for DXS1227 for all 3 families combined. Multipoint and haplotype analysis pointed to a candidate interval within a 12 cM region between markers DSXS1227 and DXS8043.

Conclusions: Our results point to a different candidate region on ch Xq in familial forms of BPP. In addition, our data places the candidate interval to a 12 cM region mapped to Xq27-q28, a more centromeric location than previously reported.

Mapping of an autosomal dominant cataract (ADC) Chilean family to a novel locus. *L. Richter[1], D. Burch[1], F.R. Barría von Bischhoffshausen[2], P. Flodman[3], M.A. Spence[3], J.B. Bateman[1].* 1) Department of Ophthalmology, Rocky Mountain Lions Eye Institute, University of Colorado, Aurora, CO; 2) Departamento de Oftalmología, Universidad de Concepcíon, Concepcíon, Chile; 3) Department of Pediatrics, University of California Irvine, Orange, CA.

Purpose: To map and identify the gene for autosomal dominant cataracts (ADC) in a large Chilean family.

Methods: ADC 54 is a four generation Chilean family consisting of 31 individuals with 13 individuals affected with cataracts. Clinically, affected individuals had cataracts with variable morphology (anterior polar, cortical, embryonal, one affected individual had microcornea). SIMLINK analysis was used to estimate the power to detect linkage in ADC 54. We screened the family with a panel of polymorphic DNA markers for known ADC loci using PCR amplifications performed separately for each primer set. The products were resolved on an ABI 373/3100 AVANT using Genemapper 3.5.1 software. Two point LOD scores were calculated using LIPED.

Results: For a tightly linked marker, we estimated that the maximum LOD score achieved over 1000 simulations would be 6.51. We calculated LOD scores between the ADC 54 locus and known ADC loci on chromosomes 1, 2, 3, 10, 11, 12, 13, 15, 16, 17, 19, 20, 21 and 22 and excluded all based on lack of evidence for linkage or co-segregation.

Conclusions: Using our ADC screening panel, we excluded linkage in this family with markers known to be linked to human ADC. This excludes all known ADC loci. Therefore, ADC 54 represents a novel ADC locus. We are currently running a genome-wide screen to identify the novel locus.

The effect of linkage disequilibrium on multipoint linkage analysis. *D.F. Levinson[1], J.A. Knowles[2], J.B. Potash[3], R.R. Crowe[4], J.R. DePaulo[3], W.A. Scheftner[5], M.M. Weissman[2], P. Holmans[6].* 1) Dept Psychiatry, Univ Pennsylvania, Philadelphia, PA; 2) Columbia University and New York State Psychiatric Institute, New York, NY; 3) Johns Hopkins University, Baltimore, MD; 4) University of Iowa, Iowa City, IW; 5) Rush University Medical Center, Chicago, IL; 6) Biostatistics & Bioinformatics Unit, Wales College of Medicine, Cardiff, UK.

Marker-marker linkage disequilibrium can inflate multipoint linkage scores when parental genotypes are missing. This is an important problem to recognize and manage now that dense SNP marker sets are available. We studied this problem using both a novel simulation method and SNP data from the chromosome 15q candidate region for major depression (GenRED). Genotypes were simulated for 176 SNPs (Affymetrix chromosome 7 map, 60 Mb, 100 replicates, 116 sib-pair families) without linkage, using parental haplotypes inferred from COGA pedigrees (GAW14). Linkage was analyzed (ALLEGRO) with and without parental genotypes. Then, in depression pedigrees, linkage was analyzed using 6 microsatellites plus either 147 high-MAF SNPs (22 MB) or 115 SNPs (low-LD map, all marker-marker r-squared values <0.05). Intermarker distances were inferred from a framework map (CRIMAP). In simulated data, if parental genotypes were missing, linkage scores were inflated in regions of high marker-marker LD, or when marker-marker distances were inflated upward. In the GenRED data, a sharp peak was observed in a region of 15q with substantial LD. Using the low-LD map, the spurious peak was eliminated, while the linkage signal remained. Marker-marker LD can result in substantial inflation of linkage scores. This can be controlled by selecting markers with low pairwise LD for linkage analysis. Other approaches to correcting for LD should be tested on data with complex patterns of LD, which is often limited to or maximal between contiguous pairs of markers.

Improvement of mapping accuracy by unifying linkage and association analyses. *X.-Y. Lou[1], J.Z. Ma[1], M.C.K. Yang[2], J. Zhu[3], P.-Y. Liu[4], H.-W. Deng[4], R.C. Elston[5], M.D. Li[1].* 1) Department of Psychiatry, UT Health Science Center, San Antonio, TX; 2) Department of Statistics, U of Florida, Gainesville, FL; 3) Department of Agronomy, Zhejiang University, Hangzhou, P.R. China; 4) Osteoporosis Research Center, Creighton University, Omaha, NE; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

It is well known that pedigree/family data record information on the coexistence in founder haplotypes of alleles at nearby loci and the cotransmission from parent to offspring that reveal different, but complementary, profiles of the genetic architecture. Either conventional linkage analysis or family-based association tests (FBATs) capture only partial information, leading to inefficiency. In this article, we propose a likelihood-based approach that embeds both linkage and association analyses into a unified framework for general pedigree data. Relative to either linkage or association analysis, the proposed approach is expected to have greater estimation accuracy and power. Monte Carlo simulations support our theoretical expectations and demonstrate that our new methodology: (1) is more powerful than either FBATs or linkage analysis; and (2) can unbiasedly estimate genetic parameters regardless of whether association exists, thus remedying the bias and less precision of traditional linkage analysis in the presence of association. The new approach also holds the theoretical advantage that it can extract statistical information to the maximum extent and thereby improve mapping accuracy and power because it integrates multilocus population-based association study and pedigree-based linkage analysis into a coherent framework. Furthermore, our method is numerically stable and computationally efficient, as compared to existing parametric methods which use the simplex algorithm or Newton-type methods to maximize the high order multidimensional likelihood functions, and also offers the computation of Fisher's information matrix. Finally, we apply our methodology to a genetic study on bone mineral density (BMD) for the vitamin D receptor (VDR) gene and find that VDR is highly associated with the BMD at the one-third region of the wrist.

Evidence for genetic loci influencing intraocular pressure: A Genome Wide Scan of the Beaver Dam Eye Study.

P. Duggal[1], A.P. Klein[2, 3], K.E. Lee[4], R. Klein[4], J.E. Bailey-Wilson[1], B.E. Klein[4]. 1) Inherited Disease Res Branch, NHGRI/NIH, Baltimore, MD; 2) Dept of Oncology,Pathology,Johns Hopkins School of Medicine, Baltimore,MD; 3) Dept of Epidemiology,Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Dept of Opthalmology and Visual Sciences, Univ. of Wisconsin-Madison Medical School.

Glaucoma is a leading cause of blindness in the world, and the identification of genes that contribute to this disease is essential. Elevated intraocular pressure (IOP) is a principal risk factor for primary open-angle glaucoma (POAG), and an intriguing quantitative trait that may strongly influence disease development. We performed a non-parametric genome-wide linkage analysis of 1019 sibling pairs with quantitative measurements for IOP. The sib pairs were ascertained through a population-based cohort, the Beaver Dam Eye Study. Higher IOP measurement between the eyes was used as a continuous trait, and treatment with drops, systolic BP, sex and age were covariates adjusted prior to analysis. IOP was normally distributed and remained normal after adjustment for covariates. We performed single point and multipoint linkage analysis using the modified Haseman-Elston regression models in SIBPAL (S.A.G.E. v4.5). We used the option that allows for non-independence of sib pairs and uses a weighted combination of squared trait difference and squared mean corrected trait sum. For each marker, pvalues were obtained using the asymptotic distribution of the likelihood-ratio test statistics. We also obtained empirical p values using Monte Carlo permutations with up to 1 million replicates. The GWS identified 3 linkage regions of interest, 1 of which reached suggestive evidence for linkage according to Lander & Krugylak thresholds in GWS. This novel linkage region had empirical p values of 2 x10-4 (singlepoint) and 5.1 x 10-5 (multipoint). These 3 regions are especially interesting since all 3 have been identified as potential linkage regions in GWS of hypertension or blood pressure. The results of this GWS scan provide evidence that a QTL may influence elevated intraocular pressure and that there may be multiple loci and heterogeneity for this trait.

A Genomewide Linkage Study of Retinal Vessel Caliber in the Beaver Dam Eye Study. *C. Xing[1], B. Klein[3], R. Klein[3], G. Jun[1], K. Lee[3], S. Iyengar[1,2].* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Ophthalmology, Case Western Reserve University, Cleveland, Ohio; 3) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, Wisconsin.

Retinal vessels can be observed non-invasively and provide a window to microvascular systems elsewhere in the body. It was believed that the retinal vessels are susceptible to changes in blood pressure, and that generalized retinal arteriolar narrowing represents structural changes resulting from persistent high blood pressure. However, recent studies also support an alternative hypothesis that generalized retinal arteriolar narrowing may precede hypertension, and may be genetically determined. We performed a genome wide model-free linkage scan by Haseman-Elston regression on the central retinal artery equivalents (CRAE) and central retinal vein equivalents (CRVE) using data from the Beaver Dam Eye Study (487 families, 812 sib pairs). Prior to linkage analyses, data were adjusted for significant covariates age age2, gender, smoking status, serum high density lipoprotein cholesterol for both traits (and diastolic blood pressure for CRAE). There were 7 regions on 6 chromosomes (1p36, 6p25, 6q14, 8q21, 11p15, 13q34, 14q21) showing linkage signals for either covariate -unadjusted or -adjusted CRVE, and were 7 regions on 5 chromosomes (3q28, 5q35, 7q21, 7q32, 11q14, 11q24, 17q11) showing linkage signals for either covariate -unadjusted or -adjusted CRAE, at the nominal multipoint significance level of 0.01. The best evidence for linkage was on 8q21 at marker D8S2324 with a multipoint p-value of 5.8 x 10-4, and 3q28 at marker D3S2418 with multipoint p-value of 8.7 x 10-7 for CRVE and CRAE, respectively. CRAE and CRVE shared linkage signals at 1p36, 6p25 and 7q21. In conclusion, retinal vessel caliber for arterioles and venules is dictated by both shared as well as distinct genetic components.

A genome-wide scan of Familial Benign Recurrent Vertigo by use of a high-density single-nucleotide-polymorphism (SNP) genotyping assay: Suggestive linkage to 5p15, 15q21 and 22q12 with evidence of heterogeneity. *H. Lee[1], J.C Jen[2], H. Wang[5], C. Sabatti[1,5], R.W. Baloh[2,3], S.F. Nelson[1,4].* 1) Dept Human Genetics; 2) Dept Neurology; 3) Dept Surgery; 4) Dept Psychiatry and Biobehavioral Science, UCLA School of Medicine; 5) Dept Statistics, Univ California, Los Angeles, Los Angeles, CA.

Vertigo is a perception of movement, either of oneself or of the surround and it is caused by disturbances of the vestibular system from inner ear to brain pathways. Familial benign recurrent vertigo (BRV) is one of the most common reasons for referral to Neurotology Clinic, and many of these patients report a family history as well as an increased incidence of migrainous headaches. However, there is little understanding of the molecular basis of BRV, nor its possible molecular association with migraine, and there have been no prior systematic linkage studies in families with BRV. We present a genome-wide scan by both parametric (model-based) and non-parametric (model-free) analysis of 29 families with BRV showing strong association with co-morbid migraine. With the Affymetrix 10K SNP Mapping Assay, we could perform rapid, accurate and efficient genotyping across the whole genome at a mean intermarker distance of 210kb. Heterogeneity LOD (HLOD) score results show strong evidence of heterogeneity in the BRV population. We could exclude most of the genome as harboring a single gene causing the disease in half of the families in our sample set. Non-parametric analysis shows excess sharing among the affected members of the families. Three regions of the genome are indicated as being suggestively linked to BRV: Chromosome 22q12 by HLOD analysis (2.99), Chromosome 5p15 (2.85) and Chromosome 15q21 (1.9) by NPL. We conclude that BRV is a heterogeneous genetic disorder and that additional family and population based linkage and association studies will be needed to determine the causative alleles.

Genome-wide linkage study for rate of change in blood pressure with longitudinal data in a Nigerian population.

X. Wu[1], T. Bamidele[2], A. Adeyemo[3], A. Luke[1], G. Cao[1], D. Kan[1], X. Zhu[1], R.S. Cooper[1]. 1) Dept Preventive Med/Epidemiol, Loyola Univ, Chicago, Maywood, IL; 2) Dept Social and Preventive Medicine, University of Buffalo, Buffalo, NY; 3) Dept Pediatrics/Institute of Child Health, College of Medicine, University of Ibadan, Nigeria.

Most genome scans for blood pressure (BP) have been cross-sectional using phenotypic measurements at one time point. It is known that multiple longitudinal blood pressure measurements are more representative of a persons average or true blood pressure. In addition, rate of change in blood pressure over the study period can be estimated. Three sets of measurements of systolic blood pressure (SBP) and diastolic blood pressure (DBP) were obtained every 2 years from 1998-2002 in families recruited from a rural area in west Nigeria. Genotypic data from 1,219 individuals in 286 families were included in this analysis. Linear mixed-effects models were utilized to obtain the estimates of random effect of rate of change of SBP and DBP for each individual adjusted for gender and BMI. Genome scans were performed on these derived phenotypes. The estimates of heritability for the rate of change of SBP and DBP are 33% and 35%, respectively. The strongest linkage evidence for rate of change of SBP was found at 10p14 region (marker D10S1412, LOD = 2.36). Likewise, the strongest linkage evidence for the rate of change of DBP (marker D10S1430, LOD = 1.96) was also found in this region.

Autosomal genome scans for two clinical phenotypes (psychosis and manic episode) in multiplex Ashkenazi Jewish pedigrees with schizophrenia, schizoaffective disorder and/or bipolar disorder. *J.A. McGrath[1], V.K. Lasseter[1], M.D. Fallin[2], K.Y. Liang[3], N. Cheng[1], P.S. Wolyniec[1], D. Valle[4,5], D. Avramopoulos[1], P.L. Belmonte[2], A.E. Pulver[1,2].* 1) Department of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Epidemiology, the Johns Hopkins Bloomberg School of Public Health; 3) Department of Biostatistics, the Johns Hopkins Bloomberg School of Public Health; 4) McKusick-Nathans Institute, The Johns Hopkins School of Medicine; 5) Howard Hughes Institute, The Johns Hopkins School of Medicine.

Previously we reported significant linkage to chromosome 10q22 for schizophrenia using 29 Ashkenazi multiplex pedigrees (Fallin et al., 2003) and suggestive evidence for chromosomes 1, 3, 11, and 18 using an independent sample of 22 multiplex bipolar 1 pedigrees (Fallin et al., 2004). Given potential clinical and genetic overlap for the diseases, we have identified clinical phenomena to serve as phenotypes (psychosis and manic episodes). For our multiplex Ashkenazi Jewish families with schizophrenia, schizoaffective disorder, and bipolar disorders, sixty-one families had at least two individuals who have experienced psychotic symptoms and thirty six families had at least two individuals who were reported to have had a manic episode. Linkage analyses of 390 autosomal markers (average 9 cM density) were completed (GeneHunter V2.1). Moderate support for chromosomes 1q (NPL=2.47, p=.005) and 10q (NPL=2.29, p=.01) were obtained for psychosis. For mania, we report moderate support for chromosome 11 (NPL=2.05, p=.02). Given the symptom/syndrome overlap between schizophrenia, schizoaffective disorder and bipolar disorders, evidence that these disorders may co-segregate in families and presumed genetic heterogeneity in both schizophrenia and bipolar 1 disorder, we conducted exploratory analyses using two phenotypes based on consensus ratings of symptom-level data (manic episodes and psychosis) in an Ashkenazi Jewish sample. These analyses may help in prioritizing for further study chromosomal regions related to syndromes that transcend current disorder classifications.

Cleft lip genome scan reveals major loci, heterogeneity and genetic interactions. *L. Moreno[1], M. Arcos-B.[2], B.S. Maher[3], T. Goldstein McHenry[3], M.E. Cooper[3], C. Valencia-R.[4], K. Krahn[1], A. Hing[5], M. Moreno[1], H. Mishima[1], E.M. Lammer[6], M. Jones[7], N.H. Robin[8], M.L. Marazita[3], A.C. Lidral[1].* 1) University of Iowa, Iowa City, IA; 2) NIH, Bethesda, MD; 3) University of Pittsburgh, Pittsburgh, PA; 4) University of Antioquia, Medellín, Colombia; 5) University of Washington, Seattle, WA; 6) Children's Hospital Oakland Research Institute, Oakland, CA; 7) Children's Hospital, San Diego, CA; 8) University of Alabama, Birmingham, AL.

Nonsyndromic cleft lip and palate (NSCL/P) is a common birth defect with complex etiology. The purpose of this study is to identify regions containing susceptibility genes for (NSCL/P). A 10 cM genome scan was performed on 48 multiplex families from Colombia-SA and 9 multiplex families from Ohio, USA using genotypes generated by the Center for Inherited Disease Research (CIDR). Parametric, nonparametric and association analyses were performed. Also, conditional and covariate-based linkage methods were used to screen the Colombian families for genetic interactions and heterogeneity using both candidate gene and genome scan data. The Colombian families showed suggestive linkage at 3q26-q28, 9q22-q33, 14q24-q31, 15q11-q13.3 and 19q13 with the most significant findings at 9q22-q33 (Maximum LOD score (MLS)=2.94) and 3q27 (MLS=2.99). The addition of SNPs within 9q22-q33 candidate genes on 72 families revealed the most significant multi-point linkage at TGFBR1 (HLOD= 2.24). Suggestive linkage for the Ohio families was observed at loci in 3p14-p23, 9q22-q33, 12q24, 14q11-q22, 17q11-q21, 18q12 and significant linkage was observed at 1p22-p33 (MLS=3.52). Interactions were observed in the Colombian families between candidate gene markers in 9q22-q33 and 1p36.3 ($p = 0.00011$), 8q24.1 ($p= 0.000076$), and 11q22 ($p = 0.00011$). Furthermore, genetic heterogeneity was suggested since a subset of families showed linkage to 2q24.1-q32.1 and not 9q22-q33. In conclusion we have identified a major locus for NSCL/P at 9q22-q33 that may be modified by genes at other loci and another locus for CL/P maps to 2q24.1-q32.1. Supported by NIH P50-DE016215, NIH/NIDCR RO1DE14677, KO2DEO15291 and MOD Grant #6FY01-616.

A novel X-linked locus for retinitis pigmentosa. *Z. Tong, Z. Yang, Y. Zhao, L. Xue, J. Barid, A. McGinnis, Y. Chen, E. Pearson, K. Zhang.* Department of Ophthalmology and Visual Science, Program in Human Molecular Biologoy and Genetics, Eccles Institute of Human Genetics, University of Utah, Salt lake city, UT. 84112.

PURPOSE: Retinitis pigmentosa (RP) is a heterogeneous group of inherited diseases which cause the progressive loss of night and peripheral vision. It affects over 1.5 million people worldwide. Linkage analyses indicate that there are at least five X-linked RP genes. We investigated a large Utah pedigree spanning 6 generations with 191 individuals with X-linked RP. METHODS: Peripheral blood was taken from fifty-three members, including 13 affected males and 15 carriers. Participants underwent ophthalmologic examination. Genotyping to X-linked RP loci (RP2, RP3, RP6, RP23 and RP24) were performed, and mutation screening of RP2 and RPGR was performed by PCR and direct DNA sequencing. RESULTS: Age of onset ranges from 5-8 years, visual acuity ranges from 20/25 in children to light perception in older adults. Linkage analysis and direct sequencing showed that no known loci/genes were associated with the phenotype in this kindred. CONCLUSION: Our results excluded all known X-linked loci for RP, and suggested a novel disease gene associated with X-linked RP. Linkage mapping is in progress. Identification of a new gene for X-linked RP will increase our understanding of RP and provide new therapeutic avenues.

Back to genetics: increasing the power of tiny families for linkage analysis using haploid cell lines from an ALS family. *K.A. Dick[1, 2], J.C. Dalton[1, 2], M.B. Miller[3], J.W. Day[2, 4], L.P.W. Ranum[1, 2].* 1) Dept of Genet Cell Biol & Devel; 2) Inst of Hum Genet; 3) Dept of Epid & Comm Health; 4) Dept of Neurol, University of Minnesota, Minneapolis, MN.

The requirement of collecting families with many affected individuals is a major impediment to mapping novel disease genes. Identifying novel ALS genes is particularly problematic because the rapidly fatal disease course limits the ability to collect affected individuals. Over 16 yrs, we collected 12 ALS family members including 5 affected with a dominant, typical, adult-onset form of the disease. Based on family relationships only ~3% of the genome should be shared among the affected individuals, however, LOD score analysis is not effective in predicting these shared regions. To overcome these power limitations, we developed a novel mapping approach using haploid cell lines. Panels of haploid cell lines were generated for 8 individuals and an 800 marker genome scan performed on DNA from the haploid cells and diploid lymphocyte DNA. The chromosome separated cell lines enabled haplotypes to be directly defined along entire chromosomes, allowing common regions transmitted from a founder in generation I to be determined. Haploid mapping identified 8 regions (3.9% of the genome) shared among the 5 affected individuals and definitively excluded 87.7% of the genome as unshared. LOD score analyses excluded only 67.8% or 63.0% (LOD<-2 for FASTLINK and MERLIN, respectively), failed to identify any shared regions (LOD>3), and generated suggestive scores (most between 0.5-1.2) for areas that were both shared and definitively excluded by haploid analysis. These results enabled us to exclude previously reported ALS loci and coarsely map this novel gene to one of 8 regions spanning a total of ~117cM. The mapping and identification of additional disease genes will lead to a better understanding of gene function and disease mechanisms. Our haploid method will enable genetic investigations of a whole class of families with Mendelian disorders too small for classic linkage studies. In addition, haploid mapping provides a novel and independent approach to characterize and compare traditional linkage strategies.

Inclusion of a Propensity Score as a Single Covariate in a Genome Wide Mega-Linkage Analysis Identifies New Significant Regions on 5p, 9p, 20p for Ulcerative Colitis and on 19q for Crohns Disease. *B.Q. Doan[1,2], C.E. Frangakis[3], J.E. Bailey-Wilson[2], R.H. Duerr[4], J.D. Rioux[4], M.S. Silverberg[4], H. Yang[4], S.R. Brant[4], P. Schumm[4], J.H. Cho[4], Y.Y. Shugart[1].* 1) Epidemiology, JHSPH, Baltimore, MD; 2) IDRB, NHGRI/NIH, Baltimore, MD; 3) Biostatistics, JHBSPH, Baltimore, MD; 4) NIDDK IBD Genetics Consortium.

A genome wide (GW) covariate-based linkage analysis was performed on a dataset (993 affected relative pairs) of five published scans for inflammatory bowel disease (IBD). Age at diagnosis, gender, and smoking status at diagnosis were included as covariates as they are known risk factors for disease onset. However, each covariate analyzed requires an additional parameter to be estimated in the linkage test which can reduce power or increase the type I error rate. A propensity score (PS) defined as the predicted conditional probability of being affected given the observed covariate data was considered to collapse multiple covariates into one, and was used to distinguish linked and unlinked subgroups where those with high scores can be interpreted as being less genetic. With no covariate data on unaffected individuals, the conventional PS values could not be computed. However, since IBD consists of two distinct subtypes, Crohns disease (CD) and ulcerative colitis (UC), a subtype-specific PS (predicted probability of having a specific subtype of IBD given the observed covariate data) was instead considered. Significance was determined by permutation-based p-values. With no covariates analyzed, the IBD3 locus on 6p yielded the greatest evidence of linkage ($p<0.005$) for IBD and CD, while the 2p locus was the most significant peak for UC ($p<0.005$). Incorporating smoking status increased power to detect the 5q locus for IBD, and using a PS based on age at diagnosis and gender identified new significant loci on 19q for CD, as well as 5p, 9p, and 20p for UC. These results suggest that covariates, such as a subtype-specific propensity score, can potentially increase power to detect linkage for a complex disease such as IBD, especially when multiple important covariates can be modeled to minimize heterogeneity within the pooled datasets.

A linkage analysis test statistic which models relationship uncertainty. *A. Ray[1], D.E. Weeks[1,2].* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA.

Linkage analysis methods assume that the stated familial relationships are correct. However, misspecified relationships can lead to reduced power for linkage. Possible solutions are to discard the erroneous data or to use the most likely alternative pedigree structures or to statistically model the uncertainty by weighting over the possibilities. Consider the situation where we have collected affected relative pair (ARP) data and carried out a genome-wide scan for linkage. In such a situation, we have two sources of information about relationships, the stated apparent relationship and the genome-wide marker data. Our method is an extension of the affected relative pair LOD score analysis approach of Cordell et al. (2000). In our extension, we statistically model any relationship uncertainty via weights, the weights being the conditional probability of a true relationship type given the apparent one and the genome-wide marker data. For an ARP with an apparent relationship, we consider several possible true relationship types. The estimates of the weights can be used to fit a likelihood model to the IBD sharing among ARPs. To assess our method and to compare it to the maximum likelihood statistic of Cordell et al. and a nonparametric linkage statistic from MERLIN, we are performing a simulation study. Each simulated dataset consists of 300 pedigrees with 660 affected apparently full sib pairs having several underlying true relationship types with marker data having 367 markers and a disease locus on chromosome 10 with a dominant reduced penetrance mode of inheritance. For each simulation, we also construct both the true relationship structure and the pedigree after discarding the individuals with erroneous relationships and obtain the MLS of our method, the MLS of Cordell et al. and the NPL statistic from MERLIN at each position in the genome. Preliminary results indicate our method perfoms well: Based on 1,650 replicates using genome-wide empirical 0.01 significance thresholds, power at 25 cM and 20 cM from the disease locus is: 0.90, 0.94 (our method); 0.93, 0.95 (MERLIN, true structure) and 0.86, 0.91 (MERLIN, discarded structure).

Fine mapping of a region linked to low high-density lipoprotein cholesterol on chromosome 16q23-24. *J. Lee[1], E. Suviolahti[1,3], A. Jokiaho[1], A. Huertas-Vazquez[1], R.M. Cantor[1], E. Sobel[1], R. Mar[1], T.W.A. de Bruin[4], A.J. Lusis[1], M.-R. Taskinen[2], P. Pajukanta[1].* 1) Dept of Human Genetics, David Geffen School of Medicine at UCLA; 2) Dept of Medicine, Helsinki University Central Hospital, Finland; 3) Dept of Molecular Medicine, National Public Health Institute, Finland; 4) Dept of Internal Medicine, Maastricht University, Netherlands.

Low level of plasma high-density lipoprotein cholesterol (HDL-C) is a major risk factor for coronary heart disease and a component trait of familial combined hyperlipidemia (FCHL). Linkage of the low HDL-C trait to the 16q23-24 region has previously been observed in the combined analysis of Finnish and Dutch FCHL families and in Mexican American families. We used a two-step strategy to fine map a 12.4-Mb region with LOD scores within 1.0 of the top LOD scores in the combined Dutch/Finnish and Mexican American linkage analyses. First, a dense set of SNPs are tested for association in the Finnish and Dutch families. Second, SNPs with preliminary association signals are confirmed in an independent Caucasian case-control study sample. To ensure selection of the most informative and non-redundant SNPs, we selected tagSNPs utilizing the HapMap data and the LD Select program. A total of 1411 SNPs comprised of 1348 tagSNPs with MAF 0.1, representing a SNP density of 5 kb, and 63 nonsynonymous SNPs were genotyped in Finnish and Dutch families. These SNPs were analyzed for association given linkage using the FBAT program. In the first step, analysis of the Finnish families identified two genes, spaced ~10 Mb apart, with clusters of several associated, non-redundant SNPs per gene with P-values of 0.0005-0.01. When analyzing the Dutch and Finnish families together, only one of these two genes exhibited further support for association. Currently, we are testing the associated SNPs in an independent Caucasian low HDL-C case-control study sample to reduce false positive results and confirm the association. To conclude, in our preliminary analysis of 1411 SNPs for the 12.4-Mb region on 16q23-24, two genes show evidence for association with low HDL-C, and efforts to confirm the associated gene(s) are underway in case-control samples.

Genome scan of age of onset of Alzheimers disease: Preliminary findings in Caribbean Hispanic families. *I. Chacon[1], H.S. Lee[1], V. Santana[1], J. Williamson[1], R. Lantigua[2], M. Medrano[2], E. Rogaeva[2], P. St George-Hyslop[3], R. Mayeux[1], J. Lee[1].* 1) Taub Inst & Sergievsky Ctr, New York, NY; 2) Univ Tecnologica de Santiago, Santiago, Dominican Republic; 3) Center for Research in Neurodegenerative diseases, Univ of Toronto, Toronto, Canada.

Alzheimer disease (AD) is the most common form of dementia and its risk increases with age. To date, three known AD genes, namely APP, PS1 and PS2, are found primarily in early onset of AD. In late onset AD, apolipoprotein E (APOE) has shown that genes can influence age at onset (AAO), and there likely to be other genes with similar function. Thus, AAO phenotype may enhance power to detect AD susceptibility genes by allowing us to look for genes that increase AD risk by lowering AAO. To localize genes related to AAO of AD in Caribbean Hispanic families, we conducted a genome scan on 1062 family members from 210 Caribbean Hispanic families with at least two affected individuals and recruited through AD probands. We genotyped 430 microsatellite markers across the genome with an average distance of 10 cM. To perform linkage analysis on AAO as a quantitative trait, we used the variance component approach as implemented in SOLAR. AAO was computed two ways. First, we used AAO if affected and age of last examination if unaffected, while adjusting for AD status, sex, education and APOE genotype. Second, we used the residual from a Cox regression model after adjusting for sex, education, and APOE. Our linkage analysis under the first definition revealed that 1q32-q41, 5q-ter, 6p11.2, 11q22, 12q24.1-.2, 17p12-17q11.1 and 21q21-22 were significant. When we used the second definition of AAO, the LOD scores decreased somewhat but the linkage remained significant for 5q-ter, 6p11.2 and 21q21-22. We did not observe linkage on 10q that was previously reported by us and others for both AD as well as onset phenotypes. However, we did observe linkage in regions (e.g., 12q24.1 and 17p12-17q11.1) previously reported by others using Caucasian samples. Our results show that AAO can be an important phenotype to search for AD susceptibility genes; however, further investigations are needed to confirm linkage to these locations.

First evidence that one or more rare genetic polymorphisms with high penetrance may be involved in the etiology of endometriosis. *K.T. Zondervan[1], J. Lin[2], G. Dawson[3], D. Zabaneh[3], V. Smith[3], S.T. Bennett[3], A. Lambert[2], A. Carey[3], D.E. Weeks[4], S.A. Treloar[5], G.W. Montgomery[5], D.R. Nyholt[5], N.G. Martin[5], L.R. Cardon[1], I.J. Mackay[3], J. Mangion[3], S.H. Kennedy[2].* 1) Wellcome Trust Cntr Human Genet, Univ Oxford, UK; 2) Nuffield Dept Obstet Gynaecol, Univ Oxford, UK; 3) Oxagen Ltd, Abingdon, United Kingdom; 4) Dept Human Genet, Univ Pittsburgh, USA; 5) Queensland Institute of Medical Research, Brisbane, Australia.

Endometriosis (endometrial-like deposits outside the uterus) is a common complex disease associated with pelvic pain and subfertility in women. Its etiology is unknown, but familial aggregation has been shown in humans and non-human primates. For a genome-wide linkage study in Oxford (UK), 256 Caucasian families with 2+ sister-pairs with endometriosis were recruited; 52 families contained 3 or more affecteds. Non-parametric genome-wide linkage analyses in the 52 families were conducted, using sex-specific information from the Rutgers map. Parametric maximum LOD (MOD) scores were found by iterating across different inheritance models. Results were compared with those in a replication sample of 196 Caucasian families from Australia. Six non-parametric LOD score peaks with K&C LODs 1 were found. One of the peaks, on chromosome 7, reached a LOD of 3.49 (genome-wide p-value: 0.007). Parametric analyses showed MOD scores at 58.4 cM for 3 models: 1) allele frequency = 0.002 (MOD= 3.66); 2) 0.005 (MOD = 3.73), and 3) 0.07 (MOD = 3.91); penetrances 0.4-0.6; proportion of linked families : 0.87-0.97. In the Australian sample, the 3 models showed peak heterogeneity LODs (HLODs) at 46.0 cM of 1.02, 0.83 and 0.61 (: 0.17-0.23). The combined UK-Aus analysis showed 1 peak at 53.3 cM, with max HLODs of 2.51, 2.43, and 1.91. Further phenotypic analyses showed significant associations between the posterior probability of linkage for individual families and the severity of disease, likely to account (in part) for the different magnitude of results between the two samples. The results suggest that one or more rare genetic polymorphisms on chromosome 7 with moderate to high penetrance are involved in the aetiology of a subgroup of women with endometriosis.

A gene-centric approach to fine-mapping a type 2 diabetes gene on chromosome 10q23-26. *T.M. Frayling[1], S. Heath[2], J.G. Garnier[2], M. Foglio[2], D. Lechner[2], C.J. Groves[3], S. Wiltshire[3], M.N. Weedon[1], G. Hitman[4], M. Walker[5], M.I. McCarthy[3], M. Lathrop[2], A.T. Hattersley[1], I.G. Gut[2].* 1) Peninsula Medical School, University of Exeter, United Kingdom; 2) Centre National de Genotypage, Evry, France; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK; 4) Queen Mary School of Medicine and Dentistry, University of London, UK; 5) School of Medicine, Newcastle upon-Tyne, UK.

There is strong evidence that a type 2 diabetes gene exists on chromosome 10q23-26. The region is one of the thirteen highest regions in a combined analysis of twelve type 2 diabetes genome scans. The region has the second highest LOD score (1.99) in the UK-based Warren2 genome scan of 573 affected sibships. The evidence for linkage is disproportionately provided by the subset of 245 sibships diagnosed 55 years (LOD = 3.07, p = 0.02 for increase vs. 573). The type 2 diabetes gene on 10q has not been found. We selected SNPs in genes from the 24MB region designated by the flanking microsatellites of the region of linkage (LOD >0.59). We genotyped a panel of 1536 non-redundant hapmap single nucleotide polymorphisms (SNPs) in 420 unrelated UK controls and 437 unrelated cases using the illumina bead-station. Cases were selected from sibships with the best evidence for linkage. We assessed how well successful SNPs captured common variation across the region by calculating pairwise r^2 values between genotyped SNPs and non-genotyped phase1 hapmap SNPs. We excluded SNPs with less than 80% calls and those with significant deviations from Hardy-Weinberg equilibrium in controls after Bonferroni correction. The resulting 1378 SNPs captured 57%; and 76%; of all Phase1 hapmap SNPs in the region at r^2 0.8 and r^2 0.5 respectively. Allelic tests identified 58 nominally significant SNPs (p 0.05). Thirty of these SNPs had higher odds ratios using the 206 cases from families diagnosed before age 55 compared to the 231 cases from the families diagnosed after 55. These thirty SNPs occurred in twelve genes, three of which, TLL2, KCMA1 and COX15 are expressed in the islets of langerhans. Further analyses are needed to more fully examine these and other genes in the region.

Genetic studies of stuttering in a founder population. *J.K. Wittke-Thompson[1], N. Ambrose[2], E. Yairi[2], C. Roe[1], C. Ober[1], N.J. Cox[1, 3].* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Department of Speech and Hearing Science, University of Illinois Urbana-Champaign, Champaign, IL; 3) Department of Medicine, The University of Chicago, Chicago, IL.

We conducted genome-wide linkage and association analyses to identify genetic determinants of stuttering in a founder population, in which 48 individuals affected with stuttering are connected in a single 232-person genealogy. A novel approach was devised to account for all relationships within four smaller sub-pedigrees from this genealogy, because the size of the pedigree including all affected individuals would have been prohibitively large for multipoint linkage analyses to be conducted. Regions on chromosomes 1, 3, 5, 9, 13, and 15 had evidence of linkage to stuttering, with the three strongest linkage signals on chromosome 3 (P = 0.013, 208.8 cM), chromosome 13 (P = 0.012, 52.6 cM), and chromosome 15 (P = 0.02, 100 cM). The three regions with the strongest evidence for association with stuttering that overlapped with a linkage signal are located on chromosome 3 (P = 0.0047, 195 cM), chromosome 9 (P = 0.0067, 46.5 cM), and chromosome 13 (P = 0.0055, 52.6 cM). In order to locate regions showing evidence for linkage across studies, we conducted the first meta-analysis for stuttering and identified regions on chromosomes 2, 3, 5, 7, 9, 13, and 15 with evidence for linkage in both the Hutterites and The Illinois International Genetics of Stuttering Project. The two regions showing the strongest evidence for linkage in the meta-analysis were on chromosome 5 (P = 0.0051, 105-120 cM; P = 0.015, 120-135 cM) and chromosome 2 (P = 0.013, 180-195 cM). The current findings identify several new regions with evidence for susceptibility to stuttering, as well as replicate results from previous studies concerning stuttering or language disorders, including a region on chromosome 13 that was previously implicated in Specific Language Impairment.

Incorporating length of peak in test statistics for disease gene mapping. *B.P.C. Koeleman[1], F. Dudbridge[2].* 1) Dept Medical Genetics, UMCU, Utrecht, Netherlands; 2) MRC Biostatistics Unit, Cambridge, UK.

Genome wide scans are frequently used to locate disease gene regions, either by family based linkage analysis, or, more recently, by case-control association. The result of such analyses is a number of regions containing peaks of increased statistics. Particularly in the context of complex genetic disorders, for which more than one susceptibility gene is expected, the question arises of which of the multiple peaks represent true signals and which are false. A promising argument was presented by Terwilliger et al (Am J Hum Genet 61:430-8), who used renewal theory and simulations to show that length of a true peak is expected to be longer than that of a false peak of similar magnitude. Subsequently, Visscher and Haley (Genet Epidemiol 20:409-14) argued that this increased length is not a property of disease risk and that there is no additional information in the length of a peak to distinguish loci with true effects from those with no effect. However their results do not contradict the original argument. Also, a simulation study exploring power to detect true disease regions with statistics that incorporate length of peak has not been performed. Here we perform such a simulation study. For linkage analysis we used the area under the multipoint linkage curve. We explored different scales of the length and height dimensions. For association analysis, a similar area was calculated using the distance between markers showing significant association and a function of the association p-value. A peak was defined as all markers showing significance at the nominal level around the most associated marker of a screen, and allowance was made for gaps of one non significant marker. Our results show that incorporating length of peak into the test statistic can result in significantly improved power to detect a true disease locus. Power of area statistics seemed to converge to that of height statistics at around 80%, which may be improved by using different scalings of the length. While most studies remain underpowered to detect the low risk susceptibility genes that are expected to underlie complex disorders, length of peak statistics may prove very valuable.

Analysis of 5319 SNPs covering regions of linkage to autism on chromosomes 5 and 17. *J. Stone[1], B. Merriman[1], D.H. Geschwind[2,4], S. Nelson[1,3].* 1) Dept Human Genetics; 2) Program in Neurogenetics, Dept of Neurology; 3) Dept of Psychiatry and Biobehavioral Sciences; 4) Center for Autism Research, Neuropsychiatric Institute, University of California-Los Angeles, Los Angeles.

Autism is a complex disorder identified by impaired language and social skills, restricted repetitive behaviors, and an early childhood onset. Previously, our group has identified a region of linkage to chromosome 5 (MLS 2.54, Yonan et al. 2003) and a region of male-specific linkage to chromosome 17 (MLS 4.3, Stone et al. 2004) using multiplex families collected by the Autism Genetic Resource Exchange (AGRE). We have fine-mapped these two regions with high density SNPs - 3366 SNPs on chromosome 5 and 1953 SNPs on chromosomes 17 - in 227 trios from the AGRE resource. A total of 17.2 MB and 13.5 MB of non-repetitive sequence are analyzed on chromosomes 5 and 17, respectively. Cumulatively over both regions, 204 known or proposed genes along with the intergenic spaces were included in this study. SNPs on chromosome 5 were individually analyzed for association with transmission disequilibrium test (TDT) followed by haplotype block analysis using all 227 families. The analysis of chromosome 17 was restricted to the 140 trios with only male affected children, as these are primarily responsible for the linkage signal. SNP and haplotype analysis on chromosome 5 has provided evidence for association to 20 regions/haplotype blocks, 8 of which are located in known genes, at an uncorrected p-value < 0.01. Analysis of transmission bias on chromosome 17 has resulted in evidence for association at an uncorrected p-value < 0.01 for 11 regions/haplotypes. These regions include 5 known genes and 5 unconfirmed genes with no available functional information from public databases. Here we present the results from a first stage, high density screen for association under two regions of linkage to autism. The nominal associations detected here are being tested in a replication sample to eliminate expected false positives inherent in a high density SNP screen.

Linkage scans for HDL-C, Triglycerides and Apolipoprotein AI in three populations and comparison with the NHLBI GeneLink meta-analyses. *K.L.E. Klos[1], S.L.R. Kardia[2], S.T. Turner[3], C. Hanis[1], L.A. Cupples[4], S.C. Hunt[5], M.C. Mahaney[6], S.R. Patel[7], M.A. Province[8], T. Rice[8], G.S. Berenson[9], E. Boerwinkle[1].* 1) Dept Human Genetics, Univ Texas, Houston, TX; 2) University of Michigan, Ann Arbor, MI; 3) Mayo Clinic, Rochester, MN; 4) Boston University, Boston, MA; 5) University of Utah, Salt Lake City, UT; 6) Southwest Foundation for Biomedical Research, San Antonio, TX; 7) Brigham and Women's Hospital, Boston, MA; 8) Washington University School of Medicine, Saint Louis, MO; 9) Tulane School of Public Health and Tropical Medicine, New Orleans, LA.

We used linkage analysis to identify regions of the genome with evidence of quantitative trait loci that influence variation in plasma levels of Apolipoproteins AI (ApoAI), High-Density Lipoprotein-Cholesterol (HDL-C) and Triglycerides (TG) in sibships of the Genetic Epidemiology Network of Arteriopathy (GENOA) study. The strongest evidence of linkage was LOD = 3.68 on chromosome (chr) 18 for plasma ApoAI level in African-Americans. LOD scores greater than 2.0 were also observed on chr 3 for HDL-C (LOD = 2.12) and chr 4 for lnTG (LOD = 2.42) in European-Americans; and on chr 11 for HDL-C (LOD = 2.28) in Mexican-Americans. The chr 11 HDL-C peak in Mexican-Americans is supported by an overlapping HDL-C LOD peak of 1.31 at 21 cM on chr 11 in the NHLBI Family Heart Study. Statistically significant evidence of linkage for TG levels (LOD = 3.55 at 45 cM on chr 20) in Caucasians of the Framingham Heart Study overlaps with suggestive evidence (LOD = 1.93 at 42 cM) in GENOA African-Americans. An HDL-C peak on chr 16 (LOD = 4.35 at 102 cM) in the San Antonio Family Heart Study (SAFHS) was not replicated in GENOA. However, in a second GENOA analysis ApoAI and TG level was incorporated into the HDL-C adjustment to approximate the SAFHS adjustment, resulting in a LOD = 3.16 at 95 cM in African-Americans. We compare these results with the GeneLink meta-analysis (https://genelink.nhlbi.nih.gov/index.jsp).

Genetic linkage analysis of osteoarthritis at multiple joint sites in Dutch sibpairs. *J.L. Min[1], I. Meulenbelt[1], N. Riyazi[2], M. Kloppenburg[2], J.J. Houwing-Duistermaat[3], A.B. Seymour[4], N. Lakenberg[1], C.M. van Duijn[5], P.E. Slagboom[1].* 1) Molecular Epidemiology, Leiden University Medical Centre, The Netherlands; 2) Rheumatology, LUMC, The Netherlands; 3) Medical Statistics, LUMC, The Netherlands; 4) Pfizer Global Research and Development, Groton, USA; 5) Epidemiology & Biostatistics, Erasmus Medical Centre, The Netherlands.

Osteoarthritis (OA) is a common late-onset joint disease and is an important cause of pain and disability in the general population. Previous studies have suggested a strong genetic component to multiple definitions of OA, which appears to be transmitted as a complex and multifactorial trait. Association studies and genome wide scans in OA-affected subjects have revealed multiple positive linkage areas and susceptibility loci. In our studies, consisting of OA-affected sibpairs (the GARP study) and a population-based cohort (the Rotterdam study), associations were found with variants within the *FRZB* and the *MATN3* gene with different OA phenotypes. In these studies, we focus on the localisation and identification of susceptibility loci for OA at multiple joint sites, which systemic phenotype thus far received little attention. We have performed a genomewide scan in 191 sibpairs from the GARP study and in 79 sibpairs from the Rotterdam study. The GARP study consists of Caucasian sibpairs of Dutch ancestry with predominantly symptomatic familial OA at multiple joint sites. The sibpairs from the Rotterdam study consist of Dutch probands and their siblings with radiographic OA at multiple sites (heritability 0.78, Bijkerk et al. 1999). Previously, we have shown association of the *FRZB* locus in the GARP study corresponding to an odds ratio of 1.6 (95% CI, 1.1-2.3). Furthermore, we observed associations of the *MATN3* locus corresponding to an odds ratio of 2.9 (95% CI, 1.2-7.3) for spinal OA in the Rotterdam study and 2.0 (95% CI, 1.3-3.1) for CMC1 OA in the GARP study. Since these loci do not explain the genetic component, a complete genome scan using the Human Linkage Set v2.5 MD10 (Applied Biosystems), containing 399 microsatellite markers with an average spacing of 10cM was recently finished. Results of the linkage analysis will be presented.

A novel bayesian approach to localising disease genes. *J. Marchini, S. Myers, G. McVean, P. Donnelly.* Mathematical Genetics Group, Department of Statistics, Oxford University, Oxford, UK.

Many association studies will not actually type the disease locus. Instead, they will rely on linkage disequilibrium between the true but untyped disease locus and the markers which are typed in the study. There has been considerable discussion about whether to test each SNP separately, or to use haplotype information, and if so, in which ways. In effect, haplotype-based tests aim to capture the variation at SNPs not typed in the study. Here we describe a different approach to the problem. We use local haplotype information to impute genotypes at loci not explicitly typed in the study, and then base inference on these inferred genotypes. The imputation relies on a new "hidden SNP simulator", which uses a computationally convenient approximation to the coalescent. Conditional on the imputed genotypes, we fit a disease model using Bayesian logistic regression. With dense SNP data around a mapped locus, our method can be used for fine mapping and seems to outperform existing coalescent-based approaches. Perhaps more importantly, because it avoids reconstructing coalescent trees, it is very much faster (by about two orders of magnitude compared to the best coalescent method), and so applicable to much larger data sets. But the next generation of genome-wide association studies, for example those based on the HapMap, will give dense genotype information across much or all of the genome. In this setting, which motivated our approach, localisation is essentially the same as traditional fine-mapping, and our new approach provides a novel and efficient route to the detection of disease susceptibility loci.

Fine-mapping reveals two SNPs associated with multiple sclerosis in an Australian sample of 359 case-relative trios. *J. Stankovich[1], R.B. Tan[1], M. Bahlo[1], J.P. Rubio[2], S.J. Huxtable[1], C. Cox[3], H. Butzkueven[2], I. van der Mei[4], T.J. Kilpatrick[2], T.P. Speed[1], S.J. Foote[1,4].* 1) Walter and Eliza Hall Institute of Medical Research, Parkville, Victoria, Australia; 2) Howard Florey Institute, University of Melbourne, Victoria, Australia; 3) GlaxoSmithKline, Harlow, United Kingdom; 4) Menzies Research Institute, University of Tasmania, Australia.

In a previous genome-wide scan of Tasmanian multiple sclerosis (MS) cases and controls, we identified haplotypes associated with multiple sclerosis on chromosomes 6q and 10q. After genotyping with additional microsatellite markers, the associations were replicated and the regions of association were narrowed. The two regions, of lengths 3.7 Mb and 1.3 Mb, have now been fine-mapped with 630 SNPs and 222 SNPs respectively. 63 case-parent trios from the original Tasmanian sample were genotyped, plus an additional 198 case-parent trios and 98 case-parent-sibling trios from the neighbouring Australian state of Victoria.

The SNP with the strongest association signal was at the distal end of the 1.3Mb region (nominal p=0.0004, corrected p=0.06 after permutation testing). This SNP tags a five-SNP haplotype that was slightly more strongly associated (p=0.0003). A SNP at the proximal end of the 1.3Mb region also displayed a strong association (p=0.0005). These two SNPs are currently being genotyped in a further 681 Victorian MS cases and 738 unrelated controls.

480 of the 852 SNPs we genotyped in the two regions were also genotyped in Phase I of the International HapMap project. For these 480 SNPs patterns of linkage disequilibrium in the 30 Caucasian HapMap trios were compared with patterns of LD in 30 Tasmanian and 30 Victorian case-parent trios. LD patterns are very similar in the Tasmanian and Victorian samples; LD patterns in the HapMap trios differ much more markedly.

Resequencing & fine map association study of G72/G30 region in bipolar disorder. *M. Maheshwari[1], L. Chunyu[2], J.A. Badner[2], C.K. Smith[1], S.L. Chrisitian[2], H. Zou[2], S.D. Detera-Wadleigh[3], T. Bonner[4], F.J. McMahon[3], E.S. Gershon[2], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston,TX; 2) Department of Psychiatry, University of Chicago, Chicago IL; 3) MAP Genetics, Mood & Anxiety Disorders Program, National Institutes of Health,Bethesda,MD; 4) Laboratory of Genetics, National Institutes of Mental Health, Bethesda, MD.

Earlier we reported association between G72/G30 gene locus on 13q33 and bipolar illness (Hattori et al., Am J Hum Genet 72, 1131-1140, 2003). In this study, we resequenced the entire 50 kb region of G72/30 genes in 11 affected individuals of bipolar families. 50 kb of genomic region was resequenced using big dye terminator sequencing chemistry and analyzed using Sequencher software. We discovered 106 SNPs in this region. Of these, SNPs in and around exons, within conservative genomic regions or previous association signals were selected for further genotying. Genotyping was done in two large pedigree sets- the Intramural NIMH Clinical Neurogenetics Branch (CNG) & the NIMH Genetics Initiative (NIMH) pedigrees. 34 SNPs in CNG series and 27 SNPs in NIMH series were genotyped. Genotyping was done using SNPlex and/or TaqMan assays. Genotype data was tested for significance of association using ASPEX/Sib_tdt and EATDT analyses. Several SNPs were significant in CNG data set by TDT as compared to 1 SNP in NIMH dataset which did not overlap with CNG data set suggesting different variant alleles may account for two population sets. The EATDT analysis in the CNG series had one SNP that was significant by permutation, and several SNPs and haplotypes that were nominally significant. In the NIMH series, nothing was significant by permutation although several haplotypes were nominally significant. Conclusions: Significant association signals with additional SNPs confirm the presence of a susceptibility variant for bipolar disorder in the vicinity of the G72/G30 genes.

Trivariate linkage analysis in SOLAR. *D. Warren[1], J.M. Soria[2], A. Buil[2], J.C. Souto[2], J. Fontcuberta[2], J. Blangero[1], L. Almasy[1].* 1) Genetics, SFBR, San Antonio, TX; 2) Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Multivariate linkage analyses allow simultaneous examination of linkage for multiple traits. Whereas this approach is often used to investigate pleiotropy, multivariate linkage screens may also improve power relative to univariate screens. Recent extensions of SOLAR's maximum-likelihood, variance components based linkage analysis routines permit three or more quantitative traits in models. Here, we use data from 396 individuals in 21 Spanish families enrolled in the GAIT study to illustrate the potential of trivariate linkage screens. We used genome-wide uni-, bi-, and trivariate linkage screens using 485 microsatellite markers spaced at 7.1 cM to localize quantitative trait loci (QTLs) influencing variation in clotting factor X (FX), a vitamin K-dependent protein involved in blood coagulation. Additional measured covariates included age, sex, and exogenous hormone use. All LODs were corrected to a standard equivalent to 1 degree of freedom. In the univariate screen, a maximum multipoint LOD of 1.25 occurred on chromosome 2q. A bivariate linkage screen was then conducted using FX and another vitamin K-dependent protein, clotting factor VII (FVII). FVII had marginal genetic (0.31, $p = 0.06$) but significant environmental (0.69, $p < 0.01$) correlations with FX. This yielded a maximum multipoint LOD of 4.14 near marker D13S285 on chromosome 13q, in the region of the FX structural gene. A third hemostasis-related phenotype, functional protein S (PS), was then added to the linkage model. PS is also vitamin K-dependent, and had significant genetic (0.59, $p < 0.01$) and marginal environmental (0.25, $p = 0.07$) correlations with FX. Using the trivariate approach, we estimated a maximum multipoint LOD of 4.71 on chromosome 13q, again near marker D13S285. QTL effect size estimates provide marginal evidence for a FX QTL and strong evidence for a FVII QTL at this locus. QTL-specific genetic correlations are not different from zero, suggesting that the amplified linkage signal of the trivariate screen is not due to pleiotropic effects of a chromosome 13q QTL. Instead, residual genetic and/or environmental correlations may underlie the linkage signal.

Familial aggregation, linkage, and association analyses of autoantibody traits in systemic lupus erythematosus (SLE). *P.S. Ramos[1], J.A. Kelly[2], C. Gray-McGuire[3], R. Graham[4], C. Gillett[1], K. Espe[1], W. Ortmann[1], G. Bruner[2], T.W. Behrens[1], J.B. Harley[2], K.L. Moser[1].* 1) University of Minnesota, Minneapolis, MN; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Case Western Reserve University, Cleveland, OH; 4) Broad Institute, Boston, MA.

The goal of this study was to identify genes that contribute to SLE using autoantibody traits as intermediate phenotypes. We performed familial aggregation and linkage studies using our Oklahoma collection consisting of 229 multiplex SLE pedigrees. We found that a large percentage of unaffected individuals in these families have significant titers of a variety of autoantibodies. There is also strong familial aggregation of antinuclear antibodies (ANAs), anti-dsDNA, anti-La, anti-Ro, anti-nRNP, IgM aPL antibodies (Abs) and low titer rheumatoid factor. Genome-wide linkage analysis was performed for the following autoantibodies: Ro, La, nRNP, Sm, dsDNA, rheumatoid factor, ANAs and antiphospholipid Abs. Using an approach to rule out likely false positives and adjusting for multiple comparisons, we found evidence for linkage to anti-La Abs on 3q21 (adjusted P-value=1.9x10-6), to anti-nRNP and/or anti-Sm Abs on 3q27 (P=3.5x10-6), to anti-Ro and/or anti-La Abs on 4q34-q35 (P=3.4x10-4), and to anti-IgM aPL Abs on 13q14 (P=2.3x10-4). Another 45 loci of interest were also identified. Comparison of these results with loci identified in several autoimmune diseases revealed that 4q35 has also been previously implicated in autoimmune skin disorders and subsets of SLE patients with dermatological manifestations. The interferon regulatory factor 2 (IRF2) gene was chosen for initial association studies in our Minnesota collection of 215 SLE pedigrees. Four single nucleotide polymorphisms (SNPs) were evaluated using the Pedigree Disequilibrium Test (PDT). Association of a coding variant (rs3775543) was found using the following pedigree subsets: malar rash (P-value=.027), discoid rash (P=.043), oral ulcers (P=.005), photosensitivity (P=.016) and anti-Ro and/or anti-La (P=.005). Our studies show that autoantibody production in SLE is a complex trait and suggest IRF2 may play a role in dysregulation of IFN-related pathways in SLE.

A QTL analysis of macrocephaly in autism families. *S. Spence[1], N. Kono[2], D.H. Geschwind[1], R.M. Cantor[2].* 1) UCLA Depts of Neurology & Psychiatry, Program in Neurogenetics, Center for Autism Research & Treatment; 2) UCLA Dept of Human Genetics, LA, CA.

Autism Spectrum Disorder (ASD) is a highly heritable complex neuropsychiatric syndrome, yet results of susceptibility gene searches have been modest and inconsistent due to its genetic and phenotypic heterogeneity. Macrocephaly (occipital frontal head circumference (OFC)98%) is a common feature in ASD that is highly heritable in the general population. In a sample of 200 nuclear families ascertained for at least two children with ASD from the Autism Genetic Resource Exchange, a significantly increased incidence in macrocephaly (20%) was observed, occurring equally in ASD probands and their non-autistic 1st degree relatives. OFC was also correlated in siblings ($r=.26$, $p<.0001$) and with their mid-parent values ($r=.30$, $p<.0001$) supporting its familiality in the ASD population. We hypothesized that analyzing age and sex adjusted head circumference as a quantitative trait within ASD pedigrees could identify loci harboring genes contributing to ASD risk through this phenotype. A quantitative trait locus (QTL) analysis was performed on OFC percentile measurements in 233 sibpairs from 134 pedigrees that included both ASD and non-ASD sibs. Because the distribution was skewed and the median OFC at the 80th %ile, the QTL analysis was conducted using the nonparametric option of the Genehunter software. Scores with a p-value of <.05 were found at 7 loci on 5 chromosomes: chr 1 @ 1p36($p=.04$) and 1p31.3($p=.04$); chr 2 @ 2p25.1($p=.02$) and 2q22($p=.005$); chr 8 @ 8q13.2-8q21.3($p=.03$); chr 10 @10q25.2($p=.04$); chr 18 @18p11.32($p=.02$). The 2q22 QTL is near a locus related to language delay in ASD. The 10q25.2 QTL is near PTEN, a gene implicated in various overgrowth syndromes and found to have mutations in macrocephalic patients with ASD. Those with macrocephaly and normocephaly did not differ on measures of cognition, language and behavior. We conclude that these loci may contain genes predisposing to macrocephaly in ASD. Given the frequency of the occurrence of this trait in ASD families (increased 10-fold over the general population) we propose that these genes may also confer risk to ASD.

MCMC linkage analysis with multiallelic trait loci. *E.A. Rosenthal, E.M. Wijsman.* University of Washington, Seattle, WA.

Complex traits are influenced by multiple contributing genes. One approach to detect linkage is to allow for multiple underlying loci. Another is to focus on quantitative phenotypes. A method that incorporates both approaches is the reversible jump Markov chain Monte Carlo (RJMCMC) joint linkage and segregation analysis that is implemented in the package Loki: the number of quantitative trait loci (QTLs) need not be specified so that complex traits with unknown etiology can be modeled more adequately than with other methods. However, virtually all known trait genes have more than two alleles with respect to phenotypes of interest. One possible additional hindrance to linkage detection may be that current methods are either restricted to, or are carried out under, the assumption of underlying diallelic genes.

We propose an algorithm for extending the RJMCMC process to allow for an unspecified number of alleles at the underlying QTLs under the assumption of additivity for QTLs with three or more alleles. The algorithm includes three steps. The first is a transition between dominant and additive diallelic QTLs. This involves equating the genetic variances of the current and proposed QTL states and then calculating the additive and dominance variances of the proposed state while keeping the allele frequencies the same. The second step is the birth or death of an additive diallelic QTL which increases the acceptance rate of additive QTLs. This involves generating or removing, respectively, the additive genetic variance and allele frequencies at the QTL. The third step is the birth or death of an allele at additive QTLs. The frequency of a new allele is generated via sampling from the Dirichlet(1) distribution and subsequent normalization of all allele frequencies. An effect for the new allele is also sampled. The death of an allele involves its removal as well as the adjustment of the remaining allele frequencies. For this last step, the genetic variance of the current and proposed QTLs are not necessarily equal. Upon implementation, the algorithm may help in detecting multiallelic trait loci. [Supported by NIH HG 00035 and GM 46255.].

Searching for genetic variations associated with schizophrenia in the *GRID1* gene region on chromosome 10q23.
P. Chen, D. Avramopoulos, M.D. Fallin, A. Pulver, D. Valle. Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

Schizophrenia (SZ, [MIM 181500]), with a prevalence ~1% worldwide, is a complex psychiatric disorder with many lines of evidence supporting a strong genetic component. To reduce genetic heterogeneity, we performed a genomewide linkage scan on 29 multiplex families of Ashkenazi Jewish (AJ) descent (Fallin *et al*. Am. J. Hum. Genet. 73:601-611, 2003), and got the strongest linkage signal at chromosome 10q22 (NPL score: 4.27, empirical P = 0.00002). *GRID1* (glutamate receptor, ionotropic, delta 1) is a candidate gene in this region, based on its predicted function as a glutamate receptor. In a subsequent family-based association study with AJ trios, we found independent evidence implicating the *GRID1* region ($P < 0.01$ for two SNPs and their haplotypes). Given these results, we initiated a search for a genetic variant(s) responsible for the association signal in and around the *GRID1* gene, which has 16 exons spanning 767 kb. The peak of our association study is in intron 2, which is about 157 kb in length and contains a microRNA (*hsa-miR-346*) whose mouse counterpart we find expressed in brain. We thus picked the first 4 exons of *GRID1*, the *hsa-miR-346* and additional 6 conserved non-coding regions in intron 2 of *GRID1* as our candidate segments and sequenced them in 10 AJ SZ probands and 3 AJ controls. We found 24 variants including 11 novel and 13 known SNPs. None of these is obviously pathologic and we are proceeding with an association study with ~600 AJ SZ patients and controls.

Fine mapping a chronic obstructive pulmonary disease susceptibility locus on chromosome 2q. *C.P. Hersh[1,2], R. Lazarus[1], B.J. Klanderman[1], B.A. Raby[1], A.A. Litonjua[1], D.L. DeMeo[1,2], J.J. Reilly[2], D. Sparrow[3], S.T. Weiss[1], E.K. Silverman[1,2].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 3) Veterans Affairs Medical Center, Boston, MA.

Rationale: In the Boston Early-Onset Chronic Obstructive Pulmonary Disease (COPD) Study families, significant evidence for linkage of COPD-related traits has been demonstrated on chromosome 2q. We hypothesized that a high-resolution single nucleotide polymorphism (SNP) mapping strategy could be used to identify regions where COPD susceptibility genes are located.

Methods: With SNP genotype data from the HapMap project, we used a linkage disequilibrium (LD) tagging algorithm to select a set of 1536 SNPs across the 20 Mb linked region (1.5 LOD-unit support interval). These SNPs were genotyped on the Illumina platform in a case-control study comprised of cases with severe COPD from the National Emphysema Treatment Trial (NETT) and control smokers without airflow obstruction.

Results: 1402 SNPs were successfully genotyped (91.3%). These SNPs adequately captured the LD relationships across the region (mean of best LD with non-genotyped SNPs: $r^2 = 0.83$). Comparing 298 NETT cases to 317 control subjects, 103 SNPs were associated at $p<0.05$ and 23 at $p<0.01$ levels (smallest p-value = $2x10^{-5}$). 7 regions were identified with haplotype associations at $p<0.001$, including 2 regions with haplotype associations at $p<10^{-7}$.

Conclusions: Using a high-density SNP-based fine mapping approach, with both single SNP and haplotype analyses, we were able to identify several promising regions on chromosome 2q. Further genotyping will be necessary to confirm these associations and locate the functional variants that influence COPD susceptibility.

Support: NIH grants T32HL07427, HL71393 and HL075478 and an American Lung Association Career Investigator Award.

Secondary Analyses of a Genome-wide Screen for Stuttering Susceptibility Loci. *R. Suresh[1,2], C.A. Roe[2], T.C. Gilliam[2], N.J. Cox[2,3].* 1) Dept. of Genetics & Development, Columbia Univ., New York, NY; 2) Dept. of Human Genetics, Univ. of Chicago, Chicago, IL; 3) Dept. of Medicine, Univ. of Chicago, Chicago, IL.

A genome-wide scan to identify loci that contribute to stuttering was carried out in 105 families, with at least two affected relative pairs. Genotyping was carried out with the Affymetrix 10k SNP chip. Primary analysis of the dataset showed highest evidence of linkage at chr. 9 at 60cM with a LOD score of 2.3. In order to assess potential interactions between this linkage signal and the rest of the genome, conditional analyses using weighting functions, generated based on the evidence for linkage in each family at this peak, was carried out. A strong positive interaction between the chr. 9 linkage signal and one on chr. 2 at 192.5cM ($p = 0.01$) was detected. This region on chr. 2 has been previously implicated in several linkage and association studies focusing on autism, and more specifically autism with phrase speech delay (*Shao Y, 2002*). There is also a significant sex bias in the incidence of stuttering, with a male:female ratio of approximately 2:1 during childhood, and increasing up to 4:1 or 5:1 in adulthood. Sex-specific analyses of the dataset indicated significant evidence for linkage with the female families (n=9) on chr. 21 (33.5cM) with a LOD score of 4.5 (genome-wide $p=0.017$). Analysis of the male families (n=74) showed suggestive evidence for linkage on chr. 7 (153.2 cM) with a LOD score of 2.99 (genome-wide $p=0.074$). These sex-specific findings were replicated in an independent stuttering dataset as well. Conditional analyses based on the chr. 7 linkage signal showed a positive interaction with chr. 12 at 114.5cM ($p = 0.001$). The location of the chr. 12 signal incidentally overlaps with the primary finding of whole-genome scan for stuttering in 46 highly consanguineous Pakistani families (*Riaz N, 2005*). Interestingly, a negative interaction between the chr. 7 linkage signal and the one on chr. 2 at 192.5cM was also detected ($p = 0.013$). The pattern of results is consistent with the possibility that there are two largely non-overlapping sets of families with different sets of genetic risk factors.

Polymorphisms in the Vitamin K Epoxide Reductase (VKOR) gene are strongly associated with warfarin dosage requirements in patients receiving anticoagulation. *L.A. Lange[1], T. Li[2], X. Li[3], L. Susswein[1], B. Bryant[1], R. Malone[1], E.M. Lange[1], T.-Y. Huang[1], D.W. Stafford[1], J.P. Evans[1].* 1) University of North Carolina, Chapel Hill, NC; 2) Salk Institute for Biological Sciences, La Jolla, CA; 3) Scripps Research Institute, La Jolla, CA.

Warfarin is a mainstay of therapy for conditions which result in an increased risk of thromboembolic events. Yet the use of this common agent is fraught with complications, including major bleeding episodes and death. Little is known regarding inter-individual variation in warfarin response. We tested for association between single nucleotide polymorphisms (SNPs) in the recently identified VKOR gene (which encodes the target for warfarin activity) and weekly warfarin dose required to maintain patients at their desired anticoagulation target. The sample consisted of 115 (Caucasian, N=96; African American, N=19) patients from anticoagulation clinics at the University of North Carolina at Chapel Hill who were being treated with warfarin. A combination of direct sequencing and genotyping were performed, resulting in the identification of six SNPs in VKOR. Mean weekly warfarin dose required to achieve each patients target International Normalized Ratio (INR) was collected over a mean treatment period of 20.6 months. Analysis of covariance models and haplotype analysis (using Haplo.Stat) were performed. Three of the VKOR SNPs were found to be very strongly associated with the average warfarin dose required to achieve the target INR (p-values ranging from 0.0000021 to 0.0000095), with results similar for both race-stratified and combined samples. The range in mean weekly dose by genotype ranged from approximately 27mg (more common allele homozygote) to 47mg (less common allele homozygote), which is of considerable clinical interest. These three SNPs are in very strong linkage disequilibrium (LD) and haplotype analyses were consistent with single SNP results. The current results combined with the recent results of Rieder et al. (N Engl J Med) represent a potentially clinically useful proof-of-principal for the use of pharmacogenomic information in medicine and may lead to an improved understanding of warfarins actions.

Common polymorphisms in the promoter of the Visfatin gene (PBEF1) in a french canadian population. *S.D. Bailey[1], K. Desbiens[2], P. Lepage[3], J. Faith[3], C. Doré[3], J. Fontaine[3], T.J. Hudson[1,3], C. Bouchard[4], L. Pérusse[5], D. Gaudet[6], M.C. Vohl[5], J.C. Engert[1,2].* 1) Human Genetics, McGill Univ., Montreal, QC; 2) McGill Univ. Health Centre, Montreal, QC; 3) McGill Univ. & Genome Quebec Innovation Centre, Montreal, QC; 4) Pennington Biomedical Research Centre, Baton Rouge, LA; 5) Laval Univ., Ste. Foy, QC; 6) Université de Montréal, Complexe hospitalier de la Sagamie, Chicoutimi, QC.

The occurrence of obesity and non-insulin-dependent diabetes mellitus (NIDDM) are highly correlated. The newly characterized adipokine visfatin has been shown to exhibit insulin mimetic effects and to correlate strongly with visceral adiposity. Therefore, genetic variants of visfatin are potentially involved in either obesity and/or NIDDM. We sequenced approximately 1000 bps of the promoter and all coding regions of the PBEF1 gene in 18 individuals with varying degrees of visceral fat from the Quebec Family Study (QFS) as well as five individuals with high waist to hip ratios selected from the Saguenay-Lac-Saint-Jean (SLSJ) region of Quebec. We identified one silent mutation in Exon 7 (SER301SER), but no missense mutations. This is in accordance with dbSNP, which lists the SER301SER variant but no other coding SNPs. However, our sequencing identified six intronic SNPs and four SNPs within the promoter region with allele frequencies from 0.02 to 0.50. Further sequencing of an 856 bp region of the promoter led to the discovery of five additional SNPs in the QFS population. To investigate whether visfatin gene variants play a role in obesity-related phenotypes or the pathogenesis of NIDDM, we have genotyped and analyzed 10 potential regulatory SNPs from the promoter region of the gene (the nine discovered through our sequencing and one additional SNP chosen from a database search). Using QTDT, an association was found between one of the genotyped SNPs (rs7789066) and triglyceride levels (p=0.0251) in the QFS study (approximately 930 participants). In addition, we genotyped this promoter SNP in an additional 360 individuals from an NIDDM case-control cohort from the SLSJ region of Quebec, but no association was found between NIDDM and this SNP.

Haplotype Sliding Windows Approach in Chromosome 12q Yields Priority Association Regions for Asthma and Total IgE Levels in a Family-Based Population of African Descent. *A.V. Grant[1, 2], S. Zhang[1], P. Chi[2], D. Baltadzhieva[1], T. Berg[1], L. Shao[1], A. Zambelli-Weiner[1], E. Ehrlich[1], M.L. Stockton[1], P.N. Levett[3], R.G. Ingersoll[4], A.F. Scott[4], D.M. Fallin[2], R.A. Mathias[5], T.H. Beaty[2], J.G.N. Garcia[6], K.C. Barnes[1, 2].* 1) Division of Allergy and Clinical Immunology, Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 3) Faculty of Medicine, University of the West Indies, School of Clinical Medicine and Research, Barbados; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland; 6) Department of Medicine, University of Chicago Pritzker School of Medicine, Chicago, IL.

Previously, we reported evidence of linkage on chromosome 12q to asthma and high total IgE levels in African Caribbean families selected for asthma from Barbados. To fine map this region, we genotyped 750 SNPs spanning ~50 Mb in this 12q region in 670 individuals from 119 Barbadian families. The joint hypothesis of linkage and association between markers and two phenotypes (asthma, log[total IgE]) was tested using the Family Based Association Test. Two-six SNP sliding window haplotypes were examined. In the final set of 726 SNPs, regions of interest were defined by segments of contiguous SNPs within 500 kb of any SNP with a global p-value ≤ 0.05 for at least one window including that SNP or single-SNP association test. This strategy yielded significant regions for asthma comprising 354 SNPs, and 324 SNPs for log[total IgE]. Significant regions overlapped considerably for these two phenotypes. By graphically juxtaposing genes available from public databases with p-values from windowing for both phenotypes, we identified 14 genes, one of which is a candidate for other immune disorders (MYF5) , containing variants showing associations with p-values ≤ 0.05. Additional SNP fine-mapping is underway to adequately cover candidate genes identified in this study for asthma and atopy.

Genetic Variation in ACDC and ADIPOR2 genes are Associated with Insulin Resistance Syndrome (IRS)-Phenotypes in Mexican Americans. *D.K. Richardson, J. Schneider, L.M. Rodriguez, R. Arya, M.P. Stern, R.A. DeFronzo, J. Blangero, R. Duggirala, C.P. Jenkinson.* San Antonio, TX.

Adiponectin (ACDC) is an adipocyte-derived hormone implicated in energy homeostasis, and insulin resistance. Two receptors for adiponectin have been identified (ADIPOR1 and -2) both of which are highly expressed in skeletal muscle. Analysis of genetic variants in the ACDC, ADIPOR1 and ADIPOR2 genes has not previously been reported in Mexican Americans (MA). We genotyped variants in the ACDC (n=3), ADIPOR1 (n=5), and ADIPOR2 (n=12) genes in the San Antonio Family Diabetes Study (SAFDS) population. We performed SNP-phenotype association analyses using the quantitative trait linkage disequilibrium (QTLD) test, within a variance components analytical framework as implemented in SOLAR. When a variant exhibited evidence of potential population stratification, we used the quantitative transmission disequilibrium test (QTDT). Linkage disequilibrium (LD) between SNP pairs was estimated using the absolute correlation coefficient |p|. Of 20 SNPs examined, 10 (ACDC=3, ADIPOR1=1, and ADIPOR2=6) were polymorphic. Several of these SNPs exhibited significant association with IRS-related traits. SNPs 29661, 33371, 33447, 33630 and 33775 in the ADIPOR2 gene were associated with triglyceride levels (P=0.009, 0.00024, 0.044, 0.047, and 0.0045). SNP 349 in ACDC was associated with sum of skin fold thickness (P=0.013). In addition, SNPs 29661 and 33630 of ADIPOR2, and SNP 276 of ACDC, were significantly associated with fasting plasma glucose concentrations (P=0.048, 0.044 and 0.015). SNP 712 of the ACDC gene showed evidence of potential population stratification and yielded a significant QTDT association with fasting plasma glucose concentration (P=0.002). For the ADIPOR2 variants, the minor alleles were associated with decreased triglyceride levels and increased fasting plasma glucose concentration. The minor alleles in the ACDC variants were associated with increased fasting plasma glucose concentration and an increase in sum of skin fold thickness. In conclusion, we have found evidence for association of variants in ACDC and ADIPOR2 genes with some components of the IRS in the MA population.

Genetic analysis of polymorphisms in the growth factor receptor binding protein-2 and obesity phenotypes: the IRAS Family Study. *B.S. Sutton[1,2], C.D. Langefeld[3], J.K. Campbell[3], S.M. Haffner[5], J.M. Norris[6], L.E. Wagenknecht[3], D.W. Bowden[1,2,4].* 1) Ctr Human Genomics,Wake Forest Univ Sch Med, Winston Salem, NC; 2) Dept Biochem, Wake Forest Univ Sch Med, Winston Salem, NC; 3) Dept Public Health Science, Wake Forest Univ Sch Med, Winston Salem, NC; 4) Dept Internal Med, Wake Forest Univ Sch Med, Winston Salem, NC; 5) Dept Med, Univ of TX Health Science Ctr, San Antonio,TX; 6) Dept Preventative Med and Biometrics, Univ CO Health Science Ctr, Denver, CO.

Growth factor receptor binding protein 2 (GRB2) has been suggested to inhibit fat cell differentiation and to be involved in the leptin signaling pathway. Expression of GRB2 protein in obese insulin-resistant diabetic KKAy mice was dramatically decreased compared to non-diabetic mice. In a genome-wide scan of Hispanic families in the IRAS Family Study (IRASFS) significant evidence of linkage (LODs 2.5-3.1) was observed to several obesity phenotypes on chromosome 17q24-25, the location of GRB2. Thus, due to the suggested role of GRB2 in obesity and the genes location under the linkage peak, 9 polymorphisms were genotyped across the 87.5 kb GRB2 genomic region. SNPs were genotyped on 1425 individuals from 91 Hispanic families in the IRASFS. Linkage disequilibrium (LD) was high for all SNPs, D>0.97 suggesting GRB2 lies in a single LD haplotype block. SNPs were tested for association with six obesity phenotypes [BMI, waist, waist: hip ratio (WHR), subcutaneous adipose tissue (SAT), visceral adipose tissue (VAT) and visceral: subcutaneous ratio (VSR; a measure of fat compartmentation/distribution)] by computing a series of generalized estimating equation (GEE1). Significant evidence of association to VSR was detected with the majority of the SNPs, with the remaining SNPs showing a trend of association (P-value 0.03-0.09). Quantitative pedigree disequilibrium test (QPDT) analysis complemented these results with eight SNPs showing single SNP association (or trending toward association; P-value 0.01-0.08). No additional obesity phenotype revealed evidence of association suggesting GRB2 may be involved in controlling the pattern of fat deposition in the Hispanic population.

Genetic Predictors of Asthma Exacerbations among Children in the Childhood Asthma Management Program (CAMP) Study. *J.C. Celedon[1,2,3], K. van Steen[4], C. Lange[4], B. Raby[1,2,3], K. Tantisira[1,3], E.K. Silverman[1,3], S.T. Weiss[1,3].* 1) Channing Lab, Brigham & Women's Hosp; 2) Div. of Pulmonary/Critical Care Medicine, Beth Israel Deaconess Med. Ctr; 3) Dept. of Medicine, Harvard Medical School; 4) Dept. of Biostatistics, Harvard School of Public Health, Boston, MA.

Little is known about genetic determinants of asthma exacerbations. We examined the relation between 235 single nucleotide polymorphisms (SNPs) in 51 candidate genes and asthma exacerbation phenotypes among 1,990 members of 645 families of children with asthma in the CAMP Genetics Ancillary Study. Information on asthma exacerbation phenotypes (use of oral corticosteroids, visits to urgent care or the emergency department, and hospitalizations) was obtained initially at the two-month follow-up visit and then every four months for a total follow-up period of 60 months. The analysis of association between SNPs in candidate genes and asthma exacerbation phenotypes was performed with an extension of the Family-Based Association Test (FBAT) statistic for analysis of repeated measures (FBAT-PC), as implemented in the PBAT program (http://www.biostat.harvard.edu/clange/default.htm). Because corticosteroid treatment influences the development of asthma exacerbations, the analysis was stratified by treatment arm (inhaled budesonide vs. nedocromil/placebo). Single nucleotide polymorphisms (SNPs) in the gene for the corticotropin-releasing hormone receptor 1 [CRHR1]) were associated with asthma exacerbation phenotypes in both treatment groups ($P <= 0.03$ in all cases). Among families of asthmatic children treated with placebo or nedocromil, variants in the gene for T-box 21 (TBX21) were associated with asthma exacerbation phenotypes ($P <= 0.02$ in all cases). Among families of asthmatic children treated with oral corticosteroids, SNPs in the promoter of the gene for interleukin 10 (IL10) were associated with asthma exacerbation phenotypes ($P <= 0.0009$ in all cases). Similar results were obtained when the analysis was restricted to white individuals. Our results suggest that SNPs in three genes (CRHR1, TBX21, and IL10) interact with treatment in influencing the development of asthma exacerbations among children with asthma.

Linkage disequilibrium mapping for Tourette Syndrome in two population isolates. *D. Keen-Kim[1], C.A. Mathews[2], S.K. Service[1], V.I. Reus[3], T.L. Lowe[3], L.D. Herrera[4], C. Budman[5], R.D. Bruun[5], E. Erenberg[6], A. Naarden[7], N.B. Freimer[1].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 2) Department of Psychiatry, University of California, San Diego, CA; 3) Department of Psychiatry, University of California, San Francisco, CA; 4) Hospital Nacional de Ninos, San Jose, Costa Rica; 5) Movement Disorders Center in Psychiatry, North Shore University Hospital, Manhasset, NY; 6) Department of Neurology, Cleveland Clinic Foundation, OH; 7) Department of Neurology, University of Texas Southwestern Medical School, Dallas, TX.

Tourette Syndrome (TS) is a childhood disease characterized by uncontrollable movements and sounds (motor and vocal tics) that affects approximately one in 2000 individuals worldwide. The considerable genetic and clinical complexity of TS has made genetic mapping difficult in the past, and to date there are no known candidate genes with a clear role in the etiology of the disease. The Tourette Syndrome Association International Consortium on Genetics (TSAICG) recently completed genome-wide linkage scans of 252 unrelated sib-pair families (465 sib-pairs) and 23 large nuclear families. Separate and combined data set analyses identified several regions with genome-wide significant or suggestive linkage to TS. Recent studies have shown that linkage disequilibrium (LD) is detectable over much longer genomic segments within isolated populations than in older and more heterogeneous populations. We therefore hypothesize that mapping genes for complex traits such as TS is simpler in isolated than in outbred populations. To this end, we are fine-mapping four of the broad linkage regions identified in the TSAICG scans (chromosomes 2p, 3p, 14q and 20p) in cohorts with strict genealogic and diagnostic criteria from the Central Valley of Costa Rica (CVCR) and US and Israeli Ashkenazim.

Fine-mapping of a susceptibility gene locus on 3q for nephropathy in patients with type 1 diabetes. *B. He[1], A.M. Österholm[1], J. Pitkäniemi[2], C. Sarti[2], J. Tuomilehto[2], K. Tryggvason[1].* 1) Matrix Biology, MBB, Karolinska Institute, Stockholm, Sweden; 2) Dept. of Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland.

Diabetic nephropathy (DN), the leading cause of end-stage renal disease, is one of the severe complications of type 1 and type 2 diabetes. Almost 30 % of all patients with diabetes develop DN. Clinically, DN manifests with proteinuria and progresses into impaired renal function. Epidemiological studies have provided evidence for genetic factors regulating the development of DN. To map loci linked to DN, we performed a genome scan using Finnish discordant sib pairs (DSPs), sibs affected with type 1 diabetes but discordant for nephropathy. One region on 3q has been identified with a suggestive linkage (LOD score 2.6, P = 0.0004). This region was before reported with significant linkage in American-Caucasians. Therefore, the 3q region most likely harbors a major susceptibility gene for DN. To identify a susceptibility gene for DN, we firstly re-defined a Finnish set consisting of 206 cases (type 1 diabetic nephropathy) and 220 controls (type 1 diabetes alone). In the following step, we carried out case-control studies to test for association by genotyping 55 microsatellite markers across the 64 cM region of the 3q locus in the Finnish case-control set. Two markers showed significant association (P = 0.0007 and 0.003) between cases and controls. After Bonferroni correction, the P value of 0.038 for the most significant marker remained significant. We designate these two marker regions as the LOC1 and 2. We studied LOC1 by genotyping three additional flanking markers. One marker, 50 kb centromeric from the most significant marker, showed significant association (P = 0.037), while the other two markers, 330 and 670 kb telomeric from the most significant marker respectively, did not. Therefore, we narrowed LOC1 to a critical region of 380 kb. LOC1 contains an interesting candidate gene that is expressed in kidney glomeruli. We have sequenced all exons of this candidate gene, but no mutations were shown to be associated with DN. A large-scale SNP genotyping is under way.

Identification of a novel locus for Myotonic Dystrophy in human chromosome 16. *L.L. Bachinski[1], F. Lehmann-Horn[2], K. Jurkat-Rott[2], J. Gamez[3], S. Raskin[4], R. Krahe[1].* 1) Sect. Cancer Genetics, Dept. Molecular Genetics, Univ. of Texas M.D. Anderson Cancer Center, Houston, TX; 2) Dept. of Applied Physiology, Ulm Univ., Germany; 3) Dept. of Neurology, General Hospital Vall d'Hebron University, Barcelona, Spain; 4) Neurology Service, Dept. of Internal Medicine, Universidade Federal do Parana, Curitiba, Brazil.

Myotonic dystrophy types 1 and 2 (DM1 and DM2) are caused by expansion of $(CTG)_n$ and $(CCTG)_n$ repeats located in *DMPK* (19q13.3) and *ZNF9* (3q21.3), respectively. A third DM locus was mapped to chromosome 15q21-q24, but the mutation is unknown. During the course of a genome scan, one family without expansions in *DMPK* or *ZNF9* and whose disease did not segregate with these loci gave a LOD score of >1.3 in chromosome 16. We genotyped additional markers in this and other families segregating autosomal dominant progressive myotonic myopathy that were also negative for expansions in *DMPK* or *ZNF9*. Using 9 such families (4 German, 4 Spanish and 1 Brazilian), we obtained a LOD score of 3.83 in 16p. Haplotype analysis determined the minimal region shared by these 9 families. Hypothesizing that DM in these families is due to an expanded repeat of the type $(CTG)_n$, $(CCTG)_n$, or other similar sequence, we interrogated all such repeats in the shared region having a length 4. We used amplification across the repeat to check for non-Mendelian inheritance, a hallmark of expanded repeat diseases, and a repeat-primed assay (RP-PCR) to identify expansions. None of the candidate repeats gave evidence of expansion by either RP-PCR or non-Mendelian inheritance. These families are small and each contributes only minimally to the total LOD score. However, in all cases the LODs observed are near the simulated ELODmax. Nevertheless, it is impossible to exclude locus heterogeneity within this set of families, thus complicating localization of the shared region. We conclude that a locus responsible for DM in most of these kindreds maps to chromosome 16, and we are continuing to search for the causative mutation by interrogating repeat sequences in the surrounding regions.

Genetic Heterogeneity of Cataract at Chromosome 22q. *G. Billingsley[1, 4], S. Santhiya[2], J. Graw[3], A.D. Paterson[1], D. Malaiyandi[1], E. Héon[1, 4].* 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) Dr. ALM Postgraduate Institute of Basic Medical Sciences, Department of Genetics, University of Madras, Taramani Chennai, India; 3) GSF-National Research Center for Environment and Health, Institute of Developmental Genetics, Neuherberg, Germany; 4) Dept of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Canada.

Autosomal dominant cataract is a phenotypically and genetically heterogeneous disorder. The chromosomal region 22q11.2-q12, containing the -crystallin gene cluster, has now been associated with a number of congenital cataracts. Mutations in exon 6 of CRYBB1 and CRYBB2 have been associated with pulverulent cataract, congenital nuclear cataract with microcornea and central nuclear cataract. The Q155X mutation in exon 6 of CRYBB2 has marked phenotypic variability producing cerulean, Coppock-like and sutural/cerulean cataracts. Recently a homozygous mutation in exon 6 of CRYBB3 was reported in a family with AR congenital cataract.

We have mapped an autosomal dominant congenital lamellar cataract to the -crystallin gene cluster on chromosome 22q11.2 in a large four generation Indian family with nineteen available members (11 affected and 8 unaffected). All affected individuals had nonprogressive cataract since birth, with partial vision even when not operated. The affected status (presence of cataracts) was determined using slit lamp biomicroscopy or direct ophthalmoscope prior to genetic analysis. Functional candidate genes CRYG (A ->D) and GJA8 were excluded by direct sequencing. Following a genome wide scan (388 microsatellite markers), linkage was detected with marker D22S1167 (LOD score 3.17, = 0). Haplotype analysis with closely flanking markers could not exclude any of the -crystallin genes from the critical disease interval. Sequencing exon 6 of CRYBB1, CRYBB2, and CRYBB3 (previously published to contain mutations) did not reveal any disease-associated mutations in this family. This work further outlines the genetic heterogeneity of congenital cataracts at the 22q locus.

Autosomal dominant retinitis pigmentosa in a large Belgian family: linkage-based exclusion mapping of 13 known loci. *B.P. Leroy[1,2], K. Robberecht[2], F. Coppieters[1], D. Beysen[1], J. Hellemans[1], P.J. Coucke[1], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

Purpose: Linkage-based exclusion mapping of candidate genes for autosomal dominant retinitis pigmentosa (ADRP) in a large Belgian family with ADRP.

Patients and Methods: Genetic material from twenty-four affected and twenty-six unaffected individuals of a 4-generation Belgian ADRP family was available for the study. A clinical diagnosis was made either on the basis of a clinical examination or an extensive questionnaire unequivocally differentiating affected from unaffected family members. Linkage-based exclusion analysis was performed using 26 microsatellites closely linked to 13 currently known ADRP genes (*CA4, CRX, FSCN2, IMPDH1, NRL, PRPF3, PRPF8, PRPF31, RDS, RHO, ROM1, RP1, RP9*).

Results and Conclusion: Segregation analysis of the 26 markers in affected and unaffected family members allowed exclusion of these 13 known ADRP genes. Exclusion of a fourteenth gene (*GUCA1B*) is ongoing, although its causal relationship with ADRP is not clear as yet. The results of our study suggest the involvement of a novel ADRP disease gene as the cause of the phenotype in this family. A genome-wide linkage analysis will be performed to identify this novel locus. Computer simulation of the power of this family predicted significant LOD-scores (> 9) potentially generated from genome-wide linkage analysis.

Association of KCNJ11 E23K polymorphism with type 2 diabetes in the Saudi population. *O. Alsmadi[1], K. AL-Rubeaan[2], S.M. Wakil[1], F. Imtiaz[1], H. Khalil[1], P. Carroll[1], M. Rajab[1], S. Al-Katari[2], M. Al-Katari[2], B.F. Meyer[1].* 1) Aragene, KFSH&RC, Riyadh, Saudi Arabia; 2) Diabetes Center, King Saud University, Kingdom of Saudi Arabia.

E23K Polymorphism in KCNJ11alters the ATP-potassium channel function of pancreatic beta cells leading to insulin release inhibition, and development of type 2 diabetes. Previous studies indicated that E23K polymorphism is associated with type 2 diabetes in Caucasian populations. Type 2 diabetes pathogenesis is underlined by both polygenic and environmental factors. To date there is no data available on the role or the association of E23K polymorphism with type 2 diabetes in any Arab population. The incidence of type 2 diabetes in Saudi population is substantial bringing high significance to this study. We developed a high throughput molecular beacon based real-time PCR assay for E23K genotyping. We studied a group of 1331 Saudi patients diagnosed with type 2 diabetes based upon WHO criteria, and 219 normal controls (age >60 yr and fasting blood glucose <7mmol/L). The KCNJ11 normal E allele frequencies were 0.80 and 0.89 in type 2 diabetes patients and normal controls respectively. The KCNJ11 risk K allele frequencies were 0.20 and 0.11 in type 2 diabetes patients and normal controls respectively. The difference between the E and K allele frequencies was highly significant comparing type 2 diabetes patients to normal controls ($p = 0.00001$, and OR = 2.02). While this data does not exclude the role of other genes involved in development of type 2 diabetes in Saudi population, it indeed suggests a strong association between E23K and susceptibility to or pathogenesis of type 2 diabetes in the Saudi population.

Epidemiological and Genetic Aspects of the Metabolic Syndrome in the Family Blood Pressure Program. *A.T. Kraja[1], D.C. Rao[1], A.B. Weder[2], R. Cooper[3], J.D. Curb[4], C.L. Hanis[5], S.T. Turner[6], M.de Andrade[7], C.A. Hsiung[8], T. Quertermous[9], X. Zhu[3], M.A. Province[1].* 1) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 2) University of Michigan Hospitals, Ann Arbor, MI; 3) Loyola University Medical Center, Maywood, IL; 4) Pacific Health Research Institute, Honolulu, HI; 5) Human Genetics Center University of Texas-Houston Health Science Center; 6) Division of Hypertension,; 7) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 8) National Health Research Institutes, Division of Biostatistics, Taipei, Taiwan; 9) Stanford University School of Medicine, Stanford, CA.

Metabolic syndrome (MetS) was investigated in the Family Blood Pressure Program. Information on a total of 11,343 participants was considered in the qualitative MetS (c-MetS). Quantitative MetS (q-MetS) was analyzed in 7,562 participants with no missing values for any of the 10 risk factors. The prevalence of c-MetS as defined by the NCEP criteria, differed by ethnicity. The combined c-MetS prevalence was 37.4% in African Americans and 46.1% in Whites. The percentage of Japanese above the NCEP threshold for WAIST was half that of Hispanics, African Americans, or Whites, but twice that of the Chinese. The percentage of Japanese participants above the NCEP threshold for TG was similar to that in Whites, but about twice as large as in the Chinese. Twice as many Whites were above the TG threshold than African Americans. The prevalence of c-MetS by design in Hispanics was high at 73%. Asians had a c-MetS prevalence of 21.4%. Heritabilities ranged from 66% for Obesity-INS to 11% for BP factor. Linkage analysis detected two major QTLs: one for Obesity-INS with a lod score 3.94, located on chromosome 18p11.21 in GENOA African Americans (D18S53, 41.24 cM), and another for BP with a lod score 3.22, located on chromosome 17q23.1 in Hispanics (D17S1290, 82 cM). These two QTLs, together with 4 additional QTLs with lod scores above 2.5 and 30 additional QTLs with lod score above 1.7, offer hope for dissecting the genetic architecture of MetS with positive implications for molecular diagnosis, prognosis and potential medical intervention.

APOE allele frequencies and Alzheimers disease risk in the Midwestern Amish population revisited. *J. Virgadamo[1], J.M. van der Walt[1], W.K. Scott[1], S. Slifer[1], P. Gallins[1], P.C. Gaskell[1], E.R. Martin[1], K. Welsh-Bohmer[1], M. Creason[2], A. Crunk[2], D. Fuzzell[2], L. McFarland[2], C.E. Jackson[3], J.L. Haines[2], M.A. Pericake-Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN 37232; 3) Department of Medicine, Scott and White Memorial Hospital, Temple, Texas.

Apolipoprotein E (APOE) has been confirmed as a major risk factor for Alzheimers disease (AD) in multiple populations. Previously, we reported low APOE4 allele frequencies in an Amish pedigree from the Midwest (Adams, Co., IN) and suggested that low prevalence of AD reported in this Amish population may be due to the decreased frequencies of APOE4. In this study, we have expanded our data set to include 9 pedigrees located within three midwestern Amish communities (Adams Co. IN, Elkhart/LaGrange Co., IN and Holmes Co., OH). Frequencies for APOE 2,3,and 4 alleles were computed for the affected (AD + mild cognitive impairment) and unaffected groups in each community. Overall, we observed a significant increase in APOE4 frequency in the affected group (n=114) compared to Amish controls (n=102) (p=0.004). However, when we examined frequencies within each community separately, we observed a significant difference in allele frequency between affected (29.3%) and unaffected (8.82%) groups only in Holmes Co.(p=0.02). Linkage analysis of SNPs indicated significant evidence for linkage only in Holmes Co. with maximum two-point LOD scores of 2.26 for the dominant model and 2.08 for the recessive model. Furthermore, APOE4 allele frequencies were significantly decreased in the Adams Co. unaffected group when compared to a set of outbred Caucasians (p=0.03) which replicates our earlier finding. Thus it appears that a minority of the genetic effect responsible for AD in the Holmes Co. Amish community may be related to APOE but that APOE has little influence on AD in the Adams and Elkhart/LaGrange communities. We are currently conducting a fine mapping study on these pedigrees to identify chromosomal regions that influence AD risk in each community.

Do variations in genes involved in the potassium-recycling pathway contribute to noise-induced hearing loss? *L. Van Laer[1], P.-I. Carlsson[2,3], A. Raes[4], M.-L. Bondeson[5], A. Vandevelde[1], A. Konings[1], E. Borg[3], D. Snyders[4], G. Van Camp[1].* 1) Dept Med Genet, Univ Antwerp, Belgium; 2) Dept Audiol, Örebro Univ Hosp, Sweden; 3) Ahlsén Res Inst, Örebro Univ Hosp, Sweden; 4) Lab Mol Biophysics, Physiol, Pharmacol, Univ Antwerp, Belgium; 5) Dept Genet Pathol, Uppsala Univ, Sweden.

Noise-Induced Hearing Loss (NIHL) is one of the most important occupational diseases; 400 to 500 million people in the USA and Europe are being exposed to excessive noise on a daily basis. NIHL is a complex disease caused by an interaction between genetic and environmental factors. The various environmental factors involved in NIHL have been relatively extensively studied. On the contrary, little research has been performed on the genetic factors responsible for NIHL. To test the hypothesis that variation in genes involved in potassium recycling in the inner ear might partly explain the variability in susceptibility to noise, we performed an association study using several Single Nucleotide Polymorphisms (SNPs) selected in these genes. Audiometric data from 1261 noise-exposed laborers were examined. DNA was extracted from the 10 % most susceptible and the 10 % most resistant individuals. 23 SNPs selected in 10 genes involved in the potassium-recycling pathway were genotyped. No significant differences were obtained between susceptible and resistant individuals except for 2 SNPs of the KCNE1 gene. One of the associated SNPs was a non-synonymous coding SNP. The possibility that the latter SNP was causative was investigated with electrophysiological studies. The susceptibility variant was introduced into wild-type KCNE1 cDNA and transfected into CHO-cells. Patch-clamp experiments were performed in high K+-concentration to investigate the functional relevance of the KCNE1 variant. The normalized current generated through channels containing the susceptibility variant significantly differed from that through wild-type channels. Furthermore, we obtained a different $V_{1/2}$ for the two types of channels. This putative association still needs to be replicated in other, independent noise-exposed populations.

Neuropathology of LRRK2 6055G>A (G2019S) Mutation. *O.A. Ross, D.W. Dickson, M.J. Farrer.* Departments of Neuroscience and Pathology, Mayo Clinic, Jacksonville, FL.

In 2002 Funayama and colleagues reported a novel locus, chromosome 12p11.2-Q13.1, for autosomal dominant Parkinsons disease (ADPD; PARK8). Linkage to this region was independently confirmed in a number of kindreds and in November 2004, causal mutations in the novel gene leucine-rich repeat kinase 2 (LRRK2) were identified. A common pathogenic G2019S substitution in the Lrrk2 kinase domain, has been reported to account for ~5% of familial and ~1% of sporadic PD. To date G2019S carriers have presented clinically with typical PD, but only three autopsy reports of mutation carriers, all with typical Lewy body pathology in substantia nigra, have been reported. Our objectives were to determine the frequency of G2019S-positive cases in a large collection of parkinsonism brains. DNA was extracted from over 1500 brains and screened for the (G2019S) mutation with Taqman Probe Chemistry on an ABI7900 sequencer. Positive and negative controls were used. The screened samples included PD (n=405), progressive supranuclear palsy (n=326; PSP) and multiple system atrophy (n=43; MSA). Control groups consisted of brains of clinically normal, aged individuals (n=156), and subjects with a clinical diagnosis of Alzheimers disease (AD; n=654). We identified 10 G2019S-positive cases, with material available for pathological review on eight of the cases. Eight of the ten individuals demonstrated Lewy body pathology, ranging from brainstem predominant to diffuse cortical Lewy body disease. One AD and one control harboring the mutation were identified. This is the first comprehensive screening for G2019S in a large collection of pathologically-confirmed neurodegenerative disorders. The presence of Lewy bodies in 80% of the G2019S cases would indicate that this mutation is responsible for alpha-synuclein pathology. The absence of Lewy pathology in some G2019S carriers may reflect reduced penetrance of the mutation or the pathological pleomorphism that has been described for other Lrrk2 variants. In this context, diverse pathological processes not due to a common mutation raises questions about whether pathology or genetics is the gold standard.

Patients with eating disorders show increased blood levels of BDNF irrespectively of the Val66Met functional variant. *J. Mercader[1], M. Ribasés[1], M. Gratacòs[1,2], F. Fernandez-Aranda[3], X. Estivill[1,2].* 1) Genes & Disease Program, Ctr Genomic Regulation, Barcelona, Spain; 2) CeGen, National Genotyping Center, Barcelona, Catalonia, Spain; 3) Department of Psychiatry, Hospital Princeps d'Espanya, L'Hospitalet de Llobregat, Barcelona, Catalonia, Spain.

Association of the Val66Met and -270C/T SNPs of the BDNF gene with Eating Disorders (ED) and the results of murine models suggest that increased levels of BDNF in the central nervous system (CNS) could be involved in restricting food intake and low body weight. We have studied if these variants are related to high BDNF levels, which could be contributing to the development of ED. The BDNF levels of 118 ED patients were quantified by ELISA and were analyzed depending on the Val66Met and -270 C/T genotypes. We further compared the levels of 50 of these patients to their 50 unaffected siblings. BDNF levels were higher in the ED patients homozygous for the -270C risk allele (41.0 ng/ml vs 26.9 ng/ml; $p = 0.012$), while we could not detect any effect of the Val66Met variant. Furthermore, plasma BDNF levels were higher in ED patients than in their unaffected sibs (57.7 ng/ml vs. 40.9 ng/ml; $p = 0.004$). Odds ratio were two-fold for the individuals with levels between 31.1 and 58 ng/ml, and ten-fold for individuals presenting levels higher than 58 ng/ml. Finally, a negative correlation between BDNF plasma levels and Global Severity Index and Positive Symptom Distress index of the Symptom Check List (SCL-90R) was found in AN patients. These results provide physiological evidence for a role of this neurotrophic factor in ED, and argue for its involvement in eating behavior and body weight regulation. Strategic Identification and Prioritization of Human Ion Channel Genes as Candidate Neurological Channelopathy Targets. *N. Gupta[1], M. Simoneau[1], J.-F. Poulin[1], K. Boisvert[1], F. Lafreniere[1], M.K. Charles[1], M. Albanese[1], R.G. Lafreniere[1], G.A. Rouleau[1, 2].* 1) Emerillon Therapeutics Inc., Montreal, Quebec, Canada; 2) Universite de Montreal, Montreal, Quebec, Canada.

Ion channel dysfunction is the basis of many episodic neurological disorders. To identify relevant drug targets for such diseases, we have initiated a high throughput mutation detection screen of 150 brain-expressed human ion channel genes using a panel of 368 DNA samples from unrelated patients with epilepsy, Tourette syndrome (TS), bipolar affective disorder (BD), essential tremor (ET) or migraine. The first phase of this project was to compile a systematic list of all the known human ion channel genes, which was done by querying publicly available human genome assemblies through websites such as the UCSC Genome Browser, Ensembl, NCBI and OMIM. The list also took into account comprehensive reviews on ion channels or channelopathies. Finally, homology searches were conducted to identify paralogs or pseudogenes of each of the genes. A list consisting of 547 human ion channel genes and 11 pseudogenes was assembled, which included all major families of ion channels. Of these, 468 genes have been further analyzed through literature and database mining to determine: i) expression pattern, ii) subcellular localization, iii) physical proximity to a region linked through genetic studies to any of the disorders, iv) implication in a given human disease, and v) effect of null mutations in animal models. An algorithm was developed to take into consideration these various criteria and calculate a prioritization score for each gene. Genes previously identified as being involved in epilepsy, such as SCN1A and CLCN2, scored high in our selection scheme, validating our candidate gene selection criteria. So far we have prioritized 138 ion channel genes and are screening them in our panel of samples. Identification of causative mutations in ion channel genes will help the diagnosis and treatment of such inherited neurological epoisodic disorders.

SAGE Expression Analysis of Trabecular Meshwork to Identify POAG Susceptibility Genes. *M. Hauser[1], D. Layfield[1], J. Yang[1], T. Wang[1], E. Hoffman[3], D. Stamer[3], R. Allingham[2].* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Dept of Ophthamology, Univ of Arizona, Tuczon, AZ; 3) Dept of Ophthamology, Duke Univ Medical Ctr, Durham, NC.

Elevated intraocular pressure is the leading risk factor for primary open angle glaucoma. We hypothesize that gene expression changes in the trabecular meshwork (TM) will reveal determinants of fluid flow facility and thus the mechanism of this IOP elevation. We have profiled gene expression in the TM to shed light on the metabolic activity of this tissue and to identify candidate susceptibility genes for POAG. Serial Analysis of Gene Expression (SAGE) was performed on human TM tissue. Candidate genes were sequenced in 16 POAG patients and controls. Taqman was used to genotype single nucleotide polymorphisms for association analysis. Among the most abundantly expressed genes in the TM is Cathepsin S, which degrades extracellular elastic lamina and could lead to increase resistance to fluid flow in the TM. The fluid transporters Aquaporin 3 and 5 are also expressed in the TM, as are over 50 genes involved in cell-cell adhesion that could influence fluid flow facility. The SAGE data also reveal alternative splicing of transcripts. For example, there are two common splice forms of the serine arginine-rich pre-mRNA splicing factor (SR-A1), but only one of these forms is expressed in the TM. We have combined these SAGE expression profiles with our existing genomic linkage data for POAG (HMG 9: 1109). Those four linkage regions contain 1065 UNIGENE clusters, but only 118 of these genes are expressed in the TM, and even fewer are also differentially expressed in patients and controls. Because they are both positional and functional candidates, these genes are prioritized for analysis in POAG patients and controls. High throughput SNP association and gene sequencing is underway for these candidates. To date no variants associated with POAG have been found in NDN (Necdin homolog), NDNL2 (Necdin-like 2), and the receptors GABRA5, B3, and G3.

A new web tool: the Italian Bank of Rett Syndrome. *F. Ariani, I. Meloni, C. Pescucci, K. Sampieri, I. Longo, F. Mari, M. Bruttini, E. Scala, R. Caselli, C. Speciale, A. Renieri.* Dept Mol Genet, Med Genet, University of Siena, Siena, Italy.

Rett syndrome (RTT) is a progressive neurodevelopmental disorder almost exclusively affecting females. MECP2 mutations are found in 70-80% of cases. Recently, CDKL5 mutations have been found associated with the early onset seizure variant of RTT. The genetic alteration in the remaining cases is unknown. In order to favour the clarification of the pathogenic mechanisms of RTT we have created a bank collecting a large panel of patients. Researchers can access to the bank from the introductory page available at http://www.bank.unisi.it. On the main page users can see a list of all patients available with additional specific information. At present the site contains 187 probands and their relatives. In 137 probands a pathogenic mutation has been identified. The database is organized on two levels: a public level freely available to the general public and an administrator level accessible only to bank administrators through the use of a username and password and containing personal data of patients and relatives and detailed clinical information. In both cases, the main page of the site consists in a table containing a list of all samples available. The following information is available for each sample: a) CODE and INTERNAL CODE (a progressive number which identifies the single families and family members); b) PHENOTYPE (classic, variants); c) MUTATED GENE NAME; d) MUTATION TYPE; e) NUCLEOTIDE and AMINOACID CHANGE; f) ADDITIONAL INFO; g) AVAILABLE BIOLOGICAL SAMPLES; h) PUBMED REFERENCE. In addition users can rapidly find the patients of interest by exploiting the Search by option allowing users to select patients by: i- Mutated gene; ii- Mutation type; iii- Nucleotide change; iv- Aminoacid change; v- Phenotype. Finally, on the main page of the bank, users can find links to three additional pages: a) List of mutations; b) Graphic of mutations; c) Non pathogenic rare variants. This bank collecting a large number of patients will represent an important tool for all researchers working on RTT.

Investigation of TNF cleavage enzyme (TACE) gene polymorphism with rheumatoid arthritis. *C. Potter, J. Worthington, A. Barton.* ARC-EU, The University of Manchester, Manchester, United Kingdom.

Background: The tumour necrosis factor alpha (TNF) cleavage enzyme (*TACE*) is an important regulator of the pro-inflammatory cytokine TNF. It, therefore, represents a strong candidate susceptibility gene for diseases such as rheumatoid arthritis (RA) in which inflammation is mediated by TNF. Methods: 18 SNPs spanning the *TACE* gene were genotyped (Taqman, ABI, UK) in a test cohort comprising 96 Caucasian RA affected sibling pairs (ASP) (192 cases) and 183 Caucasian unrelated controls. Associations were evaluated using a method that accounts for the relatedness of cases (1). Any SNPs showing association ($p<0.05$) were genotyped in a larger replication cohort of 891 unrelated cases and 547 unrelated controls. In addition, haplotype-tagging (ht) SNPs defining the surrounding region were identified from the HapMap data (www.hapmap.org) and genotyped in a 3rd cohort of 359 unrelated cases and 368 controls using RealSNP assays (Sequenom Inc, Cambridge, UK). Haplotype and linkage disequilibrium analysis were undertaken using HelixTree software (Golden Helix, USA). Results: One SNP (rs11684747), mapping to the 5' region of the *TACE* gene, was significantly associated with RA ($p=0.0087$) in the test cohort, with cases being 1.6 and 3.9 times more likely to carry a single or two copies of the minor G allele, respectively (OR AG genotype = 1.6, 95% CI 1.0-2.6, $p=0.04$ and OR GG genotype = 3.9, 95% CI of 1.1-16.6, $p=0.015$). However, this finding was not observed in the replication cohort (OR GG genotype = 0.8, 95% CI 0.4-1.5, $p = 0.4$). In addition, no difference in haplotype frequencies was observed for the promoter htSNPs when compared in the 3rd cohort. Conclusion: The initial association to a promoter polymorphism was not replicated in other cohorts of RA patients and is likely to represent a false positive finding in the test group. Through a combination of random SNPs and htSNPs, the *TACE* gene has been thoroughly screened for association to RA. Therefore, we conclude that polymorphism within the *TACE* gene is unlikely to play a major role in determining susceptibility to RA. References [1] Slager and Schaid, Am J Hum Genet. 2001.

Variation in the complement C5 gene is not associated with rheumatoid arthritis. *K.B.S. Spreckley, S. Eyre, J. Bowes, J. Worthington, A. Barton.* University Of Manchester, ARC Epidemiology Department, Stopford Building, Oxford Road, Manchester. M13 9PT.

Background: Complement 5 (C5) is a key mediator of the inflammatory response and has been implicated in several autoimmune diseases including rheumatoid arthritis, RA. The collagen induced arthritis model of RA has shown that the *C5* gene is involved in the regulation of the inflammatory response. Hence, the *C5* gene is a strong candidate susceptibility gene for RA.

Aim: To investigate association of the *C5* gene with RA.

Methods: In a screening cohort of 192 UK Caucasian RA cases and 180 controls, 19 single nucleotide polymorphisms (SNPs) spanning the *C5* gene were tested for association with RA. Haplotype tagging SNPs were preferentially selected using Hapmap (http://www.hapmap.org/) and Perlegen (http://www.perlegen.com/) to ensure total coverage of the gene. Genotyping was performed using the Sequenom mass spectrometry platform. Haplotypes were estimated using the EM algorithm executed in Helix Tree (http://www.goldenhelix.com) and genotype, allele and haplotype frequencies were compared between RA cases and controls.

Results: The median inter marker spacing of the SNPs was 3.2 Kb. One SNP (rs17292882) deviated from Hardy Weinberg expectations ($p<0.01$) and was eliminated from subsequent analysis. For the remaining 18 SNPs no difference in allele, genotype or haplotype frequencies were observed between RA cases and controls. Given the sample size and allele frequencies of the SNPs tested, association of the gene with RA was excluded for modest effect sizes.

Conclusion: Data from this study provides no evidence for the involvement of the *C5* gene in determining susceptibility to RA. However, the C5 pathway appears crucial to the inflammatory process. Interestingly, C5a-receptor (C5aR) knockout mice are resistant to induction of CIA suggesting that polymorphisms within the *C5aR* gene may play a role in RA disease susceptibility, but this requires further investigation.

Evaluation of the human *LITAF*(*SIMPLE*) gene as a candidate gene for rheumatoid arthritis in two distinct Caucasian populations. *S.K. Hall[1], M. Man[3], Y.-T. Fan[2], B. Dalziel[4], A.B. Seymour[1], J. Mobley[5], D.P. King[1].* 1) Discovery Pharmacogenomics; 2) Non-Clinical Biostatistics; Pfizer Global Research & Development, Groton, CT 06340; 3) Non-Clinical Biostatistics; 4) Clinical Pharmacogenomics; 5) Inflammation Pharmacology, Pfizer Global Research & Development; Ann Arbor, MI 48105.

Rheumatoid arthritis is a chronic inflammatory disease with multiple systemic features in addition to joint destruction. Patients with rheumatoid arthritis are characterized by excessive TNF- production and, although some controversy exists regarding its predicted amino acid sequence, the human *LITAF* gene (also referred to as *SIMPLE*) has been reported to play a role in the regulation of TNF- expression, inhibition of which has demonstrated therapeutic effects in patients with rheumatoid arthritis. In this study, we sought to determine whether genetic variation in *LITAF* is associated with susceptibility to rheumatoid arthritis using a case control study design. In our initial population, 10 single nucleotide polymorphisms in the *LITAF* gene were genotyped in 133 Caucasian subjects with mild to moderate rheumatoid arthritis and 346 ethnically matched control subjects, with no personal history of RA or first-degree relatives with the disease. Potential control subjects were also screened for Rheumatoid Factor and C-reactive Protein (CRP) and excluded if positive. These data were analyzed using a generalized linear model, including covariate terms for ethnicity, sex, and age. A preliminary significant association was identified for SNP rs2868424 in the first intron of the *LITAF* locus (p0.01). Based on these findings, a second study was performed using 570 rheumatoid arthritis subjects and 570 matched controls in an attempt to replicate the initial positive association with SNP rs2868424. However, no significant association was observed for this SNP and rheumatoid arthritis in this population. These data provide some suggestive evidence for a role of *LITAF* in rheumatoid arthritis but, taken together, do not provide consistent genetic evidence for its involvement in this disease.

Association studies of two functional *CTLA4* polymorphisms with Juvenile Rheumatoid Arthritis. *S. Prahalad[1], M. Honeggar[2], S.D. Thompson[3], D.N. Glass[3], J.F. Bohnsack[1], M.J. Bamshad[1,2].* 1) Dept Pediatrics, Univ Utah Sch Medicine, Salt Lake City, UT; 2) Eccles Institute of Human Genetics, Univ of Utah, Salt Lake City, UT; 3) Cincinnati Children's Hosp Med Center, Cincinnati,OH.

Cytotoxic T-lymphocyte Antigen 4 (CTLA4), expressed on the T-cell surface, plays a negative role in regulating T-cell activation. Single nucleotide polymorphisms (SNPs) in *CTLA4* have been associated with susceptibility to several T-cell mediated autoimmune disorders including type 1 diabetes, rheumatoid arthritis, and thyroiditis. A SNP in the promoter region of *CTLA4* has been associated with juvenile rheumatoid arthritis (JRA), a disorder in which activated T-cells predominate the inflamed synovium. To test the hypothesis that variants in *CTLA4* will be associated with susceptibility to JRA or subtypes of JRA, 340 affected children with JRA (138 pauci, 114 poly and 88 systemic onset) and their families were genotyped for SNPs located in the promoter region (-318 C/T) and in exon 1 (49A/G) of *CTLA4*, by PCR amplification and digestion with Mse1 and Tse1, respectively. SNPs were tested for association with JRA by transmission disequilibrium testing using Transmit 2.5.4. Analyses were repeated after stratification by onset-type, age of onset, and course. No significant deviation of transmission of either the -318C/T SNP or the 49A/G SNP to the children with JRA was found. Furthermore, neither SNP showed any deviation of transmission- after stratification by onset type, onset age (early <6 years or late onset > 6 years), or course (pauciarticular or polyarticular course). A second independent cohort of 120 children with JRA (61 pauci, 59 poly) and 180 unrelated ethnicity-matched controls were similarly genotyped for case-control analyses of these two SNPs. There were no significant associations between genotypes or alleles of either SNP with JRA or subtypes. We were unable to replicate the association of the -318C/T SNP previously reported in children of German ancestry with JRA, in two cohorts of children with JRA from the U.S. Our results suggest that these two functional *CTLA4* variants, implicated in numerous autoimmune disorders, are not associated with susceptibility to JRA or subtypes of JRA.

Is the LRP1/A2MR gene expression indicative for degenerative cell metabolism and disease? *C. Glaeser[1], G. Birkenmeier[2], S. Schulz[1], K. Huse[3].* 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Inst Biochemistry, Univ Leipzig, Leipzig, Germany; 3) Inst Molec Biotechnology, Jena, Germany.

The final state of degenerative diseases like Alzheimer's disease (AD) or coronary artery disease (CAD) can be described as a result of disordered cellular metabolism characterized by a disordered supply and disposal system. One hallmark of these degenerative processes is the LDL receptor-related protein 1 (LRP1/A2MR) which functions as a multi-ligand cargo-receptor for several components like A2M, ApoE, and APP. Patients: We performed a comparative study about the in vivo LRP1 gene expression in 3 groups of probands, all from Germany and of Caucasian origin. The 1st group consisting of 9 individuals with Alzheimer's disease (AD) (mean age 71y, SD 8.62; 4 males), the 2nd group consisting of 68 patients with coronary artery disease (CAD) (mean age 58.43y, SD 4.09; 49 males) and the 3rd group with 20 clinically normal individuals (58.9y, SD 3.39; 18 males) serving as control. Methods: LRP1 gene expression was measured in freshly isolated monocytes from venous blood by real-time RT-PCR procedure. Results: The expression level in monocytes of the three groups of probands differed significantly from each other (p=0.015). The highest LRP1 expression level was observed in AD patients (290.96 ag/cell) followed by CAD patients (174.49 ag/cell) and by the lowest expression level in monocytes from controls (158.79 ag/cell). There was no significant correlation between age or gender with LRP1 expression. The results demonstrate a disease-related increase of LRP1 gene expression level in monocytes which might serve as a diagnostic feature for AD and CAD.

Role of homo- and heterozygous PINK1 mutations in a large German family with Parkinson's disease. *K. Hedrich[1], J. Hagenah[1], A. Djarmati[1], A. Hiller[1], C. Schneider-Gold[2], P. Vieregge[3], A. Muenchau[4], C. Klein[1].* 1) Depts Neurology and Human Genetics, Univ Luebeck, Germany; 2) Dept Neurology, Univ Goettingen, Germany; 3) Dept Neurology, Hospital Lippe-Lemgo, Lemgo, Germany; 4) Dept Neurology, University Medical Center Hamburg Eppendorf, Hamburg, Germany.

Background: While homozygous mutations in the PINK1 gene have been unequivocally associated with Parkinson's disease (PD), the role of single heterozygous PINK1 mutations is less clear. **Patients and methods:** After obtaining informed consent, 153 mostly early-onset PD patients underwent a standardized neurological examination. In addition, 19 family members of a homozygous German mutation carrier were included (Family W). We screened for PINK1 mutations by dHPLC (Exons 2-8) and SSCP (Exon 1) analyses, followed by sequencing in cases with a conspicuous elution/band pattern. We also performed gene dosage studies in PINK1 by quantitative duplex PCR. **Results:** We identified two German PINK1 mutation carriers (1.3%), one homozygous (Case 1; index patient of Family W; c.1366C>T; p.Gln456X) and one heterozygous (Case 2; c. 952A>T; p. Met318Leu) patient. Case 1 presented with a phenotype closely resembling idiopathic PD with a late onset, Case 2 had an early onset and additional signs. Family W comprised a total of four affected homozygous (age: 60-71 yrs., age of onset: 47-61 yrs.), seven slightly or mildly affected heterozygous (age: 31-49 yrs.), and four unaffected heterozygous mutation carriers (age: 34-44 yrs.). None of the heterozygous affected family members was aware of their symptoms (asymptomatic). All symptomatic members in Family W had a very benign clinical course and responded extremely well to small doses of L-Dopa. **Conclusions:** Our study suggests that a small but considerable percentage of PD patients carries PINK1 mutations. Heterozygous PINK1 mutations may predispose to PD, as was previously suggested by the presence of dopamine hypometabolism in asymptomatic mutation carriers. Long-term follow-up of our large family provides an excellent opportunity to further evaluate the role of single heterozygous PINK1 mutations later in live, which will have major implications on genetic counseling.

Familial multiple slerosis is not associated with eIF2B5 gene mutation in Southern Italy. *C. Ungaro, M. Liguori, FL. Conforti, T. Sprovieri, A. Magariello, A. Patitucci, AL. Gabriele, M. Muglia, R. Mazzei.* ISN-CNR, Mangone, CS, Italy.

A lot of evidence has provided that genetic factors contribute to the familial Multiple Sclerosis (MS) susceptibility, a chronic inflammatory demyelination of the central nervous system (CNS). On the basis of the absolute risk of MS in a first-degree relative of a patient is 20-40 times the risk in the general population, an autosomal recessive model of inheritance of MS candidate gene has been suggested. Up to date, the only MS locus has been mapped to the Major Histocompatibility Complex (MHC) superlocus on chromosome 6p21.3. Other genetic elements located within the Human Leukocyte Antigen (HLA) Complex, i.e., Heat Shock proteins (HSPs) have been shown to be strikingly elevated in MS lesions, thus suggesting their role in the pathophysiology of MS. The eukaryotic translation initiation factor (eIF2B), encoded by different genes (eIF2B1-5) is an important factor in preventing the synthesis of denatured proteins during cellular stress and whose function seem to work in parallel with HSPs. Mutations in this gene inherited as autosomal recessive trait cause a stress-sensitive leukoencephalopathy called Vanishing White Matter Disease (VWM) (OMIM 603896). Previous studies have reported cases of VWM with MR images similar to that observed in MS. In the present study we performed the eIF2B5 gene mutational screening in 11 italian pairs of siblings affected by MS. The molecular analysis of the eIF2B5 gene was carried out by Denaturing High Performance Liquid Chromatography (DHPLC) and direct sequencing. We did not find any mutations in the coding regions in both patients and controls, except for a common variation in exon 13 (Ile587Val) in the heterozygous state in 6 MS patients and in the homozygous state in only one MS patient. The same variation was also found in the heterozygous state in 3 out of 10 healthy controls. Therefore, the current data demonstrate that the eIF2B gene is not involved in the development of familial MS and that VWM and familial MS are distinct diseases.

Eating disorders and related psychopathological traits are associated with serotonin receptor 5HT2C alleles. *M. Ribases[1], J.M. Mercader[1], M. Gratacos[1], M. Morell[1], A. Badia[2], L. Jimenez[2], R. Solano[2], F. Fernandez-Aranda[2], X. Estivill[1].* 1) Genes and Disease Program, Center for, Genomics regulation, Barcelona, Catalonia, Spain; 2) Psychiatric Service, Ciutat Sanitaria Bellvitge, LHospitalet, Catalonia, Spain.

Several lines of investigation support a serotoninergic participation in eating behaviour and body weight regulation and suggest its involvement in the aetiology of eating disorders (ED) and some related psychopathological traits. to test this hypothesis we have analyzed the -995G/A, -759C/T, -697G/C and Cys23Ser SNPs within the serotonin receptor 5HT2C gene by a population-based association study in a total sample of 151 ED patients and 116 sex-matched unrelated controls. We also analyzed the potential involvement of the 5HT2C gene in different psychiatric symptoms measured by the Symptom Checklist 90-revised (SCL90-R) questionnaire. The case-control study showed that the -995G/-759C/-697C/Ser23 haplotype was associated to the purging ED categories of and binge-eating/purging anorexia and bulimia nervosa (P = 0.01). We also observed that bulimic patients carrying the -995A/-759T/-697C/Cys23 5HT2C haplotype showed increased symptomatology for seven of the nine subscales of the SCL90R questionnaire. These include somatization (p = 0.029), obsessive-compulsiveness (p = 0.021), depression (p = 0.032), anxiety (p = 0.004), hostility (p = 0.028), phobic anxiety (p = 0.029) and paranoid ideation (p = 0.008). The results presented here suggest that the 5HT2C gene may participate in the physiopathology of ED, not only through its direct effect on eating behaviour, but also on the anxiety and depressive traits associated to anorexia and bulimia nervosa. Supported by the Fondo de Investigaciones Sanitarias (PI040632 and Psychiatry Genetics network, G03/184), and the Departament dUniversitats i Societat de la informació, Generalitat de Catalunya.

Several BDNF SNPs, but not the Val66Met functional variant, show association with panic disorder. *M. Gratacos[1,2], R. Martín-Santos[3,4], R. Navinés[3,4], M. Bayés[1,2], R. de Cid[1,2], M. Cabré[4], A. Puig[2], X. Estivill[1,2].* 1) Genes & Disease Program, Center for Genomic Regulation, Barcelona, Catalonia, Spain; 2) Spanish Genotyping Network (CeGen), Barcelona, Catalonia, Spain; 3) Psychiatric Genetics, Pharmacologic Research Unit, Institut Municipal d'Investigació Mèdica (IMIM), Barcelona, Catalonia, Spain; 4) Department of Drug Abuse and Psychiatry (IAPS), Hospital del Mar, Barcelona, Catalonia, Spain.

Different studies point to brain-derived neurotrophic factor (BDNF) as involved in the pathophysiology of mood disorders. Several studies have evaluated the functional BDNF Val66Met variant with opposing results. The Val66 allele has been associated with bipolar disorder in Caucasians but not in Asians, a haplotype incorporating Met66 appeared to be protective against bipolar disorder or obsessive-compulsive disorder and, finally, the Met66 allele is strongly associated with anorexia and bulimia. With respect to panic disorder (PD), a recent study has found that genotype and allele frequencies for the BDNF gene Val66Met variant did not differ between PD patients and controls in a group of Chinese patients. Methods: To study the association between BDNF and PD, we performed a casecontrol study in a total sample of 198 PD outpatients diagnosed by SCID-DSM-IV and 178 unrelated sex-matched controls with 30 SNPs covering the entire BDNF gene and using the SNPlex technology. Results: Significant differences in genotype frequencies between PD patients and controls were observed for four BDNF SNPs, but no with the Val66Met variant. Haploview defined two different LD blocs and a haplotype associated to the disease (p=0.04). Conclusions: This study defines BDNF as a gene involved in the susceptibility to PD and reinforces the view that variants in BDNF play a role in different psychiatric disorders that may share common underlying biological features. Profiling cytogenetic abnormalities in autism using array CGH. *L.A. McInnes, L. Edelmann.* Dept Psychiatry/Human Gen, Mount Sinai Sch Medicine, New York, NY.

Introduction: The advent of array comparative genomic hybridization (array CGH), among other methods, has permitted genome-wide investigation of large genomic duplications and deletions ranging from 1 kb to several hundred kb. Surprisingly, more than one-half of these polymorphic dups/dels have been found to overlap with known genes and likely contribute substantially to human phenotypic variation. We are interested in the role these dups/dels might play in autism, especially as sex ratios of affecteds indicate that autism with mental retardation and dysmorphology may be far less heritable than autism without those features. Autism is associated with at least 8 microduplication/deletion syndromes and we suspect that there will be many more. For instance, recent array CGH profiling studies of children with MR and learning disability show that 10-20 percent of these individuals have microdups/dels that appear to be responsible for the phenotype. Therefore, we screened 20 cases with autism and severe MR from the isolated population of the Central Valley of Costa Rica (CVCR) to look for known and novel microdups/dels associated with autism.

Results: We found 9 unique, novel microdups/dels that may be pathological. We also found one duplication of a clone in 15q12, the Prader-Willi/Angelman region. We also found 3 novel dups/dels in more than one individual including 22q12, 4q32 and 7q21. The latter deletion is of greatest interest as this clone lies immediately next to the breakpoint of a chromosomal rearrangement previously identified in a case of autism.

ConclusionWe will go on to map the break-points of these microdups/dels in order to find potential autism susceptibility genes. Interestingly, Sharp et al. 2005 recently noted that they saw virtually no polymorphic dups/dels that were exclusive to any population in the 4 major population groups they tested. We will continue our study in the CVCR on a larger scale to see if this observation holds true.

Human BDNF/BDNFOS sense and antisense genes and association study of their genomic polymorphisms with substance abuse vulnerability. *Q.R. Liu, T. Drgon, D. Walther, G.R. Uhl.* Molecular Neurobiology Branch, NIDA/NIH, Baltimore, MD.

Molecular and genetic studies in human have identified brain-derived neurotrophic factor (BDNF) as a candidate locus for involvement in addictions. Human BDNF gene is transcribed from at least 7 promoters and each of the seven alternative exons is independently spliced to a main coding exon. We discovered a novel alternatively spliced natural antisense non-coding gene termed ¡BDNFOS¡ that is transcribed from the opposite strand, using a single promoter. The BDNFOS 225 bp fifth exon is complementary to BDNF's main protein coding exon (exon VIII). The human BDNFOS gene is conserved in chimpanzee but not found in other nonprimate mammalian genomes searched. We have identified novel SSLP and SNP markers within BDNF/BDNFOS genes, several with remarkably- different frequencies in members of different ethnic groups. Allele 228 of the SSLP ss13534842, located at the 5' flanking sequence of the BDNF main coding exon, displayed significant association with drug abuse vulnerability of NIDA European-American samples. The Met66/rs6265 SNP was associated with reduced vulnerability in both African- and European-American samples. BDNF genomic variants remain candidates for modest contributions to human addiction vulnerability (Support NIDA-IRP).

THE HOLOPROSENCEPHALY-LIKE PHENOTYPE - CHALLENGES IN DIAGNOSIS AND GENETIC COUNSELING. *L. Ribeiro, A. Richieri-Costa.* Hosp Rehab Craniof Anomalies, Univ Sao Paulo, Sao Paulo, Brazil.

Mutations involving the SHH, SIX3, GLI2 and TGIF genes result in a wide phenotypic variability, ranging from normal phenotype to typical holoprosencephaly. We focused our attention in a cluster of 22 patients with normal neuropsychological development and with facial appearance within the so called Holoprosencephaly-like phenotype which have been previously screened for SHH, SIX3, TGIF and GLI2. The main objective of the present study was to observe the evolution of the phenotype and to compare with the type of observed mutation, when present. From this sample, 5 patients showed mutations in the SHH gene, and 1 in the GLI2, the remainder patients showed no mutations in the genes screened. In these patients, several clinical signs are associated randomly and the definition of a heterogeneous condition such as the HPE not always is a simple task. Molecular assays have been mandatory, since 27% of these patients have shown different mutations in SHH or in other genes within the SHH cascade. When we compare the present sample with Mulikens patients there are enough similarities to conclude that we are dealing with the same condition, especially when we consider the changing phenotype with age, moreover, the assumption that most of the patients within the HPE spectrum present neuropsychological delay should be regarded with caution.

Cross-species micro array analysis identifies Prolactin as a candidate hypothalamic signaling molecule for sexual orientation in sheep. *S. Bocklandt[1], C.E. Roselli[2], E. Vilain[1].* 1) Dept Human Genetics, Sch Med, Univ California, Los Angeles, Los Angeles, CA; 2) Dept. Physiology & Pharmacology, Oregon Health & Science University, Portland, OR.

Sheep are a unique animal model in which to study the hormonal, developmental, and genetic contributions to sexual partner preference. Most domestic rams are sexually attracted to and active with estrous ewes and are referred to as female oriented rams (FORs). However, 8-10% of rams exhibit a sexual partner preference for other males classifying them as male oriented rams (MORs). An ovine sexually dimorphic nucleus (oSDN) was identified in the Medial Preoptic Area of the Anterior Hypothalamus (MPOA), and this nucleus was found to be larger in FORs than in MORs and similar in size in MORs and ewes. We performed a cross-species micro array expression analysis using human spotted cDNA arrays on RNA from the anterior hypothalamus and amygdala of 4 MORs, 3 FORs and 3 ewes in the luteal phase of the estrous cycle, during the breeding season. Using a stringent spot quality filter, 3347 unique genes were selected for analysis. The ovine Prolactin (Prl) transcript showed the most consistent expression difference between the MORs and the FORs, both in the amygdala and the anterior hypothalamus. Quantitative real-time PCR performed on the same subjects showed that Prl was expressed 20.3 times higher in the anterior hypothalamus, and 6.1 times higher in the amygdala, however, no expression differences were found in the frontal cortex or in the pituitary. Furthermore, circulating Prolactin levels were not different between the MORs and FORs. The differences in hypothalamic and amygdala Prolactin expression were not found in animals sacrificed outside the breeding season. We hypothesize that the Prolactin signaling pathway plays a role in the regulation of sexual orientation in sheep. The extremely high prolactin mRNA levels observed in male oriented rams indicate a dysregulation of Prl expression in the hypothalamus and amygdala. It may reflect an unusual expression during brain development, creating a female-typical expression level that would orient rams to a female-typical partner preference.

Loss of endogenous AR accelerates motor neuron dysfunction and androgen insensitivity in a mouse model of spinal and bulbar muscular atrophy. *P.S. Thomas Jr[1], G. Fraley[2], L. Woodke[3], V. Damian[1], B.L. Sopher[1], S. Plymate[3], A.R. La Spada[1].* 1) Lab Medicine, Univ Washington, Seattle, WA; 2) Biology, Hope College, Holland, MI; 3) Medicine, Univ Washington, Seattle, WA.

X-linked spinal and bulbar muscular atrophy (SBMA) is a slowly progressive motor neuronopathy that also results in mild androgen insensitivity. Evidence from SBMA and other polyglutamine (polyQ) repeat diseases suggests that polyQ expansion causes pathology by imparting a toxic gain of function. However, androgen insensitivity reflects a deficit of wild-type AR function, suggesting that the androgen insensitivity of SBMA involves loss of function as well. In order to investigate the role of normal AR function in SBMA, we compared male mice carrying the human AR with 100 polyglutamine repeats (AR100) to mice carrying the same transgene, but lacking the endogenous Ar (AR100-tfm). Both AR100 and AR100-tfm mice express the same amount of polyQ-expanded AR; however, AR100-tfm mice exhibit earlier onset of weight loss, kyphosis, and hindlimb atrophy, and performed slightly worse on the grip-strength test than did AR100 mice. In addition to the neuromuscular phenotype, absence of Ar uncovered signs of androgen insensitivity. The anogenital distance of male AR100-tfm mice is indistinguishable from females, whereas the anogenital distance of male AR100 mice is normal. AR100-tfm mice display elevated levels of luteinizing hormone (LH) ($p < .01$) and an increased androgen insensitivity index (LH x Free Testosterone); however, testes size in AR100-tfm mice was markedly diminished ($p < .05$). Furthermore, the size of the spinal nucleus of the bulbocavernosis (SNB), which is extremely sensitive to androgen function, is markedly reduced in AR100-tfm mice ($p < .05$). We thus hypothesized that the androgen insensitivity results from a diminished ability of polyQ-expanded AR to activate transcription. Reporter assays using AR-null PC-3 cells revealed a substantial decrease in the transactivation ability of polyQ-expanded AR ($p < .05$). These results suggest that the endogenous Ar ameliorates pathology in a mouse model of SBMA, and supports a role for the loss of wild-type function of AR in SBMA pathogenesis.

Genome-wide Scan for Autism in an Extended Pedigree from a Regional Subisolate in Finland. *T. Ylisaukko-oja[1,2], T. Varilo[1], H. Kilpinen[1], R. Alen[3], R. Vanhala[4], E. Kempas[1], M. Elmohandess[1], L. von Wendt[4], I. Järvelä[2,5], L. Peltonen[1,2].* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Department of Child Neurology, Central Hospital of Central Finland, Jyväskylä, Finland; 4) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 5) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland.

As a part of the study of autism spectrum disorders (ASDs) in the Finnish population, we performed an extensive genealogical search and identified common ancestors for a set of study families. We were able to connect 21 Finnish families with ASDs (n_affected = 31) by genealogical links extending to 17th century. Although the earlier work in the Finnish population has revealed some interesting loci (Auranen et al. 2002; Ylisaukko-oja et al. 2004), the benefits of this isolated pedigree have not been maximally utilized so far. Therefore, we have carried out a dense genome-wide screen in this unique sample using 1100 microsatellites, which yields an average intermarker spacing of 4 cM. Joint analysis of linkage and linkage disequilibrium was performed using Pseudomarker statistics. The best evidence for joint linkage and LD emerged for loci at 1q23 (p=0.0008) and 15q12 (p=0.0008). 1q23 has been among the best loci also in the two earlier genome-wide scans in the Finnish sample (Auranen et al. 2002; Ylisaukko-oja et al. 2004). Furthermore, it is of interest that cytogenetic abnormalities at 15q11-13 are reported to be frequently present in association with autism. Fine mapping of the identified loci and analyses of positional candidate genes are performed in an extended sample of 100 Finnish autism families. The candidates selected for the follow-up analyses include ATP1A2, ATP1A4, KCNJ9, KCNJ10, RGS4 and CAPON at 1q23 as well as UBE3A, ATP10C and GABAA receptor cluster at 15q12.

An association analysis of candidate genes in the Chromosome 15 q 11-13 (Prader-Willi/Angelman Syndrome Critical Region) and Autism Spectrum Disorder. *S. Curran[1,2], J. Powell[3], B. Neale[2], K. Dworzynski[2], T. Li[2], S. Thomas[4], J. Brown[5], M. Veltman[6], S. Roberts[4], D.G.M. Murphy[1], P. Sam[1,2], P.F. Bolton[2].* 1) Psychological Med, Inst Psychiatry, London, United Kingdom; 2) MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, De Crespigny Park, London SE5 8AF; 3) Department of Neuroscience, Institute of Psychiatry, De Crespigny Park, London SE5 8AF; 4) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, Wiltshire, U.K; 5) Paediatric Medical Unit, Southampton General Hospital, Southampton, UK; 6) Section of Developmental Psychiatry, University of Cambridge.

Autism spectrum disorder (ASD) is a spectrum of related diagnostic categories, comprising subtypes: autism, atypical autism, Aspergers syndrome and other pervasive developmental disorders (ICD-10). Chromosome 15q11-q13 has been identified as a strong candidate region on the basis of autistic symptoms in patients with chromosomal abnormalities in that region as outlined in Bolton et al. (2004) and numerous suggestive linkage and association findings (see Spence, 2004). We have tested 148 simplex U.K. families, characterised by both ADI-R and ADOS to have an autism spectrum disorder (ASD), for association to the GABRB3 gene on chromosome 15q11-13. Single nucleotide polymorphisms (SNPs), spaced on average by 13 kb were genotyped across the gene that had not been previously parsed in autism. Global significance for all marker p-values was obtained with region-wide empirical significance. Short range linkage disequilibrium was observed, but there is evidence for large amounts of recombination in the gene. A high LD haplotype of 4 SNPs was tested, including the two most significant markers, and was significant at $p = 0.0007$ when haplotypes of >2% were included and at $p = 0.006$ when haplotypes of >1% were included. Furthermore, we have genotyped other genes in the PWACR on this sample, namely GABRG3 and the maternally expressed genes UBE3A and ATP10C, using a dense array of SNPs across each gene. We are currently analysing these data and plan to present these plus gene-gene interaction analyses in the region.

Testing and analysis of folate metabolism candidate genes for association with spina bifida meningomyelocele.

M.R. Dewhurst[1], K.-S. Au[1], T.M. King[2], J.M. Fletcher[1], I.T. Townsend[1], G.B. Villareal[3], G.H. Tyerman[4], H. Northrup[1,5]. 1) Pediatrics, Univ of TX Med Sch at Houston, Houston, TX; 2) Internal Medicine, Univ of TX Med Sch at Houston, TX; 3) Pediatrics, Baylor College of Med, Houston, TX; 4) Shriners Hosp for Children, Los Angeles, CA; 5) Shriners Hosp for Children, Houston, TX.

Spina bifida meningomyelocele (SBMM) is the most common form of neural tube defect (NTD) that, with surgical and medical intervention, is compatible with survival. While, folate supplementation in the periconceptional period reduces both occurrence and recurrence risk of NTDs, the underlying mechanism is not understood. Thus, the folate metabolic pathway genes deserve study to determine their role in SBMM formation. We have tested single nucleotide polymorphisms (SNPs) across a number of the genes involved in folate metabolism in a sample including ~490 SB patients and their parents to assess for association. We utilized the SNPlex high throughout genotyping system to genotype approximately 1500 individuals. The SNPlex system allowed us to interrogate 47 SNPs in 14 genes of the folate metabolic pathway including: 1) MTHFR, MTRR, MTR, MTHFD1, BHMT, CBS, MAT2A, MAT2B, AHCY, DHFR involved in the enzymatic processes of folate metabolism and 2) RFC1, FOLR1, FOLR2, FOLR3, that respectively mediate transportation, delivery and secretion within this pathway. Thus far, we have successfully determined the genotype of 42 SNPs in ~1300 subjects. We are analyzing the data. The genotype data will allow us to determine the potential involvement of individual SNPs as well as variant haplotypes in these candidate genes that may confer risk for susceptibility to SBMM. It will also allow us to evaluate gene-gene effects by assessing two or more SNP combinations within different genes in the folate pathway. With this genotypic data in hand we can combine it with phenotypic data, such as brain dysmorphology and neurobehavioral outcomes, collected by one of our collaborating groups, to determine if single or combinations of multiple genetic variants can result in NTD susceptibility and the associated phenotypic variability observed in these disorders.

Genome-wide association study of idiopathic Parkinson's disease using 27,000 microsatellite markers. *W. Satake[1, 2], Y. Hirota[1], Y. Momose[3], I. Mizuta[1], A. Oka[4], G. Tamiya[5], S. Sakoda[2], M. Yamamoto[6], N. Hattori[7], M. Murata[8], H. Inoko[4], T. Toda[1].* 1) Div. Clinical Genetics, Osaka Univ. Grad. Sch. Med., Osaka; 2) Dept. Neurol., Osaka Univ. Grad. Sch. Med., Osaka; 3) Dept. C.B.I., Grad. Sch. Med., Univ. Tokyo, Tokyo; 4) Dept. Mol. Life Sci. II, Tokai Univ. Sch. Med., Kanagawa; 5) Inst. Health Bioscience, Tokushima Univ. Grad. Sch. Med., Tokushima; 6) Dept. Neurol., Kagawa Pref. Central Hosp., Kagawa; 7) Dept. Neurol., Juntendo Univ. Sch. Med., Tokyo; 8) Dept. Neurol., NCNP, Tokyo, Japan.

Parkinsons disease (PD), one of the most common neurodegenerative diseases, is a complex disorder with multiple genetic and environmental factors influencing disease risk. To identify susceptibility genes for idiopathic PD, we performed a genome-wide association study with pooled DNA using approximately 27,000 microsatellite markers arranged at intervals of approximately 100 kb throughout the genome. For the 1st screening, we performed the association study with pooled DNA from 124 PD patients and 124 normal controls. We analyzed the PCR products with the GeneScan software, and compared the pattern of the PCR products of pooled DNA from PD patients with pooled DNA from controls by the PickPeak software, and found associations (p0.05, 2xm Fishers test) in approximately 8% (2,205 markers) of the markers. To exclude false positive associations, we performed 2nd and 3rd screenings using different sets of pooled DNA from 250 PD patients and 250 normal controls for each screening. 348 markers showed associations (p0.05, 2xm Fishers test) throughout all three screenings. We have been confirming these associations using individual samples of 624 PD patients and 624 normal controls. The markers which showed a consistent peak pattern throughout the three screenings were given priority for individual genotyping. So far, we have performed individual genotyping on 71 markers, and 16 markers still showed an association. Among these, 2 markers showed a stronger association (p0.001). Genes in linkage disequilibrium with these markers may be associated with the pathogenesis of PD.

Frequency of mitochondrial DNA T8993G mutation in the ATPase 6 gene encoding subunit a, in patients with Alzheimer disease. *E. Martinez-Cano[1,2], M.P. Gallegos[3], M.A. Macias[4], G.G. Ortiz[1].* 1) Lab. Desarrollo-Envejecimiento, CIBO, IMSS, Guadalajara, Jalisco. Mexico; 2) Doctorado en Genetica humana, Universidad de Guadalajara; 3) Laboratorio de Genetica Molecular, CIBO, IMSS; 4) Departamento de Neurologia, HE, CMNO, IMSS, Guadalajara, Jalisco. Mexico.

BACKGROUND : Alzheimer disease (AD) is a progressive and neurodegenerative disorder characterized by cognitive and memory deterioration. Alzheimer's disease occurs gradually, and is not a normal part of the aging process, is the most common cause of dementia. Recently evidence indicates that a low in the energy generation of the mitochondria is characteristic that unifies the neurodegenerative diseases. In order to obtain direct evidence that mitochondrial function is altered in Alzheimer's disease. Different reports had pointed mutations in the mitochondrial ATPase gene. Mutation T8993G cause the NARP (neurogenic muscle weakness, ataxia and retinitis pigmentosa) and Leigh syndromes. OBJECTIVES: Determined the frequency of T8993G mutation of mitochondrial ATPasa6 gene, and their correlation with ATP synthase enzymatic activity, in AD patients and control group. MATERIAL AND METHODS: Controls (n=14) and the same number of patients with AD were selected. The AD patients were according to NINCDS/ARDRA criteria. The diagnosis was supported by Magnetic Resonance Imaging (MRI), Single Proton Emission Computed Tomography (SPECT) and the Mini Mental State Examination (MMSE) neuropsychological test. The ADN genomic extraction was according Miller method. Activity enzymatic was according Summer. RESULTS: The data revealed that the hydrolytic activity of ATP synthase was significantly increased in patients with AD (14.3 1.4 nmol PO4 min-1(mg protein)-1, n = 10) to compared with the control group (10.0 0.6 nmol PO4 min-1 (mg protein)-1, n = 10). The mutation T8993G was observed only in AD patients 71.42% (10/14) mutation homozygotes, 7.16% (1/14) heterozygotes and 21.42% (3/14) normal homozyotes. CONCLUSION: These results probably suggest that weak activity functional can be explained by T8993G mutation in ATP synthase that serve as proton channel for enzymatic activity.

Exploring the association of glyceraldehyde-3-phosphate dehydrogenase (GAPD) gene and late-onset Alzheimer disease. *C.A. Browning[1], P.I. Lin[1], E.R. Martin[1], P.G. Bronson[1], G.S. Small[2], D.E. Schmechel[3], K.A. Welsh-Bohmer[3, 4], J.L. Haines[5], G.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Center for Human Genetics, Duke Univ, Durham, NC; 2) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, CA; 3) Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC; 4) Joseph and Kathleen Bryan Alzheimer's Disease Research Center, Duke University, Durham, NC; 5) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Previous linkage studies have shown that chromosome 12 harbors susceptibility genes for late-onset Alzheimer disease (LOAD). However, association studies of several candidate genes on this chromosome region have obtained conflicting results. Recently, Li et al. (2004) reported the association of the gliceraldehyde-3-phosphate dehydrogenase (GAPD) gene on chromosome 12p and the risk of LOAD. GAPD is closely related to neural apoptosis. Here, we carried out association studies on 12 single nucleotide polymorphisms (SNPs) in the GAPD gene and its paralogs. Overall we saw no evidence for single-locus association in the GAPD gene and its paralogs with LOAD, but there was marginally significant association in a SNP in the GAPD gene particularly in the later-onset LOAD subgroup (age-at-onset greater than the mean of 71 years). Family-based association tests showed that two SNPs in the GAPD gene and in PPM1H gene (a GAPD paralog) respectively were associated with the later-onset LOAD. None of these associations were significant after we performed multiple testing corrections. However, haplotype-based association analyses in the unrelated case-control sample revealed a two-locus haplotype significantly associated with the disease risk particularly for the later-onset LOAD (experiment-wide empirical p-value = 0.001). Additionally, we found suggestive evidence for the multi-locus effect of GAPD gene and PPM1H gene on the risk of LOAD, by using the Extended Multi-factor Dimensionality Reduction method. The results suggest that the role of susceptibility genes of minor effect, such as the GAPD gene for LOAD, may be revealed by multi-locus association analysis.

A Meta-Analysis of the Relationship of the HOPA^{12bp} Polymorphism and Schizophrenia. *R. Philibert.* Dept Psychiatry, Univ Iowa, Iowa City, IA.

Uncommon polymorphisms, and in particular, balanced uncommon polymorphisms, present a significant challenge to our understanding of their role in behavior. Over a series of studies, we have demonstrated that an uncommon candidate gene polymorphism for schizophrenia, known HOPA^{12bp}, is the defining polymorphism for a large X-chromosome haplotype in population disequilibrium and that it is associated with a positive syndrome of psychosis. However, not all studies have shown this effect and our other studies have shown a broad, sex dependent effect of this allele on behavior and endocrine function. We reviewed prior studies and conducted meta-analysis of studies using probands of Northern European extraction. We find that the presence of the HOPA^{12bp} is a significant risk factor for psychosis for both men and women and suggest that differences in the case definition of schizophrenia may affect the strength of the association of this allele with behavioral illness.

Pharmacogenetics of risperidone therapy in autism. *C. Correia[1], G. Oliveira[3], P. Santos[1], J. Almeida[3], A.M. Coutinho[1], C. Marques[3], C. Bento[3], A. Ataíde[3], T. Miguel[3], A.M. Vicente[1,2].* 1) Instituto Gulbenkian Ciencia, Portugal; 2) Instituto Nacional Saúde Dr Ricardo Jorge, Portugal; 3) Hospital Pediátrico Coimbra, Portugal.

Treatment of autism with the atypical antipsychotic risperidone is mainly effective in the control of disruptive behaviors associated with autism, while in some cases improving typical symptoms. The objective of this ongoing pharmacogenetic study is to identify genetic factors underlying the variability in individual response to this drug. Ten autistic patients (3 females, 7 males, mean age 12.73.6 years) were selected for risperidone therapy. Efficacy and tolerability was monitored at baseline and after one month, using the Autism Treatment Evaluation Checklist (ATEC) and assessing prolactin (PRL) levels and weight gain. Genotyping of *CYP2D6* alleles *3,*4,*5,*6 and gene duplication, and of polymorphisms in the *DRD2* and *HT2C* genes were performed. ATEC scores improved after one month in all patients except one, and were positively correlated with increase in PRL levels. Risperidone affinity for the D2 dopamine receptor is influenced by a 3UTR *DRD2* polymorphism, with allele A1 reported to be associated with PRL increase, and might therefore mediate the clinical response. Although the only patient with a PRL increase of clinical significance carried the A1 allele, we did not find an overall correlation between ATEC scores and *DRD2* genotypes, indicating an influence of other factors. The patient who did not respond to therapy had the *CYP2D6* gene duplication associated with the ultrametabolizer (UM) phenotype. Interestingly, this patient is obese but did not show any weight gain with treatment. Two other patients were homozygous for the poor metabolizer (PM) *CYP2D6*4* allele, but showed no evidence for increased side effects, while their ATEC scores improvement was variable. Overall, we found no correlation of ATEC scores, PRL levels or weight gain with *CYP2D6*, *DRD2* or *HT2C* genotypes. Our preliminary results indicate that the response to medication is determined by a complex interplay of factors, pointing out the need for a multiparametric approach to dissect genetic influences in drug response.

Functional characterization of GRIK2 haplotypes associated with bipolar affective disorder. *S. Buervenich[1], R. Blumenthal[2], W.R. Corona[1], H.M. Alosh[1], R. Bachmann[2], J. Du[2], P. Yuan[2], N. Akula[1], H.K. Manji[2], S.D. Detera-Wadleigh[1], F.J. McMahon[1].* 1) Genetic Basis of Mood and Anxiety Disorders Unit, Mood and Anxiety Disorders Program, NIMH, Bethesda, MD, USA; 2) Laboratory of Molecular Pathophysiology, Mood and Anxiety Disorders Program, NIMH, Bethesda, MD, USA.

Bipolar affective disorder (BPAD) is one of the world's ten most disabling conditions with a suicide rate of up to 15 percent. Very little is known today about the biological causes of this disease, which has been shown very consistently in twin and adoption studies to be highly heritable. We recently identified association of GRIK2 (also known as GluR6) haplotypes with the disorder. The GRIK2 gene codes for a kainic acid-type ionotropic glutamate receptor expressed in several brain regions that have been implicated in the etiology of BPAD. Furthermore, it is involved in circadian-rhythm generating pathways and also has metabotropic effects that are conveyed at least in part by a PKC-dependent pathway, one of the pathways that have been shown to be regulated by the mood stabilizer lithium. We now report results from detailed investigation of the genomic sequence surrounding the markers defining the risk-haplotypes (rs6922753 and D6S1642). Re-sequencing of 24kb of genomic sequence revealed five new sequence changes, none of which, however, was located in coding regions. Functional studies using lymphoblast cell lines from homozygous risk-haplotype carriers support the hypothesis that the risk-haplotypes may be regulatory: Preliminary results from western-blot analyses on homozygous carriers of the rare allele of the SNP (located 7bp downstream of an exon/intron splice site) suggest high expression of a 55 kDa protein product (the wildtype GRIK2 product is approximately 115 kDa). Furthermore, expression of the shorter protein was found to be inducible by hydrocortisone treatment. Results from further analyses on the identity of the 55kDa protein product as well as studies on potential regulation of GRIK2 expression by mood stabilizers will be presented.

Association of autism with serotonin-related genes. *J.D. Buxbaum[1, 2], N. Ramoz[1, 2], G. Cai[1, 2], J.G Reichert[1, 2], C.J. Smith[2], T.E. Corwin[2], J.M. Silverman[2], E. Hollander[2].* 1) Laboratory of molecular neuropsychiatry, Mount Sinai School of Medicine, New York, NY; 2) SEARVER center, Dept. of Psychiatry, Mount Sinai School of Medicine, New York, NY.

Autism (MIM#209850) is a complex neurodevelopmental disorder that is associated with hyperserotonemia in 30 percent of individuals, and functional variants of the serotonin transporter gene (SLC6A4) have been considered as susceptibility loci. To address the role of serotonin in autism, we have begun a detailed analysis of serotonin-related genes in autism. We have screened 10 variants of SLC6A4, including the insertion/deletion 5-HTTLPR in the promoter locus, 16 variants in TPH1 and TPH2, and 41 additional variants in 10 other serotonin-related genes, in 352 families with autism (90 simplex and 262 multiplex), including 653 autism subjects. Markers were analyzed for linkage disequilibrium using Haploview, linkage using the GENEHUNTER package, and association using family-based methods (Transmit, TDTPhase, and PDTphase). No evidence for linkage or association was found between autism and markers in SLC6A4 or TPH2. Some preliminary evidence for association was observed in two serotonin receptor genes, although this might reflect a Type I error. SLC6A4 and TPH2 may not be involved in the susceptibility to autism. To confirm association with autism and specific serotonin receptor genes, screening of additional SNPs in these genes and replication in additional populations are needed.

Identification of a haplotype in *TAAR6* (*TRAR4*) associated with susceptibility to schizophrenia in a Caucasian population. *S.A. Paciga[1], Y.-T. Fan[2], K.M. Walton[3], D.P. King[1].* 1) Discovery Pharmacogenomics; 2) Non-clinical Biostatistics; 3) Discovery CNS; Pfizer Global Research & Development, Groton, CT 06340.

Schizophrenia is a chronic, often debilitating mental disorder with a substantial genetic risk that affects ~1% of the population worldwide. Estimates of the percentage of disease risk attributable to genetic variation exceed 80%. Several candidate genes have been described recently that show association with susceptibility to schizophrenia. Among these is a G-protein coupled receptor on chromosome 6q, *trace-amine-associated-receptor 6* (*TAAR6*, formerly *TRAR4*), which is expressed in multiple CNS tissues implicated in schizophrenia (Duan *et al*., AJHG 75:624-638, 2004). We describe here results of an independent genetic association study that provide additional positive evidence for the involvement of *TAAR6* in susceptibility to schizophrenia. We genotyped 11 single nucleotide polymorphisms spanning the *TAAR6* locus, including 9 markers reported by Duan *et al*., in 878 patients with schizophrenia or schizoaffective disorder (644 Caucasian, 234 African American) and 604 ethnically matched control subjects (407 Caucasian, 197 African American). DNA samples were genotyped using a 5 nuclease assay. In our populations of Caucasians and African Americans, no single-marker associations were found with the 11 SNPs tested. However, in Caucasians, a common two-marker haplotype (rs6907909, rs9373026) was identified that showed strong association with susceptibility to schizophrenia (p0.001). These data provide additional evidence supporting a possible role for *TAAR6* in schizophrenia.

Evidence for autism loci in the chromosome 2q24-q33 region: association at AGC1, STK39, and ITGA4. *N. Ramoz[1, 2], J.G. Reichert[1, 2], C.J. Smith[2], T.E. Corwin[2], J.M. Silverman[2], J.D. Buxbaum[1, 2].* 1) Laboratory of molecular neuropsychiatry,Dept Psychiatry, Mount Sinai School of Medicine, New York, NY; 2) SEAVER center, Dept Psychiatry, Mount Sinai School of Medicine, New York, NY.

We recently reported linkage and association of AGC1 with autism (MIM#209850). Our current goal is to further assess the role of AGC1 in autism, and to explore whether there may be additional susceptibility loci in 2q24-q33. A total of 175 SNPs were genotyped in 352 families with autism (90 simplex and 262 multiplex), including 653 autism subjects. Eighty SNPs were selected to cover 40 Mb of the 2q24-q33 region. A further 95 SNPs within this region were chosen to increase the density of markers across 26 candidate genes, including 14 SNPs that encompass the AGC1 gene. Intermarker linkage disequilibrium was computed with Haploview. SNPs were analyzed for linkage using the GENEHUNTER (GH) program, and for association using family-based methods. Linkage analysis demonstrated a maximum multipoint non-parametric lod (NPL) score value of 1.9 (p=0.02) with SNPs across the AGC1 gene. The NPL value went up to 3 (p=0.0009) in a subset of the cohort with delayed onset of phrase speech. Two other peaks were detected that cover the STK39 gene and the ITGA4-NEUROD1 region. Significant association was observed between autism and SNPs in the AGC1, STK39, and ITGA4 genes. Evidence for haplotype association have been found. We have provided further evidence for linkage and association between autism and AGC1, and also potential linkage and association with other autism susceptibility loci in 2q24-q33.

A-Synuclein gene SNCA variation is associated with Parkinsons disease. *A. Parsian[1], A.J. Parsian[1], B. Racette[2], J.H. Zhao[3], J.S. Perlmutter[2].* 1) Dept Pediatrics, Univ Arkansas Medical Sci, Little Rock, AR; 2) Dept of Neurology, Washington University School of Medicine, St. Louis, MO;; 3) Dept of Epidemiology and Public Health, University College London, London, UK.

Several studies have replicated our preliminary report of an association between a dinucleotide repeat (SNCA) in a-Synuclein gene and sporadic Parkinsons disease (PD, Parsian et al., 1998). To replicate our previous finding in a larger sample and further determine the role of a-Synuclein in the development of PD, we screened a sample of 226 familial PD, 353 sporadic PD, and 130 controls with the SNCA marker and 3 SNPs (770, int3, and int4) in the gene. There was Hardy-Weinberg disequilibria only with SNP int3 that was excluded in the haplotype analysis. There was also significant difference in allele frequency between African American and American Indian groups for SNCA marker (p=0.03). These two samples were excluded from further analysis because of sample size. Comparison of allele frequency differences between PD and controls for single-locus was significant only for SNCA (0.0025). This result was further shown via haplotype analysis of SNCA-770-int4 markers. One of the interesting results of our haplotype analyses is with inclusion/ exclusion of SNP int3. The global case control association was not significant when the SNP int3 was included in four loci haplotype analysis. Otherwise, two and three loci haplotpes comparisons were significant. The explanation is that inclusion of locus in Hardy-Weinberg disequilibria in haplotype analysis will reduce power as shown by Epstein and Satten (2003). Our results indicate that SNCA locus may be in linkage disequilibrium with a mutation in the gene or itself could be a risk factor for PD.

Parsing the genetic heterogeneity of chromosome 12q for Alzheimer disease by family-based association studies.

P.I. Lin[1], X. Liang[2], C.A. Browning-Large[1], E.R. Martin[1], G.R. Gilbert[1], J.L. Haines[2], M.A. Pericak-Vance[1]. 1) Center for Human Genetics, Duke University, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Previous evidence has suggested that multiple genetic variants are involved in the etiology of late-onset Alzheimer disease (LOAD). So far no susceptibility genes for LOAD other than the apolipoprotein (APOE) gene have been conclusively identified due to inconsistent findings. We recently found increased evidence for linkage to a 12q region in autopsy-confirmed families particularly without linkage to alpha-T catenin gene on chromosome 10 (LOD score increased from 0.1 to 4.2; p 0.0001 for the increase in LOD score). Encouraged by these findings, we genotyped 83 single nucleotide polymorphisms (SNPs) in this 12q region spanning 6 megabases, and performed association analyses by using three programs: PDT, FBAT, and APL, for the overall sample (591 families) and an autopsy-confirmed subset (189 families). We observed no convergent significant results in the overall sample. However, in the autopsy-confirmed subset, we obtained convergent significant results at two SNPs: RS4759018 and RS1683151 in the activation transcription factor 7 (ATF7) gene. Additionally, we identified a multi-locus risk haplotype in the ATF7 gene (p = 0.0009) in this same subset. These two intronic SNPs are not in linkage disequilibrium with any functional polymorphism in the haplotype block retrieved from the HapMap data, but they are located in a highly conserved region. We further found that homozygotes for the C allele at RS1683151 had an increased risk for LOAD particularly for individuals carrying no APOE e4 allele. These results suggest that using subset and covariate analyses may help identify the elusive novel susceptibility genes for LOAD, such as ATF7 gene on 12q. Furthermore, the ATF7 gene may act independently of APOE gene to contribute to risk for LOAD. The ATF7 gene is related to the ATF/CREB family associated with neural plasticity and apoptosis, and hence may serve as a novel candidate susceptibility gene for LOAD.

Locus-wide association study in the 5q33.1 region for schizophrenia susceptibility genes. *H. GOTO[1], H. SHIBATA[1], M. TAKAJI[1], H. NINOMIYA[2], N. TASHIRO[3], N. JARUSURAISIN[4], Y. FUKUMAKI[1].* 1) Medical Institute of Bioregulation, Kyushu University, FUKUOKA, FUKUOKA, Japan; 2) Fukuoka Prefectural Dazaifu Hospital Psychiatric Center, Dazaifu, FUKUOKA, Japan; 3) Department of Neuropsychiatry, Graduate School of Medical Sciences, Kyushu University, FUKUOKA, FUKUOKA, Japan; 4) Department of Psychiatry, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand.

Schizophrenia is a common psychiatric disorder with a multifactorial background. As the Japanese Schizophrenia Sib-pair Linkage Group (JSSLG), we have reported that 11 chromosomal regions showed the nominal significance by genome-wide scan for linkage, although no evidence for significant linkage was obtained (JSSLG 2003). Out of these regions, we selected the 5q33.1 region for further analyses, where suggestive linkage with schizophrenia has been reported in multiple studies. We conducted locus-wide association studies of all annotated genes in the region (43 genes in about 4.9 Mb). We genotyped 100 Japanese cases and 100 controls for 131 single nucleotide polymorphism (SNP) makers distributed at intervals of less than 30 kb within each gene region. We observed significant associations of schizophrenia with 8 SNPs in 7 genes by single-point analyses and with 16 pairs of SNPs in 11 genes by haplotype analyses. All of the nominal significance was subsequently examined with additional 100 Japanese cases and 120 controls. We replicated the significant association of schizophrenia with one SNP in *SP329* by single-point analyses (P = 0.0434 in the first set and 0.0140 in the second set). We also replicated one significant haplotype association in *PERC* and *PDE6A* (P = 0.0031 in the first set and 0.0409 in the second set). We conclude that these genes were likely responsible for the genetic susceptibility to schizophrenia in the 5q33.1 region.

Association of AKT1 with schizophrenia confirmed in the Irish Study of High Density Schizophrenia Families (ISHDSF). *D.L. Thiselton[1], V. Vladimirov[1], P-H. Kuo[1], B. Wormley[1], F.A. O'Neill[2], D. Walsh[3], K.S. Kendler[1], B. Riley[1].* 1) Dept. of Psychiatry, Virginia Commonwealth Univ, Richmond, VA; 2) Dept. of Psychiatry, The Queen's University, Belfast, Ireland; 3) The Health Research Board, Dublin, Ireland.

AKT1 was recently implicated as a schizophrenia susceptibility gene by association in a large family sample of European origin. Decreased AKT1 protein levels were detected in lymphocytes and brain tissue of schizophrenic patients. Two follow-up Japanese case-control studies provided conflicting replication evidence. AKT1 is critical to cell survival, growth, transcriptional regulation and nutrient metabolism via a signal transduction pathway involving PI3K and GSK3B. It appears to be involved in neurodevelopment and working memory formation, domains potentially impaired in schizophrenia. Functional studies suggest that defective PI3K-Akt signaling in schizophrenic brains may be due to decreased expression of dysbindin (DTNBP1). The presence of a high-risk DTNBP1 haplotype in the ISHDSF thus prompted our investigation of AKT1. Eight SNPs spanning AKT1, incorporating 4 from previous reports, were genotyped on the 270 ISHDSF families. The data was analysed for association with schizophrenia using FBAT, TRANSMIT, PDT and PDTphase, across 4 diagnostic categories. Although no single marker showed significant association with disease, the data was consistent with global association of the common alleles for haplotypes consisting of 3 SNPs or more, thus supporting association of AKT1 with schizophrenia. The 4-marker common haplotype for SNPs rs2498802-rs3803304-rs2494732-rs2498799 showed the most significant over-transmission using TRANSMIT (p=0.002), and a similar trend by FBAT and PDTphase. Analysing the data after stratification based on the DTNBP1 high-risk haplotype showed no evidence of epistasis. We are currently analyzing expression of AKT1 in schizophrenia brain RNA samples by real-time qPCR to see if the previously reported protein down-regulation is detected at the RNA level.

Trace Amine Receptor 4 (TRAR4) gene is associated with Schizophrenia in the Irish Study of High Density Schizophrenia Families. *V.I. Vladimirov[1], D.L. Thiselton[1], P-H. Kuo[1], B. Wormley[1], J. Vittum[1], R. Ribble[1], F.A. ONeill[2], D. Walsh[3], K. Kendler[1], B. Riley[1].* 1) Dept. of Psychiatry, Virginia Commonwealth University, Richmond, VA; 2) Dept. of Psychiatry, The Queen's University, Belfast, Ireland; 3) The Health Research Board, Dublin, Ireland.

The Trace Amine Receptor 4 (TRAR4) gene was recently implicated as a potential liability locus for schizophrenia. The original study analyzed 192 schizophrenia pedigrees of European and African ancestry. Marker rs4305745 within TRAR4 was associated (P = 0.0014) after correction for multiple testing. We sought to replicate these findings in the Irish Study of High Density Schizophrenia Families (ISHDSF). We genotyped 15 single-nucleotide polymorphisms (SNP), including eight SNPs from the original study, in our 270 pedigrees. TRANSMIT analysis of single markers showed association with rs12189813 (P = 0.0084), which was confirmed by PDT. SNP markers rs8192622, rs8192624, rs8192625 SNPs lie in the coding sequence of TRAR4 and rs7772821 is in the 3 UTR 8bp downstream from the stop codon. Of those four SNPs, rs8192624 and rs7772821 show a trend towards association (P = 0.0676 and 0.0729 respectively), whereas the haplotype of these 4 markers was significantly associated with the disease (P = 0.006). Pedigree disequilibrium testing (PDT) of single markers showed association only with a one SNP, rs12189813 (p = 0.0057), which is 35kb away from the 3 end of TRAR4. However, a haplotype of four SNPs (rs7772821, rs4305745, rs6903874, rs7765655) which extend from within the 3 UTR of the gene showed significant association with the disease (p = 0.0000529). Although different analytic methods emphasize different subsets of the markers tested, the overall evidence for association of this gene in our sample is highly significant.

Haplotype analyses of the serotonin receptor 2C gene (HTR2C) show evidence of association with male affected with autism spectrum disorders. *G.M. Orabona[1], E.S Moreira[1], L.O. Avelar[1], K. Griesi-Oliveira[1], E. Vadasz[2], L.M. Biason[2], S. Matiolli[1], P.A. Otto[1], M.R. Passos-Bueno[1].* 1) Centro de Estudos do Genoma Humano/Departamento de Biologia/IB, Universidade de São PauloInstituto de Biologia, USP, São Paulo, SP., Brazil; 2) SEPIA, Instituto de Psiquiatria/FM, Universidade de São Paulo, São Paulo, Brazil.

Autism spectrum disorder (ASD) is a group of behaviorally defined neurodevelopmental disabilities with core deficits in socialization and communication, and restricted and repetitive patterns of interests or behaviors. Fewer is known about its genetic mechanisms but there are evidences showing that it involves multiple biochemical pathways. Serotonin has long been implicated in the development of autism since at least 30% of subjects are hyperserotonemic. A recent mathematical model related the serotonin receptors with mechanisms leading to abnormalities in the regulation of serotonergic system in ASD. In our study, we investigated the serotonin receptor 2C gene (HTR2C) for association with ASD. The HTR2C is widely expressed in brain regions implicated in behaviors altered in ASD such as amygdala and hippocampus. Our sample consists of 163 subjects from Brazil (132 males: 31 females), diagnosed using DSM-IV and ADI-R methods and previously excluded for known medical and genetic conditions associated with ASD. The control group consisted of 274 individuals (164 males: 110 females) with comparable ancestry with our subjects. Four SNPs were genotyped (SNuPE) and analyzed for case-control haplotype analysis: two were intronic SNPs rs2248440, rs5946005, one functional rs6318 (Cys23Ser) and a non-described polymorphism 25bp next to the intron encoded snoRNA HBI-36 gene (IVS2 + 16895 G A), all in H-W equilibrium. A total of eight haplotypes were observed both in cases and controls with different levels of linkage disequilibrium. We observed that one of them is significantly associated with male subjects (P=0,0008 - broader diagnosis of ASD; P=0,001 - narrow diagnostic of autism). This is the first report of association of HTR2C and ASD, further highlighting the importance of the serotonin system with this disorder.

Association between iNOS and early-onset Parkinson disease. *D.B. Hancock[1,2], B.S. Wheeler[2], E. Tegnell[1], M.A. Hauser[1], E.R. Martin[1], J.M. Vance[1], W.K. Scott[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) University Program in Genetics and Genomics, Duke University, Durham, NC.

Parkinson disease (PD), the second most common neurodegenerative disorder following Alzheimer disease, is characterized by progressive depletion of dopaminergic neurons within the substantia nigra. Excess synthesis of nitric oxide (NO), a messenger molecule with diverse physiological functions, has been implicated as a neurotoxic effector in PD by inducing numerous detrimental cellular effects including reduced mitochondrial complex I activity. Previous case-control studies observed an association between sporadic PD risk and the main source of NO synthesis, iNOS (inducible nitric oxide synthase), and suggested participation by iNOS as a modifier in PD. In a genomic screen to identify genes influencing age-at-onset of PD, we previously reported linkage (LOD=1.93 at 25cM) to chromosome 17 in the vicinity of the iNOS location (51cM). Consequently, we set out to investigate a possible iNOS association with PD in the context of age-at-onset. We genotyped seven coding and intronic single nucleotide polymorphisms (SNPs), including the previously implicated SNP rs1060826, in 291 multiplex (two or more members with PD) and 483 singleton families. Allelic association analysis using the Association in the Presence of Linkage (APL) test revealed significant association between rs1060826 and PD risk in the 78 families with at least one member affected with PD prior to age 40 (p=0.001). The association remained significant in the 290 families with onset before age 50 but was somewhat less significant (p=0.005). Quantitative Transmission Disequilibrium Test (QTDT) analysis using age-at-onset as the trait demonstrated a significant association of rs1060826 with age-at-onset in the 291 multiplex and 483 singleton families (p=0.006). These data support the prior association of the iNOS SNP rs1060826 with PD but limit the effect to earlier onset of PD. As rs1060826 is a synonymous change with no known functional significance, these data suggest that the true functional variant associated with PD likely resides in linkage disequilibrium with rs1060826 and remains to be identified.

Multiple candidate gene analysis identifies -*synuclein* as a susceptibility gene for sporadic Parkinsons disease. *I. Mizuta[1], W. Satake[1], A. Oka[2], H. Inoko[2], M. Yamamoto[3], N. Hattori[4], M. Murata[5], T. Toda[1,6].* 1) Div Clinical Genetics, Depat Medical Genetics, Osaka Univ Grad Sch Med, Suita, Osaka, Japan; 2) Dept Mol Life Sci, Tokai Univ Sch Med, Kanagawa, Japan; 3) Dept Neurol, Kagawa Prefectural Central Hosp, Kagawa, Japan; 4) Dept Neurol, Juntendo Univ Sch Med, Tokyo, Japan; 5) Dept Neurol, Musashi Hosp, NCNP, Tokyo, Japan; 6) CREST, JST, Saitama, Japan.

Parkinsons disease (PD), one of the most common human neurodegenerative diseases, is characterized by loss of dopaminergic neurons in the substantia nigra of the midbrain. PD is a complex disorder, with multiple genetic and environmental factors influencing disease risk. To identify causative genes for sporadic PD, we performed case-control association studies of 268 single nucleotide polymorphisms (SNPs) in 121 candidate genes. In two independent case-control populations, we found that a SNP in -*synuclein (SNCA)*, rs7684318, showed the strongest association with PD (P=5.0x10^{-10}). Linkage disequilibrium (LD) analysis using 29 SNPs in a region around rs7684318 revealed that the entire *SNCA* gene lies within a single LD block (D0.9) spanning about 120 kb. A tight LD group ($r^2$0.85) of six SNPs, including rs7684318, associated most strongly with PD (P=2.0x10^{-9}-1.7x10^{-11}). Haplotype association analysis did not show lower *P*-values than any single SNP within this group. Allele C of rs7684318 was positively associated with PD, more strongly in the recessive model than in the dominant model. *SNCA* expression levels tended to be lower for the CC genotype of rs7684318 than for CT and TT in lymphoblastoid cells and autopsied brain tissue. These findings establish *SNCA* as a definite susceptibility gene for sporadic PD and suggest that reduced SNCA expression also relates to the etiology of the disease.

Mutation Analysis of the Rett syndrome gene (MECP2) exon 1 in autism and mental retardation, and genetic studies of the distal portion of chromosome Xq. *B. Stachowiak[1,2], S.D. Menon[3], C. Harvey[1,2], A.K. Mensah[1,2], G.N. Mnatzakanian[4], S.E. Alfred[1,2], R. Guo[4], S.W. Scherer[4], B.A. Minassian[4], A.K. Srivistava[3], J.B. Vincent[1,2].* 1) Molecular Neuropsychiatry & Development Lab, Ctr Addiction & Mental, Toronto, ON, Canada; 2) Neurogenetics Section, CAMH and Dept. of Psychiatry University of Toronto; 3) J.C.Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood,; 4) . Program in Genetics and Genomic Biology, and 5. Autism Research Unit, The Hospital for Sick Children, Toronto.

A new isoform for the Rett syndrome gene, MECP2, was recently identified, that includes coding sequence from exon 1, and is the predominant transcript in the central nervous system. This sequence encodes polyalanine and polyglycine stretches within the N-terminal portion of Mecp2, and may confer novel properties to the protein. We screened autism, mental retardation (MR), and control populations for sequence variation within this region, and identified variation in ~0.6% of MR cases screened (N=1,274). Most of these variants occur within a trinucleotide repeat region and result in change in number of alanine or glycine residues within the repeat stretches. We suggest some of these variants may be a relatively frequent cause of non-specific mental retardation or developmental delay. Skewed X-inactivation is frequently associated with X-linked mental retardation. Thus, we have performed X-inactivation studies by quantitative genotyping of a microsatellite marker at the androgen receptor gene. We have also attempted to confirm evidence of genetic linkage for autism on the distal portion of chromosome Xq, by genotyping 9 microsatellite markers across the region of interest.

Novel splice isoforms for NLGN3 and NLGN4 with possible implications in autism. *Z. Talebizadeh[1], D.Y. Lam[1], M.F. Theodoro[1], D.C. Bittel[1], G.H. Lushington[2], M.G. Butler[1].* 1) Childrens Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Kansas, Lawrence, KS.

Mutations in two X-linked neuroligin genes, NLGN3 and NLGN4, have been reported recently in individuals with autism spectrum disorders (ASD). To further characterize the role of these genes in ASD, we screened lymphoblastoid cDNA from 10 young autistic females with X chromosome inactivation skewness (80:20%) and 30 non-autistic males and females. Interestingly, a novel NLGN4 isoform lacking exon 4 was identified in one of the autistic females which was predicted to result in an in-frame exclusion of 62 amino acids containing a highly conserved esterase-like domain critical for the function of neuroligins as postsynaptic adhesion molecules. Monoallelic expression of NLGN4 was also seen in this subject as well as 11 of 14 informative females (both autistic and non-autistic) using a SNP found at 3 UTR. This informative SNP indicated that skipping of exon 4 occurred *de novo* on the paternal allele. In addition, the NLGN3 transcript was present in two isoforms (with and without exon 7) in 9 of 10 autistic females, 30 non-autistic subjects including parents of the autistic female not producing a transcript without exon 7 and a control female brain. The isoform lacking exon 7 absent in our autistic female has not previously been described and was predicted to produce a truncated product with premature termination following exon 6. We suggest the novel truncated NLGN3 product may have a regulatory role as reported for other proteins (e.g., vasopressin receptor) by attenuating the function of the full length isoform resulting in a reduction of the mature NLGN3 protein. To evaluate the impact of these two isoforms on protein structure, 3D structures of the NLGN3 and NLGN4 proteins were characterized using comparative modeling (e.g., Modeller program) and significant changes were suggested in the protein cores. Our study further suggests that genetic alterations besides mutations (e.g., splice variants) may lead to potentially abnormal function of neuroligins in the causation of ASD.

Mutational analysis of EFHC1 gene in families with JME. *F. Annesi[1], F.E. Rocca[1], A. Labate[1], P. Tarantino[1], S. Carrideo[1], I.C. Cirò Candiano[1], D. Civitelli[1], P. Spadafora[1], E.V. De Marco[1], A. Gambardella[1,2], G. Annesi[1].* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Juvenile myoclonic epilepsy (JME) is a common form of generalized epilepsy that starts in adolescence. Recently, a major JME locus was mapped to chromosomal region 6p12.p11 and it was associated with mutations in the EFHC1 gene. This gene contains 11 exons and encodes a protein of 640-amino acids that contains 3 DM10 domains and an EF hand calcium-binding motif. In this study, we screened for mutations in the EFHC1 gene ten families from southern Italy in which at least two members had a typical form of JME. Ten families were selected and families with fewer than two affected members were excluded from the study. In each patient the diagnosis of JME was done after a detailed clinical and EEG investigation, according to the ILAE criteria. All investigated subjects signed informed consent to the genetic investigation. DNA was isolated from peripheral blood lymphocytes by standard methods. PCR amplification for each exon of EFHC1 gene was performed using intronic primers. Sequencing of PCR products were determined on the ABI 3100 automated sequencer using ABI PRISM sequencing kit according to the manufacturers protocol. At least the proband of each family with JME phenotype was screened for mutational analysis of EFHC1 gene. We have identified a previously described heterozygous dominant (F229L) mutation in one family. Recently, EFHC1 gene has been associated with JME in six out 44 families from Belize, Los Angeles, and Mexico. The authors detected 3 heterozygous mutations (F229L, D210L, D253Y) and one double heterozygous mutation (P77T, R221H) that cosegregated with epilepsy among 21 affected members of 6 families. Several unaffected members had mutations, indicating low disease penetrance. The results of our study are important as they extend for the first time the distribution of EFHC1 mutations to Caucasian populations. Moreover, our data provide further evidence for the high level of genetic heterogeneity associated with JME, as most of our JME families did not carry any mutations.

A High Throughput Mutation Screen of Human Ion Channel Genes in Episodic Neurological Disorders. *R. Lafreniere[1], M. Simoneau[1], J.-F. Poulin[1], N. Gupta[1], F. Lafreniere[1], K. Boisvert[1], M. Albanese[1], M.K. Charles[1], S. Laurent[1], G. Ebers[2], Z. Cader[3], J. Sequeiros[4], J.M. Pereira Monteiro[5], G. Turecki[6], M. Alda[6], P. Grof[7], S. Chouinard[8], B. Brais[8], P. Cossette[8], G.A. Rouleau[1,8].* 1) Emerillon Therapeutics Inc., Montreal, Canada; 2) Wellcome Trust Centre for Human Genetics, Oxford, UK; 3) Oxford University, Oxford, UK; 4) UNIgene, IBMC, University of Porto, Portugal; 5) Hospital Santo António, Porto, Portugal; 6) McGill University, Montreal, Canada; 7) University of Ottawa, Ottawa, Canada; 8) Universite de Montreal, Montreal, Canada.

Common neurological conditions such as epilepsy and migraine are episodic disorders showing significant heritability. Mutations in several ion channel genes have been identified as the genetic basis of these disorders in some patients. Additional diseases such as bipolar disorder, essential tremor and Tourette syndrome share some aspects of episodic disorders, and may be caused by dysfunction of ion channel genes. In an effort to identify relevant drug targets for these neurological disorders, we have initiated a high throughput mutation detection screen of brain-expressed human ion channel genes. Our goal is to screen 150 genes in 368 DNA samples from unrelated patients with these five disorders. Patient samples were selected based on clear family history and diagnosis, and availability of additional family samples to allow segregation analysis. Samples are screened for DNA variants using denaturing HPLC and DNA sequencing. RFLP analysis or allele-specific oligonucleotide hybridization is then used to determine allele frequencies. To date, we have screened 276 unrelated patient samples through 100 ion channel genes, identifying a total of 659 variants. Of these, 96 missense mutations are being further validated using: (1) association studies comparing allele frequencies in patients and controls; and (2) segregation analysis in extended pedigrees. Several interesting candidate genes have been identified and will be presented. Identification of genetic factors causing these neurological disorders will benefit patients and families through better molecular diagnosis and improved therapeutics.

Autosomal Dominant Inheritance of Stuttering in a West African Population. *B. Levis[1, 2], J. Lukong[3], J. Mundorff[4], D. Drayna[1, 2].* 1) NIDCD, National Institutes of Health, Rockville, MD, USA; 2) Neuroscience and Cognitive Science Program, University of Maryland, College Park, MD, USA; 3) Speak Clear Association of Cameroon, Douala, Republic of Cameroon, Africa; 4) Hollins Communications Research Institute, Roanoke, VA, USA.

Stuttering is a common speech disorder characterized by interruptions in the flow of speech, including prolongations of sounds, repetition of sounds or syllables and/or silent blockages. Although the fundamental causes of stuttering are unknown, both genetic and non-genetic factors are involved. Evidence for genetic factors in stuttering come primarily from twin studies, suggesting concordance rates of ~60% and ~20% in MZ and DZ twins, respectively, and previously published linkage studies of stuttering identifying loci on chromosomes 12 and 18. In our further investigations of the genetic causes of stuttering, we have identified a cluster of families in which this disorder occurs as a trait with a simple inheritance pattern. We have ascertained 5 families from North West Province in the Republic of Cameroon that present with familial nonsyndromic stuttering that occurs at a frequency of ~0.40 (0.35 - 0.44; s.d. = 0.039). These families contain 3-5 generations, and persistent adult stuttering has been documented in up to 3 generations using standardized recorded speech samples. These families contain a total of 278 affected individuals, ranging from 15 to 106 per family. Affected individuals in these families show no neurological or developmental deficits other than stuttering. Although English is spoken in these families, all five families also speak Bamileke, one of the ~270 languages of Cameroon as their native tongue. All five families are descendants of Bantu lineage, and originate in a limited geographic region of Cameroon near the border with Nigeria, in which a high prevalence of stuttering has been reported. These features are consistent with the view that a common founder mutation may underlie stuttering in these families, and provides a unique and powerful population to help identify genetic effects in developmental stuttering.

The sortilin-related receptor SORLA is functionally and genetically associated with Alzheimer Disease. *Y. Meng[1], E. Rogaeva[2], J.H. Lee[3], Y.J. Gu[2], T. Kawarai[2], T. Katayama[2], P. Erlich[1], C.T. Baldwin[1], R. Cheng[3], H. Hasegawa[2], F. Chen[2], N. Shibata[2], K.L. Lunetta[1], L.A. Cupples[1], Y. Song[4], P.E. Fraser[2], D. Westaway[2], R. Mayeux[3], L.A. Farrer[1], P. St George-Hyslop[2].* 1) Boston University, Boston, MA; 2) University of Toronto, Toronto, Canada; 3) Columbia University, New York, NY; 4) University of Hong Kong, Hong Kong.

Several lines of evidence implicate the retromer complex, which mediates subcellular protein sorting, in processing the amyloid precursor protein (APP). To test the hypothesis that genes in the retromer trafficking pathway modulate risk for Alzheimer disease (AD), we investigated associations between AD and 3 SNPs located in each of the coding sequences for the SORT1 (1p21-p13), SORCS2 (4p16), VPS26 (10q21), SORCS1 (10q23-q25), SORCS3 (10q23-q25), SORLA (11q23-q24), and VPS35 (16q12) genes in 7 large, family-based and case-control AD cohorts of Caucasian, African American and Hispanic heritage. Based on evidence of association with SORLA in more than one dataset, we genotyped 29 SNPs spanning ~175 kb in the SORLA region. Significant association (0.0007 p 0.05) was observed with 23 SNPs in at least one dataset. Adjustment for APOE genotype, age and sex had little impact on the inferences about association in any of the datasets. Haplotype analyses using a sliding window of 2-6 contiguous SNPs confirmed an association between SORLA and AD. The greatest consistency of results across datasets was observed in one region encompassing 3 SNPs, however, the most significant results were observed in one dataset with overlapping 6-marker haplotypes in another region spanning 16 SNPs (global p-values 0.001). These results support the existence of multiple unique pathogenic variants, each of which might be associated with AD in different populations. Functional studies investigating the effects of increasing or decreasing the expression of SORLA on the secretion of A showed that suppression of the expression of SORLA in vitro increases the production of A. Our genetic and functional data suggest that variants in SORLA increase AD risk, and this increased risk might arise from changes in APP processing.

Genetic Association between endothelial Nitric Oxide Synthase (NOS3) and Alzheimer disease: The MIRAGE Study. *A. Akomolafe[1], K.L. Lunetta[2], P.M. Erlich[3], L.A. Cupples[2], C.T. Baldwin[3], M. Huyck[3], R.C. Green[2,3], L.A. Farrer[2,3].* 1) Morehouse School of Medicine; 2) Boston University Schools of Public Health and; 3) Medicine.

Evidence suggests that vascular and inflammatory components may be important in the etiology of Alzheimer disease (AD). Studies in UK and Italian samples have reported significant associations between the Glu allele of the Glu298Asp polymorphism in NOS3 and late-onset AD, while studies in two other Italian samples, as well as Japanese, US white and Hispanic samples failed to find association. These studies did not consider Glu298Asp in the context of other NOS3 polymorphisms. We genotyped Glu298Asp and 10 additional SNPs spanning 25.3kb of NOS3 in the MIRAGE Study sample, collected from multiple centers in the US, Canada and Germany. We used a generalized estimating equation approach to test for association in African American (N=235) and Caucasian (N=259) subgroups of AD affected patients, their unaffected siblings (N=144, N=326), and unrelated spouse/neighborhood controls (N=82, N=127). The Glu298 allele was more common in the African American than the Caucasian sample (allele frequency 0.91 vs. 0.65). The Glu298 allele was associated with higher risk of AD in the African American (p=0.038) but not the Caucasian subgroup. We tested sliding windows of 2-5 SNP haplotypes along the gene for association with AD in the unrelated case-control samples. In the African Americans, haplotypes including the Glu298Asp SNP and an intron boundary SNP 2.8kb downstream were the most significantly associated with AD risk (global p=0.008). In the Caucasians, low frequency haplotypes in the 3 end of the gene were protective (global p=0.0002); no haplotypes were significantly associated with AD risk. Adjusting for APOE-4 carrier status did not substantively affect our results. This study is the first to examine the association of NOS3 Glu298Asp in an African American AD sample, and the first to look at multiple NOS3 polymorphisms in the context of AD risk. Our results give further evidence that the Glu298-AD association is sample-dependent, and suggest that other variants within NOS3 may also influence AD risk.

A scheme for comprehensive analysis of candidate gene associations: TNF and schizophrenia genesis. *B. Shirts[1], M. Bamne[1], J. Kim[2], M. Talkowski[1], J. Woods[1], R. Yolken[3], V. Nimgaonkar[1].* 1) Dept Psychiatry & Human Gen, U of Pittsburgh, Pittsburgh, PA; 2) Dept of Psychiatry, Catholic U of Korea, Seoul, Korea; 3) Stanley Division of Neurovirology, Johns Hopkins, Baltimore, MD.

Several association studies and a recent meta-analysis have indicated that the TNF -308G>A polymorphism may contribute to schizophrenia (SZ) risk in Caucasian populations. We designed a study to address the following explanations for differing findings in past association studies: 1) Rare risk polymorphisms in LD with the associated SNP may be present; 2) Exposure to infectious agents may cause increased risk in combination with associated SNPs; 3) Differential TNF expression may affect risk and be caused by one or several common haplotypes. We used a systematic approach to address these issues. We sequenced the entire TNF gene including introns and 3kb of 5 and 3 UTRs in DNA pooled from 115 Caucasian SZ cases and 200 controls to identify over-represented polymorphisms in SZ cases. We then selected 8 SNPs, which we genotyped individually in 250 cases and 250 controls. Using this information we identified 6 common haplotypes (freq > 1%) in our Caucasian sample. We analyzed genotype and haplotype associations and evaluated subgroups defined by gender, HSV1, HSV2, CMV, and Toxoplasma exposure. Finally, we used a dual-luciferase expression assay to quantify TNF expression driven by each common promoter haplotype. We identified 18 SNPs with frequencies > 5% in SZ cases, none of which were novel. Neither individual SNPs nor haplotypes were associated with SZ risk in our sample or in subgroups of SZ cases defined by infectious disease exposure or gender. Differences in TNF promoter driven expression were not correlated with case/control haplotype frequency differences. Our study shows no evidence to implicate TNF in SZ risk. We cannot rule-out the possibility of other genes in LD with TNF being associated with SZ. We have addressed the possibility of over-represented polymorphisms by pooled DNA sequencing, stratified for infectious exposure, and addressed the possibility of differential expression. We suggest these methods are generalizable and will be useful in association studies of other genes.

Genetic and epigenetic analysis of MeCP2 expression defects in autism and other neurodevelopmental disorder brain samples. *R.P. Nagarajan, A.R. Hogart, Y. Gwye, J.M. LaSalle.* Dept of Med Micro & Immun, UC Davis, Davis, CA.

Mutations in the gene *MECP2*, encoding methyl CpG binding protein 2 (MeCP2), are responsible for most cases of Rett syndrome (RTT), an X-linked neurodevelopmental disorder. Both RTT and autistic disorder share a loss of social, cognitive and language skills and a gain in repetitive stereotyped behavior, following apparently normal prenatal and perinatal development. Although *MECP2* coding mutations are a rare cause of autism, MeCP2 expression defects were previously found in autism brain. To determine the frequency of MeCP2 expression defects, MeCP2 protein expression in autism and other neurodevelopmental disorders was compared with control postmortem cerebral cortex samples on a large tissue microarray. MeCP2 isoform-specific immunofluorescence was detected with laser scanning cytometry, normalized to control histone H1 staining and confirmed by Western blotting. Significantly reduced expression of total MeCP2 was found in 11/14 autism brain samples compared to multiple age-matched controls, whereas 9/14 showed significant MeCP2_e2 expression defects. In addition, significantly reduced MeCP2 protein expression was observed in other autism spectrum disorders, including Angelman syndrome (4/4), Prader-Willi syndrome (3/4), and Down syndrome (3/5). To investigate the possibility that some MeCP2 expression defects in autism are caused by mutations in non-coding regulatory regions of *MECP2*, DNA sequencing was performed. While 4/5 autism DNA samples showed wild-type sequence (-1700 to +300), one autistic female with significantly reduced MeCP2 expression was heterozygous for a novel T>C transition. This variant was not found in 80 autistic individuals and 15 controls, suggesting a rare regulatory mutation. As an alternative explanation for reduced MeCP2 expression, methyl-sensitive restriction digestion and bisulfite sequencing are being performed to detect putative aberrant *MECP2* promoter methylation in male autism DNA samples. These results demonstrate that MeCP2 expression defects are a common, but not unique, characteristic of the autism brain and suggest that both genetic and epigenetic factors play a role in abnormal expression of MeCP2 in autism.

Screening for PINK1 mutations in patients with early- and late-onset Parkinson's disese. *I.C. Cirò Candiano, F.E. Rocca, P. Tarantino, F. Annesi, S. Carrideo, P. Spadafora, D. Civitelli, E.V. De Marco, G. Annesi.* 1Institute of Neurological Sciences, National Research Council, Mangone (CS), Italy.

Objective Mutations in the PTEN-induced kinase (PINK1) gene located within the PARK6 locus on chromosome 1p35-p36 were recently identified in patients with recessive early-onset Parkinsons disease. In this study, we performed a mutational analysis of PINK1 in 12 families, 4 with early-onset and 8 with late-onset parkinsonism, and in 23 sporadic patients with early-onset (age of onset 45 years of age) Parkinsons disease. The patients originated from Southern Italy. Mutations in parkin and DJ-1 were excluded previously in all patients. Materials and methods DNA was extracted from peripheral blood according to standard protocols. The 8 exons of the gene with their exon-intron boundaries were amplified using polymerase chain reaction (PCR). Obtained fragments were sequenced on ABI3100 automated DNA sequencer (Perkin Elmer- Applied Biosystems). Results A novel homozygous deletion (889delG) was detected in the affected members of a consanguineous family with early-onset parkinsonism and was absent in 100 normal chromosomes. We also identified several exonic and intronic polymorphic variants, most of whom already described. Discussion and conclusions Sequence analysis of the PINK1 gene led to the identification of a homozygous deletion in exon 4 in two sibs from a consanguineous family with early-onset parkinsonism. The deletion produces a premature stop codon and a protein lacking in most of the kinase catalytic domain. The screening of the remaining patients revealed presence of several polymorphic variants. These findings confirm that recessive mutations in PINK1 cause early-onset parkinsonism, although PARK6 is not a common locus for PD in our population.

Interaction or coincidence: mutations in *PARKIN* and *LRRK2*. *I.F. Mata[1,2], C. Huerta[2], C. Lahoz[3], M. Blazquez[3], L.M. Guisasola[3], C. Salvador[3], R. Ribacoba[4], C. Martinez[5], M.J. Farrer[1], V. Alvarez[2].* 1) Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Laboratorio de Genetica Molecular, Instituto de Investigacion Nefrologica (IRSIN-FRIAT), Hospital Universitario Central de Asturias, Oviedo, Spain; 3) Servicio de Neurologia, Hospital Universitario Central de Asturias, Oviedo, Spain; 4) Servicio de Neurología, Hospital Alvarez-Buylla, Mieres, Spain; 5) Servicio de Neurología, Hospital de Cabuenes, Gijon, Spain.

The genetic contribution in Parkinsons disease (PD) has been established over the last decade. Mutations in seven genes (*SNCA, PRKN, UCHL-1, PINK1, DJ1, MAPT* and *LRRK2*) have been associated with the development of parkinsonism. Pathogenic substitutions in parkin are the most frequent genetic cause of PD, and an extensive list of mutations has been identified worldwide. However, mutations in the recently cloned *LRRK2* gene have been shown to explain a substantial number of late-onset typical PD cases. The G2019S pathogenic substitution has been reported to account for up to 41% of the familial cases in North Africa although this frequency decreases to less than 5% in European populations. An R1441G mutation is also frequent (~3%) in PD patients from Northern Spain. The objective of this study was to determine the frequency of mutations in the PRKN gene and the presence or absence of three *LRRK2* mutations. We screened more than 300 PD patients, from Asturias in the North of Spain, for variants in the Parkin gene using Single Strand Conformation Analysis (SSCA). All those samples showing a different electrophoresis pattern were sequenced and mutations were confirmed by restriction enzyme digestion. R1441G, R1514Q and G2019S ABI assay-by-design probes were used to identify these substitutions. We identified 27 patients carrying 10 different parkin pathogenic substitutions; the N52/Stop80 and M192V are the most frequent in our population. Two of the patients were compound heterozygous carrying two and three parkin mutations each. Interestingly, four of our heterozygous parkin carriers also carried one of the three Lrrk2 substitutions analyzed. The impact of carrying both a *PRKN* and *LRRK2* mutation must now be examined at the clinical and pathological level.

Follow-up of the 7q32 and 16p13 regions linked to epilepsy-related photosensitive families. *D. Pinto, D. Kasteleijn-Nolst Trenite, B. Westland, D. Lindhout, B. Koeleman.* DBG-Department Medical Genetics, University Medical Center Utrecht, Utrecht, the Netherlands.

Recently, we mapped two susceptibility loci for photosensitivity (PPR) at 7q32 and 16p13 in 16 PPR-multiplex families with prominent myoclonic epilepsy background. Here, we present the follow-up studies performed on these two regions. The inheritance model for these two loci was explored, showing that the 16p13 locus may have a recessive inheritance. A two-locus linkage analysis was also performed to test for different interaction models. Several potential candidate genes reside in these regions. The genes encoding for the metabotropic glutamate receptor 8 (GRM8), the cholinergic-muscarinic type 2 acetylcholine receptor (CHRM2), the voltage-dependent T-type calcium channel alpha-1H subunit (CACNA1H) and the somatostatin receptor type 5 (SSTR5) are known to participate in the neuromodulation of cortical dynamics. To evaluate the relevance of these high-ranking positional and functional candidate genes in the susceptibility for PPR in our families, we screened two patients from each family and Dutch controls for mutations in the coding region, 100 bp of exon-intron boundaries, 5 and 3untranslated regions and promoter regions. We found novel variants not reported in the NCBI dbSNP, and detected several known variants which were also present in Dutch controls. We are currently evaluating their familial segregation and putative biological meaning. The variants identified may be useful to conduct future association studies. The identification of susceptibility gene for PPR would advance our understanding of epileptogenesis.

Clinical follow-up of multiplex late-onset Alzheimer Disease families. *R.M. Carney, P.C. Gaskell, W.K. Scott, M.A. Slifer, C.M. Hulette, K.A. Welsh-Bohmer, D.E. Schmechel, J.M. Vance, M.A. Pericak-Vance.* Duke University Medical Center, Durham, NC.

Eighty-one families with multiple living members affected with AD were ascertained for genetic analyses of late-onset Alzheimer Disease (LOAD; mean age-at-onset 60 years). Initial data collection included pedigree and clinical information establishing affection status and a blood sample. Two to 17 years after original contact, we successfully re-contacted 63 LOAD families to update our clinical and family history information. Follow-up data include clinical status changes, age at onset, and supplemental pedigree information.

Of those 230 individuals who were previously unclear or unaffected, 48 converted to affected (10/19 [53%] of those initially unclear and 38/211 [18%] of those initially unaffected) upon clinical re-evaluation. Additionally, 25 of the 211 (12%) of the initially unaffected converted to unclear. Expanding the family history data to include information on new family members identified an additional 20 affected individuals.

We were able to augment clinical diagnosis with neuropathological diagnosis on 101 individuals through our autopsy program. Despite all 101 individuals presenting with a clinical diagnosis of AD, only 73 individuals had a pathologic diagnosis of AD alone; 9 had non-AD dementia, and 19 had AD and additional neuropathologic features.

The variation in neuropathologic diagnoses despite a uniform clinical diagnosis further obfuscates the dissection of this complex disorder. Gene X gene or gene X environment interactions may alter neuropathologic features, similar to the range of pathologic findings seen in individuals with Parkinsonism carrying identical mutations in the LRRK2 gene (Zimprich et al., 2004). Our follow-up study demonstrates the clinical importance of serial contacts and longitudinal evaluation of families in genetic analyses, particularly in age-dependent penetrance disorders.

Alzheimer disease, association of UBQLN1. *E.R. Martin[1], M.A. Slifer[1], J. Gilbert[1], L. Bertram[3], R.E. Tanzi[3], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 3) Genetics and Aging Research Unit, Massachusetts General Hospital, Charlestown, MA.

Alzheimer Disease (AD) is the most common cause of dementia affecting the elderly. AD is a heterogeneous and complex disease with a strong genetic diathesis. Linkage studies have identified chromosome 9q as a region containing a possible AD candidate gene. Functional protein studies have suggested that the UBQLN1 gene on chromosome 9q may be a likely candidate for a role in late onset Alzheimer disease pathogenesis. A recent family-based study by Bertram et al. NEJM 2005 reported a putative AD risk allele of an intronic single nucleotide polymorphism (SNP) within the UBQLN1 gene. In this study, we sought to assess whether polymorphisms within the UBQLN1 gene are associated with AD in another large family-based data set, as well as an independent case-control data set. We found no significant association of AD with any of the seven SNPs genotyped (including SNP4, previously reported by Bertram et al.) in either the family-based (n= 1161) or case-control (n = 1551) data set. Analyses varying age range and analyses conditional on Apolipoprotein E (ApoE) genotype and sex also revealed no significant associations in either data set. Using age at onset (AAO) as a quantitative trait revealed possible modifying effects associated with two of the SNPs. SNP6 was associated with an earlier AAO in the family based data set (p=0.02), and SNP 4 was associated with a later AAO in the case-control data set (p=0.01). However, the comparator groups in these two analyses were relatively small (n= 24 of 506 affected individuals and n=25 of 546 affected individuals respectively). Our results suggest that UBQLN1 variants do not increase risk for AD in these data. However, there may be a role for an effect modifying age at onset, though the evidence remains limited and inconsistent between the data sets.

SCN1A may be a susceptibility factor for idiopathic generalised epilepsy. *J. Dean[1], C. Sinclair[2], D. Shaw[2].* 1) Dept Medical Genetics, Argyll House, Aberdeen, United Kingdom; 2) Dept Molecular and Cell Biology, University of Aberdeen, Foresterhill, Aberdeen, United Kingdom.

Idiopathic generalised epilepsy is thought to be a multifactorial disorder, with many genetic aetiologies. Many patients have a distant family history of epilepsy or febrile seizures. GEFS+ (generalised epilepsy with febrile seizures plus, OMIM 604233) is an autosomal dominant form of epilepsy with a variable phenotype in which patients may have febrile seizures in childhood, febrile or non-febrile seizures in later childhood, and partial or generalised seizures as adults. Mutations in SCN1A, SCN1B, SCN2A and GABRG2 have been described in different families. In a study of 156 women with epilepsy, family and personal histories of febrile and non-febrile seizures were noted, suggesting that GEFS+ may be more common that generally thought. To investigate this further, we genotyped these cases and 42 population controls for four SNPs in SCN1A. One non-synonymous coding SNP, T1067A, had a significantly higher frequency in cases (0.51) than in controls (0.33, p=0.001). This suggests that this SNP is a susceptibility factor for epilepsy in this unselected case series from North East Scotland. A previous study in another population suggested that this SNP was not pathogenic (Escayg Am J Hum Genet 2001;68:866-873). Further research is needed to clarify the reasons for these different findings.

Analysis of opioid receptor variants in the study of pain. *L. Kaplan[1], R.B. Fillingim[2,3], G.N. Verne[3,4], R. Staud[4], M. Agbandje-McKenna[5], C. Haskell-Leuvano[6], M.S. Wood[6], M.C. Moore[6], N.A. Sorensen[6], R. Wu[7], C. Sumners[8], M.R. Wallace[1].* 1) Dept Molec Gen/Microbiol, UF College of Medicine Univ FLorida, Gainesville, FL; 2) Division of Public Health Services, UF College of Dentistry; 3) Malcom Randall V.A. Medical Center in Gainesville, FL; 4) Dept. of Medicine, UF College of Medicine; 5) Dept. of Biochemistry and Molec. Biology, UF College of Medicine; 6) Dept. of Medicinal Chemistry, UF College of Pharmacy; 7) Dept. of Statistics, UF College of Liberal Arts and Sciences; 8) Dept. of Physiology and Functional Genomics, UF College of Medicine.

Baseline pain sensitivity and analgesia response are complex traits, having clear genetic contributions as shown previously with polymorphisms of the OPRM1 and COMT genes (including studies from our group). We have focused our current studies on OPRD1 and OPRK1 (opioid receptors delta and kappa, respectively), which have not yet been extensively studied in this system in humans. Polymorphisms in these two genes are being genotyped in 336 healthy individuals who have undergone experimental pain testing (thermal pain, temporal summation of pain, ischemic pain, and pressure pain). Genotyping of the same variants is also being completed for subjects in two chronic pain populations: fibromyalgia (FMS, n=94) and irritable bowel syndrome (IBS, n=74). Although these syndromes overlap, we have included subjects with just one of these disorders, under strict phenotype criteria. Statistical analysis of allele frequencies in the populations, and associations with phenotypes, is underway. The results will be highly significant for this field regardless of whether the data point to positive or negative associations. We are also analyzing the functional effects of the polymorphisms in OPRD1 and OPRK1, by expressing the variant proteins and testing binding affinity of different selective agonists, and the activation of the receptors. Protein modeling has predicted that at least one of the variants is likely to affect receptor function. We will present our completed data in these novel studies, to shed light on the involvement of the OPRD1 and OPRK1 proteins/pathways in pain.

The role of hMRE11-hMLH1 interplay in DNA mismatch repair. *F. Zhu[1], N. Zhao[1], F. Yuan[2], G. Li[2], C. Her[1].* 1) SMB, Washington State University, Pullman, WA; 2) University of Kentucky Medical Center, Lexington, KY.

Defective MMR attributes to increased mutation rate and cancer development in humans. Hence, a thorough understanding of human MMR is essential for the development of effective diagnostic and therapeutic strategies. We have recently demonstrated that hMRE11-deficiency led to increased microsatellite instability (MSI) and defective MMR. The involvement of hMRE11 in MMR is presumably mediated by its interaction with hMLH1. In the present study, we investigated the functional implications of the interplay between hMRE11 and hMLH1 in MMR. Briefly, we have created a series of stably transfected 293T cell lines expressing hMLH1 as well as two truncated forms of hMRE11, and nuclear extracts from these cell lines were used to perform an in vitro MMR assay. Our data suggest that overexpression of hMLH1 in MMR-deficient 293T cells could restore a functional MMR, and concomitant expression of the dominant negative hMRE11 aa452-634 but not hMRE11 aa1-634 in these cells caused a significant reduction in both 3 excision and 3 repair activities. Consistent with hMRE11 aa452-634 being the interaction domain for hMLH1, our results suggest that disruption of the interaction between hMRE11 and hMLH1 could have significant effects on MMR. Remarkably, among 33 hMLH1 HNPCC missense mutations that we have analyzed thus far, 31 of them caused significant reduction (> 50%) in their interactions with hMRE11, suggesting disruption of hMRE11-hMLH1 interaction could underlie the functional effects of these mutations in humans. To our surprise, although the hMLH1-complemented 293T cells are MMR proficient, overexpression of hMLH1 in these cells has little, if not none, effect on MSI when compared with that of the parental 293T cells. This result is reminiscent of previous observations that the overexpression of MLH1 could result in a mutator phenotype equivalent to that of MLH1 mutant in yeast. Together, our present study shows that the hMRE11-hMLH1 interaction is essential for functional MMR. In addition, our data suggest that the molecular basis to support functional MMR and microsatellite stability might be mechanistically different in human cells.

Interaction between GNB3 gene C825T and ACE gene I/D polymorphisms in essential hypertension in Koreans.

Y.S. BAE[1], D.J. Shin[1], E.M. Kim[1], J.K. Kim[1], J.H. Han[1], C.M. Park[2], Y.S. Jang[2], S.J. KimYoon[1]. 1) Research Institute of Molecular Genetics, Catholic Research Institutes of Medical Sciences, Seoul, Korea; 2) Cardiovascular Genome Center, Yonsei University Medical Center, Seoul, Korea.

An epistatic interaction effect between G-protein beta-3 subunit (GNB3) C825T and angiotensin I-converting enzyme (ACE) insertion/deletion (I/D) polymorphisms on blood pressure (BP) regulation has been studied. In order to evaluate whether the polymorphisms in the GNB3 gene and ACE gene are associated with essential hypertension (EH) in Koreans, we carried out a case-control study of 691 hypertensive and 763 ethnically- and age-matched control subjects recruited from Cardiovascular Genome Center in Korea. The ACE I/D and GNB3 C825T genotypes were determined by polymerase chain reaction (PCR) and PCR- restriction fragment length polymorphism (RFLP), respectively. The distribution of genotype and allele for the two polymorphisms were not significantly different between the normotensives and the hypertensives. Logistic regression analysis indicated that the GNB3 C825T polymorphism (CC/CT+TT) was strongly associated with EH in the male subjects (OR, 0.656; 95% CI, 0.450-0.955, p = 0.027). In the gene-gene interaction analysis, we found the combined action of GNB3 and ACE genotypes accumulated in the carriers of the ACE D allele and GNB3 CC homozygotes (ID+DD/CC carriers), showing a decrease in risk for hypertension (OR, 0.624; 95% CI, 0.464-0.839, p = 0.0017). In particular, the decrease in the risk for EH was prominent in males (OR, 0.511; 95% CI, 0.315-0.829, p = 0.0061). Stratification analyses of the normotensives and the hypertensives according to the genotypes showed that the levels of triglycerides and fasting glucose were significantly higher in the normotensives carrying the CC genotype in comparison to those carrying T allele (p = 0.036 and p = 0.002, respectively). In our study, we suggest that an interaction between GNB3 C825T and ACE I/D polymorphisms is a positive genetic marker of predisposition for EH in Koreans.

Characterization of TGFbeta signaling in aortic smooth muscle cells derived from patients heterozygous for R460C TGFBR2 mutation. *S. Duraisamy[1], T. McArthur[1], H. Pannu[1], X.H. Feng[2], D.M. Milewicz[1].* 1) Internal Medicine/Med.Genetics, University of Texas Medical School, Houston, TX; 2) Department of Surgery, Baylor College of Medicine, Houston, TX.

Thoracic aortic aneurysms leading to type A dissections (TAAD) are inherited in an autosomal dominant manner and we have determined that 5% of families with TAAD carry mutations altering arginine 460 in the intracellular kinase domain in transforming growth factor- receptor type II (TGFBR2). We transfected cDNA for the mutant TGFBR2 into cells (DR-26) lacking the TGFBR2 to determine if the mutation disrupted the kinase activity of the receptor, which indicated that the mutation prevented downstream signaling of the receptor. Aortic smooth muscle cells (SMCs) explanted from 2 unrelated patients heterozygous for R460C TGFBR2 mutations were studied; along with two control aortic SMCs. Analysis of patients cells Smad 2/3 phosphorylation in response to TGFbeta indicated that in the absence of TGFbeta the control cells showed no p-Smad, whereas the patients cells surprisingly showed p-Smad in the absence of TGFbeta, suggesting the TGFbeta pathway was stimulated in the absence of TGFbeta signaling. Both control and patients cells phosphorylated Smad 2/3 in the presence of TGFbeta. These results were supported by immunofluorescence analysis showing increased p-Smad localization in the nucleus of SMCs derived from the patient heterozygous for a TGFBR2 mutation when compared to control in the absence of TGFbeta. Furthermore, RNA was isolated from control and TGFbeta mutant SMCs after serum starvation and the expression of TGFbeta targeted genes was examined by quantitative RT-PCR. The expression of plasminogen activator inhibitor-I ($p<0.009$), connective tissue growth factor ($p<0.02$) was increased and matrix metalloproteinase 2 ($p<0.0009$) was decreased in TGFBR2 mutant cells when compared to control cells, supporting basal stimulation of the TGFbeta pathway. In summary, SMCs heterozygous for R460C TGFBR2 mutation demonstrate paradoxical activation of TGFbeta signaling in the absence of ligand, data that potentially provides insight into a pathway leading to aortic aneurysms and dissection.

C-reactive protein (CRP) gene variation is associated with serum CRP in dialysis population. *L. Zhang[1], W. Kao[1], Y. Berthier-Schaad[1], N. Fink[1], N. Powe[1], M. Klag[1], M. Smith[2], J. Coresh[1].* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD.

Elevated serum CRP level is an important risk factor for cardiovascular disease in both the general population and in high-risk groups, such as dialysis patients. Although previous studies have demonstrated association between CRP genetic variation and serum CRP levels in the general population, it is not known whether the same associations would be detectable in the dialysis population, where CRP levels are much higher than those in the general population due to dialysis-related factors. We examined this association in 417 white and 196 African-American incident dialysis patients with mean age 58 yrs. Bins of SNPs in strong linkage disequilibrium (r2>0.60) were identified by SeattleSNPs program and seven tagging SNPs (minor allele frequency>5%) were selected to cover all bins of the gene. Genotyping was conducted using the Illumina platform. High sensitivity CRP and IL-6 were measured at the beginning of the dialysis session. Haplo.stats was used to examine the association of haplotype with log-transformed CRP. Haplotypes with <5% frequency were combined. An a priori specified additive genetic model was assumed. Median CRP level was 3.96 mg/l and 3.30 mg/l in whites and African Americans, respectively. Four major haplotypes were identified in whites, and 7 in African Americans. In both whites and African Americans, significant association between haplotypes and serum CRP levels were observed, even after adjusting for age, gender, body-mass index, systolic blood pressure, serum albumin and total cholesterol levels, and co-morbidities. A permutation global test of all haplotypes with CRP resulted in a p-value of 0.08 in whites and 0.0003 in African Americans. Compared to the common haplotype, haplotype 3 was associated with higher levels of CRP in whites while haplotypes 4 and 6 were associated with lower levels of CRP in African Americans. The association was independent of baseline IL-6 level. Variation in the CRP gene is associated with serum CRP levels in the dialysis population.

Genetic Complexities of Molecular Diagnosis for Ventricular Arrhythmias. *N.H. Bishopric, T. Miller, S. Cocilova, L. You, H. Travers, S. Elliott, R. Myerburg, L. Baumbach.* Miller School of Medicine, University of Miami, Miami , FL.

Molecular diagnosis of Long QT syndrome (LQTS) and related arrhythmogenic disorders remains highly complex, due to numerous private mutations, variants of unknown significance, and low penetrance alleles. We report our experience performing mutation screens of five LQTS-associated disease genes (KCNQ1, KCNH2, KCNE1, KCNE2, SCN5A) in probands referred from a tertiary care hospital for clinically suspected LQTS or Jervell-Lange-Nielsen syndrome (n=78)or pharmacologically-induced (drug induced; DI-LQT) and torsade (n=4). Mutation screening for all genes was conducted using exon-specific PCR, SSCP, and DNA sequencing of all SSCP variants. DNA variants were reviewed for relative frequency and possible disease association using mutation databases and published literature. Presumed disease-causing mutations were detected in twenty-two (28%) suspected LQTS patients. Twelve of these were in KCNQ1; five were in KCNH2; the remaining five mutations were distributed across the three remaining loci. Of the 17 KCNQ1 and KCNH2 mutations, six were novel. Coinheritance of mutations with disease phenotype was proven in 6/7 families analyzed. It is of interest that four of the twelve (33%) cases with KCNQ1 mutations had a second mutation (D85N) in KCNE1, the beta-subunit of KCNQ1. In addition to these deleterious mutations, two synonymous and fourteen non-synonymous SNPs were also detected. Each LQTS proband displayed numerous SNPs in all five genes, including at least one SCN5A variant. Of the four DI-LQT patients, only one had a known pathogenic mutation (KCNQ1, G189R), while two had rare and/or novel SNPs (KCNH2 1809 C>T; KCNQ1 I93I + SCN5A 3183G>A). These combined results suggest that with increased availability of genetic testing for LQTS, bona fide disease-causing mutations are likely to be identified in fewer than 30% of all patients referred with suspected LQTS, and that the majority of patients will harbor novel mutations or gene variants of unknown significance. Our data suggests that additional functional and epidemiological studies are warranted to establish better predictive genotype-phenotype correlations.

Estrogen Metabolism Gene Polymorphisms and Hypertension in Women. *S. Colilla[1], S. Hollenberg[2], A. DeMichele[1], G. Bunin[1], R. Schinnar[1], B. Strom[1], T. Rebbeck[1].* 1) Dept Biostatistics & Epidemiol, Univ Pennsylvania, Philadelphia, PA; 2) UMDNJ-RWJMS, Camden, NJ.

Recent studies suggest that the protective effects of estrogen on cardiovascular disease may be due in part to intracellular estradiol metabolites. We hypothesized that polymorphisms in estrogen metabolism genes would affect the prevalence of hypertension in women. Using a randomly selected group of women from the Delaware Valley who were ascertained as controls for a case-control study for breast and endometrial cancer, polymorphisms *CYP1A2**1F, *COMT* Val158Met, *CYP1B1**3, *CYP1B1**4, *CYP3A4**1B, and *SULT1E1* 5UTR were genotyped from DNA extracted from buccal swab samples provided by 1764 women. Multivariate logistic regression was used to estimate the association between each genetic polymorphism and the prevalence of hypertension. None of the polymorphisms showed a significant association with hypertension in women of European ancestry, after adjustment for age, body mass index, and diabetes. Adjustment for menopausal status, hormone replacement therapy use, income and education did not measurably change the results. The Met (M) allele, which has been shown to reduce COMT activity three-fold, was significantly associated with a decreased prevalence of hypertension ($p = 0.04$) in women of African ancestry. African-American women who were heterozygotes (V/M) were 28% less likely to be hypertensive than African-American women who were homozygotes of ancestral allele (V/V) [OR = 0.77, 95% C.I. (0.50, 1.19), $p = 0.24$]. African-American women who were homozygous M/M were half as likely to be hypertensive as women with the V/V genotype [OR = 0.50, 95% C.I. (0.26, 0.96), $p = 0.04$]. The Met polymorphism which reduces COMT activity may cause higher intracellular levels of estradiol and explain the reduction of hypertension in African-American women with M/M genotype. Further analysis may clarify whether differences found between the two racial groups are due to residual confounding or effect modification between the *COMT* polymorphism and another factor. Nonetheless, we provide evidence that the *COMT* genotype is associated with hypertension in African-American women.

Genome-wide scan for hypertension: The National Millennium Project in Japan. *T. Miki[1], Y. Tabara[2], J. Nakura[1], K. Kohara[1].* 1) Dept Geriatric Medicine, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Environment Health & Social Medicine, Ehime Univ Sch Medicine, Ehime, Japan.

In 2000, national cooperative projects, under the banner of "Millennium Projects", were started in Japan. The identification of genetic variations linked to the development of hypertension is one of the leading missions of the Millennium Project. The whole-genome case-control analyses, using 100,000 SNP markers and 16,000 microsatellites, have been performed as a 1st screening. The SNPs were selected from the JSNP database, a database of SNPs in Japanese population (http://snp.ims.u-tokyo.ac.jp/). The microsatellites were assigned less than 600 kb apart. The case subjects (n=188) fulfilling the following criteria were recruited from Japan nationwide: male, BMI <= 25 kg/m2, SBP => 160 mmHg and/or DBP => 100 mmHg or under anti-hypertensive treatment, age of onset was between 30 and 59 (y.o.), and having family history of hypertension within parents and siblings. The contrastive patients with other four diseases were served as the control subjects (n=752). In the first-screening, 21,602 SNPs showed probability values less than 0.05 in the 2X2 and/or 2X3 chi-squared analyses. In the 2nd screening, 1,800 SNPs were analyzed in other 752 hypertensive cases and 752 normotensive controls, and 212 SNPs remained statistically significant. To further clarify the susceptible SNPs, 3rd screening was carried out using other case-control (619/1,406) subjects. Of 212 SNPs, 4 SNPs showed probability values less than 0.05 (0.003 to 0.035) in the comparison of allele frequency. The odds ratios of these SNPs were between 1.18 and 1.23 in the allelic model. In the micorosatellite markers analysis, 957 loci showed significant associations in the 1st screening. Of these markers, 257 loci remained statistically significant in the 2nd screening and the most powerful association was observed in chromosome 1 (p=1.2x10-23). To further narrow the susceptible loci and to identify the tag-SNPs, the haplotype analysis is now carrying on. The validity of these tag-SNPs will be verified using the 12,000 population samples.

A SNP association study suggests the LRP8/ApoER2 gene on chromosome 1p34-36 to be a susceptibility gene for coronary artery disease (CAD) and myocardial infarction (MI). *S.Q. Rao[1,2,3], G.Q. Shen[1,2,3], L. Li[1,2,3], E.J. Topol[1,2,3], Q.K. Wang[1,2,3].* 1) Department of Molecular Cardiology; 2) Department of Cardiovascular Medicine; 3) Center for Cardiovascular Genetics; Cleveland Clinic Foundation, Cleveland, OH 44195, USA.

Our genome-wide linkage scan of 428 nuclear families in the U.S. identified a significant genetic locus for susceptibility to MI on chromosome 1p34-36. Here we describe a population-based case-control association study for analyzing candidate genes at the locus. The 382 cases consist of the well-characterized CAD/MI probands from each family with DNA available, and the 315 controls are individuals without detectable stenosis by coronary angiography. Sixteen candidate genes were characterized, including the connexin37 gene (GJA4), the endothelin-converting enzyme-1 (ECE1), and the low-density lipoprotein receptor-related protein 8 (LRP8, or ApoE receptor 2). Genotyping of SNPs (single nucleotide polymorphisms) was carried out using the 5' nuclease allelic discrimination assay with an ABI Prism 7900HT Sequence Detection System and the genotyping data yielding positive associations were verified by direct DNA sequence analysis. The allelic associations of SNPs with CAD/MI were evaluated using Pearsons Chi-square test. Only one of the 16 candidate genes, LRP8, showed significant association with CAD and MI. Three SNPs in LRP8 are associated with MI (P-value, from 0.03 to 0.001), and two SNPs showed association with CAD (P-value from 0.02 to 0.003). These results suggest that LRP8 is a susceptibility gene for CAD and MI.

A systemic SNP survey of 123 candidate genes from important pathways for genetic susceptibility of coronary atherosclerosis in Chinese populations. *Y. Wang[1], Y. Wang[2], Y. He[2], H. Wang[1,3], L. Xu[1], Y. Liu[1,3], Y. Wang[1], W. Sun[1], Y. Wang[1], X. Xiong[1], A. Sun[4], J. Ge[4], M. Xiong[1,2], L. Jin[1,2], W. Huang[1].* 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 3) Shanghai South Gene Technology Co., Ltd., Shanghai, China; 4) Zhongshan Hospital, Fudan University, Shanghai, Chin.

It has been widely accepted that the mechanism of atherosclerosis is mainly due to response to injury. This complex and progressive procedure involved many biological pathways, such as oxidant-antioxidant, inflammation, lipid metabolism, and coagulation. Despite observations on correlations of individual genes with atherosclerosis in vitro and in vivo, systemic association studies involving all genes from each pathways and many genes from multiple pathways have yet been reported. Here we offer a systemic SNP survey of 123 candidate genes involved in multiple pathways which have been implicated in the pathogenesis of coronary atherosclerosis in Chinese populations. In this study, we typed overall 1,518 haplotype tagging SNPs from 123 candidate genes in 916 samples (492 atherosclerotic cases and 424 controls). The result demonstrated that totally 116 SNPs and 41 haplotypes representing 38 susceptive genes were observed to be highly associated with coronary atherosclerosis. The association of each individual pathway with coronary atherosclerosis was also evaluated. Furthermore, we showed that there exist a few significant interactions between the genes within and between pathways.

The Promoter Polymorphisms of HMOX1 and Cardiovascular Disease. *J. Pohorence Ferguson[1], G.E. Cooke[2], P.F. Binkley[2].* 1) Dept Pathology, Ohio State University, Davis Heart and Lung Research Institute, Columbus, OH; 2) Dept Cardiovascular Medicine, Ohio State University, Davis Heart and Lung Institute, Columbus, OH.

A loss of heme oxygenase (HO-1) activity increases susceptibility to oxidative damage and has been associated with cardiovascular disease. Transcriptional activity of HMOX1, the gene encoding HO-1, is reduced by a promoter microsatellite polymorphism, while a promoter T(-413)A polymorphism has been found to increase transcriptional activity. Sequencing analysis was performed on a total of 676 subjects, 531 Caucasians and 145 African Americans, to genotype for the HMOX1 promoter polymorphisms. The African American race was significantly associated with the L allele and LL genotype of the microsatellite polymorphism ($p < 0.001$), and the SNP-413 T allele and TT genotype ($p < 0.001$). Further work was done to explore the relationship between the HMOX1 promoter polymorphisms and cardiovascular disease, especially in the African American population. In 138 patients who underwent percutaneous transluminal coronary angioplasty (PTCA), the LL genotype was significantly associated with a history of coronary artery disease ($p = 0.04$), and the T allele was significantly associated with a history of hypertension ($p = 0.03$) regardless of race. The 55 African American PTCA patients had a 3.75-fold increased odds of having the LL genotype ($p = 0.009$). In 281 patients having congestive heart failure, 49 African American patients had a 2.26-fold increased odds of having the LL genotype ($p = 0.01$). A subset of 71 patients who received heart transplants had a significant association between the LL microsatellite allele genotype and the AA SNP-413 genotype ($p < 0.001$). Quantitative PCR analysis for HMOX1 expression was performed on tissue samples from the explanted hearts of 38 transplant recipients. Bar graphs of the mean HMOX1 expression show the SS,TT genotype combination had the highest expression, although this was not statistically significant. The results of this study reveal the African American population may be susceptible to cardiovascular diseases involving oxidative stress due to a decrease in HO-1 activity resulting from the presence of the promoter polymorphisms.

Identification of Down Syndrome Heart Defect Candidate Gene. *L.J.H. Bean[1], S.F. Freeman[1], K.J. Dooley[2], T.C. Rosser[1], C. Oxford-Wright[1], C. Koller[3], G. Capone[3], S.L. Sherman[1].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Sibley Heart Center, Department of Pediatrics, Emory University, Atlanta, GA; 3) Division of Neurology and Developmental Medicine, Kennedy Krieger Institute, Baltimore, MD.

Individuals trisomic for chromosome 21 exhibit a wide range of phenotypes known as Down syndrome (DS). DS is mainly characterized by mental retardation and clinical features that include hypotonia, abnormalities of the face, hands, and feet. Other variable phenotypes associated with DS may include congenital heart disease (CHD), digestive tract abnormalities, congenital cataracts, or leukemia. The prevalence of DS, approximately 1 in 600 to 1 in 1000 live births, makes this syndrome the most commonly identified form of mental retardation. Compared to the general population, individuals with DS are at a 2000-fold increased risk for complete atrioventricular septal defects (AVSDs), a severe form of CHD. The purpose of this study is to identify genetic variants on chromosome 21 that contribute to CHD susceptibility using a candidate gene approach in a DS population with complete AVSDs. We have asceratined the largest reported collection of DNA on complete AVSD DS cases and their parents. This study is currently being expanded from 50 to 400 individuals with DS and AVSD to facilitate molecular studies and gene identification, in part by patient identification and recruitment from the Sibley Heart Center at Childrens Healthcare of Atlanta. Studies done in the mouse indicate that several genes within the candidate region are differentially expressed during heart development. We hypothesize that genes expressed in fetal, but not adult, heart may play a role in the etiology of congenital heart defects. The human heart expression patterns of several interesting candidate genes in a 10Mb DS CHD critical region on chromosome 21 have been determined. Taking advantage of the vast array of genomic resources available for chromosome 21, we will use molecular approaches to identify candidate genes for DS CHDs within a 10 Mb heart defect critical region and elsewhere in the genome.

Epicardial coronary artery spasm and microvascular angina are differentially influenced by *PON1* A632G polymorphism in the Japanese. *G. Koike, J. Mashiba, H. Kamiunten, K. Sunagawa.* Dept of Cardiovascular Med, Kyushu Univ Grad Sch Med Sci, Fukuoka, Japan.

Background: Ethnicity and smoking are well-known risk factors for the pathogenesis of coronary vasospasm. Oxidative stress induced by smoking plays a crucial role in increasing blood vessel tonus resulting in coronary vasospasm. However, smoking is not enough to account for the pathogenesis of coronary vasospasm, indicating that genetic factors are strongly involved. Therefore, the aim of this study is to elucidate oxidative stress related genetic factors responsible for the pathogenesis of coronary vasospasm. **Methods:** One hundred sixty two epicardial coronary artery spasm patients (LASs), 61 microvascular angina patients (MVAs), and 61 non-responders (NRs) diagnosed by acetylcholine provocation test were ascertained. After collecting genomic DNA from these patients, 4 polymorphisms of oxidative stress related genes, *CYBA* (cytochrome b-245, alpha polypeptide gene) C242T and A640G, *PON1* (paraoxonase 1 gene) A632G, *PLA2G7* (phospholipase A2 group VII gene) G994T were determined. Using clinical and genotyping information, statistical analysis was carried out. **Results:** Allele frequency of *PON1* 632-G was significantly higher in both the LAS with dominant fashion (OR 2.24, 95% CI 1.04-4.82, p=0.035) and the MVA with recessive fashion (OR 2.22, 95% CI 1.08-4.58, p=0.030) compared to the NR. This association was strongly influenced by gender only in the MVA. There were no significant associations between other polymorphisms and coronary vasospasms. In addition, allele frequency of *PON1* 632-G in the Japanese was higher than that in the Caucasian. **Conclusion:** There was a significant association between *PON1* A632G polymorphism and MVA as well as LAS. But the way of this impact on LAS and MVA was different in the Japanese.

Impact of prenatal and/or early postnatal environments on the cardiovascular stress response is modified by genes on rat chromosome 20. *J. Berube[1], L. Sedova[2], M. Pravenec[3], V. Kren[2], P. Hamet[1], Z. Pausova[1,4].* 1) Centre hospitalier de l'Université de Montréal, Canada; 2) Charles University and; 3) Academy of Sciences, Czech Republic; 4) Brain & Body Centre, University of Nottingham, UK.

Prenatal and/or early postnatal environments may play an important role in programming cardiovascular health in later life. This effect can be modified by the individuals genetic makeup. Augmented reactivity and delayed cardiovascular recovery are predictors of cardiovascular morbidity and mortality. The aim of the present study was to investigate in the rat whether litter size and parity (as mother-derived early-life environments) determine the offsprings cardiovascular response to stress, and if the effect is modified by genes within a specific segment of rat chromosome 20 (RNO20). At 16 weeks of age, systolic and diastolic blood pressure (SBP, DBP) and heart rate (HR) were measured by telemetry during and after 30-min immobilization stress. Spontaneously hypertensive rats (SHR) and its congenic strain, SHR.1N, were studied. SHR.1N differs from SHR by only a segment of RNO20, which has been transferred onto the SHR background from the normotensive Brown Norway rat. Two-way ANOVA for repeated measures with parity (primipara vs. multipara), litter size (small 9 pups vs. large 9 pups) and strain (SHR vs. SHR.1N) as main factors was used. During immobilization, SBP, DBP, and HR increased in both strains, but significantly more in SHR.1N. This effect of the RNO20 segment was modified by parity but not by litter size. Thus, when compared to rats born to multiparas, SHR.1N from primiparas showed higher SBP, DBP, and HR elevations, whereas SHR born to primiparas demonstrated lower elevations. During the 30-min post-stress period, SBP, DBP and HR decreased similarly in all animals, except for SHR.1N born to primiparas or originating from large litters that showed significantly delayed post-stress recovery of SBP, DBP, and HR. Our results indicate that mother-derived early-life environments, such as parity and/or litter size, significantly influence both reactivity and recovery of the cardiovascular system from stress in adulthood. This influence is modified by a gene(s) within the RNO20 segment.

In vivo and in vitro studies support that a new splicing isoform of OLR1 gene is protective against acute myocardial infarction. *R. Mango[1], S. Biocca[1], F. del Vecchio[1], F. Clementi[1], F. Sangiuolo[1], F. Amati[1], A. Filareto[1], S. Grelli[1], P. Spitalieri[1], I. Filesi[1], C. Favalli[1], R. Lauro[1], J.L. Mehta[2], F. Romeo[1,2], G. Novelli[1,2].* 1) Centre of Excellence for Genomic Risk Assessment in Multifactorial and Complex Diseases, School of Medicine, University of Tor Vergata,Rome, Italy; 2) Division of Cardiovascular Medicine, University of Arkansas for Medical Sciences, Little Rock, Arkansas, USA.

Lectin-like oxidized low density lipoprotein receptor-1 (LOX-1), encoded by the OLR1 gene, is a scavenger receptor that plays a fundamental role in the pathogenesis of atherosclerosis. LOX-1 activation is associated with apoptosis of endothelial cells, smooth muscle cells (SMCs) and macrophages. This process is an important underlying mechanism that contributes to plaque instability and subsequent development of acute coronary syndromes. Independent association genetic studies have implicated OLR1 gene variants in myocardial infarction (MI) susceptibility. Since single nucleotide polymorphisms (SNPs) linked to MI are located in intronic sequences of the gene, it remains unclear as to how they determine their biological effects. Using quanitative real-time PCR and minigene approach, we show that intronic SNPs, linked to MI, regulate the expression of a new functional splicing isoform of the OLR1 gene, LOXIN, which lacks exon 5. Macrophages from subjects carrying the non-risk disease haplotype at OLR1 gene have an increased expression of LOXIN at mRNA and protein level, which results in a significant reduction of apoptotis in response to oxLDL. Expression of LOXIN in different cell types results in loss of surface staining, indicating that truncation of the C-terminal portion of the protein has a profound effect on its cellular trafficking. Furthermore, the pro-apoptotic effect of LOX-1 receptor in cell culture is specifically rescued by the co-expression of LOXIN in a dose-dependent manner. The demonstration that increasing levels of LOXIN protect cells from LOX-1 induced apoptosis set a groundwork for developing therapeutical approaches for prevention of plaque instability.

The Bardet-Biedl protein BBS2 has a role in mitotic spindle dynamics and chromosome alignment. *J. Wei[1,2], D.Y. Nishimura[2], Q. Qian[2], C. Searby[1,2], M. Andrews[1,2], K. Bugge[2], A. Ferguson[2], A. Fedler[2], A. Loux[2], S.R. Patil[2], V.C. Sheffield[1,2].* 1) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

Bbs2$^{-/-}$ mice exhibit a typical *Bbs*$^{-/-}$ phenotype: retinal degeneration through apoptosis, failure of spermatozoa flagella formation, obesity associated with increased food intake, and development of renal cysts. Previously, we reported that rhodopsin in some *Bbs2*$^{-/-}$ photoreceptor cells remained in the cell bodies rather than being transported to the outer segments, which normally occurs via microtubule-dependent transport. This mislocalization of rhodopsin in the cell body suggests that BBS2 plays a role in microtubule-directed transport. Therefore, we examined the localization of BBS2 to explore whether BBS2 is a microtubule-associated protein. By immunofluorescent imaging of both wt and *Bbs2*$^{-/-}$ renal cells stained with antibodies directed against tubulin and BBS2, we have shown that BBS2 is a microtubule-associated protein. Based on this observation, we examined the overall structure of the mitotic spindle. We observed that ~10% of *Bbs2*$^{-/-}$ renal cells at metaphase showed defects in chromosomal alignment on the metaphase plate. One or few chromosomes were found to attach to either one pole or two poles of the mitotic spindle in some *Bbs2*$^{-/-}$ renal cells. Interestingly, once the chromosome moved away from the mitotic spindle, the cells proceeded with the division. Further studies revealed that more than 20% of *Bbs2*$^{-/-}$ fibroblasts exhibited aneuploidy with both losses (38 to 39 chromosomes) and gains (41 chromosomes) compared to mouse euploidy (40 chromosomes). These data indicate that BBS2 contributes to mitotic spindle dynamics and mutations in BBS2 result in increased levels of chromosomal inbalances in somatic cells.

Haplotypes of DAZL Are Associated with Susceptibility to Spermatogenic Failure in the Taiwanese Population.

P. Kuo[1], *Y. Teng*[2]. 1) Dept OB/GYN, National Cheng-Kung Univ Hosp, Taiwan; 2) Department of Early Childhood Education and Nursery, Chia Nan University of Pharmacy and Science, Tainan, Taiwan.

Background: Genetic factors have been associated with impaired sperm production in humans. DAZL is a germ-cell specific autosomal gene and is a strong candidate gene for human spermatogenic failure. Methods: DAZL was genotyped in 231 men with spermatogenic failure and 191 men with proven fertility. We carried out case-control analysis to identify the DAZL haplotypes which are associated with spermatogenic failure. Results: Five SNPs were identified: 260A>G (Thr12¡÷Ala) in exon 2, 386A>G (Thr54¡÷Ala) in exon 3, 520+34c>a in intron 4, 584+28c>t in intron 5, and 796+36g>a in intron 7. Of the five SNPs, three were novel: 520+34c>a, 584+28c>t, and 796+36g>a. The linkage disequilibrium (LD) map patterns were different for infertile men and control subjects. Four major haplotypes constituted 88.0% of the patient population, while three major haplotypes constituted 87.0% of the control population. Of all haplotypes studied, three haplotypes were over-transmitted in patients with severe spermatogenic failure, while two were under-transmitted in these patients. Conclusions: Different LD maps for fertile and infertile men indicate distinct genetic backgrounds for these two groups of subjects. The haplotyes which were over-transmitted in the infertile men conferred susceptibility to spermatogenic failure, while under-transmitted haplotypes were protective against spermatogenic failure. Our study suggests autosomal DAZL gene is a strong candidate gene for human spermatogenic failure.

POLYMORPHISMS IN THE TUMOR NECROSIS FACTOR-ALPHA GENE IN TURKISH WOMEN WITH PRE-ECLAMPSIA AND ECLAMPSIA. *A. Pazarbasi[1], M. Kasap[1], A.I. Guzel[1], H. Kasap[1], M. Onbasioglu[2], B. Ozbakır[2], F.T. Ozgunen[2].* 1) Medical Biology and Genetics, University of Cukurova, Adana, Turkey; 2) Obstetrics and Gynecology, University of Cukurova, Adana, Turkey.

The genetic background predisposing pregnant women to pre-eclampsia/eclampsia (PE/E) is still unknown. Three recent reports indicated that the tumor necrosis factor-alpha gene (TNF-alpha) could be involved in susceptibility to PE/E. TNF-alpha is a potent modulator of immune and inflamatory responses, and has been implicated in a variety of diseases, including PE/E. 308G/A and 850 C/T polymorphisms within the TNF-alpha gene promoter, has been associated with negative outcome in some diseases, including PE. The association of the TT allele with Eclampsia is unknown. The aim of this current study was to investigate whether there is an association between the TNF-alpha-308 and 850 polymorphisms and PE or eclampsia. In this study, 12 cases of eclampsia, 103 cases of PE and 46 normotensive control cases were genotyped for the TNF-alpha-308 and 850 polymorphisms. The uncommon allele (TNF2) of 308G/A polymorphism in the promoter region of the TNF-alpha gene has been reported to be increased in a variety of diseases, including eclampsia. We found a significant difference between the TNF2 allele frequencies of eclamptic, pre-eclamptic and normotensive controls. TNF2 polymorphism frequency was significantly higher among those eclamptic and pre-eclamptic (control: 6.5%, PE: 13.6%, E: 33.3%). A significantly different genotype distribution of 850C/T polymorphism observed between the PE/E and control groups, with the frequency of the variant T allele being significantly reduced in the preeclamptic (17.5%) and eclamptic group (16.6%) when compared with the control group (24%). We conclude from this study that the TNF2 allele contributes to the occurence of eclampsia and pre-eclampsia and the T allele of the TNF-alpha gene may modify individual PE/E risk, being protective against the development of the complication.

Brain derived neurotrophic factor (BDNF) haplotypes are associated with opioid addiction. *R. de Cid[1,2], F. Fonseca[3], M. Bayés[1,2], M. Gratacòs[1,2], R. Martín-Santos[1,4], X. Estivill[1,2,5], M. Torrens[3].* 1) Genes & Disease Program, Center for Genomic Regulation, Barcelona, Catalonia, Spain; 2) CeGen, Spanish Genotyping Centre, Barcelona, Catalonia, Spain; 3) Institut dAssistencia Psiquiàtrica, Salut Mental i Toxicomanies (IAPS), Hospital del Mar, Barcelona, Catalonia, Spain; 4) Unitat de Recerca en Farmacologia, Institut Municipal dInvestigació Mèdica (IMIM), Barcelona, Catalonia, Spain; 5) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Brain derived neurotrophic factor (BDNF) signaling pathway have been shown essential for opiate-induced molecular adaptation of the noradrenergic system in murine models. Drug induced adaptations in reward circuits have been described as a form of synaptic plasticity. BDNF studies in drug abuse have revealed modest associations between substance abusers and controls, but until now none have assessed effect of BDNF in opiate addiction. Genetic variability in BDNF could be related to poor response to Methadone Maintenance Treatment (MMT) in opiate addicted patients. We carried out a case-control study of opioid dependent subjects consecutively admitted into a MMT, matched by gender and age with naïve controls. After 7-month follow-up patients were divided into responders and nonresponders to MMT, based on illegal opiate consumption and retention in treatment. Substance and non-substance use disorders diagnoses were obtained mean PRISM-IV. Genetic variability in BDNF was addressed by SNPlex with 44 SNPs along BDNF gene. Nineteen of 44 assessed SNPs were informative in our sample. Five out nineteen in the BDNF gene showed allelic differences with statistical nominal differences among opiate-addicted-patients and healthy-controls ^{2} test uncorrected $p<0.001$). None of the observed allelic differences itself resisted the permutation test for significance. Simple regression analysis for genotype distribution shows that one of these variants was associated with opiate addiction under a recessive model. Genetic variability at BNDF shows association with opiate addiction, but no with MMT response. Supported by Marato-TV3 (10810) and RGPG-FIS (G03/184).

Neurocognitive trait components of schizophrenia - an association study in twins. *O.P.H. Pietilainen[1], T. Paunio[1], A. Loukola[1], A. Tuulio-Henriksson[2], W. Hennah[1], J. Turunen[1], J.O. Peltonen[1], K. Silander[1], J. Lonnqvist[2], J. Kaprio[3], T.D. Cannon[4], L. Peltonen[1,5].* 1) National Public Health Institute, Dept of Molecular medicine, Biomedicum, P.O.Box 104, FIN-00251 Helsinki, Finland; 2) National Public Health Institute, Dept of Mental Health and Alcohol Research, Helsinki, Finland; 3) University of Helsinki, Dept of Public Health, Helsinki, Finland; 4) UCLA, Depts of Psychology and Psychiatry and Biobehavioral Sciences, Los Angeles, USA; 5) University of Helsinki, Dept of Medical Genetics, Helsinki, Finland.

Susceptibility to schizophrenia (SZ) is influenced by numerous genes affecting a variety of brain functions. Some of these may be inherited in a predisposing configuration without resulting in a clinical phenotype, however affecting the function of the relevant brain systems. Twins represent ideal study subjects to address the genetic background of neurobehavioral traits disturbed in SZ as they share the same environment during the fetal period and early years of their lives. We tested several variables measuring neurocognitive functions in a Finnish twin study sample consisting of 58 SZ twin pairs (8 concordant, 50 discordant), and 62 control twin pairs matched for age, sex and demographics. We analyzed 27 SNPs in three candidate genes reported to be associated with SZ: NRG1, DTNBP1, and AKT1. We used linear regression with age, gender, presence of psychosis, zygosity, and the co-twin SZ status as covariates. Among the tested neuropsychological variables, one related to attention and visual motor tracking showed association with a variant of NRG1 ($p=0.0008$). Suggestive association was observed for visual working memory and visual attention with a variant in DTNBP1 ($p=0.003$ and $p=0.008$). This study highlights the importance of quantitative neurocognitive features as endophenotypes for SZ in the characterization of the genetic background of this disorder. The study further supports the role of NRG1 in the genetic etiopathogenesis of SZ and, furthermore, elucidates the putative brain systems that seem to be primarily affected. We are currently confirming these results in a large nationwide SZ study sample.

Craniofacial features of BBS patients and Bbs4 null mice. *P.L. Beales[1], E.R. Eichers[2], P. Hammond[3], M. Garcia[2], M.J. Justice[2], J.R. Lupski[2,4,5].* 1) Molecular Medicine Unit, Inst of Child Health, University College London, London, UK; 2) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Biomedical Informatics Unit, Eastman Dental Institute for Oral Health Care Sciences, University College London, London, UK; 4) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Texas Children's Hospital, Houston, TX.

The oligogenic disorder Bardet-Biedl syndrome (BBS) is characterized by clinical heterogeneity and complex inheritance. Features of BBS include mental retardation, polydactyly, obesity, hypogenitalism, renal abnormalities, retinal dystrophy, and several secondary features, although the phenotype is variable between patients. To analyze the contribution of one gene, *Bbs4*, to the BBS phenotype in mouse we created a knockout mouse line lacking expression of *Bbs4*.

We have demonstrated previously that BBS patients may have a characteristic face. Three-dimensional surface modeling of the faces of patients has suggested that BBS features include a wider, rounder face with a shorter, flattened nose, and retrognathia.

To further explore the characteristic face of patients, we examined a mouse model of BBS for a craniofacial phenotype. By direct observation it could be discerned that null mice appeared to have a distinct face as compared to their littermates. Thus, we subjected our mice to three-dimensional soft-tissue craniofacial scanning. Analysis of data points from key landmarks on the collected images indicate that the overall distance between several of the landmarks was significantly different in the null mice when compared to their littermates. For example the mean distance from the nasion to the subnasale (nsn) was significantly shorter (i.e a shorter snout) in null animals. Analyses of comparable nsn distances in 37 human BBS patients revealed females had a significant shortening but in males this distance was longer. However, when viewed as ratios (ngn:nsn) the overall human facial length was similar to that (vgn:nsn) for null mice. These results suggest that BBS genes play a significant role in midface development in mammals.

Behavioral analyses of *Bbs4* mice. *E.R. Eichers[1], N. Katsanis[5,6], P.L. Beales[7], R. Paylor[1,3], J.R. Lupski[1,2,4].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Division of Neuroscience, Baylor College of Medicine, Houston, TX; 4) Texas Children's Hospital, Houston, TX; 5) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 6) Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD; 7) Molecular Medicine Unit, Institute of Child Health, University College, London, UK.

Bardet-Biedl syndrome (BBS) is a rare oligogenic disorder exhibiting clinical heterogeneity and complex inheritance. Although the BBS phenotype is variable both between and within families, the syndrome is characterized by mental retardation, polydactyly, obesity, hypogenitalism, renal abnormalities, retinal dystrophy, and several secondary features. Eight genes mutated in BBS patients have been identified. To investigate the etiopathogenesis of BBS, we created a mouse null for one of the Bbs genes, *Bbs4*, to analyze the contribution of one gene to the pleiotropic BBS phenotype in mouse.

One phenotype more recently explored clinically in BBS patients is that of behavior anomalies. Although the behavioral characteristics of BBS patients are variable in both penetrance and expressivity, patients have been noted to have difficulty with thought and attention span, social problems, and to be withdrawn, anxious and depressed. In order to evaluate our mouse model for any behavioral phenotypes, we performed a battery of tests on null mice and their wild-type littermates. Our test results indicate that, in a gender-independent manner, the *Bbs4* null mice have significantly higher levels of anxiety than their wild-type littermates, as evidenced by both open-field locomotor and light-dark exploration experiments. Additionally, our knockout mice are significantly less socially dominant than their wild-type littermates. These data suggest that alterations in BBS4 may contribute to behavioral anomalies observed in some BBS patients.

Detecting chromosomal abnormalities in individuals with autism using karyotyping, FISH, and high-density cDNA microarrays. *T.H. Wassink[1], V.C. Sheffield[2], E.R. Westin[3], E. Ashley[4], J. PIven[4], S.R. Patil[5].* 1) Department of Psychiatry, UIA Carver College of Medicine, Iowa City, IA; 2) Department of Pediatrics and the Howard Hughes Medical Institute, UIA Carver College of Medicine, Iowa City, IA; 3) Inter-Departmental Genetics Program, UIA, Iowa City, IA; 4) Neurodevelopmental Disorders Research Center and Department of Psychiatry, University of North Carolina, Chapel Hill, NC; 5) Department of Pediatrics, UIA Carver College of Medicine, Iowa City, IA.

As part of an ongoing study to evaluate the genetics of autism, we have studied 127 individuals cytogenetically with karyotyping and focused FISH analyses (subtelomeres: n=119; 15q11.2q13: n=49; 22q11.2: n=20). Thus far, 7/127 samples (5.5%) have had a chromosomal abnormality. Four of the abnormalities were autosomal [del(2)(q37.1q37.3); inv(8)(p23.2q13.1); inv dup (15q) supernumary marker; dup(15q11.2q13)] and three were sex-chromosome abnormalities (XXY, XYY, and a del(Y)(q12) with chromosome 15 satellites on Yq). Subtelomere-FISH and locus-specific FISH did not uncover any abnormality not known from the cytogenetic analysis. We also utilized a locally developed 35k cDNA microarray to investigate genomic copy-number changes in a subset of this group. To ensure the validity of the microarray results, we tested known chromosomal abnormalities found in our autistic individuals, including the 15q11.2q13 duplication and a terminal 2q37.1q37.3 deletion. The microarray results redefined the sizes of the duplication and deletion to 6.2Mb (from 13.1Mb) and 8.6Mb (from 12.2Mb) respectively. The 15q breakpoints reside in a proximal 36Kb region and distal 693Kb region while the terminal 2q37 breakpoints are in a 2.6kb region. The 35k microarray data confirmed the previous cytogenetic/FISH findings and was able to narrow abnormality breakpoints in a manner that would have been cumbersome with FISH techniques. Compared to commercially available array-CGH chips, the microarrays employed here were extremely cost-effective.

Result of exploring pathogenesis of congenital disorders using array-CGH. *S. Hayashi[1,2,3], I. Issei[1,2], J. Inazawa[1,2].*
1) Department of Molecular Cytogenetics, Medical Resarch Institute, Tokyo Medical and Dental University, Tokyo, Japan; 2) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Tokyo, Japan; 3) Department of Pediatrics and Developmental Biology, Graduate Medical School, Tokyo Medical and Dental University, Tokyo, Japan.

PURPOSE: We have developed genomic microarray with 4523 BAC clones covering whole genome at intervals of about 0.7 Mb. Using the microarray we investigated aberration of copy numbers of genomic DNA to understand the pathogenesis of unknown congenital anomaly and/or mental retardation. METHOD: We have analyzed copy number aberrations in patients who were diagnosed known or unknown congenital disorder and/or whose phenotypes are not explained by conventional genomic analyze. More than 150 patients were analyzed. In each of them detected aberrations were confirmed by FISH. RESULT: Genomic aberrations were detected in about quarter of patients. They were deletion or duplication of chromosome materials, including interstitial or subtelomeric region, which size was 0.2 Kb at minimum. Some of them could explain entire phenotypes of patients. For example, it is thought that 4 Mb-wide deletion of 9p subtelomeric region which had not been detected by G-banding would cause mild phenotype of 9p monosomy syndrome. Given another example, we detected in a girl 2 Mb-wide interstitial duplication of Xp including a gene associated with maturation of ovary and it was thought that overexpression of the gene related to precocious puberty. Some of aberrations had possibilities to be large-scale copy number variation (LCV). Familial analyses were carried out, and aberrations also detected in related healthy people was thought not to be pathogenic. CONCLUSION: Array-CGH is thought to be significant technique to explore genomic aberrations. However LCV makes it to more difficult to evaluate whether the aberration was pathogenesis. Thus the construction of LCV database is important. Development of LCV database information about LCV will help us to know relationship between genomic aberrations and pathogenesis of genomic disorders as well as phylogenic study.

Proximal 14q deletion overlaps with the HPE8 locus and is associated with corpus callosum agenesis. *G. Macintyre[1], K. Schlade-Bartusiak[1], L. Rodriguez[2], P.C. O'Brien[3], M.A. Ferguson-Smith[3], D.W. Cox[1].* 1) Dept Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Instituto de Salud Carlos III, Madrid, Spain; 3) Centre for Veterinary Science, University of Cambridge, Cambridge, United Kingdom.

Interstitial deletions and translocations of 14q11-12 have been associated with diseases including holoprosencephaly, schizophrenia (NPAS3), benign hereditary chorea (NKX2.1), tetramelic mirror image polydactyly (MIPOL1) and oligodontia (PAX9). We have characterized a *de novo* deletion in a female who presented in infancy with microcephaly, hypotonia and agenesis of the corpus callosum. At birth, weight was 50th percentile, length was 25th percentile and occipital-frontal circumference (OFC) was 25th percentile. At 2 years 2 months, weight, length and OFC were under 3rd percentile and generalized hypotonia, triangular facies, lack of speech and psychomotor delay were evident. Chromosomal analysis by G-banding revealed a karyotype initially interpreted as 46XX, del (14)(q11.2;q13.1). Parents were both 33 years old and of normal karyotype. FISH analysis with BAC genomic clones and STS marker analysis on flow sorted chromosomes were then used to ascertain the full extent of the deletion. The deletion was subsequently defined as del(14)(q12;q13.3), which spans at least 10Mb, and maps to a locus we have defined for holoprosencephaly (Kamnasaran et al., 2005). This region also contains a gene defective in two patients with schizophrenia (Kamnasaran et al., 2003). The proband has features in common with other cases with 14q deletions mapping to this region. The described deletion affects over 70 genes, including a number of genes expressed in the brain, such as FOXG1B and TITF1, two transcription factors required for normal forebrain development.

Genome tilepath microarray analysis of copy number polymorphisms and methylation profiles in Autism. *S.G. Gregory[1], J. Connelly[1], R. Cote[1], C. Sheedy[1], M. Schemmel[1], J. Virgadamo[1], R. Abramson[3], H. Wright[3], R. Delong[2], M. Cuccaro[1], J.M. Vance[1], M. Pericak-Vance[1].* 1) Duke Center for Human Genetics, DUMC, Durham, NC; 2) Dept of Pediatric Neurology, DUMC, Durham, NC; 3) Dept of Neuropsychiatry, SOM-USC, Columbia, SC.

Autistic disorder (AutD) is a neurodevelopmental disorder characterized by disturbances in social, communicative, and behavioral functioning. There have been several linkage genetic screens and numerous association studies, however no gene has been identified. An alternative approach is the characterization of chromosomal rearrangements within individuals with AutD. It has been established that 5% and 48% of individuals with idiopathic and non-idiopathic autism, respectively, have chromosomal rearrangements. Additionally, AutD patients have been described with mutations in MECP that are known to be associated with abnormal methylation changes in the genome. This suggests that chromosome rearrangements or epigenetic changes in gene regulation could be responsible for AutD. Here we describe the novel use of high-resolution tilepath microarray (of chromosomes 1, 3, 4, 7, 10, 15, 17, 19, X, Y and 1Mb) to identify regions of chromosomal aberration using 42 AutD individuals, 9 maternal and 2 paternal DNAs. HrCGH analysis identified a minimal region of genomic amplification of 6Mb between clones RP11-467N20 and RP11-483E23 in 15q11.2 - 15q13.1 within 12 AutD individuals with isocentric chromosomes. The interval is bordered by two regions of normal copy number polymorphism, is covered by 50 tilepath clones (containing 4 genomic gaps) and encompasses 21 genes annotated within Ensembl. Methylation profiles were generated for 6 of the individuals for whom we generated hrCGH data. Using a recently published technique (Inazawa et al.) we have been able to identify increased methylation (>2 fold) of 25 clones in at least two or more of the 7 AutD cases. Genomic localization of clones exhibiting differential methylation places 7 of the 25 clones within known regions of AutD linkage, on chromosome 3q26, 7q32, 15q11-13, 16p13 and 17q12. This novel approach has great potential in helping elucidate the causal mechanism of AutD.

Variation in IRF6 contributes to nonsyndromic cleft lip and palate. *S.H. Blanton[1], A. Cortez[2], S. Stal[3], J.B. Mulliken[4], R.H. Finnell[5], J.T. Hecht[2].* 1) Univ of Virginia Hlth Sci Ctr, Charlottesville; 2) Univ of Texas Medical School, Houston; 3) Texas Childrens Hospital, Houston; 4) Children's Hospital, Boston MA; 5) Institute for Biosciences and Technology, Texas A&M, Houston.

Cleft lip with or without cleft palate is a common birth defect found in more than 300 recognizable syndromes, but more often is observed as an isolated birth defect, called nonsyndromic cleft lip with or without cleft palate (NSCLP). NSCLP occurs in approximately 1/700 live births, causes significant facial anomalies and may result in significant morbidity, in addition to lifelong medical and social consequences. While there have been a number of attempts to identify the genes responsible for this disorder, the results have not been consistent among populations and no single gene has been identified as playing a major susceptibility role. Van der Woude syndrome, a disorder characterized by lip pits with or without cleft lip/palate, results from mutations in interferon regulatory factor 6 (IRF6) in many cases. Recently, Zucchero et al (2004) detected an association between SNPs in IRF6 and NSCLP in a number of different populations. A subsequent study by Scapoli et al (2005) confirmed this association in an Italian population. We examined the same four SNPs as Scapoli in our large, well characterized sample of NSCLP families and trios. The sample consists of 51 multiplex families, 184 simplex parent-child trios and 21 parent-child trios with a positive family history. While there was no evidence of linkage, either parametric or nonparametric, FBAT analysis of the individual SNPs in the sample detected an increase in the transmission of the C allele (major allele) (216 vs 201) ($p=0.05$) for rs2013162. In general, HBAT detected an increased transmission of haplotypes with this C allele matched by a decrease in the transmission of haplotypes with the A allele. The most significant results were obtained for the C-A-X-T haplotypes ($p=0.009$). Replication of positive findings in complex diseases has been difficult. That three different studies have yielded significant results for an association between IRF6 and NSCLP suggests that this is an important gene and clearly warrants further study.

Molecular genetics approaches in human congenital diaphragmatic hernia. *S. Kantarci[1], B.R. Pober[1,2], M. Russell[1], D. Casavant[1], C. Lee[3], P.K. Donahoe[1].* 1) MassGeneral Hospital for Children,Boston, MA; 2) Childrens Hospital, Boston, MA; 3) Brigham & Womens Hospital,Boston, MA.

Congenital Diaphragmatic Hernia (CDH) is a relatively common developmental anomaly with a high mortality primarily due to lung hypoplasia and pulmonary hypertension. Little is known about the etiology of CDH. Just over half of patients have isolated CDH, while the remainder have associated birth defects, chromosomal abnormalities or single gene disorders. We aim to identify genes involved in CDH in our carefully phenotyped cohort of patients by application of several complementary strategies. We have sequenced 45 of the 152 enrolled patients for 21 candidate genes (ROBO1, ROBO2, SLIT2, SLIT3, FOX1, GATA4, etc.) identified from animal models, expression and functional patterns, or chromosomal hot spots. A web-based polymorphism phenotyping program, PolyPhen, was used on all nonsynonymous SNPS to predict the effect of amino acid changes on the structure and function of the protein. We found several potentially damaging SNPs not previously reported in the dbSNP homepage, nor in 970 chromosomes from an ethnically matched control group recruited as part of this study. However these SNPs were present in an unaffected parent. Functional studies of selected ROBO1 SNPs are underway and we also plan to expand the size of the control group. We are using 1Mb resolution array-based Comparative Genomic Hybridization (aCGH) to detect possible microdeletions or microduplications on 30 syndromic and nonsyndromic patients and detected two abnormalities involving apparently de novo deletions of chromosomes 16q12.2 and 1q42 respectively. Prior cases with deletions of 1q42 suggest this is a CDH hotspot. We are performing homozygosity mapping by application of the 10K Affymetrix chip to a large inbred kindred. This family contains several members affected with an autosomal recessive multiple anomaly condition which has CDH as a cardinal feature. These numerous strategies will identify genes, which when deleted or mutated, contribute to the development of CDH. These approaches provide a model for elucidating the genetic basis of common, but etiologically heterogeneous, birth defects.

***AHSG* gene polymorphisms are associated with coronary artery calcification in the Diabetes Heart Study.** *K.P. Burdon, A.B. Lehtinen, J.P. Lewis, C.D. Langefeld, J.T. Ziegler, B.I. Freedman, D.W. Bowden.* Wake Forest Univ Sch Med, Winston-Salem, NC.

The 2-Heremans-Schmid glycoprotein (*AHSG* or fetuin-A) plays a major role in preventing ectopic vascular calcium by inhibiting calcium phosphate precipitation *in vitro*. *In vivo*, sequence variants in the *AHSG* gene are associated with reductions in circulating AHSG levels and increased vascular calcified plaque. This elevation in vascular calcium predicts cardiovascular disease (CVD) morbidity and mortality. The purpose of this study was to evaluate whether polymorphisms in the *AHSG* gene contribute to subclinical CVD in type 2 diabetic (T2DM) subjects. The Diabetes Heart Study (DHS) predominantly consists of European American affected sibling pairs who have been carefully phenotyped for clinical and subclinical measures of CVD. Using single base extension mass spectrometry, we genotyped 11 single nucleotide polymorphisms (SNPs) across the *AHSG* gene in 1,180 individuals from the DHS. Each SNP was evaluated for association with quantitative measures of subclinical CVD risk, including coronary artery calcified plaque (CAC), carotid artery calcified plaque (CarAC), and intimal-medial carotid wall thickness (IMT). Four SNPs were significantly associated with CAC in European American T2DM subjects (0.001P0.023) when adjusting for age, gender, smoking status, and use of lipid lowering medications. Haplotype analysis of the 11 SNPs identified two 4-SNP haplotypes encompassing exon 6, intron 6, and exon 7 that were associated with CAC when adjusting for age, gender, ethnicity, diabetes status, smoking status, and use of lipid lowering medications. The CGCC haplotype was significantly associated with increased CAC scores (P=0.030), while the TGGA haplotype was significantly associated with decreased CAC scores (P=0.012). However, only one of the SNPs in these haplotypes was individually associated with CAC. The results of this study suggest that polymorphisms in the *AHSG* gene are associated with CAC, consistent with the biological role of AHSG in vascular calcification. *AHSG* gene polymorphisms may impact CVD morbidity and mortality in diabetics.

Systematic screening of susceptibility for intracranial aneurysms on chromosome 7q11 using sliding window analysis and permutation test. *H. Akagawa[1,2], H. Onda[2], H. Kasuya[2], M. Kubota[3], A. Hata[4], T. Hori[2], A. Tajima[1], I. Inoue[1].* 1) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Department of Neurosurgery, Tokyo Women'fs Medical University, Tokyo, Japan; 3) Department of Neurosurgery, Chiba University, Chiba, Japan; 4) Department of Public Health, Chiba University, Chiba, Japan.

Rupture of intracranial aneurysms (IA) resulted in subarachnoid hemorrhage with high morbidity and mortality, therefore IA represents one of the major public health concerns.'@A genome-wide linkage study of IA and detected significant linkage on 7q11 (MLS = 3.22 near *D7S2472*), accordingly we performed systematic single nucleotide polymorphism (SNP) fine-mapping at the 4.6Mb linkage region. 166 SNPs of 26 positional genes were detected and genotyped. The SNPs were initially tested for allelic association evaluated by permutation test, which adjusts the significance level to account for multiple comparisons of the data sets. Fifteen SNPs showed significant associations (permutation P 0.05), and 9 of them were clustered within a region of ~400 kb centromeric to *D7S2472*. The locus contains *ELN*, *LIMK1*, and *CYLN2*. Systematic haplotype analyses and LD mapping in the 4.6 Mb region were performed using sliding window method showing gene-specific LD blocks in the 4.6 Mb region. Haplotypes having significant associations (permutation P 0.05) were clustered within the locus containing *ELN*, *LIMK1*, and *CYLN2* confirming the results of single-SNP associations. When the significance level was set at permutation P value under 0.01, associations were confined to only one LD block for both single and global haplotype comparisons. The pinpointed LD block involved 3'f end of *ELN* and 5'f regulatory region of *LIMK1* and SNPs in the 3'funtranslated region (3'UTR) of *ELN* and the promoter region of *LIMK1* were significantly associated with IA. The functional impact and relationship of these variants were under investigation.

Pharmacogenetic modulation of clopidogrel antiplatelet effects: role of sequence variations of the CYP3A4 gene.

E. Trabetti[1], U. Cavallari[1], M. Biscuola[1], D.J. Angiolillo[2], E. Bernardo[3], C. Ramirez[3], M.A. Costa[2], C. Macaya[3], P.F. Pignatti[1]. 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) Univ Florida-Shands Jacksonville, Jacksonville, FL; 3) Cardiovascular Inst., Hospital Clin. S. Carlos, Madrid, Spain.

Clopidogrel is activated by cytochrome P450 (CYP) 3A4 and the activity of this enzyme contributes to variability in individual response to clopidogrel. Since metabolic activity of CYP3A4 is under genetic control, we hypothesized that gene sequence variations of CYP3A4 may modify individuals' response to clopidogrel. The CYP3A4*1B (-392A>G), CYP3A4*3 (M445T) and CYP3A4*16B (IVS10+12G>A) polymorphisms of the CYP3A4 gene were assessed in 127 patients (pts) undergoing coronary stent implantation: 45 receiving a 300 mg clopidogrel loading-dose (Group A) and 82 on long-term (>1 month) clopidogrel (75 mg/d) treatment (Group B). All patients were on aspirin (100 mg/d). Activated GPIIb/IIIa was assessed by whole blood flow cytometry in 2M ADP-stimulated platelets at baseline and 24 hours after loading-dose (Group A) and following long-term treatment (Group B). In Group A, clopidogrel response was defined according to the degree of inhibition of GPIIb/IIIa activation 24 hours after clopidogrel administration vs baseline values. Pts were classified as non responders, low responders, and responders when platelet inhibition was <10%, 10 to 29%, and 30%, respectively. Group B pts were divided in tertiles of platelet reactivity (low, moderate, and high). Only the IVS10+12G>A polymorphism was sufficiently polymorphic. G/A plus A/A pts were 9/45 (20%) of Group A, and 14/82 (17%) of Group B. In Group A, a higher number of non responders were observed among G/G pts (non responders: 36% vs 13%; low responders: 36% vs 0%; responders: 28% vs 87%; p=0.003). In Group B, G/G pts continued to have higher platelet reactivity and were less responsive to treatment according to tertile distribution (p=0.02). In conclusion, a polymorphism of the CYP3A4 gene seems to modulate clopidogrel antiplatelet effects in both the acute and chronic phases of treatment, and to contribute to individual variability in platelet responsiveness to clopidogrel.

Innate Immunity Gene Polymorphisms in Regulation of CRP. *P. Kozlowski[1], D.T. Miller[1], D.I. Chasman[2], R. Lazarus[3], J. Suk Danik[2], R.Y.L. Zee[2], P.M. Ridker[2], D.J. Kwiatkowski[2].* 1) Division of Hematology; 2) Division of Preventive Medicine and Division of Cardiovascular Disease Prevention; 3) Channing Laboratory, Brigham and Womens Hospital, Boston, MA.

Atherosclerosis is a common and complex disease, and the leading cause of death and illness in developed countries. Its complex etiology includes both environmental and genetic components. In several large prospective studies, C-reactive protein (CRP) has been shown to be a marker of atherosclerotic cardiovascular disease risk, with effects that are independent of LDL-C and Framingham risk scores. We hypothesized that genetic variation with significant influence on CRP levels might be found in the genes of the innate immunity system. Therefore we performed a candidate gene association study examining common SNPs in 9 innate immunity genes (*CARD15*, *IRAK1*, *IRAK4*, *LBP*, *LY86*, *MEFV*, *TLR2*, *TLR4* and *NFKB1*) in relationship to CRP levels. 717 subjects from the Womens Health Study (WHS) population were selected: 359 samples with extremely low (<5th percentile; <0.2 mg/l) and 358 samples with extremely high CRP level (>86th percentile; >5 mg/l). We selected SNPs using publicly available resequencing data from three Programs for Genomic Applications (IIPGA, SeattleSNPs and NIEHS SNPs). Using a minor allele frequency threshold >5%; and linkage disequilibrium-based strategy (r2>0.8), we selected the 64 markers, which we genotyped by Sequenom, TaqMan and ARMS-PCR methods. In addition, we examined one non-synonymous SNP in *TLR4* and two non-synonymous SNPs in *CARD15* which were previously associated with atherosclerosis and Crohns Disease, respectively. We performed both univariate and haplotype analyses for all 67 SNPs in all 717 CRP discordant subjects. No significant association with CRP level was detected. In contrary to these results, a previous study using the same set of samples showed that SNPs in *CRP* gene are strongly associated with CRP level. Although the present study excludes a significant association of common SNPs in these innate immunity genes with CRP levels, it is possible that rarer alleles in these genes, or variation in other innate immunity genes, could be associated with variation in CRP.

Composite genotypes of the IL-1 gene cluster predict IL-1 levels. *J. Rogus[1], J. Beck[2], K. Huttner[1], K. Kornman[1], S. Offenbacher[2].* 1) Interleukin Genetics, Waltham, MA; 2) Univ of North Carolina, Chapel Hill, NC.

Interleukin-1 (IL-1) is a potent cytokine involved in critical pathobiological processes of cardiovascular disease including recruitment of blood leukocytes, activation of downstream mediators such as IL-6 and CRP, and modulation of clot formation/dissolution. Extracellular release of IL-1 is regulated by complex feedback loops involving both the IL-1B gene, encoding the proinflammatory cytokine, as well as the IL-1RN gene encoding its natural antagonist. We evaluated the joint effect of two SNPs, one in the IL-1B promoter (IL-1B(-511) C>T) and one in the IL-1RN gene (IL-1RN(+2018) T>C), on IL-1 levels measured in non-invasive sampling of gingival crevicular fluid. For each SNP, genotypes were categorized as carriers (2/*) or non-carriers (1/1) of the minor allele. In 656 Caucasians, median IL-1 levels differed among the four resulting groups (p=.0003, Kruskal-Wallis). A similar pattern emerged in 185 African Americans, trending towards significance in this smaller cohort (p=.07, Kruskal-Wallis). We conclude that both IL-1B(-511) and IL-1RN(+2018) are associated with IL-1 levels in a manner best captured by the composite genotype patterns described. This insight can serve as a useful frame of reference for studies investigating the effect of the IL-1 gene cluster on clinical events such as myocardial infarction.

IL-1B	IL-1RN	n (Caucasian)	IL-1 (Caucasian)	n (African Am)	IL-1 (African Am)
1/1	1/1	216 (33%)	185.3	35 (19%)	94.6
1/1	2/*	87 (13%)	169.4	1 (<1%)	-
2/*	1/1	144 (22%)	152.6	124 (67%)	90.6
2/*	2/*	209 (32%)	137.9	25 (14%)	68.1

Molecular analysis of impaired cholesterol efflux in subjects with familial low-HDL: The role of ABCA1. *J. Naukkarinen[1], A. Soro-Paavonen[2], M. Lee-Rueckert[3], A. Hiukka[2], H. Watanabe[2], S. Söderlund[2], M. Jauhiainen[1], P.T. Kovanen[3], L. Peltonen[1], M-R. Taskinen[2].* 1) Dept. of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 3) Wihuri Research Institute, Helsinki, Finland.

The atherogenic effect of low-HDL is primarily due to impaired reverse cholesterol transport to the liver. Controversy prevails about the exact molecular pathogenesis of low-HDL, with most studies reporting an involvement of the ATP-binding cassette transporter 1 (ABCA1), critical for cholesterol efflux. We wanted to test the potential role of ABCA1 in well phenotyped Finnish low-HDL families, ascertained for population based age-sex specific 10th HDL percentile. We studied monocyte-derived macrophages isolated from both affected (HDL<10th percentile, n=22) and non-affected (n=7) men, as well as normolipidemic controls (n=21). SNP haplotypes and transcript levels of ABCA1 and the ability of ABCA1 to facilitate efflux of cholesterol to lipid-free ApoA-I from acetyl-LDL loaded macrophages in vitro were determined. Affected individuals showed altered carrier frequencies of the R219K allele, and in the whole study sample (n=73), a common three-SNP haplotype was associated with higher HDL-levels in a dose-dependent manner. The likelihood of an individual being affected when carrying either 0, 1 or 2 copies of this allelic haplotype were 80, 48 and 30%, respectively. Loaded macrophages from affected individuals demonstrated reduced cholesterol efflux, while exhibiting a significantly higher ABCA1 transcript level, that, however, dissipated after apoA-I facilitated cholesterol efflux. In summary, the carrier status for the common haplotype appears to have an effect on HDL levels, while it doesnt directly correlate with either the transcript level of ABCA1, or efflux efficiency. We infer that while part of the low HDL pathology may be explained by allelic variation of ABCA1, its higher expression in affected subjects may reflect a compensatory/rescue effort for a defect elsewhere in the complex pathway of cholesterol efflux and HDL formation.

***LOXL2* polymorphisms are associated with susceptibility to intracranial aneurysms.** *B. Krischek[1,5], H. Yamada[1], H. Akagawa[1,2], H. Kasuya[2], H. Onda[2], M. Kubota[3], A. Hata[4], T. Hori[2], A. Tajima[1], I. Inoue[1].* 1) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Department of Neurosurgery, Tokyo Women'fs Medical University, Tokyo, Japan; 3) Department of Neurosurgery, Chiba University, Chiba, Japan; 4) Department of Public Health, Chiba University, Chiba, Japan; 5) Department of Neurosurgery, Philipps University Marburg, Marburg, Germany.

Background and Purpose- The etiology of intracranial aneurysms (IA) is complex involving both genetic and environmental factors. Four lysyl oxidase family genes (*LOXL1*, *LOXL2*, *LOXL3*, and *LOXL4*), catalyzing cross-linking of collagens and elastin that would enhance the strength of blood vessel wall, are considered to be plausible functional candidates for IA and were extensively screened for genetic susceptibility in Japanese and Korean IA patients.

Methods- Fifty-five single nucleotide polymorphisms (SNPs) of *LOXL1~4* were genotyped in 402 Japanese IA patients including 185 familial cases and 280 Japanese non-IA controls. Positively associated SNPs were further genotyped in 199 Korean patients and 194 Korean non-SAH controls. Allelic associations between the patients and controls were evaluated with ^{2} test or permutation test.

Results- In the first screening, two SNPs of *LOXL2* and two SNPs of *LOXL3* both locating next each other, showed significant association with IA (0.05). Then all of the IA patients of Japanese and Korean were genotyped. Significant allelic associations were observed with three synonymous SNPs located on exon 5 of *LOXL2* in comparison between Japanese patients and controls (Permutation P 0.05). The associations of these three SNPs were replicated in Korean group (Permutation P 0.05). The best evidence of association was observed in exon 5 [-28] GA SNP (Permutation P = 0.0024 in Japanese group, Permutation P = 0.011 in Korean group).

Conclusions- We identified the SNPs of *LOXL2* that would be a genetic risk to IA development in Japanese and Korean patients.

Family based association analyses of the Histamine Receptor HRH1 gene in allergic disorders. *U. Christensen[1], T. Yndigegn[1], T.J. Corydon[1], A. Haagerup[1,2], H.G. Binderup[1], J. Vestbo[3,4], T.A. Kruse[5], A.D. Børglum[1].* 1) Institute of Human Genetics, University of Aarhus, Denmark; 2) Department of Paediatrics, Aarhus University Hospital, Skejby, Denmark; 3) Institute of Preventive Medicine, Kommunehospitalet, Copenhagen, Denmark; 4) North West Lung Centre, Wythenshawe Hospital, Manchester, UK; 5) Department og Clinical Biochemistry and Genetics, Odense University Hospital, University of Southern Denmark, Odense, Denmark.

Allergic diseases are a major global health problem with high and rising prevalence. The pathogenesis is multifactorial and has a substantial genetic part; for asthma, atopic dermatitis and hay fever the heritability is estimated to be 60-70%. We recently found linkage between the region 3p24-26 and atopic dermatitis. The gene coding for the histamine receptor H1 (HRH1) is located at 3p25 and is an obvious candidate gene owing to the central position of HRH1 as a key mediator of atopy and a regulator of Th1/Th2 balance. Here we present the results of a family based association study of two Danish samples comprising a total of 235 nuclear families with allergic diseases. We found significant association between 2 single nucleotide polymorphisms (SNPs) in the HRH1 promoter and several atopic phenotypes (e.g. positive skin prick test: p= 0.002). Haplotype analyses also revealed association with p-values as low as 0.0009 for atopic dermatitis with positive rast test. In silico analyses of these variations showed influence on the binding potential of conspicuous activation factors. Furthermore, a cell based reporter gene assay revealed that the -89A>G promoter variation radically reduced the transcription of the HRH1 gene.

Design of a National Resource for Gene Discovery in Parkinsons Disease. *D.J. Horsford[1], J. Keen[2], J. Beck[2], D. Murphy[1], Q. Scudder[1], C. Royds[2], K. Gwinn-Hardy[1], S. Rich[3].* 1) NINDS, Bethesda, MD; 2) Coriell Cell Repositories, Camden, NJ; 3) Bowman Wake Forest University School of Medicine, Winston-Salem, NC.

The National Institute of Neurological Disorders and Stroke (NINDS) Repository at Coriell (http://locus.umdnj.edu/ninds/) is a public resource banking cell lines and DNA with clinical data in order to identify genetic risk factors in Parkinsons disease (PD) and other neurological disorders. To facilitate this, the NINDS sample collection is publicly available to both academic and industry sponsored investigators. The NINDS repository is designed to maximize gene discovery in neurological diseases by providing 1) high quality DNA from immortalized cell lines 2) detailed clinical data on both cases and controls and 3) power to detect the moderate effects of a single susceptibility gene by banking a large sample number. We hope to identify SNPs with approximately a 1.5-fold or greater relative risk. For common SNPs (with minor allele frequency >10%), this translates into an allele frequency difference of ~10% or more. With 5000 cases in a given disease, the expected allele frequency differences between cases (and controls) for a marker that accounts for 2% of the phenotypic variance ranges from 10% to 15%. Substantial statistical genetic and empirical data suggest that 5000 PD cases would be relevant for gene discovery of individual gene effects underlying risk of complex human disease. Should there be gene-gene or gene-environment interactions, the sample size required to maintain power would be increased by at least 4-fold. Thus, there is a clear rationale for continuing sample collection even once the current target of 5000 has been reached. We currently have publicly available 827 well-characterized PD subjects and 492 matched control subjects, of 2372 PD and 1217 controls collected and banked. Secondary validation of risk factor genes will also be possible in this collection, because of the availability of populations different from the original cohort which can be used.

Genomic analyses and allele specific mRNA analysis using quantitative PCR. *A. Torinsson Naluai[1,2], C. Ladenvall[2], J. Danielsson[2], T. Martinsson[1,2], C. Jern[1].* 1) Göteborg Genomics, Core facilities at the Sahlgrenska Academy, Göteborg, Sweden; 2) Department of Clinical Genetics, Göteborg University, Sweden.

The SWEGENE Göteborg Genomics core facility carries out specific analyses using high throughput techniques. We give support in the experimental design for dissection of the genetic complexity of polygenic and monogenic diseases. The different methods available are DNA sequencing, genotyping of single nucleotide polymorphisms (SNPs) as well as microsatellites and quantitative PCR using the TaqMan chemistry. In the process of analyzing data we continuously work on developing new methods and applications.

We are presently developing a method using quantitative PCR for measuring different mRNA levels of heterozygote individuals.

It is well established that single nucleotide polymorphisms can influence the amount of mRNA produced. The method currently being developed provides a means to investigate allele-specific expression in vivo, using DNA from the same individual as an internal control. Differences in cDNA levels between alleles can be detected using quantitative PCR. If the SNP is somehow involved in regulation of mRNA expression or stability, and if no imprinting or external regulatory elements are involved, one of the alleles would express more mRNA than the other allele.

This technique has great potential in discriminating between possibly functional SNPs and non-functional SNPs on a transcriptional level.

The genetics of type 1 diabetes complications: results from the National Disease Resource Interchange (NDRI) database. *M.C. Monti[1,3], E. Schlag[2], J.T. Lonsdale[2], L. Ducat[2], C. Montomoli[3], D.A. Greenberg[1].* 1) Div Stat Genetics, Dept. Biostat, Columbia Univ, NY NY; 2) National Disease Resource Interchange, Philadelphia PA; 3) Dept. Applied Health Sciences, Univ of Pavia, Italy.

Retinopathy, nephropathy and neuropathy are major complications of type 1 diabetes (T1D). Retinopathy and nephropathy show familial clustering, suggesting genes influence risk. Only a subset of diabetic patients have specific complications; thus, factors for complications may differ from those for diabetes risk. We analyzed a large cohort of T1D families to see if family history is a risk factor for retinopathy and retinopathy type, nephropathy, and neuropathy. Data: 6687 families (81,771 individuals) ascertained through at least 1 T1D offspring (index case). 5831 offspring and 694 parents had T1D; 742 parents had type 2 diabetes (T2D); 889 families were multiplex (source: NDRI database). Data on complications came from self-report questionnaires and medical records. We assessed retinopathy type using ADA guidelines. We used a case-control design nested on the cohort and logistic regression models that included potential confounding factors. We used families with exactly two, or exactly three T1D-affected offspring. Cases and controls were age-frequency matched. (Controls were T1D patients without the complication.) Our four major findings: 1) If a complication was present in a proband, that complication was significantly more likely to be found in T1D affected sibs ($p<.0001$ for all three complications). 2) If a parent had T2D, there was a significantly higher risk for retinopathy in offspring than without a T2D parent ($p=.048$). 3) If an index case has proliferative retinopathy, that form of retinopathy is more likely to appear in T1D affected sibs. 4) The presence of retinopathy increases the risk for other complications ($p=.002$), especially in T1D females. Our study shows that familial clustering exists for diabetic complications and the severity and progression of retinopathy tend to be familial. This is the largest cohort study to date of the complications of T1D and it confirms a strong familial, and likely genetically-based, risk for the devastating complications of T1D.

12-lipoxygenase non-synonymous coding variants predict albuminuria in type 2 diabetes (T2DM): The Diabetes Heart Study (DHS). *Y. Liu[1], B.I. Freedman[1], K.P. Burdon[1], C.D. Langefeld[1], T. Howard[1], D.W. Bowden[1], L.E. Wagenknecht[1], C.C. Hedrick[2], S.S. Rich[1].* 1) Public Health Science/internal Medicine/Center for Human Genomics, Wake Forest University , Winston-Salem, NC; 2) Department of Medicine and the Cardiovascular Research Center, University of Virginia, Charlottesville, VA.

Hyperglycemia induces 12-lipoxygenase (12LO) and its arachidonic acid-derived products in endothelial and mesangial cells. This process can lead to endothelial dysfunction with cell hypertrophy and proliferation and result in diabetic nephropathy. We tested whether genetic variants in the 12LO gene (ALOX12) contributed to the development of albuminuria and whether this effect could interact with the hyperglycemic environments. Three ALOX12 haplotype-tagging SNPs (rs2292350, rs1126667 [R261Q], and rs2271316) were genotyped and urinary albumin:creatinine ratio (ACR) measured in 978 European American siblings (83% with T2DM) from 369 DHS families. Participants were categorized as: non-diabetic (non-T2DM), diabetic with hemoglobin A1c < 7% (controlled T2DM), and diabetic with hemoglobin A1c > 7% (uncontrolled T2DM). Tests of association were based on generalized estimating equations. The median ACR was 11.9 mg/g (interquartile range, 5.6-39.1). In the entire DHS sample, the overall test of the R261Q SNP genotypic association with ACR was significant (p =0.009). Compared to the 261Arg (R261Q) allele carriers, mean ACR adjusted for age, sex, smoking, and diabetic status was 42% higher among the 189 carriers of two 261Glu alleles (95% confidence interval, 10% to 83%; p=0.007). This association was significantly enhanced in the uncontrolled T2DM group, who had the highest ACR values (p for interaction across the 3 groups = 0.01). Further adjustment for other determinants of ACR or haplotype analysis revealed similar results. The 261Arg (R261Q) variant of ALOX12 is associated with greater degrees of albuminuria (ACR), predominantly among those with poorly controlled T2DM. Consistent with animal and cellular studies, these results provide further evidence of the importance of the 12LO pathway in the pathogenesis of human diabetic nephropathy.

Sequence Variants and Haplotypes of the DUSP12/ATF6 Region on Chromosome 1q21 Are Associated with Type 2 Diabetes. *W.S. Chu[1], S.K. Das[1], X. Wang[1,2], R.L. Craig[1], S.C. Elbein[1,2].* 1) Medicine, University of Arkanasas for Medical Sciences, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR.

Linkage of type 2 diabetes (T2DM) to chromosome 1q21-q23 is well replicated across populations. We initially placed a 50 kb SNP map across the linked region in unrelated Caucasian individuals. We identified a strong association with marker rs1503814. We subsequently mapped the association to a highly conserved region just telomeric to this marker and extending through the gene DUSP12,10 kb downstream. Sequence analysis and typing of additional public SNPs narrowed the association to a region of 62.4 kb encompassing 10 kb upstream of DUSP12, the DUSP12 gene, and the 5 end of the ATF6 gene. We evaluated 61 variants, including 2 microsatellites, 2 insertion deletion variants, and 57 single nucleotide polymorphisms (SNPs) in Caucasians. No coding variants could explain the association. The associated SNPs were present in 3 LD blocks, the first including the index SNP, the second extending from 8.8 kb upstream to 10.3 kb downstream of DUSP12, and the third beginning just upstream of ATF6 and extending into intron 4. No single haplotype from these blocks was more strongly associated than individual variants. Of the 25 SNPs in Block 2, 15 were associated with T2DM ($p=0.0008$ to 0.042) , 2 showed a trend to association ($p<0.01$), and 5 were infrequent (MAF<0.1). Hence, only 2 SNPs in DUSP12 were both common and not associated with T2DM. Analysis of Block 2 SNPs in African Americans also showed an association of the microsatellite variant in the conserved nongenic region 8 kb upstream, but not other SNPs in this block. However, block 2 extended only 5 kb downstream in African Americans and did not encompass a second associated SNP 7.5 kb downstream from the ATG start site. We propose that SNPs and microsatellite variants in 3 blocks provide independent contributions to the association with T2DM in both Caucasians and African Americans. Both DUSP12, which regulates glucokinase activity in liver and likely -cell, and ATF6, an endoplasmic reticulum stress protein, are strong functional candidates for T2DM.

Admixture-adjusted association between the estrogen receptor alpha gene and type 2 diabetes in an African American population. *K.L. Keene[1], C.J. Gallagher[1,2], J.C. Mychaleckyj[1,3], C.J. Gordon[1], C.D. Langefeld[4], B.I. Freedman[3], D.W. Bowden[1,2], M.M. Sale[1,3].* 1) Center for Human Genomics; 2) Department of Biochemistry; 3) Department of Internal Medicine; 4) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

Evidence for association with type 2 diabetes mellitus (T2DM) has been observed in a 41 kb region spanning intron 1-intron 2 of the estrogen receptor alpha gene (ESR1) in our African American case-control population sample. Two single nucleotide polymorphisms (SNPs) in intron 2 (rs11155818 P=0.00004; and rs1033182 P=0.020) as well as three haplotype blocks of high linkage disequilibrium (LD) spanning this region (global P<0.001) were significantly associated with T2DM. The objective of this study was to adjust association analyses for the contribution of admixture. Twenty-three ancestry informative markers (AIMs) and 17 SNPs in the associated region of the ESR1 gene were genotyped in 282 non-diabetic Caucasian and 120 non-diabetic African individuals, as well as 380 African American T2DM cases and 271 African American population controls. Using ADMIXMAP, the estimate for the mean proportion of African ancestry was 0.804 (95% credible interval: 0.779-0.831) in cases, and 0.815 (0.789-0.840) in controls. SNPs rs11155818 and rs1033182 remained significantly associated with T2DM after adjusting for admixture. The allelic association p-values, based on 20,000 iterations, changed from 0.00004 (unadjusted) to 0.00016 for rs11155818, and 0.020 (unadjusted) to 0.022 for rs1033182. Haplotype analysis also indicated that the three haplotype blocks were still significantly associated with T2DM (P<0.001) after adjusting for admixture, and all 7 significantly associated individual haplotypes (P<0.05) within the three blocks remained significant at or below this level. These analyses suggest that admixture does not account for the observed single SNP and haplotype association results between this region of ESR1 and T2DM in our African American population sample.

Association of the proprotein convertase subtilisin/kexin-type 2 (PCSK2) gene with type 2 diabetes in an African American population. *T.S. Leak[1], C.D. Langefeld[2], C.J. Gallagher[1,3], J.C. Mychaleckyj[1,4], B.I. Freedman[4], D.W. Bowden[1,3], M.M. Sale[1,4].* 1) Center for Human Genomics; 2) Department of Public Health Sciences; 3) Department of Biochemistry; 4) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

The proprotein convertase subtilisin/kexin-type 2 (PCSK2) gene, located on chromosome 20p11.2, is a strong functional candidate for type 2 diabetes (T2DM). PCSK2 cleaves the proinsulin molecule on the COOH-terminal side of Lys64-Arg65, which joins the C-peptide and the A-chain domains, and proinsulin levels have been reported as a predictor of T2DM. Additionally, a genome wide scan performed in 638 African American affected sibling pairs (ASP) from 247 families revealed modest evidence for linkage to T2DM age at diagnosis at 39cM on chromosome 20p near microsatellite D20S470 (LOD 1.61; p=0.0075). Ordered subsets analysis also provided evidence for linkage to a T2DM subset with later age at diagnosis (max. LOD 2.50, p=0.027). The PCSK2 gene is within the LOD-1 interval of both linkage peaks. We genotyped 29 single nucleotide polymorphisms (SNPs) across this gene in 380 unrelated African American individuals with T2DM and end-stage renal disease (T2DM-ESRD) and 278 African American population controls without a known diabetes diagnosis. Four SNPs were found to be associated with T2DM: rs4814597 (p=0.047), rs1609659 (p=0.041), rs2021785 (p<0.001) and rs2269023 (p=0.040). Analysis with Haploview, extending the block if pairwise D>0.7, revealed two blocks of high linkage disequilibrium (LD) containing 5 SNPs and 7 SNPs. Haplotype analyses using Dandelion showed the 7-SNP haplotype in the distal region of the gene was significantly associated with T2DM, with an overall haplotype p-value of 0.008. Within this block, there was a significant risk haplotype (6.8% in cases, 2.8% in controls; OR 2.46, p=0.022) counterbalanced by a protective haplotype (14.6% in cases, 22.9% in controls; OR 0.58, p=0.0066); rs2021785 distinguishes between these two haplotypes. The PCKS2 gene appears to play a role in susceptibility to T2DM in the African American population.

Re-sequencing and Functional Testing of PTPN1 Haplotypes Associated with Type 2 Diabetes and Insulin Sensitivity in Caucasian and Hispanic Americans. *N.D. Palmer, J.C. Mychaleckyj, G.A. Hawkins, D.W. Bowden.*
Wake Forest Univeristy, Winston-Salem, NC.

Protein-tyrosine phospatase-1B (PTP-1B), encoded by the PTPN1 gene, catalyzes the dephosphorylation of proteins at tyrosyl residues. PTP-1B negatively regulates insulin signaling by dephosphorylating the insulin receptor. In four independent populations, we observed significant evidence of association between type 2 diabetes (T2DM) and quantitative measures of glucose homeostasis and SNPs contained in a single LD block spanning ~110kb, encompassing PTPN1. Haplotype analysis suggests the presence of two common haplotypes: a T2DM risk haplotype (36%) that is associated with reduced insulin sensitivity and a second common haplotype (43%) which appears to be neutral in genetic epidemiological modeling. Alternate models of risk association are possible however, including the presence of multiple uncommon PTPN1 risk variants contributing to overall observation of T2DM risk. In order to identify a causal variant(s), we have carried out detailed re-sequencing of this LD block in 24 Caucasian and 24 Hispanic Americans. The DNA sequence from the 110,037bp region was determined from 220 overlapping fragments amplified from subject DNAs. We have identified 206 polymorphisms: 123 reported in dbSNP and 83 newly identified. Of the newly identified SNPs, 19 are insertion/deletion mutations and include 2 mini- and 2 microsatellites. An additional 208 reported polymorphic sequences were not found. This re-sequencing effort provides a comprehensive collection of the DNA sequence variation of the PTPN1 gene. In an effort to assess whether PTPN1 haplotypes are associated with altered levels of mRNA expression, a total of 36 B-lymphocyte cell lines were obtained from Caucasian individuals with known genotypes. mRNA was extracted from the cells and quantitated by real-time RT-PCR. There was no statistical difference in expression levels based on genotype in these cell lines. However, these cell types are not ideal models for regulation of glucose homeostasis and parallel experiments are underway in cultured primary myocytes from skeletal muscle biopsies of patients with known PTPN1 genotypes.

Type 2 diabetes (T2D) and quantitative trait (QT) association analysis of MODY genes in Finns. *L.L. Bonnycastle[1], C.J. Willer[2], C.P. Burrill[1], A.U. Jackson[2], R.M. Watanabe[3], L.J. Scott[2], P.S. Chines[1], K.N. Conneely[2], N. Narisu[1], M.R. Erdos[1], A.J. Swift[1], N.L. Riebow[1], S.T. Enloe[1], T.A. Buchanan[3], T.T. Valle[4], J. Tuomilehto[4], R.N. Bergman[3], K.L. Mohlke[5], M. Boehnke[2], F.S. Collins[1].* 1) NHGRI, NIH, Bethesda, MD; 2) U. Michigan, Ann Arbor, MI; 3) U. Southern California, Los Angeles, CA; 4) Nat'l Public Health Inst., Helsinki, Finland; 5) U. North Carolina, Chapel Hill, NC.

T2D is a multifactorial polygenic metabolic disorder characterized by defects in both insulin action and secretion. In contrast, maturity-onset diabetes of the young (MODY), an autosomal dominant form of diabetes, is primarily due to impaired insulin secretion as a result of variations in one of at least 6 genes: *HNF4A*, *GCK*, *TCF1*, *IPF1*, *TCF2* and *NEUROD1*. Several of the MODY genes are part of a transcription factor network regulating gene expression in the pancreas and liver. Reports of T2D association with variants in *HNF4A*, *GCK*, *TCF1* and *IPF1* support the hypothesis that subtle genetic variants in MODY genes may confer susceptibility to T2D. To complement our ongoing studies of *HNF4A*, we have undertaken a comprehensive gene-based association study to determine the relevance of 5 other MODY genes in T2D in Finns. For each gene and its flanking regions (20 kb 5 and 5 kb 3), we selected non-redundant SNPs (r^2<0.8 with other SNPs) either from the HapMap database (www.hapmap.org) or a private LD map source (D. Altshuler, personal communication). Thus far we have tested 77 SNPs on 795 index cases from T2D families, and 655 normal glucose-tolerant controls. We performed permutation tests to derive empirical p-values that account for multiple testing within each SNP. Associations with *NEUROD1*, *TCF1* and *TCF2* have been identified, with p-values of 0.0007, 0.02, and 0.01 respectively. We also examined whether MODY gene SNPs were associated with diabetes-related QTs. For 6 SNPs in 3 genes (*IPF1*, *GCK* and *TCF2*), we found significant ($p< 0.05$) trait associations in the glucose-tolerant individuals. One SNP in *TCF2* exhibited association with both T2D and QTs. Our data suggest that one or more of these MODY genes may also play a role in T2D pathogenesis.
